Reed Barton, BA

October 19, 2021

This technology assessment report is based on research conducted by a contracted technology assessment center, with updates as contracted by the Washington State Health Care Authority. This report is an independent assessment of the technology question(s) described based on accepted methodological principles. The findings and conclusions contained herein are those of the investigators and authors who are responsible for the content. These findings and conclusions may not necessarily represent the views of the HCA/Agency and thus, no statement in this report shall be construed as an official position or policy of the HCA/Agency.

The information in this assessment is intended to assist health care decision makers, clinicians, patients and policy makers in making sound evidence-based decisions that may improve the quality and cost-effectiveness of health care services. Information in this report is not a substitute for sound clinical judgment. Those making decisions regarding the provision of health care services should consider this report in a manner similar to any other medical reference, integrating the information with all other pertinent information to make decisions within the context of individual patient circumstances and resource availability.

Aggregate Analytics, Inc. is a contract research organization whose team has over fifteen years of experience in performing health technology assessments, comparative effectiveness reviews and systematic reviews for a variety of clients based on accepted methodologic standards for such research. AAI's mission is to assist healthcare professionals and organizations in the objective synthesis and generation of evidence for the purpose of improving future healthcare delivery by providing timely, methodologically rigorous, transparent services and quality evidence synthesis products.

Overview of Included Figures vii

Overview of Included Tables ix

Executive Summary ES-1

1 Appraisal 1

1.1 Background and Rationale 1

1.1.1 Policy Context 1

1.1.2 Objectives 1

1.2 Contextual Questions 1

1.3 Research Key Questions 2

1.4 Key Considerations Highlighted by Clinical Experts: Cardiac Imaging for CAD (symptomatic patients with suspected or known CAD) 2

1.4.1 Interventions 2

1.4.2 Costs 5

1.4.3 Patient considerations 5

1.4.4 Professional considerations 6

1.4.5 Ethical considerations 6

1.5 Outcomes Assessed 7

1.6 Washington State Utilization Data 8

1.6.1 Population 8

1.6.2 Noninvasive cardiac imaging procedures 8

2 Background 14

2.1 Nature and Burden of Disease 14

2.2 Assessing risk of CAD 15

2.3 Diagnosis of CAD 17

2.4 Technologies and interventions 18

2.4.1 Invasive coronary angiography 18

2.4.2 Coronary Computed Tomography Angiography 19

2.4.3 Nuclear stress imaging (myocardial perfusion imaging) 20

2.4.4 Stress echocardiography 22

2.4.5 Hybrid tests 22

2.4.6 Harms 22

2.5 Management 26

2.5.1 Optimal medical therapy ... 27
2.5.2 Revascularization ... 28
2.5.3 Management of acute coronary syndromes ... 29
2.6 Previous Systematic Reviews of Noninvasive Cardiac Testing for Suspected CAD ... 30
2.7 Prior Government Report and Rapid Reviews ... 42
2.8 Clinical Guidelines ... 54
2.9 Appropriate Use Criteria ... 61
2.10 Expert Consensus Statements ... 80
2.11 Medicare and Representative Private Insurer Coverage Policies ... 92
3 The Evidence ... 113
3.1 Methods of the Systematic Literature Review ... 113
3.1.1 Objectives ... 113
3.1.2 Contextual Questions ... 113
3.1.3 Research Key Questions ... 113
3.1.4 Inclusion/Exclusion Criteria ... 114
3.1.5 Data Sources and Search Strategy ... 117
3.1.6 Data Extraction ... 119
3.1.7 Quality Assessment: RoB, QHES Evaluation, and Overall SOE ... 119
3.1.8 Analysis ... 121
4 Contextual Questions ... 123
4.1 Terms and definitions ... 124
4.2 Results for Diagnostic Accuracy ... 125
4.3 Results for Reliability ... 135
5 Key Questions Results Overview ... 140
5.1 Number of studies retained ... 140
5.1.1 Primary evidence base for Key Questions 1–4 ... 140
5.1.2 Evidence base for Key Question 5 ... 144
5.2 Comparison with the 2008 and 2013 reports ... 145
6 Coronary Computed Tomography Angiography (CCTA) Results ... 148
6.1 CCTA versus Any Functional Testing ... 148
6.1.1 Key Question 1: Primary Outcomes (MI, all-cause mortality, cardiac death) ... 150
6.1.2 Key Question 2: Clinical decision making ... 159
6.1.3 Key Question 3: Safety ... 177

6.1.4 Key Question 4: Differential Efficacy or Safety 203
6.1.5 Key Question 5: Cost-Effectiveness 213
6.2 CCTA versus ICA 230
6.2.1 Summary of results (Key questions 1, 2 and 3) 231
6.2.2 Key Question 1: Primary Outcomes (MI, all-cause mortality, cardiac death) 231
6.2.3 Key Question 2: Clinical decision making 233
6.2.4 Key Question 3: Safety 234
6.2.5 Key Question 4: Differential Effectiveness or Safety 235
6.2.6 Key Question 5: Cost-Effectiveness 235
6.3 CCTA with Fractional Flow Reserve (FFR) 236
6.3.1 Summary of Results 237
6.3.2 Key Question 1: Primary clinical outcomes (MI, all-cause mortality, cardiac death) 237
6.3.3 Key Question 2: Clinical Decision-making outcomes 238
6.3.4 Key Question 3: Safety 241
6.3.5 Key Question 4: Differential Effectiveness and Safety 241
6.3.6 Key Question 5: Cost-Effectiveness 241
7 Single Photon Emission Computed Tomography (SPECT) Results 242
7.1 SPECT versus Stress Echocardiography and versus Exercise ECG 242
7.1.1 Summary of results 242
7.1.2 SPECT versus Stress Echocardiography 242
7.1.3 SPECT versus Exercise ECG 245
7.2 SPECT versus Clinical Assessment Alone and versus NICE Guideline-Directed Care 253
7.2.1 Summary of results 253
7.2.2 SPECT versus Clinical Assessment Alone 253
7.2.3 SPECT versus NICE guideline-directed care 255
7.3 SPECT versus ICA 258
7.3.1 Summary of results 258
7.3.2 Key Question 1: Primary Outcomes (MI, all-cause mortality, cardiac death) 259
7.3.3 Key Question 2: Clinical decision making 259
7.3.4 Key Question 3: Safety 260
7.3.5 Key Question 4: Differential Effectiveness and Safety 261
8 Positron Emission Tomography (PET) Results 262
8.1 PET versus SPECT 262

8.1.1 Summary of results 262
8.1.2 Key Question 1: Primary Outcomes (MI, all-cause mortality, cardiac death) 263
8.1.3 Key Question 2: Clinical decision making 263
8.1.4 Key Question 3: Safety 264
8.1.5 Key Question 4: Differential Effectiveness and Safety 264
9 Stress Echocardiography Results 265
9.1 Stress Echocardiography versus Exercise ECG 265
9.1.1 Summary of results 266
9.1.2 Key Question 1: Primary Outcomes (MI, all-cause mortality, cardiac death) 267
9.1.3 Key Question 2: Clinical decision making 269
9.2 Stress Echocardiography versus Standard Care 276
9.2.1 Summary of results 276
9.2.2 Key Question 1: Primary Outcomes (MI, all-cause mortality, cardiac death) 276
9.2.3 Key Question 2: Clinical decision making 276
9.3 Stress Echocardiography versus ICA 277
9.3.1 Summary of results 278
9.3.2 Key Question 1: Primary Outcomes (MI, all-cause mortality, cardiac death) 278
9.3.3 Key Question 2: Clinical decision making 278
9.3.4 Key Question 3: Safety 280
9.3.5 Key Question 4: Differential Effectiveness or Safety 282
10 Strength of Evidence (SOE) 283
Table 10.1. Key Question 1: Strength of evidence: CCTA versus functional testing, primary clinical outcomes across patient populations 283
Table 10.2. Key Question 2: Strength of evidence: CCTA versus functional testing; decision-making, additional testing and management 286
Table 10.3. Key Question 3: Strength of evidence: CCTA versus functional testing; Safety, harms and consequences of testing 293
Table 10.4. Key Question 4: Strength of evidence: CCTA versus functional testing: Differential efficacy or safety for primary outcomes* 301
Table 10.5. Key Question 1, 2 and 3: Strength of evidence: CCTA vs. ICA 306
Table 10.6. Key Questions 1, 2 and 3: Strength of evidence: CCTA FFR versus any functional and versus ICA 310
Table 10.7. Key Questions 1 and 2: Strength of evidence: SPECT versus any functional 314
Table 10.8. Key Questions 1 and 2: Strength of evidence: SPECT versus NICE guideline-directed care and versus clinical assessment alone 320

Table 10.9. Key Questions 1 and 2: Strength of evidence: SPECT versus ICA 325

Table 10.10. Key Questions 3: Strength of evidence: SPECT 327

Table 10.11. Key Questions 1 and 2: Strength of evidence: Stress echocardiography versus ECG .. 329

Table 10.12. Key Questions 1 and 2: Strength of evidence: Stress echocardiography versus standard care 335

Table 10.13. Key Questions 1 and 2: Strength of evidence: Stress echocardiography versus ICA ... 337

Table 10.14. Key Question 3: Strength of evidence: Stress echocardiography 339

Executive Summary

Introduction

Clinical

Coronary artery disease (CAD), also referred to as coronary heart disease (CHD) or ischemic heart disease (IHD), is a leading cause of death for both men and women in the United States and is the most common form of cardiovascular disease. The public health and economic burdens of CAD are substantial. Atherosclerosis is the most common underlying cause of CAD and is the result of plaque buildup on artery walls. The buildup of plaque may partially or completely block blood flow (and hence oxygen and nutrient flow) in the coronary arteries via two primary mechanisms: 1) progressive narrowing of the vessel lumen and (2) thrombotic occlusion of the artery wherein the hard surface of the plaque tears away exposing inner fatty prothrombotic and platelet activating components at the site creating enlargement of the obstruction. The resulting decrease in blood flow may be chronic or acute. It may restrict blood supply to the myocardium and impair ability to supply oxygenated blood either at rest or during exertion. Atherosclerotic plaque occurs commonly and is asymptomatic for years and most people with plaque will never develop clinical coronary artery disease. Chest pain (angina) is the most common symptom of obstructive CAD and is the first presenting symptom in most patients. Plaque distribution, presence of collateral circulation and degree of vessel narrowing are factors which may influence symptom development and clinical impact of CAD, however, symptoms do **not** always correlate with lesion severity. Ischemia and impaired function may be present in the absence of observed obstruction.[57]

Diagnosis of CAD

Accurate and early assessment of patients with symptomatic CAD is important for risk stratification and initiation of appropriate treatments to reduce morbidity and mortality. Noninvasive techniques used to diagnose CAD fall into two general categories, those that evaluate the anatomical aspects of vessel occlusion and those that evaluate the functional impact of occlusion on cardiac function. Each has strengths and limitations. Noninvasive anatomic tests provide information on location and extent of blockage and include coronary CT angiography (CCTA) and cardiac magnetic resonance imaging (CMRI). Functional tests allow assessment of whether symptoms are correlated with narrowing leading to ischemic areas and generally include exercise (treadmill) electrocardiography (ECG), exercise/pharmacologic stress echocardiography, exercise/pharmacologic cardiac nuclear imaging with single-photon emission computed tomography (SPECT) or pharmacologic stress with positron emission tomography (PET). There has been recent interest in use of pharmacologic stress as part of computed tomography (CT) and magnetic resonance imaging (MRI) and in determining fractional flow reserve (FFR) with CT. The choice of testing is dependent on a variety of patient and other factors, particularly in patients with stable CAD. The patient's pre-test probability of CAD, test accuracy and the likelihood that test results would change management and lead to better outcomes important considerations. The effectiveness of non-invasive imaging tests is influenced by patient pretest probability/underlying disease prevalence which impacts test performance for measures that are influenced by disease prevalence. For any test, in patients with low pre-test probability of CAD, the number of potential false positive results necessitating further follow-up needs to be weighed against the potential for accurate

detection of CAD. In some included RCTs, the frequency of MI and death was low, reflecting the low pre-test probability in these trials. In these instances, the benefit of testing may be unclear. Clinical decision-making regarding choice of test(s) needs to also include consideration of the potential for additional/downstream testing, availability of other tests, cumulative radiation exposure and how results will inform appropriate management strategies and lead to improved outcomes while avoiding risks of testing such as additional radiation, false positives, and incidental findings.

Exercise electrocardiogram treadmill testing (ETT) and the imaging tests CTTA, stress nuclear imaging and stress echocardiography have become established as diagnostic tests for CAD. The focus of this HTA will be on the imaging tests and will not include ETT as an intervention. This review does not include evaluation of MRI (including stress MRI). As established testing modalities, the focus will be on evaluating their impact on clinical decision making for directing management that leads to improved patient outcomes.

Policy context/Reason for selection

CCTA and stress nuclear imaging were reviewed in 2008 and 2013 respectively. They are being re-reviewed in 2021 due to newly available published evidence. Stress echocardiography was not previously reviewed.

Objectives

The aim of this report is to evaluate the clinical impact, safety and cost-effectiveness of the three primary noninvasive imaging methods of diagnosing CAD, namely CCTA, stress nuclear imaging and stress echocardiography. In addition, adjuncts to CCTA including FFR and CT perfusion imaging were included. This review updates the 2008 CCTA HTA and 2013 nuclear imaging HTA and adds evaluation of stress echocardiography.

Contextual Questions

Three cardiac imaging modalities for diagnosis of CAD in symptomatic patients will be evaluated: CCTA, stress nuclear imaging, and stress echocardiography. Prior to addressing research questions related to the impact of cardiac imaging on clinical outcomes ***the diagnostic accuracy (validity)*** of these modalities compared with invasive coronary angiography (the usual reference standard) will be briefly summarized for context. Diagnostic accuracy parameters include sensitivity and specificity and prognostic value (positive and negative predictive values). Inter- and intra-rater reliability (reproducibility) will be described. Information for the contextual questions will be summarized using citations captured in the formal search for this HTA.

Key Questions and Scope

The following Key Questions focus on ***the impact on clinical outcomes*** for the use of CCTA, stress nuclear imaging, and stress echocardiography to diagnose CAD **in patients with known or suspected CAD who are *symptomatic.***

1. What is the comparative effectiveness of noninvasive cardiac anatomic or functional imaging modalities (CCTA, stress nuclear imaging, stress echocardiography) in leading to improved clinical outcomes (e.g., MI, mortality)?
2. What is the comparative effectiveness of noninvasive cardiac anatomic or functional imaging modalities (CCTA, stress nuclear imaging, stress echocardiography) with respect to clinical decision-making including additional testing and treatments?
3. What is the comparative effectiveness of noninvasive cardiac anatomic or functional imaging modalities (CCTA, stress nuclear imaging, stress echocardiography) with regard to harms or adverse events which may result directly from testing or additional, downstream testing?
4. Does effectiveness (in terms of clinical outcomes) or safety differ in special populations (e.g., women, those with comorbidities, the elderly) from noninvasive cardiac anatomic or functional imaging (CCTA, stress nuclear imaging, stress echocardiography)?
5. What is the cost-effectiveness of CCTA, stress nuclear imaging and stress echocardiography for clinical outcomes?

PICOTS/Scope:

Study Component	Inclusion	Exclusion
Patients	Adult patients (≥18 years of age) with symptoms of suspected (previously undiagnosed) CAD who present with • Stable (nonemergent) typical or atypical symptoms suspicious for CAD (e.g., chest pain, chest tightness, chest burning, shoulder pain, palpitations, jaw pain, or non-chest pain symptoms, such as dyspnea or worsening effort tolerance) • Suspected acute coronary syndrome (ACS) in emergency departments. Symptomatic adults with known/established CAD including those who have had prior MI and/or revascularization. For all questions, data on special populations and circumstances including the following will be evaluated: • Women • Patients with atypical symptoms • Elderly patients • Patients with comorbidities (including renal insufficiency, DM), LBBB)	• Asymptomatic patients • Patients presenting for evaluation of cardiac pathologies other than CAD (e.g., congenital abnormalities, valvular disease, evaluation of cardiomyopathy etiology, CHF) • Patients with STEMI
Intervention	• Coronary CT Angiography (including use of FFR) and CT perfusion imaging (pharmacologic stress) with 64 slice or higher CT • Stress nuclear imaging (including PET, SPECT) • Stress echocardiography	• CACS • Screening • Novel uses of any of these tests • MRI/MRA • Comparisons of technical performance parameters or variations of a testing modality (e.g., comparison different CT techniques) • Outdated equipment or

Study Component	Inclusion	Exclusion
		methods
Comparator(s)	• No testing • Usual care* • Comparison of the above interventions with each other • Invasive coronary angiography	
Outcomes	Clinical health outcomes (PRIMARY) • MI, cardiac death, all-cause mortality Clinical decision making • Referral for treatment • Referral for additional testing Harms, risks and consequences of testing (initial testing and subsequent testing) • Harms of testing (e.g., adverse events related to contrast agents, medication for pharmacologic stress testing), vascular complications (e.g. stroke) • Risks and consequences of testing (radiation exposure, psychological consequences of diagnosis, ramifications of additional testing, other†) Economic: Incremental cost-effectiveness or similar outcome	• Intermediate outcomes
Timing	• Emergent or non-emergent • Any point in the diagnostic workup	• None
Setting(s)	• Emergency department • Non-emergent settings	• None
Studies	• Focus will be on studies with the least potential for bias. Focus will start with RCT evidence; in the absence of RCTs, high quality comparative observational studies that control for potential confounding will be considered. Observational studies will primarily be considered for test-related harms. • Studies published in English in peer-reviewed journals, technology assessments or publicly available FDA reports. • Full (comparative) economic studies • Studies published after 2000 (except for stress echocardiography)	• Non-comparative studies • Modeling studies for prediction • Prognostic studies • Costing studies • Studies evaluating the incremental benefit of adding a test to another. • Studies published prior to 2000 (except for stress echocardiography)

CACS = coronary artery calcium scoring; CAD = coronary artery disease; CHF = congestive heart failure; CT = computed tomography; DM = diabetes mellitus; FFR = fractional flow reserve; LBBB = left bundle branch block; RCT = randomized controlled trials; MI = myocardial infarction; PET = positron emission tomography; SPECT = single photon emission computed tomography; STEMI = ST-segment elevation myocardial infarction.

*Usual care typically includes no treatment/nothing if low pretest probability, "watchful waiting", or medical treatment if high pretest probability.

†Other may include impact on patients such as days lost from work, procedures cancelled (waiting for tests), vacations cancelled, etc.

Methods

The scope of this report and final key questions were refined based on input from clinical experts. Clinical expert input was sought to confirm critical outcomes on which to focus. Draft Key Questions and PICOTS scope were published on the HCA website for public comment. None were received. Public

comments as well as those from clinical experts and peer-reviewers were considered for finalization of this report.

The 2008 review of CCTA focused on diagnostic accuracy and only one RCT measured the impact of CCTA on patient outcomes. Since 2008, many RCTs comparing CCTA with functional testing have been published and use of CCTA clinically has become more mature. In recent years, the technologies and their application have evolved and matured. Therefore, this HTA focuses on the clinical impact of CCTA. The key questions for 2013 review of cardiac nuclear imaging differed from this review evaluation and the prior review included screening of asymptomatic patients. This HTA focuses on the clinical impact of stress nuclear imaging (SPECT and PET). Given that stress echocardiography is an established modality for evaluating cardiac function, based on clinical input it is included in this HTA.

A formal, structured systematic search of the peer-reviewed literature was performed across multiple databases including PubMed to identify relevant peer reviewed literature as well as other sources (e.g., ECRI Guideline Trust) to identify pertinent clinical guidelines and previously performed assessments (Appendix B). For the systematic review portion of the report, studies were selected for inclusion based on pre-specified criteria detailed in the full report. All records were screened by two independent reviewers. Selection criteria included a focus on studies with the least potential for bias that were written in English and published in the peer-reviewed literature. Included studies reporting on primary outcomes of interest were critically appraised independently by two reviewers evaluating the methodological quality, study limitations and potential for bias based on study design as well as factors which may bias studies using defined templates and pre-specified criteria. Assessment of RCTs followed appropriate criteria based on methods described in *the Cochrane Handbook for Systematic Reviews of Interventions* [19,58] and guidance from the Agency for Healthcare Research and Quality (AHRQ) *Methods Guide for Effectiveness and Comparative Effectiveness Reviews*.[5] In keeping with the AHRQ methods and the 2016 report on non-invasive imaging for CAD,[129] each study was given a final rating of "good", "fair", or "poor" quality based on the degree to which valid methods for patient selection, inclusion, allocation to treatment were used as well as the comparability of intervention groups, attrition and use of appropriate means for controlling bias. These are more described in detail in the full report. Systematic reviews were evaluated using AMSTAR-2 and economic studies Economic studies were evaluated according to The Quality of Health Economic Studies (QHES) instrument developed by Ofman et. al.[104]

An overall Strength of Evidence (SOE) combines the appraisal of study limitations with consideration of the number of studies and the consistency across them, directness and precision of the findings to describe an overall confidence regarding the stability of estimates as further research is available. The SOE was assessed by two researchers following the principles for adapting GRADE (Grades of Recommendation Assessment, Development and Evaluation)[48,51,52] as outlined by the Agency for Healthcare Research and Quality (AHRQ).[5] The strength of evidence was based on the highest quality evidence available for the primary outcomes. Briefly, bodies of evidence consisting of RCTs were initially considered as High strength of evidence. The strength of evidence could be downgraded based on the limitations (i.e., risk of bias, consistency of effect, directness of outcome, precision of effect estimate, and reporting/publication bias). When assessing the SOE for studies performing subgroup analysis, we also considered whether the subgroup analysis was preplanned (*a priori*) and whether a test for homogeneity or interaction was done. The final strength of evidence was assigned an overall grade of high, moderate, low, or insufficient, which are defined as follows:

- High - Very confident that effect size estimates lie close to the true effect for this outcome; there are few or no deficiencies in the body of evidence; we believe the findings are stable.
- Moderate – Moderately confident that effect size estimates lie close to the true effect for this outcome; some deficiencies in the body of evidence; we believe the findings are likely to be stable but some doubt remains.
- Low – Limited confidence that effect size estimates lie close to the true effect for this outcome; major or numerous deficiencies in the body of evidence; we believe that additional evidence is needed before concluding that findings are stable or that the estimate is close to the true effect.
- Insufficient – We have no evidence, are unable to estimate an effect or have no confidence in the effect estimate for this outcome or the body of evidence has unacceptable efficiencies precluding judgment. If no evidence was identified, this was stated as such.

Methods for quantitative analysis are described in the full report. Briefly, meta-analyses were conducted using profile likelihood methods to get more precise effect estimates and focused on the primary outcomes. To determine the appropriateness of meta-analysis, we considered clinical and methodological diversity and assessed statistical heterogeneity. Sensitivity analyses were conducted excluding poor-quality studies, outlying data and related to clinical heterogeneity.

Results

To answer the key questions, from 15,443 unique citations retrieved from systematic searches, 295 were reviewed at full text and 81 studies across 112 publications were retained. The bulk of the new trials evaluated CCTA. A total of 36 studies (in 66 publications) (35 RCTs and 1 prospective comparative cohort)[3,9,17,18,23-25,27,28,42-44,50,54,59,60,62,68,73,76-79,81-84,86-89,92,94,99-102,107,108,111,117,121,123-125,131,132,135-137,139,140,142] comprised the primary evidence base for Key Questions 1–4 and an additional 31 studies (2 SRs and 29 nonrandomized observational studies)[2,7,8,10-12,16,22,30-32,34,37,38,40,46,63,64,66,67,72,90,91,95-97,103,110,112,116,128] provided supplemental data on safety (Key Question 3; see Appendix Tables O23-O25 for details). For cost-effectiveness (Key Question 5), 14 studies across 15 publications (3 systematic reviews and 11 formal economic analyses) were included.[6,13,14,41,50,61,65,74,85,93,114,115,134,138,143] Most trials were considered fair (17 RCTs) with 11 considered good and seven considered poor quality. In addition, 14 studies/reports that provided data for the contextual questions are described below.

Although we sought studies in the three symptomatic populations of interest (i.e., patients with unknown but suspected CAD, those with known/established CAD and those with suspected ACS), only 1 trial was specifically in patients with known CAD.[109] Populations in 13 trials[17,25,28,47,68,89,94,119,121,123,127,132,142] and one prospective comparative cohort[29] were predominately (≥80%) those with unknown/suspected CAD presenting to in an outpatient setting and are described as stable outpatients in the results. Five trials enrolled a mixed population of known and suspected CAD.[24,62,98,120,126] Sixteen trials were in patients presenting acutely to the ED or similar setting with suspected ACS (unstable angina or NSTEMI).[18,23,43,44,54,59,76,78,80,82,83,92,99,102,111,137] Studies in patients with STEMI were excluded. There was heterogeneity across trials regarding how pre-test risk was determined and reported. As described by authors, most populations were low to intermediate risk of CAD. Table 24 of the full report provides additional information on the pretest risk for included studies. Given this heterogeneity it was not possible to stratify results by this variable. Appendix M provides information as reported by trial authors, and patient and study characteristics can be found in Appendix Q.

Below is a summary of the key findings for this report.

An overview of results from the contextual question will be presented first followed by results for the key questions.

Contextual questions

Overall, evidence on diagnostic accuracy was available from 5 government related reports[1,55,105,106,129] and 9 systematic reviews [4,45,53,71,113,130,144] published in the peer review literature. The quality of systematic reviews was assessed; they varied with regard to whether and how individual accuracy studies were evaluated for risk of bias. Additional detail is found in the full report and Appendix L. Most studies focused on patients with stable symptoms with either suspect (not diagnosed) CAD or known CAD. The following tables summarize the general range for diagnostic accuracy parameters for each of the tests across populations and from government sources (see full report) using ICA as a referent and assuming 50% stenosis on ICA. Notes on risk of bias are included in the table. In addition, tables across populations and all sources identified are presented. Although ICA is commonly considered the gold standard for identifying CAD, there are well known limitations regarding variability, reliability, and image distortion in its use.[69,122] There have been many technological advances to ICA in the past decades that have addressed many of the limitations. Some limitations related to interpretation of ICA remain as is true of all tests included in this HTA.

ICA is an anatomic test, so accuracy for anatomic tests such as CCTA may differ from functional tests such as stress nuclear imaging or stress echocardiography when compared with ICA; a strict correspondence between ICA and functional tests is not expected.

The full report contains additional detail for accuracy parameters by population. No studies focusing on specific subpopulations were identified. Differential accuracy based on specific populations was not assessed in any of the studies identified.

Summaries from government systematic reviews including the 2008 and 2013 [redacted] HTAs: **diagnostic accuracy of imaging tests compared with invasive coronary angiography (ICA threshold ≥50% stenosis unless otherwise noted)**

Author, year	Risk of Bias	Sensitivity	Specificity	PPV	NPV	LR +	LR -	CAD prevalence

CAD prevalence ranges	32% to 100%	NR

CAD = coronary artery disease; CT = computed tomography; FFRct = CT with fraction flow reserve; LR+ = positive likelihood ratio; LR- = negative likelihood ratio; NPV = negative predictive value; PPV = positive predictive value.

Intraobserver reliability for CCTA was reported in three studies.[75,118,141] Between observer reliability was investigated in six studies.[15,49,59,75,118,141] Intraobserver reliability was investigated in two studies[20,39] for FFRct but no studies were found on interobserver agreement. CT perfusion was only investigated in one study.[21] Risk of bias for reliability studies is described in the full report.

For SPECT one intraobserver[33] and two interobserver[21,33] studies were identified ((k=0.96 and k=0.91 to 0.95) and one study[141] investigating PET was identified. Reliability studies on stress echocardiography included both exercise and dobutamine for inducing stress and included, three intraobserver[33,36,56] studies and five studies[33,35,36,45,56,70] in inter-rater reliability. Findings from these studies are summarized below.

- Intraobserver reliability in CCTA ranged from substantial agreement to almost perfect agreement (k=0.72 to 0.96), while interobserver reliability ranged from moderate to almost perfect agreement (k=0.58 to 0.94). In FFRct, intraobserver reliability ranged from fair to almost perfect agreement (k=0.40 to 0.94), but no studies were found for interobserver reliability. Likewise, only interobserver reliability was studied in CT perfusion and found substantial to almost perfect agreement (k=0.72 to 0.86).
- SPECT studies found almost perfect agreement for both intra- and interobserver agreement (k=0.96, k=0.91 to 0.95). Likewise, PET studies also saw almost perfect agreement for bother intra- and interobserver reliability (k=0.94, k=0.82).
- Intraobserver agreement studies in stress echocardiography found almost perfect agreement (k=0.81 to 0.90), while studies on interobserver agreement found moderate to almost perfect agreement (k=0.56 to 0.87).

Key Questions Results

Key Questions results are organized by testing modality for Key Questions 1 through 4 on the efficacy and safety of CCTA, stress nuclear testing (SPECT, PET) and stress echocardiography respectively. Key Question 5 is summarized separately.

The Key findings are summarized here. The bulk of the evidence identified for this report compared CCTA with functional testing. Therefore, results for will be summarized separately for Key Questions 1 through 4. Key findings for CCTA compared with ICA, and for CCTA plus FFRct, SPECT, PET and stress

echo will then be presented by outcomes for KQ 1 through 3. No studies of differential effectiveness or safety were identified for these tests. No studies of CT perfusion meeting the inclusion criteria were identified.

Please note that the Strength of Evidence (SOE) tables for KQ 1 through 4 are found section 10 and are not repeated here. Formal SOE across economic studies is not assessed.

CCTA versus functional testing

Figure A provides a summary of findings for key questions 1 and 2.

Key Question 1: Comparative effectiveness on clinical outcomes

There were 17 RCTs comparing CCTA with functional testing, six RCTs[28,68,89,94,123,132] in stable patients with suspected CAD and 11 RCTs (12 publications)[18,23,43,44,54,59,60,76,81,83,111,137] in patients with suspected ACS that reported primary clinical outcomes. Functional testing included imaging tests (stress nuclear, stress echocardiography and ETT. Given the limitations of ETT as a functional test, sensitivity analyses comparing CCTA with functional imaging tests only were conducted. There was no statistical interaction between the patient populations for any outcome.

Across studies that include stable patients with suspected CAD and patients with suspected ACS presenting to an emergency department or similar setting:

- There is no clear difference in the frequency of MI between CCTA and functional imaging tests (SOE Moderate).
    - Three smaller RCTs, one in stable patients and two in those with suspected ACS, reported no MI in either testing arm.
    - CCTA was associated with lower MI risk compared with functional testing based on pooled estimates across the 14 remaining RCTs (pooled RR 0.70, 95% CI 0.56 to 0.89, I^2=0%),[18,23,28,43,54,59,60,81,83,89,111,123,132,137], however, the RD (0.4, 95% CI 0.1 to 0.8 per 100 patients) was small. The association was no longer clearly significant following exclusion of one RCT (SCOT-HEART) in stable patients with suspected CAD in which 85% of all patients had ETT in addition to CCTA (13 RCTs, pooled RR 0.75, 95% CI 0.57 to 0.99, I^2=0) or when CCTA was compared with functional *imaging* only (11 RCTs, pooled RR 0.74, 95% CI 0.55 to 0.98) This pattern was seen across RCTs of stable patients when the one trial was excluded. Across 10 RCTs in patients with suspected ACS, there was no difference in the frequency of MI between CCTA and functional testing at any time.
- There was no association between CCTA and reduction in all-cause mortality compared with functional testing (SOE Moderate).
    - Six RCTs reported no mortality in either testing arm (one RCT in stable patients, five RCTs in suspected ACS patients).
    - There was no difference in all-cause mortality between CCTA and functional testing across the remaining 11 RCTs (pooled RR 0.99, 95% CI 0.40 to 2.68, I^2=0%). There was also no difference in all-cause mortality when the populations were considered separately.
- Cardiac death was rare in both patient populations, with six total cardiac deaths reported in patients receiving CCTA and 13 reported in patients receiving functional testing (SOE Insufficient).

- It is possible that smaller trials in particular may have been underpowered to detect differences in MI, all-cause mortality, and cardiac death between CCTA and functional testing given that many trials enrolled patients with low or low to intermediate pre-test risk.

Key Question 2: Clinical decision making

The majority of RCTs comparing CCTA with functional testing which reported one or more of the following outcomes in either stable patients with suspected CAD or patients presenting emergently with suspected ACS: Referral for ICA (19 RCTs, N=22,335), any additional noninvasive testing (17 RCTs, N=11,595), referral for any revascularization (19 RCTs, N=23,124) and referral for PCI specifically (12 RCTs, N=18,960). There was no statistical interaction between the patient populations for any outcome.

Summary of results across populations

Across studies that include stable patients with suspected CAD and patients with suspected ACS presenting to an emergency department or similar setting:

- **ICA referral:** CCTA was associated with more frequent ICA referral compared with functional testing (19 RCTs, 14.4 vs. 12 per 100 patients, pooled RR 1.25, 95% CI 1.09 to 1.47, I^2=67%, RD 2.7, 95% CI 1 to 4 per 100, I^2=59%) (SOE Moderate).
    - **In stable outpatients**, ICA referral was more frequent following CCTA, but the association bordered the null and there was substantial heterogeneity. However, exclusion of SCOT-HEART increased the effect size and strengthen the association between CCTA and ICA referral compared with functional testing and substantially reduced the heterogeneity (4 RCTS pooled, RR 1.57, 95% CI 1.21 to 1.65, I^2=0%, RD 4.1, 95% CI 3.0 to 5.2 per 100 patients).
    - **In patients with suspected ACS**, ICA referral (cumulative) was also more frequent following CCTA compared with functional testing but was less than the frequency seen in stable outpatients. Referral for ICA was highest at the index evaluation.
- **Referral for any additional noninvasive testing** was not different between CCTA and functional testing groups across populations (17 RCTs, 7.2 versus 7.6 per 100, pooled RR 0.82, 95% CI 0.53 to 1.28, I^2=83%) (SOE Low) or when populations were considered individually. Type of additional testing was inconsistently reported but appears to be primarily stress imaging.
- **Revascularization:** CCTA was associated with more frequent revascularization (9.5 per 100 patients) compared with functional testing (7.1 per 100 patients): 19 RCTs, pooled RR 1.52, 95% CI 1.26 to 1.90, I^2=66%, RD 2.4, 95% CI 1.4 to 3.3 per 100) (SOE Moderate). Again, this was also true when the populations were considered individually.
- **PCI for revascularization:** CCTA was associate with higher frequency of PCI as a revascularization procedure compared with functional testing (12 RCTs, 8.2 vs. 6.0 per 100 patients, pooled RR 1.63, 95% CI 1.22 to 2.35, I^2=74%, RD 2.4, 95% CI 1.3 to 3.6 per 100 patients) across populations (SOE Moderate).
    - In stable outpatients with suspected CAD, PCI was more common with CCTA, but the association failed to reach statistical significance (pooler RR 1.16, 95% CI 0.96 to 2.99).
    - In patients with suspected ACS the association between CCTA and PCI was seen at index testing but there was no difference between CCTA and functional testing at 1 to 6.5 months or ≥12 months.
- **Hospitalization**:

- **In stable outpatients t**here was no difference in hospitalization between CCTA and functional testing across four RCTs (SOE Moderate).
- **In patients with suspected ACS**,
  - At index testing, across comparators with CCTA there is substantial heterogeneity and results are mixed. While four RCTs comparing CCTA with any functional test suggest that hospitalization is less common with CCTA, large studies of CCTA vs echo and SPECT suggest that hospitalization may be more with CCTA (SOE Insufficient).
  - There was no difference in hospitalization between CCTA and functional testing across studies, regardless of comparator, at 1 to 6.5 months after index testing (9 RCTs, 3.0 vs. 3.9 per 100 patients, pooled RR 0.76, 95% CI 0.49 to 1.1, I^2=18%)[18,23,43,44,59,81,83,92,99] (SOE High). Similarly, there was no difference between testing arms at ≥12 months (6 RCTs 14.9 vs. 17.4 per 100 patients, pooled RR 0.90, 95% CI 0.77 to 1.03, I^2=0%).[54,60,76,78,81,137] (SOE High).

- **Subsequent ED visits:** In patients with suspected ACS there was no difference in emergency department visits after index testing between CCTA and functional testing across studies, regardless of comparator, at 1 to 6.5 months (7 RCTs, pooled RR 0.84, 95% CI 0.66 to 1.06, I^2=0%)[23,43,44,59,83,92,99] or at ≥12 months (5 RCTs, pooled RR 1.06, 95% CI 0.93 to 1.56, I^2=16%)[54,60,76,78,111] (SOE High for both time frames).
- **Medication**: CCTA was not consistently associated with initiation of, discontinuation of or changes in medications and results for many mediations were mixed. Evidence is insufficient to draw firm conclusions about the impact of testing on medication use (SOE Insufficient).

Figure A. Summary of CCTA vs. any functional test, KQ 1 and 2 results

Outcome	All patients	ED/similar setting	Stable outpatients
Key Question 1: Clinical outcomes			
MI	ϴ* Moderate SOE (14; N=21,661)	ϴ (10; N=5,977)	ϴ* (4; N=15,684)
All-cause death	ϴ **Moderate** SOE (11; N=18,935)	ϴ (7; N=4,001)	ϴ (4; N=14,934)
Cardiac death	Insufficient evidence	Insufficient evidence	Insufficient evidence
Key Question 2: Decision-making			
ICA	↑† Moderate SOE (19; N=22,335)	↑ (14; N=7,227)	ϴ† (4; N=15,107)
Any additional NIT	ϴ **Low** SOE (17; N=11,595)	ϴ (13; N=6,491)	ϴ (4; N=5,104)

Any revascularization	↑ Moderate SOE (19; N=23,124)	↑ (13; N=7,014)	↑ (19; N=16,110)
Hospitalization	Data not pooled	Index visit: Insufficient evidence ϴ High SOE 1–6.5 mos. (9; N=5,144) ≥12 mos. (6; N=3,624)	Any timepoint: ϴ Moderate SOE (4; N=14,810)
Subsequent ED visit	NR	ϴ High SOE 1–6.5 mos. (7; N=4,294) ≥12 mos. (5; N=2,855)	NR
Medication change	Insufficient evidence	Insufficient evidence	Insufficient evidence

ϴ = no difference between groups, ↓ = decreased risk with CCTA, ↑ = increased risk with CCTA
ED = emergency department; ICA = invasive coronary angiography; MI = myocardial infarction; mos. = months; NIT = noninvasive testing; NR = not reported; SOE = strength of evidence
*Excluding SCOT-HEART results not clearly statistically significant; similar results when studies comparing to ETT were excluded
†Exclusion of SCOT-HEART increased the effect size and strengthened the association between CCTA and ICA referral compared with functional testing and substantially reduced the heterogeneity

Key Question 3: Safety

Adverse events

- Major or serious test-related adverse events/harms are rare for all modalities. Complications reported across studies were minor. For stress testing most reported symptoms are expected responses to the pharmacologic agents used.
- No major complications were observed across 3 RCTS at time of index test or within 24 hours. (SOE Low) The largest RCT in stable outpatients also reported no test-related hospitalization in the CCTA arm and 0.1% (5/4837) in the functional testing arm[28] (SOE low).
- Minor complications at time of index test or within 24 hours was <4% across treatment arms across five RCTs in stable outpatients and five RCTs in patients with suspected ACS. Two other trials in patients with suspected ACS reported on a broader range of minor complications, one finding that 24% of patients in each testing arm[78] experienced them and the other that 14% of CCTA patients and 6.4% experienced minor complications (1 RCT, RR 2.16, 95% CI 1.12 to 4.14)[76] (SOE Low).
    - Contrast-related events related to CCTA occurred in ≤3% of patients at time of index testing as reported in six RCTs[18,23,28,59,68,87,123,140] and one case series. Transient creatinine elevation not requiring dialysis were reported in two trials as 0.2%[59] and 1%[23] (SOE Low) and a third RCT[18] reported that no contrast-induced nephropathy occurred (SOE Insufficient). Mild contrast reaction occurred in 0.5% to 2.1% of patients across six RCTs (SOE Low).
    - CCTA was associated with lower risk of chest pain, shortness of breath, or palpitations at the time of index testing compared with stress SPECT (1 RCT, 0.5% vs. 16% RR 0.03, 95%

CI 0.004 to 0.24, p<0.001) and stress echo (1 RCT, 0% vs. 3%, p=0.03)[76] in patients with suspected ACS (SOE Low). The symptoms are likely consistent with inducing cardiac stress with pharmacologic agents. One large RCT in stable outpatients reported much lower risk of symptoms related to nuclear stress testing (0.1%) and events related to dipyridamole or adenosine (0.2%) (SOE Low).

- Arrythmias occurred in ≤ 0.2% in all testing arm across testing arms (SOE Insufficient).

Radiation exposure

- **Radiation from index tests**: Across six RCTs comparing CCTA specifically with SPECT radiation exposure at index tended to be lower with CCTA (SOE Low). Five RCTs reported that CCTA was associated with a lower effective radiation dose for the index test; the sixth trial reported that CCTA was associated with slightly higher radiation (estimated difference 1.8 mSv). Rough estimates of difference between tests ranged from approximately 1.30 mSv to 11.9mSv. Stress echocardiography and ETT do not involve ionizing radiation (SOE Low).
- **Cumulative radiation**: Across nine RCTs, results are somewhat mixed, but suggest that cumulative radiation may be higher when CCTA is the initial test (SOE Low). Good- or fair-quality RCTs[23,28,59,76,82,99] found that CCTA was associated with higher cumulative radiation compared with functional testing with rough estimates of differences ranging from 1.9 mSv to 9.0 mSv in these trials. It is unclear from included RCTs what tests (e.g., SPECT, ICA) or procedures (e.g., PCI) were included in the estimates. Stress echocardiography does not involve ionizing radiation. It is unclear if some of the differences between arms would impact clinical decision making. CCTA was associated with lower cumulative radiation versus SPECT in two RCTs (estimated range 6 mSv to 15 mSv)[68,78] and no statistical difference between CCTA and SPECT was reported in a third smaller poor-quality RCT.[94]

Incidental Findings

Incidental findings are common with CCTA (28% to 44%) across included RCTs, systematic reviews and nonrandomized studies with pulmonary findings being most common. The proportions that were considered "potentially significant" "clinically significant" or "required follow-up" ranged from 4.9% to 16% (SOE Low).

Key Question 4. Differential effectiveness and safety

To evaluate differential efficacy and safety (heterogeneity of effect, interaction), we focused on RCTs as they have the least potential for bias and confounding thus allowing for causal inference. Further, only RCTs that formally tested for interaction between subgroups were reported for Key Question 4.

Three large RCTs comparing CCTA with functional testing reported tests for interaction between subgroups on efficacy and/or safety outcomes.[3,84,86,100,107,108,117,124,125,135,136] Only one of these pre-specified subgroup analyses and consider this in sample size determinations.[28,84,86,107,108,124,125] All performed multiple analyses for multiple outcomes, including multiple composite outcomes. None of the RCTs specified all outcomes evaluated. None specified hypotheses to be tested or expected direction.

- **Clinical outcomes**: Only one RCT[3,123] reported on the primary clinical outcomes of interest for this HTA. At a median of 3.2 years, the effect of CCTA did not appear to vary based on anginal classification (non-anginal chest pain, possible anginal chest pain) for MI (SOE Low), all-cause mortality (SOE Insufficient) or death due to CAD (SOE Insufficient). As many of these outcomes

appear to be rare, it is possible that this trial was not sufficiently powered to effectively evaluate interaction. The factors, outcomes and hypothesized direction do not appear to have been specified a priori.

- **Downstream testing:** One RCT in patients with suspected ACS found no significant variation in use of downstream testing with CCTA based on sex or race at either the index visit, or 28 day follow up. Downstream testing did vary by diabetes status; more downstream testing occurred with CCTA in patients with diabetes at index visit and by 28-day follow-up (interaction p-values 0.001 and 0.002 respectively). The factors, outcomes and hypothesized direction do not appear to have been specified a priori in this fair-quality trial (SOE Low).
- **ICA referral:** Across two RCTs, one in stable outpatients[124,125] and the other in patients with suspected ACS[136] the effect of CCTA versus functional testing on ICA referral did not vary by diabetes status. (SOE Low) Similarly, there was no effect modification in the trial in patients with suspected ACS by sex or race at index visit or by 28-day follow-up (SOE Low).
- **Revascularization**: Across two RCTs, one in stable outpatients[124,125] and the other in patients with suspected ACS[136] the effect of CCTA versus functional testing on revascularization did not vary by diabetes status (SOE Low). The effect of CCTA versus functional testing on revascularization was not modified by either sex (1 RCT) [136] or angina classification (1 RCT)[3] (SOE Insufficient).
- **Radiation exposure:** In stable outpatients, CTTA cumulative radiation may vary based on baseline heart rate. Patients with ≥75 beats-per-minute may have higher cumulative radiation with CCTA compared with functional testing. Tests for interaction by age, sex and BMI were not significant (SOE Insufficient). In patients with suspected ACS, there was insufficient evidence to confidently make conclusions about how radiation dose may vary by sex, diabetes status or race for CCTA versus functional testing index testing or within 28 days (SOE Insufficient).

CCTA versus ICA

Two RCTs (N=1,971 randomized), compared CCTA as an index diagnostic test versus direct referral to ICA in patients with suspected CAD (known CAD was an exclusion criteria). One good-quality trial included patients with atypical chest pain who had a mix of stable/chronic (treated on an outpatient basis) and acute (hospitalized) presentation.[25] One fair-quality trial included stable patients at primarily intermediate pre-test risk who were treated on an outpatient basis.[17]

- There was no difference in the risk of all-cause mortality or MI in CCTA versus ICA group at 12 and a median 40 months across one good- and one fair-quality RCT (SOE Low for both). Cardiac mortality was rare (SOE Insufficient).
- Compared with direct referral to ICA, CCTA was associated with a reduced risk of ICA without obstructive CAD (2 RCTs, N=1,019; 22 versus 65 per 100 patients; pooled RR 0.32, 95% CI 0.18 to 0.51, I^2=0%; pooled RD –48.0%, 95% CI –67.0% to –29.2%, I^2=73%) (SOE Moderate) and any revascularization (2 RCTs, N=1,832; 13 vs. 18 per 100 patients; pooled RR 0.71, 95% CI 0.55 to 0.96, I^2=0%; pooled RD –5.0%, 95% CI –8.0% to –2.0%, I^2=0%) (SOE Moderate) to include PCI but not CABG procedures, but an increased risk of additional downstream noninvasive testing (1 fair-quality RCT, N=1,503; 53 vs. 27 per 100 patients; RR 1.96, 95% CI 1.71 to 2.25; RD 26.0%, 95% CI 21.1% to 30.7%) (SOE Moderate). This latter trial found no difference between tests in the risk of cardiac hospitalization (4 vs. 4 per 100 patients) over 12 months (SOE Moderate).

- No major complications were reported in one good-quality trial and only one major complication was reported in the second fair-quality trial, major bleeding, which occurred in two patients (0.4%) in the ICA group; one patient (0.1%) required transfusion (SOE Low).

CCTA with FFR versus any noninvasive testing and versus ICA

One prospective comparative observational study was identified that enrolled patients into two simultaneous cohorts based on the planned test (per their physician) prior to enrollment: noninvasive test cohort (CCTA with FFR vs. any NIT; N=204) and (CCTA with FFR vs. direct referral to ICA; N=380).[26,29] The decision to send patients for noninvasive or invasive testing prior to enrollment was made by the patients' physicians; it is unclear what criteria were used to make this decision, though it is assumed that those patients who were being sent directly to ICA were higher risk than those being sent for noninvasive testing resulting is some selection bias.

Key Questions 1 and 2

CCTA with FFR vs. any NIT (planned NIT cohort)

- There was no difference between groups in any outcome over 12 months (SOE Insufficient for all outcomes).
- One MI occurred in the any noninvasive test group (0 vs. 1 per 100 patients). There were no deaths or hospitalizations with urgent revascularization in either group. Given that these are rare events, the study may not have been sufficiently powered to detect a difference.
- Risk of ICA was 21 vs. 16 per 100 patients; of ICA without obstructive CAD was 13 vs. 6 per 100 patients (at 3 months); and of any revascularization was 10 vs. 7 per 100 patients, respectively.

CCTA with FFR vs. ICA (planned ICA cohort)

- There were no differences between groups over 12 months in the risk of MI (1 vs. 1 per 100 patients), all-cause death (0 vs. 1 per 100 patients) or hospitalization with urgent revascularization (1 vs. 0 per 100 patients). Given that these are rare events, the study may not have been sufficiently powered to detect a difference (SOE Insufficient).
- Compared with direct referral to ICA, patients who underwent CCTA with FFR were referred to ICA significantly less often (51 vs. 100 per 100 patients; RR 0.51, 95% CI 0.45 to 0.59) and importantly, there were no events in the 61% of CCTA with FFR patients in whom ICA was cancelled in the planned ICA cohort. The risk of ICA without obstructive CAD was also significantly reduced following CCTA with FFR (39 vs. 100 per 100 patients; RR 0.39, 95% CI 0.33 to 0.47) (SOE Insufficient).
- There was no difference between groups in the risk of any revascularization (SOE Insufficient).

Key Question 3, Safety

- There was one mild contrast reaction from CCTA testing; no other information was provided (SOE Insufficient).
- Patients who received CCTA with FFR had significantly greater cumulative radiation exposure over 12 months compared to those who received any noninvasive test (planned noninvasive test cohort): 9.6 vs. 6.4 mSv, MD 3.1 (95% CI, 0.6 to 5.7); there was no difference for CCTA with FFR versus direct referral to ICA (planned ICA cohort) (SOE Low).

SPECT versus Stress Echocardiography and versus Exercise ECG

Key Questions 1 and 2, Efficacy

Four trials (1 good- and 3 fair-quality, N=1960) comparing SPECT with stress echocardiography (2 RCTs; 1 in stable, 1 in acute patients with suspected or known CAD)[120,126,133] and with exercise ECG (2 RCTs in stable, suspected CAD patients)[119,127] were identified. Given that the results across the four trials comparing SPECT with stress echocardiography and exercise ECG showed similar results in general, they are summarized together in the bullet points below.

- There was no difference in the risk of MI (SOE Insufficient), all-cause mortality (SOE low) or cardiac mortality (SOE Insufficient) between SPECT and stress echocardiography (2 trials) or exercise ECG (2 trials) across four trials (N=1,908) with varying populations and follow-up periods. The absolute risk was <2 per 100 patients across all testing arms for all outcomes over follow-up periods ranging from 1 to 24 months. Given that these are rare events, trials may not have been sufficiently powered to detect a difference.
- There was no difference in the risk of ICA (4 trials, N=1,908) (SOE Low) or additional noninvasive testing (N=3 trials, N=1,679) (SOE Insufficient) for SPECT versus stress echocardiography or exercise ECG across all four trials over follow-up periods ranging from 1 to 24 months, however, there was substantial heterogeneity. Individually, only the trials comparing SPECT versus exercise ECG reported statistically significant differences which favored SPECT for both ICA (1 trial) and additional noninvasive testing (2 trials); however, for the latter, the estimates across trials were inconsistent and imprecise. Differences in testing protocols, patient populations and/or pretest risk, and follow-up periods may have played a role in these findings.
- There was no difference in the risk of revascularization (4 trials, N=1,908) (SOE Moderate) or hospitalization (3 RCTs, N=1,451) (SOE Low) between SPECT and stress echocardiography or exercise ECG, or ED visits in 1 trial (N=229) of SPECT vs. echocardiography through 24 months of follow-up (SOE Low).

SPECT versus Clinical Assessment Alone and versus NICE Guideline-Directed Care

Key Questions 1 and 2, Efficacy

Two trials, one fair-quality trial (N=1,508)[80] comparing SPECT versus clinical assessment alone in acute patients with suspected ACS presenting to the ED and one good-quality trial (N=721)[47] comparing SPECT with NICE guideline-directed care in stable outpatients with suspected CAD, were identified. Given that the results across the two trials comparing SPECT with clinical assessment alone and with NICE guideline-directed care showed similar results in general, they are summarized together in the bullet points below.

- There was insufficient evidence to draw conclusions regarding the risk of MI and all-cause mortality in one RCT (SPECT vs. NICE guideline-directed care) with a median follow-up of 16 months and cardiac death across both RCTs (follow-up range, 1 to median 16 months). The absolute risk was ≤1.3 per 100 patients across both test arms in both trials for all outcomes. Given that these are rare events, the trials may not have been sufficiently powered to detect a difference (SOE Insufficient for all).
- SPECT was associated with a decreased risk of ICA across both trials (10.2 vs. 21.1 per 100, pooled RR 0.49, 95% CI 0.26 to 0.95, I^2=85%; pooled RD –11.1%, 95% CI –14.4% to –7.8%) (SOE

Low); the association was stronger in the trial comparing SPECT versus NICE guideline-directed care, likely due the direct referral to ICA of patients with high pretest risk per the NICE guideline algorithm, and could account for much of the heterogeneity in the pooled estimate. SPECT was also associated with a decreased risk of ICA showing no obstructive CAD (1 RCT, SPECT vs. clinical assessment alone: 21.9 vs. 39.3 per 100 patients; RR 0.56, 95% CI 0.32 to 0.96; RD –17.4%, 95% CI –33.3% to –1.4%) and unnecessary ICA (1 RCT, SPECT vs. NICE guideline-directed care: 7.1 vs. 28.8 per 100 patients; RR 0.25, 95% CI 0.17 to 0.36; RD –21.7%, 95% CI –27.9% to –15.5%) (SOE: Low for both).

- There was no difference between SPECT and clinical assessment alone or NICE guideline-directed care in the risk of any revascularization (2 RCTs, 5.9 vs. 7.0 per 100 patients; RR 0.85, 95% CI 0.57 to 1.28, I^2=0%) (SOE Low).
- SPECT was associated with decreased risk of additional downstream NIT over 12 months (12.1 vs. 68.3 per 100 patients; RR 0.18, 95% CI 0.15 to 0.21; RD –56.2%, 95% CI –60.7% to –51.7%) and hospitalization at the index visit (10.2 vs. 18.5 per 100 patients; RR 0.55, 95% CI 0.42 to 0.71; RD –8.3%, 95% CI –12.2% to –4.4%) compared with clinical assessment alone in one trial (SOE Low for both).

SPECT versus ICA

Key Questions 1 and 2, Efficacy

One good-quality trial (N=446)[126,133] comparing SPECT with ICA in stable outpatients with a mix of known and suspected CAD referred for outpatient angiography was identified.

- There was insufficient evidence to draw conclusions regarding the risk of MI, all-cause mortality and cardiac mortality between groups. Over 18 months, the absolute risk was ≤2 per 100 patients across both test arms for all outcomes; at 72 months, the absolute risk of all-cause mortality was 3 per 100 patients. Given that these are rare events, the trial may not have been sufficiently powered to detect a difference (SOE Insufficient).
- Compared with ICA, SPECT was associated with a decreased risk of additional downstream NIT (0.4 vs. 3.6 per 100 patients; RR 0.12, 95% CI 0.02 to 0.98; RD –3.2%, 95% CI –5.8% to –0.6%; timing unclear) and any revascularization after the index visit through 36 months (43.8 vs. 53.2 per 100 patients; RR 0.82, 95% CI 0.68 to 0.99; RD –9.4%, 95% CI –18.6% to –0.2%). There was no difference in the risk of any hospitalization for chest pain (SOE: Low for all).

Safety of SPECT (Key Question 3)

- Test-related complications appear to be rare following SPECT in one good-quality trial[47] (SOE Low).
- Data from one fair-quality trial was insufficient to draw conclusions regarding radiation exposure.[127] Mean exposure following SPECT was 14 mSv; exercise ECG does not use radiation.
- Adverse events from stress agents are relatively common and ranged from 2% to 13% of patients (5% to 37% of events) for dipyridamole and from 4% to 53% for regadenoson; the most common events included headache, dyspnea, GI upset/nausea and dizziness or lightheadedness (SOE Low). Most were minor and transient and are likely expected with use of pharmacologic cardiac stress.

Stress Echocardiography versus Exercise ECG

Key Questions 1 and 2, Efficacy

Five trials (1 good-, 1 fair- and 3 poor-quality) comparing stress echocardiography with exercise ECG, two (N=543) in stable patients with suspected CAD treated on an outpatient basis[50,121,142] and three (N=854) in patients with acute symptoms presenting to the ED or hospital.[24,62,102]

- There was insufficient evidence to draw conclusions regarding the risk of MI, all-cause mortality and cardiac mortality following stress echocardiography versus exercise ECG across the five trials. The absolute risks of MI and all-cause mortality across four trials were 1.3 vs. 0.9 and 0.6 vs. 0.9 per 100 patients, respectively, across follow-up periods ranging from 2 to 36 months. The absolute risk of cardiac mortality in one RCT was 0.5 vs. 0 at 36 months. Given that these are rare events, the trial may not have been sufficiently powered to detect a difference (SOE Insufficient for all).
- In stable patients with suspected CAD, stress echocardiography was associated with a reduced risk of ICA (1 good-quality RCT; 6.3 vs. 13.4 per 100 patients; RR 0.47, 95% CI 0.24 to 0.90; RD –7.1%, 95% CI –13.0 to –1.2%) (SOE Low) and additional downstream NIT (2 RCTs, 1 good and 1 poor quality; 5.8 vs. 42.7 per 100 patients; pooled RR 0.15, 95% CI 0.06 to 0.28, I^2=0%; pooled RD –31.6 (95% CI –49.3% to –14.0%, I^2=84%) (SOE Low) compared with exercise ECG over 28 to 36 months. Across the three trials in acute patients with a mix of known or suspected CAD, there was no difference between groups in either outcome, though one fair-quality trial tended to favor echocardiography for ICA (lower risk); heterogeneity was high possibly due to differences in populations, pretest risk and follow-up times (SOE Low for ICA; SOE Insufficient for additional NIT).
- Across trials in both stable (1 RCT) and acute patients (3 RCTs) with varying pretest risks of CAD, there were no differences between testing arms in the risk of revascularization (4 RCTs, 1 good, 2 fair and 1 poor quality) or (re)hospitalization (3 RCTs, 1 good, 1 fair and 1 poor quality) over follow-up periods ranging from 2 to 36 months (SOE Moderate for both).

Stress Echocardiography versus Standard Care

Key Questions 1 and 2, Efficacy

Data from one small, poor-quality trial (N=201)[102] in acute patients with suspected ACS are insufficient to draw conclusions regarding the risk of MI, all-cause or cardiac mortality, ICA, additional downstream NIT, any revascularization and rehospitalization for acute chest pain following stress echocardiography versus standard care.

- No MIs and no deaths were reported in either test arm. Stress echocardiography resulted in fewer referrals for ICA and additional NITs, and fewer rehospitalizations for acute chest pain, but no difference in revascularization rates (SOE Insufficient).

Stress Echocardiography versus ICA

Key Questions 1 and 2, Efficacy

One good-quality trial (N=448)[126,133] comparing stress echocardiography with ICA in stable outpatients with a mix of known and suspected CAD was identified.

- There was insufficient evidence to draw conclusions regarding the risk of MI, all-cause mortality and cardiac mortality between groups. Over 18 months, the absolute risk was <3 per 100 patients across both test arms for all outcomes; at 72 months, the absolute risk of all-cause mortality was 4.9 vs. 3.2 per 100 patients. Given that these are rare events, the trial may not have been sufficiently powered to detect a difference (SOE Insufficient).
- There were no differences between stress echocardiography and ICA in the risk of additional downstream NIT (SOE Insufficient), any revascularization and hospitalization for chest pain (SOE: Low for both).

Safety of Stress Echocardiography (Key Question 3)

- Data from one poor-quality trial is insufficient to draw conclusions regarding test-related complications.[102]
- Across 11 case-series,[10,22,38,46,64,90,95,103,110,112,128] the risk of major or life-threatening adverse events (e.g., death, MI, unstable angina, cerebrovascular accident, acute pulmonary edema) as a result of pharmacologic stress agents appears to be low: for dobutamine, ≤0.1% across all outcomes, and for dipyridamole and adenosine no major adverse events were reported. Minor transient events (e.g., arrhythmias, chest pain, headache, dyspnea, nausea/vomiting) were not uncommon (SOE low for all); most reported symptoms are expected responses to the pharmacologic agents used.
- Definite or suspected contrast related adverse events and allergic reactions appear to be rare (≤2% across all studies/outcomes) (SOE Low).

PET vs. SPECT

Two trials comparing PET versus SPECT, one in stable patients with a mixed of suspected or known CAD (N=210)[98] and one in stable patients with known CAD presenting with new or worsening symptoms (N=322),[109] were identified. Across both trials, there were no difference between test groups in any of the reported outcomes.

- There was insufficient evidence from one good-quality trial in patients with known CAD and new or worsening symptoms to draw firm conclusions regarding MI and all-cause mortality. The absolute risks of MI and all-cause mortality were ≤1 per 100 patients across both the PET and SPECT arms over 12 months (SOE Insufficient). There was no difference in the risk of ICA (29 vs. 28 per 100 patients); of diagnostic failure, defined as unnecessary ICA or additional confirmatory noninvasive testing within 2 months (2.0 vs. 2.5 per 100 patients); of any revascularization (16 vs. 15 per 100 patients); and of escalation in antianginal therapy (26 vs. 23 per 100 patients) (SOE Low for all).
- The only outcome reported by the older, poor-quality trial evaluating a mixed population of suspected and known CAD was cardiac mortality (absolute risk 3 vs. 4 in 100 patients over a mean 9 months) (SOE Insufficient).
- Neither trial reported on test safety or on differential effectiveness or safety.

Key Question 5: Cost-effectiveness of testing

Economic studies identified for inclusion primarily compared combinations of testing strategies involving CCTA, stress nuclear imaging (primarily SPECT), stress echocardiography, exercise ECG treadmill testing and invasive coronary angiography, with only few directly comparing one specific test to another. Only

[redacted]. A total of three systematic reviews[134,138,143] and 11 primary studies were included. Eight of the studies (in nine publications) were in stable outpatients with suspected CAD,[6,13,14,50,61,65,74,85,93] and three were in patients with suspected ACS.[41,114,115] Of these, two studies in stable outpatients[65,93] and three studies in patients with suspected ACS were conducted in the United States.[41,114,115] Industry funding was noted and/or author ties to related industries were described in three studies.[41,65,93] Full economic studies of diagnostic testing are complex, challenging to perform and challenging to interpret. A variety of assumptions and estimates from diverse sources (which may vary in quality) provide input into any economic model and impact the results of that model. These are discussed in the full report.

Most economic models described in the systematic reviews and the primary studies compared testing strategies (i.e., different scenarios for index test and subsequent sequential tests) not individual tests, making it difficult to draw definitive conclusions for specific tests. The results below attempt to focus on findings for specific tests. Variation across studies in data sources, estimation of model parameters, clinical pathways for test sequencing and decision making leading to additional testing and/or treatment make comparison across studies challenging. Evidence was mixed for demonstrating a definitive cost-effective diagnostic approach.

- Results across studies (including systematic reviews) were somewhat mixed.
- Cost-effectiveness and ICERs varied based on testing sequencing, pre-test likelihood of CAD, assumed accuracy of tests across populations. These key drivers were also identified in the prior HTAs.
- In stable outpatients with suspected CAD
    - The U.S. studies generally found CCTA to be the dominant initial testing strategy against comparators/other strategies, which included ICA and functional tests. FFRct in addition to CCTA was consider cost-effective in one industry-funded study.
    - Stress echocardiography and SPECT were found to be cost-effective compared to ICA.
    - Two systematic reviews suggest that stress echo or nuclear stress testing may be more cost effective than comparators in some settings depending on patient prior probability of CAD and prevalence of CAD. Stress echo may be more cost-effective than SPECT in patients with low to intermediate probability.
- In patients presenting with suspected ACS in an emergency setting
    - CCTA was compared with standard of care (variably defined), ETT, expert consensus based on ACC/AHA guidelines and “do nothing” strategies. CCTA was the dominant or cost-effective approach in most all comparisons.
    - In one poor-quality review of seven studies in patients with acute chest pain, stress nuclear testing was cost-effective versus traditional strategies involving ECG. However, authors note that stress nuclear testing in the acute setting may not often used in ‘real life’, due to logistical challenges.
- Common limitations across studies include
    - The assumption that ICA has 100% sensitivity and specificity.
    - Extrapolation of data to lifetime time horizon particularly when RCT data is only

available for approximately 2 years for many of the studies. Results from short-term time horizons may differ from those seen at longer term.
  - Lack of or insufficient modeling of indeterminate tests, false positive and false negative results, test accuracy based on sequencing of tests, potential adverse events and follow-up of incidental findings.
  - Some modeled strategies (e.g., some "do nothing" strategies) may not be consistent with clinical practice. Modeling of appropriate "no test" strategies was not done.
  - Models assume the availability of all tests and competence in performing and interpreting them across clinical settings.
  - Lack of information on the potential impact of radiation exposure for index and downstream testing.

Discussion

Regarding the pathophysiology of CAD and ischemia, several factors are important to consider. First, identification and degree of obstruction do not always correlate to patient symptoms, the presence or degree of ischemia or the functional impact. In addition, ischemia may be present in the absence of obstruction and would not be identified by anatomic testing.

The bulk of new evidence for this report is from RCTs comparing CCTA with functional tests.

- There is no clear difference between CCTA and functional imaging tests (i.e., stress nuclear testing, stress echocardiography) regarding impact on improving clinical outcomes (MI, all-cause mortality) in stable outpatients with suspected CAD or in patients with suspected ACS presenting to the ED or similar settings. It should be remembered that evidence of the impact of testing on clinical outcomes is indirect.
- CCTA was associated with higher frequency of ICA referral and use of PCI for revascularization compared with functional imaging. From the evidence available, it is not clear to what extent patients referred for these were considered at high risk for MI requiring revascularization. While increased ICA/PCI use may lead to fewer symptoms, related increased resource utilization and radiation exposure should be considered. No differences in the use of additional noninvasive testing between CCTA and functional tests were identified.
- Risk of serious test-related adverse events was very low across all imaging tests.
- While radiation exposure at time of index testing tended to be lower in CCTA recipients compared with SPECT (stress echo does not involve ionizing radiation), the evidence suggests that cumulative radiation may be higher with CCTA as an initial test. The extent to which this is influenced by additional non-invasive testing and/or ICA and PCI referral is unclear across included RCTs.
- Incidental findings requiring follow-up in patients receiving CCTA are common and require additional resources.
- Definitive conclusions regarding cost-effectiveness of any of the noninvasive imaging tests are not possible in large part due to substantial heterogeneity across economic studies regarding testing strategies and test sequencing.
- There was insufficient evidence for the use of FFRct in conjunction with CTTA.

The applicability of the evidence and findings reported here may be limited by the following factors.

- There was substantial heterogeneity across studies regarding patients, their pre-test risks of CAD (and how this was determined) and CAD risk factors, equipment used, testing protocols and study methods.
- Pretest CAD risk described in this HTA was as reported by study authors and included a variety of methods. Stratification by pre-test risk was not considered to be feasible given this heterogeneity.
- Stress echocardiography and SPECT are established modalities for diagnosis of CAD.
    - Fewer trials of these modalities were identified; most were older than CCTA trials and reflect older research methods and reporting standards. Included RCTs do not reflect state of the art equipment or techniques, whereas studies of CCTA involve more state-of the-equipment and methods.
    - Given that these are more established modalities, there has been less impetus and funding for RCTs and high-quality prospective observational studies than for evaluation of CCTA.
    - It is possible that more advanced techniques related to stress echocardiography using contrast for left ventricular opacification or myocardial perfusion imaging or quantitative methods for PET may have been used in included RCTs but were not assessed as separate advances.
- Substantial expertise is required to perform and interpret all diagnostic imaging tests for CAD. Across included studies, the level of expertise for all imaging tests was high. This level of expertise may not translate to all clinical settings. Similarly, the availability of updated equipment may also vary across settings. These factors need to be considered when weighing options for the “best test” for a given patient.

1 Appraisal

1.1 Background and Rationale

1.1.1 Policy Context

CCTA and stress nuclear imaging were originally reviewed in 2008 and 2013 respectively. They are being re-reviewed in 2021 due to newly available published evidence. In addition, stress echocardiography is being reviewed (not previously reviewed by HTAP).

1.1.2 Objectives

The aim of this report is to evaluate the clinical impact (i.e., patient outcomes and patient management), safety and cost-effectiveness of the three primary noninvasive diagnostic tests for CAD, namely CCTA , stress nuclear imaging and stress echocardiography as well as FFR based on CT and CT perfusion (CTP) imaging. This review updates the 2008 CCTA HTA and 2013 nuclear imaging HTA and adds evaluation of stress echocardiography. Information on diagnostic accuracy (validity) for these modalities was summarized for context only given the clinical maturity of these imaging modalities. Coronary artery calcium scoring (CACS) as a diagnostic test was excluded as it is not a standalone diagnostic test; further, it was not chosen for re-review by the Health Care Authority. Use of CT (including CACS), CCTA, nuclear imaging and stress echocardiography for ***screening*** for CAD in ***asymptomatic*** individuals was excluded.

1.2 Contextual Questions

Prior to addressing research questions related to the impact of cardiac imaging on clinical outcomes ***the diagnostic accuracy (validity)*** of these modalities compared with invasive coronary angiography (the usual reference standard) will be briefly summarized for context, given the clinical maturity of these imaging modalities.

In patients with **known or suspected CAD who are *symptomatic***:

1. What is the diagnostic accuracy of *CCTA* for anatomical confirmation of obstructive CAD? Is there evidence of differential test accuracy for specific subpopulations (e.g., women, patients with comorbidities, the elderly)?

2. What is the diagnostic accuracy of *CCTA with determination of fractional flow reserve (FFR)* for the diagnosis of CAD? Is there evidence of differential test accuracy for specific subpopulations (e.g., women, patients with comorbidities, the elderly)?

3. What is the diagnostic accuracy of *stress CCTA* for the diagnosis of CAD? Is there evidence of differential test accuracy for specific subpopulations (e.g., women, patients with comorbidities, the elderly)?

4. What is the diagnostic accuracy of *stress nuclear imaging*? Is there evidence of differential test accuracy for specific subpopulations (e.g., women, patients with comorbidities, the elderly)?

5. What is the diagnostic accuracy of *stress echocardiography*? Is there evidence of differential test accuracy for specific subpopulations (e.g., women, patients with comorbidities, the elderly)?

1.3 Research Key Questions

The following Key Questions focus on ***the impact on clinical outcomes*** for the use of CCTA, stress nuclear imaging, and stress echocardiography to diagnose CAD **in patients with known or suspected CAD who are *symptomatic.***

1. What is the comparative effectiveness of noninvasive cardiac anatomic or functional imaging modalities (CCTA, stress nuclear imaging, stress echocardiography) in leading to improved *clinical outcomes* (e.g., MI, mortality)?

2. What is the comparative effectiveness of noninvasive cardiac anatomic or functional imaging modalities (CCTA, stress nuclear imaging, stress echocardiography) with respect to *clinical decision-making* including additional testing and treatments?

3. What is the comparative effectiveness of noninvasive cardiac anatomic or functional imaging modalities (CCTA, stress nuclear imaging, stress echocardiography) with regard to *harms or adverse events* which may result directly from testing or additional, downstream testing?

4. Does effectiveness (in terms of clinical outcomes) or safety of noninvasive cardiac anatomic or functional imaging (CCTA, stress nuclear imaging, stress echocardiography) differ in *special populations* (e.g., women, those with comorbidities, the elderly)?

5. What is the *cost-effectiveness* of noninvasive cardiac anatomic or functional imaging modalities (CCTA, stress nuclear imaging, stress echocardiography) for clinical outcomes?

1.4 Key Considerations Highlighted by Clinical Experts: Cardiac Imaging for CAD (symptomatic patients with suspected or known CAD)

1.4.1 Interventions

The use and complexity of noninvasive cardiac imaging has expanded substantially in the past three decades. Despite numerous advances in the technical performance of various cardiac imaging modalities, the precise role(s) of some of these tests and when to use them remains unclear. There is lack of consensus and some controversy across the clinical community with regard to the optimal noninvasive imaging approach(es) for evaluating patients with symptoms of ischemic heart disease, particularly in patients with low to intermediate pre-test risk for CAD.[221] Some clinicians suggest that

there is overuse of such imaging and note that inappropriate cardiac stress tests in particular costs the U.S. health care system as much as one half a billion dollars each year and expose patients to unnecessary radiation.[206] In contrast, some clinicians suggest that imaging tests may assist with risk stratification and initiation of appropriate medical therapy. Many clinicians question whether noninvasive imaging is necessary at all, in patients who are at very low, low or even intermediate risk of CAD. In these populations, a large number of false positive tests are generally seen which may lead to additional testing and clinical evaluation and/or initiation of unnecessary or inappropriate treatment. In addition, many clinicians cite lack of evidence that testing in these populations leads to better clinical outcomes such as myocardial infarction. In general, appropriate use criteria indicate that imaging tests in populations with low pretest CAD probability presenting with non-acute chest pain, interpretable ECG and ability to exercise are rarely appropriate or use may be uncertain.[259]

In addition to the question of whether *any* testing is needed in patients with low to intermediate CAD risk, there continues to be controversy regarding whether anatomic tests such as CCTA or functional tests such as stress ECG, stress echocardiography or stress nuclear imaging should be the initial test for evaluating patients for suspected or known CAD or those with suspected ACS. While anatomic tests allow for visualization of coronary artery obstruction, the presence of obstruction does not always correspond to patient symptoms and does not provide information on the impact of the obstruction on myocardial function. Acute MI frequently occurs in patients without prior obstructive plaque.[206] Stress testing provides information on the functional impact of obstruction on the myocardium when hemodynamically significant stenosis is present but does not provide direct visualization of plaque (obstructive or not).[206] CCTA is the primary noninvasive imaging test that is used to specifically evaluate coronary anatomy. The primary functional *imaging* tests used to diagnose CAD are stress echocardiography and stress nuclear imaging via SPECT and less commonly, PET.

The choice of which test(s) to use for the evaluation of CAD is a function of historical practice, institutional availability, local expertise to perform and interpret exams and reimbursement. Each test has its proponents, pros and cons. All require substantial expertise for performance and interpretation; thus, the accuracy of the test will vary according to technical and reader expertise.

Stress ECG (exercise treadmill testing, ETT) has been used for decades to evaluate possible ischemic heart disease due to coronary artery obstruction and remains a common initial functional test in many settings. It has the advantages of being widely available, portable, relatively easy and quick to perform and interpret and is inexpensive. Changes on the electrical signals identified with ECG however, may not be apparent unless there is substantial ischemia (or infarction) due to obstruction of the coronary arteries and does it not provide visualization of the heart. None-the-less it is often the first test considered and may be standard of care in many settings. It is one of the functional comparators described in studies of CCTA, nuclear stress testing and stress echocardiography included in this report.

Stress echocardiography has also been used for decades to image and evaluate changes in wall motion due to myocardial ischemia (or infarction) induced when stress via exercise or pharmacologic agents is applied, thus providing functional assessment of impact of obstruction on cardiac function and anatomy. Changes in wall motion are seen earlier in a patient's clinical course if ischemia is present compared with electrical changes. Echocardiography may also provide valuable information regarding the integrity of

various cardiac structures (e.g., papillary muscle and related valve function) that may have been impacted by CAD. Stress echocardiography is widely available, portable, and relative to other imaging modalities for CAD, relatively inexpensive and does not involve ionizing radiation. Stress echo may be difficult to perform and interpret in obese patients or those with pulmonary disease. It is operator dependent and requires substantial expertise for comprehensive, accurate interpretation.

Nuclear stress testing via SPECT or PET, (often collectively referred to as myocardial perfusion imaging) also provide functional information via evaluation of cardiac wall motion and function. Both require the use of radioactive tracers in addition to pharmacologic stress agents and involve specialized equipment which may not be readily available in smaller clinical settings. SPECT is most commonly used.

PET is less commonly used largely due to its availability outside of larger institutions coupled with equipment reliability and maintenance issues. Both require expertise for comprehensive, accurate interpretation.

CCTA is used to evaluate coronary artery anatomy and visually estimate the amount of coronary artery obstruction. Its use has become more common in the past 15 to 20 years as the technology has advanced, including use of methods for reducing radiation exposure. Advantages include CCTA's ability to rapidly visualize coronary obstruction and presence of plaque in the vessels. As with SPECT and PET, CCTA involves radiation exposure and requires specialized equipment. In addition to potential concerns regarding radiation exposure, particularly if contrast is used, image artifacts in patients with substantial coronary artery calcium may render images uninterpretable. A certain level of expertise is required for interpretation.

Although a number of RCTs comparing CCTA with functional testing have been conducted in the past decade in particular, as previously mentioned, there is lack of consensus and some controversy across the clinical community with regard to the optimal noninvasive imaging approach(es) for evaluating patients with symptoms of ischemic heart disease, particularly in patients with low to intermediate pre-test risk for CAD.[221] This may be part due to somewhat conflicting results across trials on the impact of CCTA compared with functional testing on clinical outcomes, referral for ICA, diagnosis of new CAD and impact on treatment decisions. Proponents of the CCTA approach cite reduced myocardial infarctions and the ability to introduce preventative medical therapy as the advantages of it.[154] In particular, many feel that the predictive values of CCTA can reduce unnecessary downstream testing.[154] However, the 2017 meta-analysis referenced above found that CCTA leads to an increase in downstream invasive procedures. This systematic review and meta-analysis of trials published through 2017, found that CCTA, when compared to functional stress testing, may reduce the incidence of myocardial infarction but had no significant impact on death or cardiac hospitalization.[73] One included trial, the SCOT-HEART was the main driver for the reduction in myocardial infarctions.[215] In this trial, 85% of patients in the CCTA arm received functional stress testing. When it was removed from the analysis, the difference in myocardial infarctions was no longer significant. The same review found that CCTA increases rates of invasive coronary angiography and coronary revascularization, as well as new coronary artery disease diagnoses and new prescriptions for aspirin and statin medications compared with functional testing.

One primary disadvantage of CCTA is that it does not provide functional information on the impact of the hemodynamic significance of obstruction. Clinicians may therefore also order one of the functional tests previously described for further clinical decision making, including the need for referral to ICA. Recently, studies have evaluated the use of FFR derived from CCCT data (FFRct) and CT perfusion (CTP), which uses pharmacologic stress during CT to evaluate the hemodynamic impact of obstruction to complement anatomic visualization. These adjuncts to CCTA are not widely used currently and their role in routine evaluation of CAD is not established. Limited clinical studies of these have evaluated the incremental value of adding them to CCTA and have been conducted in highly specialized settings. Overall, both FFRct and CTP have showed better accuracy than CCTA alone but have low overall positive predictive value[46]; accuracy is impacted by CAD prevalence and pre-test probability. With regard to FFRct, only one device/analysis method, the HeartFlow is currently commercially available and FDA approved (510K) for use. It uses CTTA imaging data that are transferred to HeartFlow, Inc. a sole vendor, for analysis. This may limit the utility of this technology. Concerns regarding the diagnostic accuracy of FFRct (including the number of false positives), potential higher use of ICA when used as a substitute for planned noninvasive cardiovascular testing and limited evidence of clinical utility or impact on clinical outcomes have been noted in a recent review.[100] In addition, concerns regarding timely reporting of results in an acute care setting have been raised. A recent study evaluating a strategy of CCTA with selective FFRct in stable outpatients reported no difference in cost or clinical outcomes compared with standard care.[44] (This study did not meet the inclusion criteria for this HTA.) Anecdotally, it may be used in low-risk patients, particularly women, who many clinicians feel should not be tested. This may be of concern as middle-aged women may be at higher risk of radiation induced cancers.

CT myocardial perfusion imaging evaluates the impact of epicardial and microvascular disease on myocardial blood flow. There are limitations to its use including the need for extra time to prepare for and perform stress imaging in addition to the CT anatomic imaging, timing the use of pharmacologic stressors as well as additional contrast and radiation exposure that are involved.

1.4.2 Costs

Stress ECG is the least costly of the primary tests that are used to evaluate symptomatic patients for CAD. With regard to noninvasive imaging, the least expensive is stress echocardiography. CCTA is slightly less expensive than SPECT. In addition to costs related to primary testing, the costs of any additional downstream testing needed to follow-up inconclusive tests, false positives, incidental findings and treatments need to be considered. The choice of test is also influenced by reimbursement.

1.4.3 Patient considerations

The value of doing a test is related to the pre-test likelihood of disease and the extent to which a test helps confirm or rule out a given diagnosis. The pre-test likelihood of CAD is largely based on sex, age, type of chest pain as well as other symptoms and factors. This is important when considering use of a diagnostic test and in comparing the results of studies validating diagnostic tests. Predictive values are influenced by the pre-test probability of disease. Cardiac imaging in patients who are asymptomatic is

not routinely done or considered appropriate by many clinicians, evidence-based clinical guidelines and recent USPSTF evaluations and guidelines.

Evaluation of patient pre-test CAD probability has traditionally been based on the work of Diamond and Forrester[55], however a wide variety of other methods have been used and proposed. The HEART ((History, Electrocardiogram, Age, Risk factors, Troponin) methods is frequently used in emergency departments to triage patients presenting with acute chest pain or suspicion of acute coronary syndrome and determine next steps for testing and care.[16,219]

CCTA and nuclear stress testing are noninvasive imaging tests, they do, however, expose the patient to ionizing radiation. Given the cumulative nature of radiation exposure, consideration of patient age, habitus, and other factors need to be weighed in considering the types and sequences of tests. For CCTA since scanning includes not only the coronary arteries but surrounding structures as well, potential abnormalities in structures other than the coronary arteries with CCTA and heart might be observed, and further evaluation may be required. The costs and implications of incidental findings should be considered.

A recent CADTH rapid report on patient and caregiver perspectives on advanced cardiac imaging suggest that patient-provider communication needs to extend beyond the general benefits and risks of scanning to include information about the processes and pathways of attending the scan, why they are undergoing such imaging, why it is important and what they can expect from the process.[231]

1.4.4 Professional considerations

The primary goal of doing testing is to provide information on the need (or lack thereof) for initiating appropriate treatment. In many instances, guideline directed medical therapy and lifestyle change recommendations serve as the primary recommendations in patients with low to intermediate risk of CAD. Recent studies suggest that for patients at low to intermediate risk, results may be similar for guideline directed medical therapy and PCI. The local availability of testing and expertise in preforming and interpreting various types of non-invasive imaging need to be considered.

1.4.5 Ethical considerations

Although CCTA and nuclear stress testing are noninvasive tests, they do expose the patient to ionizing radiation, a factor which clinicians need to consider and put in the context of other tests that may be part of the clinical pathway which also may use ionizing radiation. Radiation accountability frameworks have been recommended to promote shared decision making with patients and drive appropriate imaging utilization.[62] There is also lack of consensus regarding how to best handle interpretations and follow-up of non-emergent incidental findings that are frequently seen particularly with CCTA.[24,124,125]

These factors should be considered when weighing the benefits, risks and costs need to be discussed with the patient.

1.5 Outcomes Assessed

The primary clinical outcomes of interest for this report are listed below.

- Myocardial infarction*
- All-cause mortality*
- Cardiac death*
- Safety/adverse events*

The clinical management outcomes of interest for this report include:

- Referral for additional testing (ICA or noninvasive imaging)*
- Referral for treatment (revascularization)*
- Changes in medication therapy
- Hospitalizations or ED visits

Other outcomes reported included, major adverse cardiac events (MACE), other cardiac events as reported (e.g., cardiac arrest, unstable angina, stroke, cerebrovascular accident), the Seattle Angina Questionnaire (SAQ), validated health-related quality of life measures, and length of hospital stay.

Outcomes are detailed in the evidence tables in the appendices and/or the body of the report.

Strength of evidence was assessed only for the outcomes with an asterisk above.

1.6 Washington State Utilization Data

1.6.1 Population

Administrative claims and encounter data for coronary computed tomography angiography (CCTA), stress nuclear imaging, and stress echocardiography from the following Washington State health programs were assessed: the Public Employees Benefit Board Uniform Medical Plan (PEBB/UMP), Medicaid managed care (MC) and fee-for-service (FFS), and the Department of Labor and Industries (L&I) Workers' Compensation Plan.

The assessment includes final paid and adjudicated claims and encounters. Denied claims or rejected encounters are excluded. Individuals that were dually eligible for both Medicare and Medicaid are excluded from the Medicaid program analysis. The PEBB/UMP experience includes claims for non-Medicare services.

1.6.2 Noninvasive cardiac imaging procedures

The assessment includes only procedures and services specific to noninvasive cardiac imaging with a date of service between January 1, 2017, and December 31, 2020. Analysis does not include additional services associated with imaging procedures.

Claims and encounters with qualifying procedures or services according to current procedural terminology (CPT) code or level II healthcare common procedure coding system (HCPCS) during the period were extracted for analysis.

Amount paid, by modality and procedure code					
SPECT	$5,500,304	$5,162,988	$4,886,019	$4,606,205	**$20,155,516**
Stress Test	$2,230,498	$2,058,511	$1,965,027	$1,821,426	**$8,075,462**
Stress Echocardiography	$945,737	$900,264	$954,111	$965,075	**$3,765,187**
PET	$180,756	$153,821	$223,613	$70,408	**$628,598**
CCTA	$133,228	$146,242	$188,466	$151,934	**$619,870**
Other Noninvasive Cardiac Imaging	$149,952	$134,222	$117,250	$125,351	**$526,775**
General Nuclear Imaging	$6,485	$11,272	$14,919	$1,500	**$34,176**

Data notes: Annual members for Medicaid excludes members that are dually eligible for Medicaid and Medicare. NR = not reported; small numbers suppressed to protect patient privacy. Managed care amount paid reflects an estimate of the amount paid for the procedure. UMP data does not reflect patient cost share. Individuals who had a procedure in more than one year are only counted once in the "Total" summary. Amounts paid of $0 were excluded from amount paid table value calculations. PET codes revised in 2020 were not included in utilization data; radiopharmaceutical codes for PET scans were not included.

Table 2. Demographics of Medicaid beneficiaries with at least one noninvasive cardiac imaging procedure, SFY 2017-2020

Age	Total (count)
20 years and below	452
21-44 years	10,204
45 years and above	28,865
Total	**39,384**

Table 3. Codes and cost by HCPCS/CPT code (maximum allowable), by state health program and setting

Code	Description	Medicaid FFS		L&I	
		Non-facility	Facility	Non-facility	Facility
75571	Computed tomography, heart, without contrast material, with quantitative evaluation of coronary calcium	$61.60	EAPG pricing	$199.40	$199.40
75572	Computed tomography, heart, with contrast material, for evaluation of cardiac structure and morphology (including 3D image post-processing, assessment of cardiac function, and evaluation of venous structures, if performed)	$146.21	EAPG pricing	$473.25	$473.25
75573	Computed tomography, heart, with contrast material, for evaluation of cardiac structure and morphology in the setting of congenital heart disease (including 3D image post-processing, assessment of LV cardiac function, RV structure, and function and evaluation of venous structures, if performed)	$196.41	EAPG pricing	Not covered	Not covered
75574	Computed tomographic angiography, heart, coronary arteries and bypass grafts (when present), with contrast material, including 3D image post-processing (including evaluation of cardiac structure and morphology, assessment of cardiac function, and evaluation of venous structures, if performed)	$211.41	EAPG pricing	$684.30	$684.30
78451	Myocardial perfusion imaging, tomographic (SPECT) (including attenuation correction, qualitative or quantitative wall motion, ejection fraction by first pass or gated technique, additional quantification, when performed); single study, at rest or stress (exercise or pharmacologic)	$202.01	EAPG pricing	$653.87	$653.87
78452	Myocardial perfusion imaging, tomographic (SPECT) (including attenuation correction, qualitative or quantitative wall motion, ejection fraction by first pass or gated technique, additional quantification, when performed); multiple studies, at rest and/or stress	$282.01	EAPG pricing	$912.83	$912.83

	(exercise or pharmacologic) and/or redistribution and/or rest reinjection				
78453	Myocardial perfusion imaging, planar (including qualitative or quantitative wall motion, ejection fraction by first pass or gated technique, additional quantification, when performed); single study, at rest or stress (exercise or pharmacologic)	$181.81	EAPG pricing	$588.49	$588.49
78454	Myocardial perfusion imaging, planar (including qualitative or quantitative wall motion, ejection fraction by first pass or gated technique, additional quantification, when performed); multiple studies, at rest and/or stress (exercise or pharmacologic) and/or redistribution and/or rest reinjection	$261.01	EAPG pricing	$844.86	$844.86
78459	Myocardial imaging, positron emission tomography (PET), metabolic evaluation	$816.02	EAPG pricing	$2,937.24	$2,937.24
78466	Myocardial imaging, infarct avid, planar	$120.01	EAPG pricing	$388.44	$388.44
78468	Myocardial imaging, infarct avid, planar	$115.41	EAPG pricing	$373.55	$373.55
78469	Myocardial imaging, infarct avid, planar	$134.01	EAPG pricing	$433.76	$433.76
78472	Cardiac blood pool imaging, gated equilibrium; planar, single study at rest or stress (exercise and/or pharmacologic), wall motion study plus ejection fraction, with or without additional quantitative processing	$136.41	EAPG pricing	$89.99	$89.99
78473	Cardiac blood pool imaging, gated equilibrium; multiple studies, wall motion study plus ejection fraction, at rest and stress (exercise and/or pharmacologic), with or without additional quantification	$172.81	EAPG pricing	$559.35	$559.35
78481	Cardiac blood pool imaging (planar), first pass technique; single study, at rest or with stress (exercise and/or pharmacologic), wall motion study plus ejection fraction, with or without quantification (single/multiple)	$105.21	EAPG pricing	$340.53	$340.53
78483	Cardiac blood pool imaging (planar), multiple first pass study at rest and stress, and requires two injections of appropriate radiopharmaceutical agent(s).	$144.01	EAPG pricing	$466.13	$466.13
78491	Myocardial imaging, positron emission tomography (PET), perfusion; single study at rest or stress	$1,502.51	EAPG pricing	$3,066.34	$3,066.34
78492	Myocardial imaging, positron emission tomography (PET), perfusion; multiple studies at rest and/or stress	$1,510.11	EAPG pricing	$3,097.99	$3,097.99
78494	Diagnostic nuclear medicine procedures on the cardiovascular system	$135.21	EAPG pricing	$437.64	$437.64

78496	Diagnostic nuclear medicine procedures on the cardiovascular system	$25.40	EAPG pricing	$82.22	$82.22
78499	Unlisted cardiovascular procedure, diagnostic nuclear medicine	By Report	EAPG pricing	By Report	By Report
93015	Cardiovascular stress test using maximal or submaximal treadmill or bicycle exercise, continuous electrocardiographic monitoring, and/or pharmacological stress; with supervision, interpretation and report	$41.40	Not covered	$134.01	$134.01
93016	Cardiovascular stress test using maximal or submaximal treadmill or bicycle exercise, continuous electrocardiographic monitoring, and/or pharmacological stress; supervision only, without interpretation and report	$12.80	Not covered	$41.43	$41.43
93017	Cardiovascular stress test using maximal or submaximal treadmill or bicycle exercise, continuous electrocardiographic monitoring, and/or pharmacological stress; tracing only, without interpretation and report	$20.00	EAPG pricing	$64.74	$64.74
93018	Cardiovascular stress test using maximal or submaximal treadmill or bicycle exercise, continuous electrocardiographic monitoring, and/or pharmacological stress; interpretation and report only	$8.60	Not covered	$27.84	$27.84
93350	Echocardiography, transthoracic, real-time with image documentation (2D, with or without M-mode recording), during rest and cardiovascular stress test using treadmill, bicycle exercise and/or pharmacologically induced stress, with interpretation and report	$111.61	EAPG pricing	$361.25	$361.25
93351	Echocardiography, transthoracic, real-time with image documentation (2D), includes M-mode recording, when performed	$138.21	EAPG pricing	$447.35	$447.35
93352	Echocardiography procedures	$19.80	Not covered	$64.09	$64.09

Data notes: Medicaid FFS from 10-1-2020 Physician-Related Services Fee Schedule and OPPS Fee Schedule (accessed October 1, 2021; webpage). L&I from 2020 provider fee schedule (accessed October 1, 2021). PEBB/UMP fees are confidential and not publicly available (proprietary).

2 Background

2.1 Nature and Burden of Disease

Coronary artery disease (CAD), also referred to as coronary heart disease (CHD) or ischemic heart disease (IHD), is a leading cause of death for both men and women in the United States and is the most common form of cardiovascular disease. The public health and economic burdens of CAD are substantial. It is estimated that around 20.1 million individuals in the United States 20 years or older have CAD, with a higher prevalence among males compared with females aged 60 and older.[251] Centers for Disease Control and Prevention (CDC) reported 690,882 deaths related to heart disease alone in the United States in the year 2020.[9] Estimates also suggest that roughly 720,000 individuals will have a new coronary event annually, and 335,000 individuals will have a recurrent event. Recent trends project an estimated incidence of 805,000 myocardial infarction events (605,000 new attacks, 200,000 recurrent attacks); roughly 21% (170,000 MIs) are estimated to be silent events.[251] Accordingly, CAD is associated with significant health system utilization and associated expenses. According to The National Ambulatory Medical Care Survey (NAMCS), around 11.1 million physician office visits occurred for CAD in 2016, and in 2018, 469,000 visits to the emergency department (ED) were identified as having a primary diagnosis of CAD. As of 2016, health care spending related to CAD was over $89 billion (54% public payer, 42% private payer, 4% out of pocket); around half (50%, or 44.5 billion) was attributed to inpatient care services and 24% (or $21.4 billion) was attributed to ambulatory care services. Selecting the appropriate assessment, testing, and treatment approach for an individual with suspected or known CAD has the potential to improve patient outcomes, patient satisfaction and optimal use of health system resources.

CAD is a disease of the blood vessels that supply the heart muscle. Atherosclerosis is the most common underlying cause of CAD and is the result of plaque buildup on artery walls. Plaque is a sticky, fatty deposit comprised of cholesterol and other cellular waste products. The buildup of plaque may partially or completely block blood flow in the coronary arteries via two primary mechanisms: 1) progressive narrowing of the vessel lumen and (2) thrombotic occlusion of the artery wherein the hard surface of the plaque tears away exposing inner fatty prothrombotic and platelet activating components at the site creating enlargement of the obstruction. The resulting decrease in blood flow can be chronic or acute and leads to a deficiency in the amount of oxygen and nutrients getting to the myocardium[50], which subsequently impairs the heart's ability to supply oxygenated blood to the body either at rest or during exertion. Atherosclerosis may lead to disruptions in normal vascular function, i.e., the ability to relax and constrict the artery walls or the microvasculature. Vascular dysfunction resulting from atherosclerosis can occur in instances of significant plaque buildup but may also occur in the absence of significant plaque in individuals with atherosclerotic risk factors or comorbidities such as diabetes, history of smoking, and sedentary lifestyle. Atherosclerotic plaque occurs commonly and is asymptomatic for years; symptoms usually don't occur until the artery is blocked by at least half. Most people with plaque will never develop clinical CAD. Ischemia and impaired function may also be present in the absence of observed obstruction on angiography.[103]

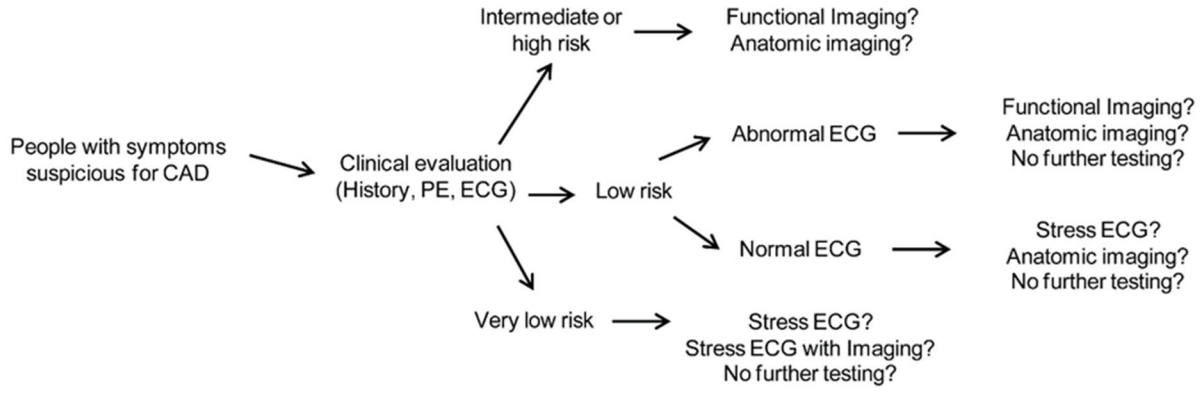
Chest pain (angina) is the most common symptom of obstructive CAD and is the first presenting symptom in most patients. Other symptoms of an acute coronary event related to CAD can include cold sweats, dizziness, light-headedness, nausea or feelings of indigestion, neck pain, shortness of breath, disturbances in sleep, and general weakness; common symptoms of chronic CAD may include shortness of breath with physical exertion, fatigue, and neck pain.[173] Plaque distribution, presence of collateral circulation and degree of vessel narrowing are factors which may influence symptom development and clinical impact of CAD; however, symptoms do not always correlate with lesion severity. For example, patients with obstructive CAD may be asymptomatic for many years (as has been observed in patients with diabetes) or may not present with symptoms until disease has progressed to the stage of heart failure.[118] It is estimated that roughly half of individuals who have a MI and no previous diagnosis of CAD did not report prior symptoms of obstructive CAD.[247] Studies have also shown that common symptoms of obstructive CAD are present in several noncardiac conditions such as gastroesophageal reflux, esophageal spasm, chronic obstructive pulmonary disease, and cervical disc disease, thus they are less reliable predictors of CAD. Non-specific symptoms may promote delayed testing or identification of obstructive CAD. Women and people with diabetes are less likely to experience classic angina, adding to the challenges of early CAD diagnosis in these populations.

2.2 Assessing risk of CAD

When assessing patients presenting with symptoms of CAD, their pretest risk or probability of CAD helps inform the choice and flow of testing. There are many available tools to assess pre-test risk of CAD, but the methods and models used can vary widely. Across included studies for this HTA, a wide variety of methods was used.

The American College of Cardiology (ACC) risk stratification model offers a framework for determining the likelihood that a patient's symptoms are related to obstructive CAD, according to age, sex and presenting symptoms.[71] Other factors, such as comorbid conditions (diabetes, hypertension, dyslipidemia) and the person's health history (smoking, family history of heart disease) may also be considered. A patient's chest pain symptoms are further characterized as typical, atypical, or non-anginal.[230] Risk groups are defined as low (<10%), intermediate (10% to 90%), and high (>90%). Patients assessed to be in the low to intermediate risk group comprises a broad spectrum of patients for whom a noninvasive test is usually recommended. Diagnostic challenges for intermediate risk patients will be discussed more the following section.

Figure 1. Overarching conceptual flow for initiating noninvasive testing based on risk assessment following initial clinical evaluation



Evaluation of patient pre-test probability of CAD has traditionally been assessed according to the Diamond and Forester method[55], a validated risk prediction tool. Recent studies suggest the model may overestimate pre-test risk of CAD among low-risk patients.[38] New prediction tools and methods have since emerged to address concerns of applicability and relevance to certain populations and settings; however, they may not be commonly used in clinical practice and may not prevent unnecessary invasive treatment and testing.[42,150] An assessment of patient history and physical evaluation remains the most routinely used to determine a patient's risk of CAD and is most cost effective. In accordance with the core factors identified in Diamond and Forester and current guidelines, clinicians typically consider patient age, sex, and current symptoms (such as type of chest pain) when assessing pre-test risk of CAD. Recent studies suggest that clinical discretion to defer testing among patients with low pre-test risk of CAD may decrease unnecessary studies and downstream treatments.[221]

In the emergency department setting, the HEART risk score (History, Electrocardiogram, Age, Risk factors, Troponin) is frequently utilized to objectively assess pre-test probability of CAD to support clinical decision making. The AHA recommends this assessment approach in the ED; however there remains uncertainty about the ideal thresholds to define low, moderate, and high pre-test risk to prevent unnecessary testing and invasive procedures.[219] In this setting, clinician assessment of type of chest pain is often a primary factor when determining the course of care, if electrocardiography (ECG) or troponin test results are unclear; however, this subjective assessment may not be accurate in correctly distinguishing patients for next line testing.[12,28,32] Other risk assessment and clinical decision-making tools have been developed for patients presenting with acute coronary syndromes (ACS) (e.g., Global Registry of Acute Coronary Events [GRACE], thrombolysis in myocardial infarction [TIMI] risk scores), but evidence suggests they may not prevent unnecessary care and may increase early invasive testing and treatment.[12,39]

The effectiveness of non-invasive imaging tests is influenced by patient pretest probability/underlying disease prevalence which impacts test performance for measures that are influenced by disease prevalence. The choice of test is influenced by pre-test probability. For example, in patients at high risk of CAD invasive testing is typically the approach taken. In contrast, Anecdotally, in patients with a low

pre-test probability of CAD, CCTA may be more likely to be used, while in patients with intermediate to high pre-test probability, stress echo or SPECT may be more frequently used and be more predictive of CAD presence, based on general precepts from the ACCF/AHA 2012 guideline. For any test, in patients with low pre-test probability of CAD, the number of potential false positive results necessitating further follow-up needs to be weighed against the potential for accurate detection of CAD. In some included RCTs, the frequency of MI and death was low, reflecting the low pre-test probability in these trials. In these instances, the benefit of testing may be unclear as the event rate in a low-risk population would likely be similar whether or not testing was employed.

2.3 Diagnosis of CAD

Accurate and early assessment of patients with symptomatic CAD is important for risk stratification and initiation of appropriate treatments to reduce morbidity and mortality. Noninvasive techniques used to diagnose CAD fall into two general categories, those that evaluate the anatomical aspects of vessel occlusion and those that evaluate the impact of occlusion on cardiac function. Each has strengths and limitations. Noninvasive anatomic tests provide information on location and extent of blockage and include coronary CT angiography (CCTA) and cardiac magnetic resonance imaging (CMRI). Functional tests allow assessment of whether symptoms are correlated with narrowing leading to ischemic areas and include exercise ECG, exercise/pharmacologic stress echocardiography, exercise/pharmacologic cardiac nuclear imaging with single-photon emission computed tomography (SPECT) or positron emission tomography (PET). There has been recent interest in using pharmacologic stress with magnetic resonance imaging (MRI) or computed tomography (CT perfusion imaging) and in determining fractional flow reserve (FFR) with CT. The choice of testing is dependent on a variety of patient and other factors, particularly in patients with stable CAD. The patient's pre-test probability of CAD in addition to accuracy of the test and the likelihood that test results would change management and lead to better outcomes are important considerations, as outlined above. Clinical decision-making regarding choice of test(s) needs to include consideration of the potential for additional/downstream testing, availability of other tests, cumulative radiation exposure and how results will inform appropriate management strategies and lead to improved outcomes while avoiding risks of testing such as additional radiation, false positives and incidental findings. There remains a lack of consensus regarding a single testing strategy or sequence of testing for the diagnosis of CAD, particularly for those at low to intermediate pre-test risk.[19] Low to intermediate pre-test risk as defined in the ACC/AHA guidelines (10% to 90%) may overestimate pre-test risk and observed prevalence has been shown to be much lower in real world clinical setting.[38] It also constitutes a very wide range of CAD risk. There is also recent evidence that suggests guidelines that focus on symptomology at presentation, as opposed to guidelines that take a more formal risk-based assessment, may safely characterize as low risk and prevent unnecessary testing.[5]

Historically, in the outpatient setting, the exercise stress test is used as a gatekeeper to more invasive cardiac testing, though the evidence is unclear on the prognostic benefit for patients with suspected CAD.[206,222] With the advent of low risk, non-invasive cardiac tests, there is a debate about the optimal diagnostic testing strategies for patients with suspicion of CAD[34,201,221] or known CAD. Some experts question the need for testing particularly among low-risk patients. Guidelines and expert opinion are

mixed when it comes to defining the current reference standard among non-invasive cardiac tests.[199,222] ACCF guidelines and ACR AUC recommend that for patients with suspected CAD and stable chest pain who are capable of physical exertion and an interpretable ECG, an exercise stress test with ECG or echocardiogram is the preferred first test among patients with intermediate pre-test probability.[71,222,259] However, NICE updated their guidance in 2016 to remove formal pre-test probability scoring and advised CCTA as the first line diagnostic test for all patients with suspected CAD presenting with chest pain or non-anginal pain with an abnormal electrocardiogram, prior to moving to functional testing as needed.[129] The 2019 ESC guidelines recommend non-invasive functional imaging, or CCTA, as the first line test for suspected CAD; like ACCF guidelines, if the first line CCTA test is equivocal, then functional imaging is recommended.[132] For patients that present to the ED with suspected ACS, CCTA has emerged as the predominant test to differentiate patients at high risk of a serious cardiovascular event.[12,18] High sensitivity troponin assays are increasingly used as a first line noninvasive test to rule out an acute coronary event. The utilization of biomarkers such as troponin may have implications for if and when noninvasive imaging, such as CCTA, is utilized in this setting.[260]

Exercise electrocardiogram treadmill testing (ETT) and the imaging tests CCTA, stress nuclear imaging and stress echocardiography have become established as diagnostic tests for CAD. The focus of this HTA is on the imaging tests and will not include ETT, except as a comparator test. As established testing modalities, the focus will be on evaluating their impact on clinical decision making for directing management that leads to improved patient outcomes. This HTA does not evaluate specific sequences of tests or incremental benefits of adding a specific test to another given the lack of consensus across the cardiology community and vagueness of evidence-based clinical guidelines.

2.4 Technologies and interventions

Given the invasive nature and risks associated with coronary angiography, non-invasive methods of assessing presence of CAD are important. All noninvasive methods have strengths and limitations. There is a continued debate with respect to the roles of various non-invasive tests in both ED and outpatient settings, such as which test should be the first-line test, and which test to use subsequently based on findings of the primary test. In the ED, the goal is to quickly identify patients without CAD who can be discharged, which reduces the need for ICA referral and observation. In an outpatient setting, the focus is on appropriate testing of patients presenting with stable, non-emergent symptoms of suspected CAD. Among patients presenting with stable CAD, there is no definitive algorithm for determining which imaging test to use based on patient outcomes and costs; variations in guidelines present additional complexity for clinical decision making.[250]

2.4.1 Invasive coronary angiography

ICA (also called coronary catheterization) is a 20-to-30-minute procedure where X-rays are taken of the heart's arteries while radiopaque contrast is injected simultaneously via catheter inserted in the wrist or groin artery. ICA provides information about the anatomy of the coronary arteries and size and location of obstructions in the lumen, as well as areas that may be stenotic. This information, taken together, helps to quantify the degree of disease that may be present. When determining a diagnosis of CAD,

thresholds of anywhere from ≥50% to ≥70% occlusion have been used. The rate of nondiagnostic or indeterminate studies from ICA is estimated to be 10%.[27] Potential harms include exposure to radiation, allergic reaction to contrast dye, bruising at site of catheter insertion; major harms are rare but may include arrythmias, blood clots, heart attack or stroke, and very rarely, death.

As stated previously, the advantage of ICA is that it provides accurate information about blockages in the heart's arteries and help identify reasons why the heart may not be functioning correctly. Historically, ICA has been considered the standard reference diagnostic test for anatomic CAD. However, an increasing body of evidence suggests it is an imperfect diagnostic standard. While size and location of plaques are visible, plaques with characteristics that may indicate high risk for future coronary events are not evident when reviewing images obtained from ICA, limiting the prognostic value of the test.[230] Only about 41% of patients undergoing elective procedure of catheter-based coronary angiographies are diagnosed with obstructive CAD.[202] A long-known limitation of the test is in the interpretation of results, due to variation in interobserver and intraobserver findings.[49,214,265] One study however suggests substantial interobserver agreement based on per-segment analysis.[31] There may be issues with accuracy, as evidence has shown that for lesions with less than 60% percent stenosis there may be significant under or over estimation of the severity of lesions.[242,254] Toth et al. similarly found the 50% threshold for the left main region significantly underestimated legion severity when compared to fractional flow reserve.[242] While there have been technological advances for decreasing radiation contrast toxicity and improving effective diagnosis with ICA in the past few decades, potential sources of error due to the equipment operation, technical interpretation, and natural biological fluctuations that may occur in response to the dye or during the procedure, remain. As noted elsewhere, expertise for performance and interpretation is important with all tests for CAD.

2.4.2 Coronary Computed Tomography Angiography

CCTA is a noninvasive, relatively quick anatomic imaging test that obtains x-ray images of the heart. Using contrast dye (iodine-based), images taken by CCTA will visualize the structure of the heart and any obstructive disease present in the heart's anatomy. Many hospitals have access to the machine and complimentary software packages used to process images and state of the art machines have a 64-slice or greater scanner. CCTA is typically used to rule out CAD diagnosis in patients with chest pain and low pretest probability of disease due to its perceived high negative predictive value and high sensitivity. It is also recommended for patients with atypical symptoms, with nondiagnostic results of a stress test or at high risk of catheterization. Abnormal findings on CCTA are defined as any irregularities of the lumen, which will determine next steps in prevention of disease progression and other possible disease sequalae. High risk findings on CCTA are typically defined as ≥50% stenosis in the left main region, proximal LAD stenosis ≥70%, or 3 vessel disease. CCTA is also useful for identifying causes of chest pain unrelated to heart function. The rate of nondiagnostic or indeterminate studies from CCTA imaging is estimated to be 2%.[27]

Key disadvantages to CCTA include exposure to radiation, moderate specificity (60-80%), and issues around diagnostic image quality.[52] There are quantification challenges due to cardiac motion artifact, "bloom artifact" due to calcification, and uncontrolled or irregular heart rate. Optimizing temporal

resolution can be challenging. In addition, distal vessels may be difficult to visualize. Furthermore, CCTA as a standalone test will not confirm ischemia. Regarding harms, aside from exposure to low levels of radiation during the procedure, some patients may experience allergic reaction to the contrast dye, and additional consideration is taken for patients with impaired renal function. Incidental findings on CCTA are not uncommon and can sometimes lead to unnecessary worry for the patient.

2.4.2.1 Fractional flow reserve (FFR) with coronary computed tomography angiography (CTTA)

FFR CT combines the anatomic coronary CT test with a functional test of coronary artery blood flow, providing both a quantification of anatomical obstruction and a calculation of pressure and flow for all coronary artery branches. FFR is defined as the ratio of maximum flow in a stenotic artery to maximum blood flow if the same artery were normal. Thus, the pressure measurements at the distal vessels illustrate the cumulative loss of pressure or blood flow and the effect of any diseased tissue near where the measurement is taken.[178] This relatively new combination approach requires previously acquired CT images of good image quality and there remains uncertainty about the extent to which biological factors affect test accuracy.[67] Currently, the only Food and Drug Administration (FDA) approved device/software for measuring FFR during either ICA or CCTA is Heart Flow. Information on the diagnostic accuracy of FFR CT can be found in the Contextual Question section of this report.

2.4.2.2 CT perfusion imaging

Like FFR CT, stress myocardial computed tomography perfusion (CTP) is a novel examination that provides both anatomic and physiological information (i.e., myocardial perfusion). CTP assesses blood flow distribution to the different regions of the myocardium at rest and after stress by using coronary vasodilator agents (adenosine, dipyridamole, or regadenoson), similarly to other non-invasive imaging techniques such as nuclear imaging myocardial perfusion imaging (MPI).[170] CTP utilizes iodinated contrast which attenuates X-rays proportionally to iodine content in tissue. Thus, myocardial perfusion defects can be directly visualized as hypoattenuating or non-enhancing areas containing reduced amounts of contrast material.[78] Information on the diagnostic accuracy of CTP can be found in the Contextual Question section of this report.

2.4.3 Nuclear stress imaging (myocardial perfusion imaging)

Nuclear stress imaging is a functional, non-invasive imaging test that shows how well blood flows through (perfuses) the heart muscle. It can show areas of the heart muscle that aren't getting enough blood flow by evaluating how well the heart muscle is pumping. It does not directly visualize the coronary arteries. This test is often called a nuclear stress test. There are 2 techniques for MPI: SPECT and PET. Both require injection of radioactive tracers (called radionuclides) which transmit radiation, allowing a specialized camera to take images of the heart that can be converted by a computer program for interpretation.

2.4.3.1 Single Photon Emission Computed Tomography (SPECT)

SPECT is a noninvasive nuclear imaging test. After injection of radionuclides (99mTc- sestamibi or 99mTc- tetrofosmin) into the blood, thin slice images of the heart are taken as a camera detects signals from the tracers and a computer program translates this information into 3-D images. Imaging takes about 20 minutes, with the stress imaging (exercise or pharmacologic) occurring 1 hour after the rest study is complete; overall, the rest-stress protocol is typically completed over 3-4 hours and may be completed in one- or two-day protocols. SPECT can show how well blood is flowing to the heart, how well the heart is working, and whether the patient previously experienced a heart attack. Providers can assess the ventricular size and function, wall motion abnormalities, and overall viability of the heart. SPECT can be used to diagnose CAD. It is a preferred approach for patients with left bundle branch block and is useful for patients with poor echocardiography windows. The rate of indeterminate studies from SPECT imaging is estimated to be 6.9%.[27,220] Compared to other noninvasive methods such as ECG, SPECT provides improved sensitivity and specificity. SPECT can also be used to inform decisions about treatment or therapy, based on findings.

Abnormal findings on SPECT are defined as detection of any perfusion defect and any wall motion abnormalities. High risk findings include a perfusion defect impacting ≥10% of heart tissue, more than one perfusion of moderate concern, a large, fixed defect with transient left ventricular dilation or increase in lung to heart ratio, or a stress induced defect of moderate severity with transient ischemic left ventricular dilation or increase in lung to heart ratio. SPECT results can be limited by soft tissue attenuation and motion artifact. SPECT is also limited in the quantification of blood flow since it measures relative flow, as opposed to absolute flow (and may miss three vessel disease). Harms may include exposure to some radiation from radionucleotides.

2.4.3.2 Positron Emission Tomography (PET)

PET is a noninvasive nuclear imaging test. Radionuclides (15O, 82Rb, 13NH3 or 18F- flurpiridaz) are injected into the blood, and a PET scanner will detect the radiation released by the tracer to produce images of the heart.[54] PET scans can identify diseased or damaged tissue, as well as healthy tissue, and assess whether enough blood is flowing through the heart. Scans take about 30-60 minutes, and the full rest-stress protocol may be completed in either 1 or 2 days. PET scans can be used to diagnose CAD and can identify damage to the heart due to heart attack. PET assesses ventricular size and function, as well as ischemia and viability. PET is also used to determine which patients may benefit from PCI, CABG, or another treatment. PET is the preferred approach for assessment of suspected CAD in women and patients who are obese. Abnormal findings on PET are defined as any perfusion defect. High risk findings are defined as a perfusion defect ≥10% of heart tissue, with particular attention to the anterior myocardium. The rate of indeterminate studies from PET imaging is estimated to be 4%.[220]

PET provides a more accurate assessment of blood flow than SPECT, due to measurement of absolute blood flow with trace kinetic modeling and attenuation correction. PET scans also have high image quality, which support clearer interpretation of findings. Regarding disadvantages, PET scans are expensive, and PET scanners are less available than other noninvasive imaging technologies in clinical

settings due to space and storage requirements. PET scans are limited to pharmacologic stress. Harms may include allergic reaction to the radioactive tracers and minimal exposure to radiation. Patients who are claustrophobic may be uncomfortable during a PET scan.

2.4.4 Stress echocardiography

Echocardiography is a noninvasive test that uses high frequency sound waves (i.e., ultrasound), to produce live images of the heart. Stress echocardiography is an established technique for assessing CAD. It evaluates how the well the heart is functioning under stress and is commonly used to identify areas of the heart affected by ischemia; the coronary vessels are not directly visualized, however. Stress can be induced by either exercise (stationary bicycle or treadmill) or pharmacologic agents (dobutamine typically). The major advantages of stress echocardiography are that the test protocol is simple, inexpensive, takes a relatively short amount of time to complete and it does not expose the patient to radiation, unlike other noninvasive imaging techniques. However, it tends to be less sensitive in detecting single vessel disease or mild stenosis since a significant amount of myocardium needs to be affected by ischemia for the test result to be positive; specificity has been, on average, somewhat higher than nuclear cardiology techniques and exercise ECG. Stress echocardiography also requires a high level of expertise to achieve accurate and reproducible results. Interpretation of findings may be limited by image quality, and it does not allow for quantitative analysis.

Abnormal findings on stress echocardiography are defined as new wall motion abnormalities and abnormal left ventricular ejection function during stress. High risk findings include left ventricular ejection function <35% (rest or exercise), wall motion abnormalities that include a minimum of 2 segments that develops with either exercise or pharmacologic stress, more than two segments displaying wall motion abnormalities at heart rate of <120 bpm, or evidence of severe ischemia during the stress test. The rate of nondiagnostic or indeterminate studies from stress echocardiography imaging is estimated to be 15%.[27,98]

2.4.5 Hybrid tests

Diagnostic tests that combined more than one imaging type also were considered if at least one component focused on myocardial perfusion, including PET/CT, and SPECT/CT. All of these tests are performed in conjunction with exercise- or pharmacologically-induced stress.

2.4.6 Harms

Primary harms identified for noninvasive imaging for suspected CAD include radiation exposure, reactions to stressor or contrasts agents used during the imaging test, possibility of incidental findings unrelated to heart disease, and multifaceted effects of downstream testing.

2.4.6.1 Radiation exposure

Radiation exposure is a measure of the quantity of ionization produced in air by photon irradiation. Radiation dose ("absorbed radiation dose") refers to the amount of radiation energy deposited in the human body as a result of exposure to ionization and is typically calculated from the exposure and from estimates of energy absorption per kilograms of body weight.[167]

Medical imaging is the largest controllable source of radiation exposure in the United States.[79] Cardiovascular-related tests and procedures comprise about 40% of all medical radiation exposure.[107] There is conflicting evidence regarding the risk of developing cancer at the levels and types of radiation associated with medical imaging and with the exception of mammography, there is currently no federal regulation of patient radiation dose.[167] Potential benefits and risks, including any related to not performing the test, should be carefully considered before ordering tests that will expose patients to ionizing radiation. Patient-centered shared decision making can prompt a discussion and improve transparency and education related the justification for the test, expected level of exposure to radiation, and steps the laboratory has taken to optimize the radiation dose used.[62]

As cardiac imaging has increased over time, there are concerns about the effects of increased radiation not only on a test-by-test basis, but also in consideration of the cumulative exposure across other tests that may be utilized as part of a patient's course of care. Excluding radiation therapy, the average per capita radiation exposure from medical sources increased 6 times from the period 19080-1982 to 2006.[61,212] In response, the National Council on Radiation Protection issued a report in 2017 indicating that the steep increase in imaging procedures may have plateaued, and that greater awareness of radiation risk may be a factor. However, large scale registries and international studies have shown wide variation in average radiation dose per procedure, indicating at least one area for improvement in and implementation of best practices (e.g., standard reporting, regional diagnostic reference levels) to minimize or reduce radiation exposure.[106]

A variety of factors can affect the radiation dose administered for a given test, including the model of the machine, the length of the scan, the number of scans, if gating is used, x-ray tube potential, tube current-time product, and patient size.[30] The values in the following table (Table 4) are based on literature estimates and are subject to change dependent on the imaging parameters utilized.

Table 4. Overview of radiation exposure ranges*

Radiation Exposure Type		Total Effective Dose (mSv)
Environmental Exposures	Round-trip flight, New York – Seattle	0.06
	Naturally occurring	3/year
	July 1971 lunar landing	5
	Nuclear worker	20
Diagnostic and Procedural Exposures	Echocardiography	0
	CMRI	0
	ECG	0
	Dental CT	0.2
	Mammogram	0.4

Radiation Exposure Type			Total Effective Dose (mSv)
	ICA	Range reported by Einstein 2014	2–20
		Range reported by ACR	1–10 (with or without ventriculography)
		Carpeggiani, 2017†	Mean (SD): 9.64 (9.7)
	CCTA	Range from studies included in Skelly 2016 (AHRQ report)	3.8–15.1
		Range reported in Einstein 2007 and 2014	<0.5–30
		Range reported by ACR	1–30 (using various contrast and dose techniques)
		Range reported by Cerqueira 2010	5–10
		Hirshfeld, 2018 (consensus document)‡	Helical, no tube current modulation: 8.0 to 30
			Helical, tube current modulation: 6.0 to 20
			Prospectively triggered axial: 0.5 to 7.0
			High-pitch helical: <0.5 to 3.0
		NICE, 2016 (guideline)	2.0 to 5.0
		Carpeggiani, 2017†	Mean (SD): 11.2 (8.1)
		Husmann, 2010	2.1 (0.7)
		Pursnani, 2015	All protocols and scanners: 9.9 (4.9)§
			Prospectively gated CCTA: 6.5 (3.8)
			Retrospectively gated CCTA: 10.4 (4.9)
			128-slice DSCT (n=78): 5.7 (3.7)
			CT scanners, excluding 128-slice DSCT: 10.7 (4.7)
		Mettler 2020 (non-cardiac CCTA)	Based on ICRP Publication 60 tissue weighting factors: 5.4
			Based on ICRP Publication 103 tissue weighting factors: 5.4
		Studies included in this report	Studies reporting mean effective dose: 5.3 to 12.7
			Studies reported median effective dose: 3.5 to 11.8
	Fluoroscopy for PCI	Range reported by Einstein 2014	5–57
	PET	Range from studies included in Skelly 2016 (AHRQ report)	6.0
		Range reported in Einstein	2 (^{13}N ammonia); 4 (^{82}Rb); 7

Radiation Exposure Type			Total Effective Dose (mSv)

2.4.6.2 Contrast materials

Contrast materials are used to better visualize the endocardium and improve interpretability and diagnostic accuracy of noninvasive imaging tests. Contrast materials may lead to decreased renal function or have serious adverse effects in persons with impaired renal function at baseline. Contrast induced nephropathy (CIN) is associated with reduced renal function within 48-72 hours of IV contrast administration. Definitions of CIN have varied over time, and other risk factors for CIA have been proposed in addition to renal insufficiency (e.g., diabetes, dehydration).[255] Patients may experience allergic reactions to iodine-based contrast agents, such as hives, rash, or anaphylaxis. There is evidence that allergic reactions may be infrequent; one study suggested roughly 1.7% of patients experienced an allegoric reaction (mild to severe) during the CCTA test.[23] Similarly, some studies of contrast use in stress echo suggest similar adverse event rates and infrequent allergic reactions when comparing patients who received contrast and those that did not.[4,15] Patient risk for adverse reaction to contrast should be considered when selecting the test technique.

2.4.6.3 Pharmacologic stress agents

Pharmacologic stress agents are used in noninvasive cardiac imaging when a patient does not have the capacity to undergo exercise induced stress, or for MPI tests such as PET (since the radionuclides used

for PET tests have a short half-life, pharmacologic stress is required). Agents include dobutamine (which increases coronary flow reserve in a manner similar to exercise), and coronary vasodilators, such as adenosine, dipyridamole, and regadenoson. Use of pharmacologic stress agents requires patients to limit caffeine intake prior to the test and may necessitate temporary halting of any cardiac medications to minimize risk of interfering with test procedures or results.[183] Side effects of pharmacologic induced stress include dizziness and chest pain; however, the safety profile of specific agents may be lacking in specific subpopulations or patients with certain conditions (e.g., obesity, history of seizures).[65]

2.4.6.4 Incidental findings

Some noninvasive imaging modalities, including CCTA, image other non-cardiac structures, such as the lungs, bones, and upper abdomen. Findings of pathologies unrelated to the heart may be incidentally identified when reviewing the test output. The most common extracardiac findings are pulmonary nodules; other common emphysema, pulmonary infiltration, hiatal hernia, and aortic abnormalities.[125] This can lead to additional specialty referrals and possible invasive procedures. Studies of patients undergoing CCTA suggest that any incidental extracardiac findings are common (range 28-35% of patients); one study suggested that 21% of incidental extracardiac findings led to additional clinical follow up or testing, and that the number of extracardiac findings was associated with increasing patient age and greater experience of the clinician reading the scan.[24,124,200] The potential for identification of other non-cardiac related pathologies is a factor to consider when deciding on a noninvasive diagnostic testing strategy for suspected CAD. The follow-up of incidental findings requires additional resources.

2.4.6.5 Subsequent testing

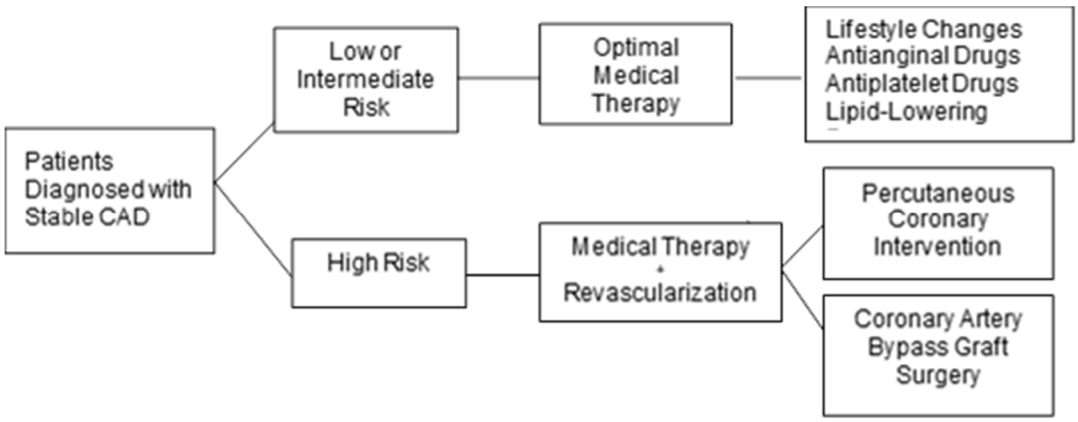
Downstream testing may be ordered if findings are equivocal or indeterminant. Additional testing may increase risk of false positive findings, increase patient anxiety, increase cost of care, and increase potentially avoidable tests.

2.5 Management

This HTA focuses on noninvasive imaging modalities as diagnostic tests for patients with symptomatic CAD. For a diagnostic test to be of value, it must lead to use of effective and appropriate treatments that impact patient outcomes. Where treatment outcomes are comparable, a treatment with higher specificity is a judicious choice to prevent a false positive result. Patients tested for symptomatic CAD have a variety of treatment pathways available and may be referred to different options depending on findings of the diagnostic test. A comparison of referral for treatment by noninvasive imaging modality critical to understanding how utilization of strategies affect the clinical course for the patient.
Once results of the diagnostic test are available, the patient risk of can be calibrated, in combination with pertinent patient history, symptoms and pre-existing comorbidities. Guidelines recommend categorizing patients into three primary risk groups according to their predicted risk of cardiac mortality per year, with low risk defined as <1% , intermediate risk as 1%-3% per year, and high risk defined as >3% rate of cardiac death annually among comparable patients. Patients determined to be at low or

intermediate risk are recommended medical therapy; more intensive revascularization procedures are reserved for patients categorized as high risk, based on their diagnostic test findings. Ultimately, the goal of treatment for stable CAD is to reduce the probability of death or other complications related to CAD, while optimizing the health, well-being, and function of the patient by minimizing symptoms. These considerations are balanced with the preferences and treatment goals of the patient.[71]

Figure 2. Initial treatment pathways for patients diagnosed with CAD



2.5.1 Optimal medical therapy

Optimal (or guideline-directed) medical therapy is optimized on a per-patient basis depending on patient characteristics and guideline recommendations. This may include lifestyle changes to physical activity, smoking cessation, weight management and diet modifications. Therapy will also encompass treatment of comorbidities that can affect (or be affected by) disease progression (e.g., diabetes, hypertension). Evidence suggests that 90% of the risk of having an MI is associated with modifiable risk factors, such as diabetes, smoking, hypertension, obesity; lifestyle modifications are a prudent foundation of any treatment approach for symptomatic CAD.[261] Other risk management strategies may be included, such as antiplatelet drugs and lipid-lowering drugs. Management of comorbidities with appropriate pharmacologic treatment can prevent further plaque buildup, rupture, and thrombosis.[71,232] To support relief of chest pain symptoms, beta-blockers, calcium channel blockers, nitrates, or ranolazine may be prescribed. These drugs reduce oxygen demand by the heart and aim to prevent the occurrence of anginal episodes; there is evidence suggesting up to 50% reduction in anginal episodes for use of beta-blockers and calcium channel blockers, but effect on serious cardiovascular outcomes is uncertain.[253] Medical therapy may be recommended alone, or in addition to revascularization procedures. Evidence suggests that for patients referred for revascularization procedures (along with medical therapy) a reduction in death was not observed, when compared to patients referred to medical therapy alone.[233] The recent ISCHEMIA trial found that patients with moderate to severe ischemia randomized to invasive treatment (revascularization) experienced increased rates of early MI and similar rates of death, when compared to patients randomized to medical therapy only.[152] Most patients with

symptomatic CAD will benefit from comprehensive and personalized guideline directed medical therapy, allowing for the prevention or deferral of unnecessary invasive procedures.

2.5.2 Revascularization

Revascularization methods include coronary artery bypass graft surgery and percutaneous coronary interventions (PCI). The selection of the type of procedure depends on patient presentation and diagnostic findings, as well as patient history. The severity of CAD and related anatomic features, such as the number of vessels involved and the spread and scale of stenosis, is a primary consideration when determining if the patient is a suitable candidate for a particular revascularization approach. The SYNTAX score is recommended as a tool to characterize the complexity, scale, and scope of CAD. In addition to other patient characteristics including age, findings of peripheral vascular disease and whether the patient has a history of smoking are important factors. Revascularization procedures aim to reduce risk of future serious cardiac events and death and have demonstrated success in reducing the risk of death in patients with severe left main artery stenosis, and patients determined to be at highest risk for poor cardiovascular outcomes.

Percutaneous coronary interventions (PCI) are non-surgical, invasive procedures to reduce the narrowing or obstruction of affected coronary arteries to improve blood flow to the heart tissue. PCI involves insertion of a catheter through a main artery to the site of the affected vessel, guided by x-ray images of the heart and the use of contrast dye. There, a device, such as a balloon, is used to open the vessel; a stent may be placed to keep the vessel open. The procedure is performed in a catheterization lab and can take 1-3 hours. A variety of PCI have emerged beyond the standard balloon angioplasty, such as angioplasty with implantation of bare metal stents or drug eluting stents. The introduction of drug eluting stents aims to prevent formation of scar tissue at the site of the stent placement to preserve blood flow and prevent development of further stenosis.

There is mixed evidence on which patient groups may benefit most from PCI, compared to medical therapy alone. There is some evidence suggesting improvement in angina symptoms and events, compared to medical therapy alone.[71] The evidence is less clear for prevention of serious cardiovascular events. One meta-analysis suggested that for patients with symptomatic CAD with ischemia identified by functional diagnostic testing, a significant reduction in death or nonfatal MI was not observed among those treated with PCI (with medical therapy) compared to patients who received medical therapy alone.[236] More recently, a meta-analysis of 10 797 patients with obstructive CAD and ischemia yielded similar results – patients treated with PCI (with medical therapy) did not experience a significant reduction in nonfatal MI, compared to patients who received medical therapy alone at median follow-up of 5 years.[233] This is concordant with earlier trials where the reduction in death and serious nonfatal events from PCI, vs medical therapy lone, yet to be clearly proven.[127,128,244]

Coronary artery bypass graft surgery (CABG) is a surgical procedure to divert blood flow from stenotic or obstructed vessels to improve blood flow to the heart. The procedure involves grafting arteries or veins from another part of the body, such as mammary arteries, radial arteries, or greater saphenous veins, to above and below the ischemic area of the heart. The typical duration of the procedure is 3 to 6

hours. Recent studies in patients with symptomatic CAD suggest that CABG (with medical therapy) appeared to reduce nonfatal MI compared to medical therapy alone; this was not observed when comparing PCI to medical therapy alone.[233] Patients undergoing CABG have a higher rate of complete revascularization, compared with patients undergoing PCI, which has been suggested as an explanation for the observed improved outcomes among patients who undergo CABG vs. PCI long term.[121] CABG may be preferred in patients where the primary goal of treatment is reduction in risk of mortality.

ACC guidelines recommend CABG for patients with significant left main coronary stenosis but suggest PCI as an alternative when patient has low risk of complications with PCI, and clinical factors that would suggest an increased risk of poor surgical outcomes.[71] When comparing PCI to CABG, trials suggest that while survival is similar at 1 and 5 years, relief of chest pain may be more effective with CABG than with PCI at 1 and 5 years, and repeat revascularization was less frequent for patients with CABG than those with PCI.[29]

2.5.3 Management of acute coronary syndromes

The primary goal of treatment for patients presenting with acute coronary syndromes is to relieve pain, improve blood flow and restore heart function as quickly as possible. This typically requires a combination of medical therapy and revascularization, depending on the type of acute coronary syndrome. In patients presenting with STEMI, non-STEMI or unstable angina, revascularization with PCI is considered appropriate if presenting within the first 12 hours of symptom onset.[190] All patients will receive guideline-directed medical therapy as well. Due to the acute presentation of the patient, if PCI is not available or patient is a suitable candidate for PCI then fibrinolytic therapy is recommended (for STEMI only). For non-STEMI patients, pharmacologic therapy, such as antiplatelet therapy and anticoagulants is recommended no matter the initial treatment strategy. Other pharmacologic treatments for either STEMI or non-STEMI may include beta blockers, angiotensin-converting enzyme inhibitors, angiotensin receptor blockers.

2.6 Previous Systematic Reviews of Noninvasive Cardiac Testing for Suspected CAD

Systematic reviews (SRs) were found by searching PubMed, the Cochrane Database of Systematic Reviews, and the ECRI Guideline Trust from database inception to March 23rd, 2021. Reference lists of relevant studies and the bibliographies of SRs were hand searched. See Appendix B for search terms and full search strategy.

Twelve SRs evaluating the effectiveness and/or safety of noninvasive cardiac stress testing in adult patients with suspected coronary artery disease (CAD) (stable or acute) were identified. Of these, eight included high-quality evidence (i.e., RCTs only) of which four were considered to provide the most comprehensive summary of the evidence to date, including trials summarized in the prior HTA and those published subsequently and are summarized below (Table 5).[73,113,227,228] Studies contained in these reviews that met inclusion criteria for this HTA were included. All four SRs provided quantitative syntheses; three did meta-analyses of head-to-head trials[73,113,227] and one conducted a network meta-analysis[228]. All four SRs compared CCTA with functional testing; in addition, the network meta-analysis compared one functional stress test versus another.

Across all three SRs evaluating head-to-head trials, compared with functional stress imaging, CCTA as an initial diagnostic strategy was associated with a reduced incidence of myocardial infarction (MI) but an increased incidence of downstream invasive procedures (i.e., ICA and revascularizations), with no difference in mortality. One SR also reported a reduction in downstream noninvasive testing with CCTA. Similar results were seen across the subgroups of stable chest pain and acute chest pain. One SR[73] evaluated the extent to which stable and unstable patients had different risk estimates by performing a formal test for interaction and found no difference between the two populations. The network meta-analysis found similar results regarding increased ICA and revascularization rates with CCTA versus any functional testing, but no difference in the risk of future MI in either low-risk ACS or stable CAD; however, authors notes that estimates were imprecise, especially for patients with stable CAD, and any differences could not be ruled out. No conclusions could be drawn regarding one functional test versus another, mainly because of the limited number of trials contributing to each comparison.

These SRs differ from our current review in a few important ways. Some include RCTs that were excluded from our review (i.e., did not meet our inclusion criteria) and there were differences in how time periods were considered or evaluated. Regarding statistical methods, we conducted our meta-analyses using profile-likelihood random effects models, which is a more conservative than the Dersimonian and Laird model; this approached is considered standard methodology for meta-analyses.

Table 5. Previous systematic reviews evaluating noninvasive testing for CAD.

Author (year), Search Funding	Patient Population Setting	Objective, Key Questions	Critical Appraisal of Studies Evidence Base Analysis	Outcomes/Conclusions
				Overall Author's Conclusions: Compared with functional stress imaging, CCTA was associated with a significant reduction in downstream MIs, hospital visits, and follow-up testing, but increased ICA and revascularizations; there was no difference in mortality. In the future, more RCTs are needed utilizing scoring methods to identify more robust downstream investigations, cost analysis, and radiation exposure.

No diagnostic strategy had an apparent effect on the

Author (year), Search Funding	Patient Population Setting	Objective, Key Questions	Critical Appraisal of Studies Evidence Base Analysis	Outcomes/Conclusions
				subsequent risk of MI, although estimates were imprecise. **Among patients with suspected stable CAD**, no clear discrimination was seen across *individual diagnostic strategies* for ICA referrals, mainly because of the limited number of trials contributing to each comparison. Stress echocardiography and SPECT resulted in less overall downstream testing than CCTA, whereas exercise ECGs required the most downstream testing. *After grouping of widely available functional tests*, a functional testing approach yielded fewer referrals for ICA and subsequent revascularizations than CCTA. Again, estimates were imprecise for the outcome of MI, and any differences could not be ruled out.

ACS = acute coronary syndrome; CAD = coronary artery disease; CCTA = coronary computed tomographic angiography; CI = confidence interval; CMR = cardiovascular magnetic resonance; ECG = electrocardiography; echo=echocardiography; ED = emergency department; ICA = invasive coronary angiography; MI = myocardial infarction; NR= not reported; RCT = randomized controlled trial; ROB = risk of bias; RR = risk ratio; RTMCE = real time myocardial contrast echocardiography; SPECT = single photon emission computed tomography; ST = stress testing; WHO = World Health Organization.

* No plot provided in article, number of RCTs (n patients) contributing to estimate not reported.

†Authors evaluated the extent to which stable and unstable patients had different risk estimates, and did a formal test for interaction – there was no modification of the treatment effect by the different populations.

2.7 Prior Government Report and Rapid Reviews

Two prior reports, one comparative effectiveness review published in 2016 by the Agency for Healthcare Research and Quality (AHRQ)[230] and one rapid review from 2019 prepared by the Veterans Affairs (VA) Evidence Synthesis Program[100], were identified searching PubMed, the Cochrane Database of and the ECRI Guideline Trust from database inception to March 23rd, 2021, and our summarized in Table 6 below. See Appendix B for search terms and full search strategy.

The most recent report was a VA Evidence Synthesis rapid review that evaluated evidence related to the capabilities, benefits and harms, and impact on resource use within the VA health system of CCTA with fractional flow reserve (FFRCT) technology (i.e., HeartFlow) for the diagnosis of CAD.[100] Since it is a rapid review, however, it does not provide a formal, systematic review of the available evidence. Evidence related to diagnostic accuracy from this review can be found in the Contextual Questions section. Regarding clinical and management outcomes (Table 6 below), the authors concluded that regular use of HeartFlow FFRCT in place of other noninvasive tests does not appear warranted, as HeartFlow FFRCT led to a higher rate of use of ICA when used as a substitute for planned noninvasive cardiovascular testing. They also found no evidence to support wider use of CCTA in place of other noninvasive tests in the VA healthcare system.

The AHRQ comparative effectiveness review evaluated noninvasive testing strategies for the diagnosis of CAD in symptomatic patients with suspected CAD, who had no known history of CAD, and whose condition was stable.[230] Results were stratified first based on pretest risk and then by anatomic versus functional tests and functional versus functional tests. Given the heterogeneity in how pretest risk was measured and defined across the studies, the results were organized by pretest risk as defined by the study authors (rather than by distinct pretest risk groups as originally intended), which included low-risk, intermediate-risk, low-to-intermediate-risk, intermediate-to-high-risk, high-risk, and mixed-risk populations (or pretest risk not reported). This review found no clear differences between testing strategies across settings with regard to clinical or management outcomes to recommend one strategy over another for any given pretest risk group that included intermediate pretest risk patients. Limited evidence from RCTs suggest anatomic testing may result in a higher frequency of referral for ICA and revascularization. The frequency of all-cause mortality and MI was low across studies in all settings. Assessment of harms was limited and there was inadequate comparative evidence to make judgments regarding radiation exposure for initial test or downstream testing. (See Table 6 below for details.) In contrast to the AHRQ report, this current report included symptomatic patients both with and without a history of CAD, as well as those who presented with acute coronary syndrome (ACS). We did not stratify results by pretest risk but did indicate pretest risk as defined by the authors. Since the AHRQ report, several new trials evaluating noninvasive treatment for CAD have been published and are included in this re-review.

A third review was identified by the Health Evidence Review Commission (HERC) which provided evidence on nuclear cardiac imaging for screening, diagnosis or risk stratification of CAD[99]; however, this report essentially relied on the evidence from the prior WA State HTA on nuclear cardiac imaging, so it is not summarized below.

Table 6. Prior government reports and rapid reviews evaluating noninvasive testing for CAD

				an CCTA-FFR cost weight of zero, but were higher when using an CCTA-FFR cost weight equal to CCTA.
				
				CCTA-FFR vs. ICA
				MACE: 1% vs. 1%, p=NS
				Planned ICA with no obstructive disease: 12% vs. 73%, RD –61% (95% CI –68.7% to –53.0%)
				Revascularization: 34% vs. 36%, p=NS
				Safety/Harms:
				• Cumulative radiation exposure: 10.7 vs. 10.4 mSv through 12 months, p=NS
				Economic
				• Mean 1 year patients' cost was 33% lower in CCTA-FFR vs. ICA group.
				
				CCTA-FFR vs. CCTA alone
				MACE
				• 1 registry:
				  ○ CCTA-FFR >0.80 = no death/MI within 90 days
				  ○ CCTA-FFR ≤0.80 = MACE, 0.6%; death/MI, 0.3%
				• 2 retrospective cohorts:
				  ○ No significant difference in 1-year cardiovascular events between patients with changed vs. unchanged management after CCTA-FFR
				  ○ 4 serious clinical events occurred, but not in any patients with cancelled ICA by CCTA-FFR
				Change in management plans (1 registry, 1 retrospective cohort)
				• 55% to 67% of patients
				Impact on subsequent ICA (2 retrospective cohorts)
				• Potentially reduced in the need for ICA in 48%

Author (year), Search Funding AMSTAR-2	Patient Population Setting	Objective, Key Questions	Critical Appraisal of Studies Evidence Base Analysis	Outcomes/Conclusions
				• In high-risk CCTA-FFR patients, ICA was cancelled in 75% Economic • According to the authors, key factors that could influence the impact and cost-effectiveness of HeartFlow FFRCT in VA include: reasons for direct referral to ICA with no noninvasive testing, frequency of CCTA use, probability of ICA referral after positive CCTA, and prevalence of intermediate stenosis identified by CCTA and functionally significant CAD in the population. The authors did not find data on these factors. Author's Conclusions: Regular use of HeartFlow FFRCT in place of other noninvasive tests does not appear warranted, as HeartFlow FFRCT led to a higher rate of use of ICA when used as a substitute for planned noninvasive cardiovascular testing. We found no evidence to support wider use of CCTA in place of other noninvasive tests in VA. The effect of FFRCT on MACE outcomes is uncertain. Future research should evaluate MACE outcomes on a longer-term basis. The effect of FFRCT on MACE outcomes is uncertain. Future research should evaluate MACE outcomes on a longer-term basis.

				1.52, 95% CI 1.37 to 1.69) through 6 months in the observational cohort of Medicare patients; and for any revascularization through 6 months in the Medicare population (11.41% vs. 4.59%, adjusted OR 2.76, 95% CI 2.56 to 2.98) and a median 1.42 years in the second observational study in the general population (% NR, adjusted OR 1.62, 95% CI 1.20 to 2.18) (Low SOE).
				• SPECT vs. Exercise ECG:
				  ○ No differences between tests for all-cause mortality and MI but SPECT was associated with significantly fewer revascularizations (10.8% vs. 17.9%, RD -7.1, 95% CI -13.6 to -0.6 per 100) in 1 RCT with 22 months of follow-up (SOE Low).
				• Exercise ECG vs. Nuclear MPI:
				  ○ No differences between tests for all-cause mortality at 6 months in 1 observational study (Low SOE).
				  ○ ECG was associated with significantly fewer referrals for ICA (9.04% vs. 12.13%, adjusted OR 0.72, 95% CI 0.70 to 0.75), any revascularization (4.31% vs. 4.59%, adjusted OR 0.90, 95% CI 0.85 to 0.94), and PCI (2.57% vs. 3.37%, adjusted OR 0.72, 95% CI 0.68 to 0.77), and significantly higher rates of CABG (1.82% vs. 1.29%, adjusted OR 1.37, 95% CI 1.26 to 1.49) and additional noninvasive testing (19.34% vs. 3.22%, adjusted OR 7.46, 95% CI 7.16 to 7.77) through 6 months in 1 observational study, although it is unclear if the differences for any revascularization, PCI and CABG are clinically meaningful (Low SOE).
				• Stress echocardiography vs. Nuclear MPI:

Author (year), Search Funding AMSTAR-2	Patient Population Setting	Objective, Key Questions	Critical Appraisal of Studies Evidence Base Analysis	Outcomes/Conclusions
				○ No between tests for all-cause mortality at 6 months in 1 observational cohort (Low SOE). ○ Stress echocardiography was associated with significantly fewer referrals for ICA (9.50% vs. 12.13%; adjusted OR 0.78, 95% CI 0.76 to 0.81), any revascularization (4.22% vs. 4.59%, adjusted OR 0.93, 95% CI 0.88 to 0.98), and PCI (2.61% vs. 3.37%, adjusted OR 0.76, 95% CI 0.72 to 0.81), and significantly higher rates of CABG (1.69% vs. 1.29%, adjusted OR 1.40, 95% CI 1.29 to 1.52) and additional noninvasive testing (5.57% vs. 3.22%; adjusted OR 1.92, 95% CI 1.83 to 2.0) through 6 months in 1 observational cohort, although it is unclear if the differences for any revascularization, PCI and CABG are clinically meaningful (Low SOE). • Stress echocardiography vs. Exercise ECG: ○ Insufficient evidence from 2 observational studies. Author's Conclusions: A review of current studies found no clear differences between testing strategies across settings regarding clinical or management outcomes to recommend one strategy over another for any given pretest risk group that included intermediate pretest risk patients. No conclusions regarding low-risk patients or those without ACS at high risk are possible. Limited evidence from RCTs trials found no clear differences between CCTA versus other strategies in clinical outcomes across risk groups, although anatomic testing may result in a higher frequency of referral for ICA and revascularization. The frequency of all-cause mortality and MI was low across studies in all settings. The absence of

Author (year), Search Funding AMSTAR-2	Patient Population Setting	Objective, Key Questions	Critical Appraisal of Studies Evidence Base Analysis	Outcomes/Conclusions
				information on posttest risk stratification and subsequent decision-making precluded evaluation of the impact of testing on patient management or outcomes of management. Testing strategies vary in radiation exposure; there is inadequate comparative evidence to make judgments regarding exposure for initial test or downstream testing. Assessment of harms was limited. Future research using more refined, evidence-based definitions of pretest risk coupled with information on posttest risk stratification, its impact on clinical management (treatment and referral for additional testing), and longer term follow up to assess clinical outcomes is needed to determine optimal testing strategies and roles of tests in different pretest risk groups.

ACS = acute coronary syndrome; CABG = coronary artery bypass graft; CAD = coronary artery disease; CCTA = coronary computed tomography angiography; CCTA FFR = coronary computed tomography angiography with fractional flow reserve; CI = confidence interval; ECG = electrocardiography; ED=emergency department; CABG = coronary artery bypass graft; ICA= invasive coronary angiography; MACE = major adverse cardiovascular events; MD = mean difference; MI = myocardial infarction; MPI = myocardial perfusion imaging; NR= not reported; OR = odds ratio; PCI = percutaneous coronary intervention; PET = positron emission tomography; RCT = randomized controlled trial; RD = risk difference; ROB= risk of bias; RR = risk ratio; SOE = strength of evidence; SPECT = single positron emission computed tomography; UC = usual care; VA = Veterans Affairs.

2.8 Clinical Guidelines

Table 7. Summary of Clinical Practice Guidelines for the Diagnosis of CAD in patients with chest pain

	Imaging Modality or Diagnostic Consideration	Evidence Base	Recommendation	Strength of Recommendation
American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines, and the American College of Physicians, American Association for Thoracic Surgery, Preventive Cardiovascular Nurses Association, Society for Cardiovascular Angiography and Interventions, and Society of Thoracic Surgeons[71] 2012* *Guideline for the Diagnosis and Management of Patients with Stable Ischemic Heart Disease*	CCTA in patients able **or** unable to exercise	5 meta-analyses, 3 controlled clinical trials	Because the presence of significant calcification often can preclude the accurate assessment of lesion severity or cause a false positive study, CCTA should not be performed in patients who have known extensive calcification or a high risk of CAD. CCTA is reasonable for patients with a low to intermediate pretest probability of IHD who are incapable of at least moderate physical functioning or have disabling comorbidity. CCTA might be reasonable for patients with an intermediate pretest probability of IHD who have at least moderate physical functioning or no disabling comorbidity.	• Class of recommendation: IIa • Level of evidence: B (Recommendation in favor of treatment or procedure being useful. Some conflicting evidence from single randomized trial or nonrandomized studies)
	CCTA in patients with inconclusive functional tests	1 prognostic study	CCTA is reasonable for patients with an intermediate probability of CAD who has any of the following: a) Continued symptoms with prior normal test, or b) Inconclusive exercise or pharmacological stress, or	• Class of recommendation: IIa • Level of evidence: C (Recommendation in favor of treatment or procedure being useful.

	Imaging Modality or Diagnostic Consideration	Evidence Base	Recommendation	Strength of Recommendation
			c) Unable to undergo stress with MPI or Echo	Only divergent expert opinion, case studies, or standard of care available).
	Exercise with nuclear MPI or Echo in patients able to exercise	5 meta-analyses, 2 cost effectiveness studies, and 2 additional publications of unknown study design	Exercise stress with nuclear MPI or echocardiography is recommended for patients with an intermediate to high pretest probability of IHD who have an uninterpretable ECG and at least moderate physical functioning or no disabling comorbidity.	• Class of recommendation: I • Level of evidence: B
			Exercise stress with nuclear MPI or echocardiography is reasonable for patients with an intermediate to high pretest probability of obstructive IHD who have an interpretable ECG and at least moderate physical functioning or no disabling comorbidity.	• Class of recommendation: IIa • Level of evidence: B (Recommendation in favor of treatment or procedure being useful. Some conflicting evidence from single randomized trial or nonrandomized studies)
			Exercise stress with nuclear MPI is not recommended as an initial test in low-risk patients who have an interpretable ECG and at least moderate physical functioning or no disabling comorbidity.	• Class of recommendation: III (no benefit) • Level of evidence: C
	Pharmacological stress with nuclear MPI, Echo, or CMR in	1 observational study, 2 economic evaluations	Pharmacological stress with nuclear MPI, echocardiography, or CMR is not recommended for patients who have	• Class of recommendation: III (no benefit)

	Imaging Modality or Diagnostic Consideration	Evidence Base	Recommendation	Strength of Recommendation
	patients able to exercise		an interpretable ECG and at least moderate physical functioning or no disabling comorbidity.	• Level of evidence: C
	Pharmacological stress with nuclear MPI or Echo in patients unable to exercise	5 meta-analyses, 1 observational study, 1 position statement, 1 economic evaluation	Pharmacological stress with nuclear MPI or echocardiography is recommended for patients with an intermediate to high pretest probability of IHD who are incapable of at least moderate physical.	• Class of recommendation: I • Level of evidence: B
	Pharmacological stress CMR in patients able to exercise	3 meta-analyses	Pharmacological stress with CMR can be useful for patients with an intermediate to high pretest probability of obstructive IHD who have an *un*interpretable ECG and at least moderate physical functioning or no disabling comorbidity.	• Class of recommendation: I • Level of evidence: B
	Pharmacological stress CMR in patients unable to exercise	3 meta-analyses, 1 RCT	Pharmacological stress CMR is reasonable for patients with an intermediate to high pretest probability of IHD who are incapable of at least moderate physical functioning or have disabling comorbidity.	• Class of recommendation: IIa • Level of evidence: B (Recommendation in favor of treatment or procedure being useful. Some conflicting evidence from single randomized trial or nonrandomized studies)

	Imaging Modality or Diagnostic Consideration	Evidence Base	Recommendation	Strength of Recommendation
	Hybrid Imaging	N/A	This diagnostic imagining modality is discussed, but no specific recommendations for the use of hybrid imaging are included in this guideline.	N/A
The Task Force for the diagnosis and management of chronic coronary syndromes of the European Society of Cardiology (ESC)[133] 2019 *2019 ESC Guidelines for the diagnosis and management of chronic coronary syndromes*	Stress echocardiography, stress CMR, SPECT, PET, or CCTA	5 RCTs, 1 meta-analysis, and 1 recommendation document	Stress echocardiography, stress CMR, SPECT, PET, or CCTA is recommended as the initial test to diagnose CAD in symptomatic patients in whom obstructive CAD cannot be excluded by clinical assessment alone.	• Class of recommendation: I • Level of evidence: B
	Selection of initial non-invasive diagnostic test.	None cited.	It is recommended that selection of the initial non-invasive diagnostic test is done based on the clinical likelihood of CAD and other patient characteristics that influence test performance (e.g. characteristics determining ability to exercise, likelihood of good image quality, expected radiation exposure, and risks or contraindications), local expertise, and the availability of tests	• Class of recommendation: I • Level of evidence: C
	CCTA	None cited.	CCTA should be considered as an alternative to invasive angiography if another non-invasive test is equivocal or non-diagnostic.	• Class of recommendation: IIa • Level of evidence: C
			CCTA is not recommended when extensive coronary calcification, irregular heart rate, significant obesity, inability to cooperate with breath-hold commands, or any other conditions make obtaining good image quality unlikely.	• Class of recommendation: III • Level of evidence: C

	Imaging Modality or Diagnostic Consideration	Evidence Base	Recommendation	Strength of Recommendation
National Institute for Health and Care Excellence (NICE)[2] 2016 *Recent-onset chest pain of suspected cardiac origin: assessment and diagnosis*	CCTA	Specific references used to make this recommendation were not explicitly stated.	Offer 64-slice (or above) CCTA if: • clinical assessment indicates typical or atypical angina†, or • clinical assessment indicates non-anginal chest pain but 12-lead resting ECG has been done and indicates ST-T changes or Q waves. The committee's view is that CCTA should be considered the first choice diagnostic test for all people assessed as having typical or atypical angina. However individual circumstances, including potential contraindications, should be considered when deciding the most appropriate strategy for diagnostic investigation.	NR
American College of Cardiology (ACC) and the American Heart Association (AHA)[14] 2014 *Guideline for the Management of Patients With Non–ST-Elevation Acute Coronary Syndromes*	ECG	1 position statement	In patients with chest pain or other symptoms suggestive of ACS, a 12-lead ECG should be performed and evaluated for ischemic changes within 10 minutes of the patient's arrival at an emergency facility.	• Level of evidence: C • Class of recommendation: I
	ECG	None cited.	If the initial ECG is not diagnostic but the patient remains symptomatic and there is a high clinical suspicion for ACS, serial ECGs (eg, 15- to 30-minute intervals during the first hour) should be performed to detect ischemic changes.	• Level of evidence: C • Class of recommendation: I
	Treadmill ECG, Stress MPI, Stress Echo	Treadmill ECG: 3 RCTs	It is reasonable for patients with possible ACS who have normal serial	• Treadmill ECG - Level of evidence: A

	Imaging Modality or Diagnostic Consideration	Evidence Base	Recommendation	Strength of Recommendation
		Stress MPI/Stress Echo: 1 comparative cohort, 1 prognostic study	ECGs and cardiac troponins to have a treadmill ECG, stress myocardial perfusion imaging, or stress echocardiography before discharge or within 72 hours after discharge.	- Class of recommendation: IIa • Stress MPI, stress echo - Level of evidence: B - Class of recommendation: IIa
	CCTA	3 RCTs	In patients with possible ACS and a normal ECG, normal cardiac troponins, and no history of CAD, it is reasonable to initially perform (without serial ECGs and troponins) coronary CT angiography to assess coronary artery anatomy	• Level of evidence: A • Class of recommendation: IIa
	MPI	1 RCT, 1 case series	In patients with possible ACS and a normal ECG, normal cardiac troponins, and no history of CAD, it is reasonable to initially perform (without serial ECGs and troponins) rest myocardial perfusion imaging with a technetium-99m radiopharmaceutical to exclude myocardial ischemia	• Level of evidence: B • Class of recommendation: IIa
	Stress testing	4 observational studies	Noninvasive stress testing is recommended in low and intermediate-risk patients who have been free of ischemia at rest or with low-level activity for a minimum of 12 to 24 hours	• Level of evidence: B • Class of recommendation: I
	Exercise stress test	3 observational studies	Stress testing with an imaging modality should be used in patients who are	• Level of evidence: B

	Imaging Modality or Diagnostic Consideration	Evidence Base	Recommendation	Strength of Recommendation
			able to exercise but have ST changes on resting ECG that may interfere with interpretation. In patients undergoing a low-level exercise test, an imaging modality can add prognostic information.	• Class of recommendation: I
	Pharmacological stress test	None cited.	Pharmacological stress testing with imaging is recommended when physical limitations preclude adequate exercise stress.	• Level of evidence: C • Class of recommendation: I

CCTA = coronary computed tomography, CMR = cardiac magnetic resonance, ECG = electrocardiogram, ECHO = echocardiography, IHD = ischemic heart disease, MPI = myocardial perfusion imaging, N/A = not applicable, NR = not reported, PET = positron emission tomography, RCT = randomized control trial, SPECT = single photon emission computed tomography.

* In 2014, an update to this guideline was published. However, none of the updates involved imagining modalities of interest to this review.

† According to NICE Guideline recommendation 1.3.3.1, assessing the typicality of chest pain should be done as follows:

· Presence of three of the features below is defined as typical angina.

· Presence of two of the three features below is defined as atypical angina.

· Presence of one or none of the features below is defined as non-anginal chest pain.

Anginal pain is:

· constricting discomfort in the front of the chest, or in the neck, shoulders, jaw, or arms

· precipitated by physical exertion

· relieved by rest or GTN within about 5 minutes.

2.9 Appropriate Use Criteria

Table 8. Summary of Appropriate Use Criteria for the Diagnosis of CAD in patients with chest pain

AUC Developing Organization(s) Year Title	Imaging Modality	Recommendation	AUC score
American College of Cardiology Appropriate Use Criteria Task Force, American Association for Thoracic Surgery, American Heart Association, American Society of Echocardiography, American Society of Nuclear Cardiology, Heart Rhythm Society, Society for Cardiovascular Angiography and Interventions, Society of Cardiovascular Computed Tomography, Society for Cardiovascular Magnetic Resonance, and the Society of Thoracic Surgeons[56]* 2019 *2019 Appropriate Use Criteria for Multimodality Imaging in the Assessment of Cardiac Structure and Function in Nonvalvular Heart Disease*	F-18 FDG PET	Use of F-18 FDG PET for the initial evaluation when symptoms or signs suggest heart disease is rarely appropriate (test is not generally acceptable and is not a reasonable approach for the indication).	Median Appropriate Use Score: 2
		Use of F-18 FDG PET for the Initial evaluation of known or suspected HF (systolic or diastolic) based on symptoms, signs, or abnormal test results to assess systolic or diastolic function and to assess for possible etiology (CAD, valvular disease) is rarely appropriate (test is not generally acceptable and is not a reasonable approach for the indication).	Median Appropriate Use Score: 3
	MPI (SPECT/PET)	Use of MPI (SPECT/PET) for the initial evaluation when symptoms or signs suggest heart disease is rarely appropriate (test is not generally acceptable and is not a reasonable approach for the indication).	Median Appropriate Use Score: 2
		Use of MPI (SPECT/PET) for the Initial evaluation of known or suspected HF (systolic or diastolic) based on symptoms, signs, or abnormal test results to assess systolic or diastolic function and to assess for possible etiology (CAD, valvular disease) is appropriate (test is generally acceptable and is a reasonable approach for the indication). 		Patients with abnormal exercise treadmill test (performed without imaging). (This guideline applies to patients with suspected or established CAD). **Patients with abnormal findings on cardiac CT or CCTA** • PET perfusion imaging is considered medically necessary in the following scenarios: • Symptomatic patients with EITHER of the following: - Coronary artery calcium score > 400 Agatston units - Intermediate severity coronary stenosis on coronary CTA	

ACS = acute coronary syndrome, ASCVD = AHA/ACC risk calculator, AUC = appropriate use criteria, CAC = coronary artery calcium, CAD = coronary artery disease, CCTA = coronary computed tomography, CT = computed tomography, ECG = electrocardiogram, ED = emergency department, FDG = Fludeoxyglucose, FFR = fractional flow reserve, IV = intravenous, MI = myocardial infarction, MPI = myocardial perfusion imaging, NR = not reported, NSTEMI = Non-ST-Segment Elevation Myocardial Infarction, PET = positron emission tomography, SPECT = single photon emission computed tomography, TIMI = Thrombolysis in Myocardial Infarction

* Imaging for each indication was then rated and classified as Appropriate (A), May Be Appropriate (M), or Rarely Appropriate (R) on the basis of these multiple rounds of review and revision.

Median Score 7 to 9: Appropriate test for specific indication (test is generally acceptable and is a reasonable approach for the indication).

Median Score 4 to 6: May Be Appropriate test for specific indication (test may be generally acceptable and may be a reasonable approach for the indication). May Be Appropriate also implies that more research and/or patient information is needed to classify the indication definitively.

Median Score 1 to 3: Rarely Appropriate test for specific indication (test is not generally acceptable and is not a reasonable approach for the indication).

† Score 7–9: Appropriate test for specific indication (test **is** generally acceptable and **is** a reasonable approach for the indication).

Score 4–6: Uncertain for specific indication (test **may** be generally acceptable and **may** be a reasonable approach for the indication). (Uncertainty also implies that more research and/or patient information is needed to classify the indication definitively.)

Score 1–3: Inappropriate test for that indication (test **is not** generally acceptable and **is not** a reasonable approach for the indication).

2.10 Expert Consensus Statements

Table 9. Summary Table of Expert Consensus Statements

Contributing Organization **Year** ***Document Title***	**Consensus**
CCTA	
Society of Cardiovascular Computed Tomography[172] 2021 ***Expert consensus document on coronary computed tomographic angiography: A report of the society of Cardiovascular Computed Tomography***	**Evaluation of Stable Coronary Artery Disease: Coronary CTA in Native Vessels** • It is appropriate to perform CTA as the first line test for evaluating patients with no known CAD who present with stable typical or atypical chest pain, or other symptoms which are thought to represent a possible anginal equivalent (e.g. dyspnea on exertion, jaw pain). • It is appropriate to perform CTA as a first line test for evaluating patients with known CAD who present with stable typical or atypical chest pain, or other symptoms which are thought to represent a possible anginal equivalent (e.g. dyspnea on exertion, jaw pain • It is appropriate to perform coronary CTA following a non-conclusive functional test, in order to obtain more precision regarding diagnosis and prognosis, if such information will influence subsequent patient management. • It is recommended to perform CTA as the first line test when considering evaluation for revascularization strategies using the ISCHEMIA Trial. • It may be appropriate to perform CTA in selected asymptomatic high risk individuals, especially in those who have a higher likelihood of having a large amount of noncalcified plaque • It is rarely appropriate to perform coronary CTA in very low risk symptomatic patients, e.g., <40 years of age with non-cardiac symptoms (chest wall pain, pleuritic chest pain). • It is rarely appropriate to perform CTA in low- and intermediate risk asymptomatic patients **Evaluation of Stable Coronary Artery Disease: Coronary CTA Post Revascularization** • It is appropriate to perform coronary CTA in symptomatic patients with intracoronary stent diameter 3.0 mm. Measures to improve accuracy of stent imaging should be utilized, to include strict heart rate control (goal <60 bpm), iterative reconstruction,

Contributing Organization Year *Document Title*	Consensus
	sharp kernel reconstruction, and mono-energetic reconstructions (when available). Protocols to optimize stent imaging should be developed and followed. • It may be appropriate to perform coronary CTA in symptomatic patients with stents <3.0 mm, especially those known to have thin stent struts (<100 mm) in proximal, non-bifurcation locations. • It is appropriate to perform CTA for evaluation of patients with prior CABG, particularly if graft patency is the primary objective. • It is appropriate to perform CTA to visualize grafts and other structures prior to re-do cardiac surgery. **Evaluation of Stable Coronary Artery Disease: Coronary CTA with FFR or CTP** • It may be appropriate to perform CT derived FFR and CT myocardial perfusion Imaging to evaluate the functional significance of intermediate stenoses on CTA (30-90% diameter stenosis) particularly in the setting of multivessel disease to help guide ICA referral and revascularization treatment planning. LM stenosis ≥50% and severe triple vessel disease should undergo invasive coronary angiography. • Adding FFRCT and stress-CTP to CTA increases specificity, positive predictive value, and diagnostic accuracy over regular CTA. • FFRCT and stress-CTP may be largely comparable in diagnostic utility. CTP is a potentially valuable alternative particularly when CT-FFR is technically difficult (e.g., suboptimal CTA quality, prior revascularization). **Evaluation of Stable Coronary Artery Disease: Coronary CTA in Other Conditions** • It is appropriate to perform CTA for coronary artery evaluation prior to noncoronary cardiac surgery as an equivalent alternative to invasive angiography in selected patients, e.g., low-intermediate probability of CAD, younger patients with primarily non-degenerative valvular conditions. • CTA may be considered an appropriate alternative to other noninvasive tests for evaluation of selected patients prior to noncardiac surgery. • It is appropriate to perform CTA to exclude coronary artery disease in patients with suspected non-ischemic cardiomyopathy.

Contributing Organization **Year** ***Document Title***	**Consensus**
	• It may be appropriate to perform late enhancement CT imaging to detect infiltrative heart disease or scar in selected patients who have non-ischemic or ischemic cardiomyopathy and who cannot undergo cardiac MRI. Such imaging may be performed if it has the potential to impact the diagnosis and/or treatment (e.g. planning for ablation therapy) • It may be appropriate to perform CTA as an alternative to invasive coronary angiography for the screening of patients for coronary allograft vasculopathy in selected clinical practice settings. • It is appropriate to perform CTA for the evaluation of coronary anomalies. • It is appropriate to EKG gate aortic dissection and aneurysm CTA, as well as pulmonary embolus studies in men >45 years and women >55 years, and analyze and report the coronary arteries. • CTA with a limited delayed image (60e90 sec) is an appropriate alternative to TEE when the primary aim is to exclude LA/LAA thrombus and in patients where the risks associated with TEE outweigh the benefits. In all situations CTA and TEE should be discussed with the patient in the setting of shared decision making. • It may be appropriate to perform late enhancement CT imaging for the evaluation of myocardial viability in selected patients who cannot undergo cardiac MRI. Such imaging may be performed if it has the potential to impact the diagnosis and/or treatment (e.g. planning for revascularization). **Reporting on CTA: Coronary and Non Coronary Information** • The CAD-RADs reporting is recommended. • It is appropriate to report prior myocardial infarction when its features are evident on CTA. • It is appropriate to report remote myocardial infarction when fatty metaplasia or calcification within an area of infarction are present.
Cardiovascular Medicine and Society[195] 2020	**To move forward toward a coronary CTA–first paradigm, this ACC Summit Team recommends the following:** 1. Use coronary CTA as the default test for evaluating patients with stable chest pain and low-

Contributing Organization Year *Document Title*	Consensus
Current Evidence and Recommendations for Coronary CTA First in Evaluation of Stable Coronary Artery Disease	to-intermediate pre-test probability of obstructive CAD and for those with high pre-test probability of significant obstructive CAD, to rule out the presence of left main CAD, particularly when a conservative treatment strategy is selected. 2. Increase payment for coronary CTA. Specifically, cardiac CT services should be moved to an Ambulatory Payment Classification group with tests that are more similar with respect to clinical scope and resource use. Importantly, increased advocacy, support, and collaboration with ACC will be needed to work with CMS and congress to implement such changes effectively. 3. Explore options for "bundled payments" for cardiac testing. Value-based models would increase incentives to use coronary CTA to avoid other, more costly noninvasive or invasive diagnostic procedures. To start, shared savings models that reduce current average cost from first chest pain onset to 90 days post-evaluation or postintervention could be developed. 4. Identify expert and financial support to increase the number of capable coronary CTA providers. 5. Develop strategies to improve provider and delivery team competency in performing coronary CTA: update training guidelines for cardiovascular fellows, CT technologists, and other ancillary staff, including continuing education and periodic quality assessment. Grandfather training rules to allow more practicing cardiologists to obtain credentials with the support of ACC and industry sponsors. Use remote technologies such as telemedicine to expand the reach of training and delivery. 6. Establish an ACC coronary CTA registry for evaluating chest pain. This registry should include medical and economic variables to evaluate "total cost of care" associated with coronary CTA. Ideally, commercial payers will collaborate with the ACC on this registry to validate costs. 7. Improve advocacy for coronary CTA by direct engagement with public and private payers. Work with CMS and Congress to establish more equitable payment for coronary CTA procedures. 8. Engage commercial payers in discussions on eliminating pre-approvals for coronary CTA and FFR CT for providers participating in the coronary CTA registry. 9. Improve education of cardiologists and primary care physicians on when to consider coronary CTA testing (vs. other techniques) and how to use the

Contributing Organization **Year** ***Document Title***	**Consensus**
	results in patient management.
Canadian Cardiovascular Society, Canadian Association of Radiologists Canadian Association of Nuclear Medicine, Canadian Nuclear Cardiology Society, Canadian Society of Cardiac Magnetic Resonance[22] 2007 ***Joint Position Statement on Advanced Non-invasive Cardiac Imaging using Positron Emission Tomography, Magnetic Resonance Imaging and Multi-Detector Computed Tomographic Angiography in the Diagnosis and Evaluation of Ischemic Heart Disease***	**CAD Detection with CT Angiography** *Class I Indication* 1. Assessment of anomalous coronary arteries (Level C evidence). *Class IIa Indications* 1. 16- or 64-slice MDCT for patient diagnosis of significant coronary artery disease (≥ 50% diameter stenosis)(Level B evidence); 2. 16- or 64-slice MDCT for identification of coronary artery segments with significant stenosis (≥ 50% diameter stenosis) in coronary segments ≥ 1.5 mm in diameter (Level B evidence); 3. 16- and 64-slice MDCT for the assessment of graft patency (Level B evidence). *Class IIb Indication* 1. 64-slice MDCT for the assessment of all coronary segments including those with vessel diameters < 1.5 mm (Level B evidence). *Class III (no benefit or harmful)* 1. Diagnosis of CAD in patients with a. irregular dysrhythmias (atrial fibrillation, frequent extrasystoles); b. severe coronary calcification; c. inability to perform sufficient breath-holds; d. renal failure or other contraindications to intravenous contrast agents; e. contraindications to radiation exposure.
Quantitative Cardiac Imaging Study Group[53] 2020 ***Clinical quantitative cardiac imaging for the assessment of myocardial ischemia***	**Cardiac CT** • CT perfusion imaging is not frequently used, whereas CT angiography offers highly accurate coronary angiography. • Challenges of cardiac CT include limited temporal resolution, beam and scatter artefacts, radiation dose and low contrast-to-noise ratios. • CT systems with increased rotation speed, photon counting energy-selective X-ray detectors and advanced machine learning technology, as well as two-compartment analysis could overcome the technological challenges. • The combined assessment of stenosis and characterization of atherosclerosis in

Contributing Organization **Year** ***Document Title***	**Consensus**
	relation to myocardial ischemia promises the greatest clinical value but requires testing in trials. • Evaluation of patients with insufficient angiographic image quality or borderline stenosis on coronary CT angiography might be improved with the use of CT for myocardial ischemia.
Nuclear Imaging (SPECT/PET)	
Canadian Cardiovascular Society, Canadian Association of Radiologists Canadian Association of Nuclear Medicine, Canadian Nuclear Cardiology Society, Canadian Society of Cardiac Magnetic Resonance[22] 2007 ***Joint Position Statement on Advanced Non-invasive Cardiac Imaging using Positron Emission Tomography, Magnetic Resonance Imaging and Multi-Detector Computed Tomographic Angiography in the Diagnosis and Evaluation of Ischemic Heart Disease***	**Myocardial Perfusion Imaging (MPI) using PET for Diagnosis and/or Risk Stratification of CAD** *Class I Indications* 1. Pharmacological MPI using PET for the diagnosis of CAD* and/or risk stratification of patients who a. have non-diagnostic non-invasive imaging tests or where such a test does not agree with clinical diagnosis (Level B evidence). b. may be prone to artifact that could lead to an equivocal other test, such as obese patients (Level B evidence); c. are unable to exercise or have left bundle branch block (LBBB) or ventricular pacing (Level B evidence). *Class IIa Indications* 1. Pharmacological MPI using PET for the diagnosis of CAD for patients with intermediate pretest likelihood of disease and/or risk stratification of patients who are able to exercise (Level B evidence); 2. For diagnosis and risk stratification of patients being considered for high-risk non-cardiac surgery who have intermediate clinical risk predictors; or have mild clinical risk predictors with poor functional capacity (<4 METS) (Level B/C evidence). *Class IIb Indications* 1. Exercise PET using MPI for the diagnosis of CAD and/or risk stratification (Level B evidence); 2. Quantification of myocardial flow to determine the hemodynamic significance of a given coronary stenosis or to diagnose balanced multivessel disease (Level B/C evidence); 3. Quantification of myocardial flow to define impaired microvascular function (e.g. Syndrome

Contributing Organization **Year** ***Document Title***	**Consensus**
	X) (Level B/C evidence). *Class III (no benefit or harmful)* 1. Contraindications to all pharmacological agents (dipyridamole, adenosine, dobutamine); 2. Unstable pattern of ischemic chest pain; 3. Contraindications to radiation exposure.
Quantitative Cardiac Imaging Study Group[53] 2020 ***Clinical quantitative cardiac imaging for the assessment of myocardial ischemia***	**SPECT** • SPECT is most commonly used in the clinic for myocardial perfusion imaging. • Challenges of SPECT include radiation dose and limited quantification of myocardial perfusion. • Dedicated cardiac SPECT cameras have emerged, with improved sensitivity and resolution at lower radiation doses and in patients with challenging features (including those with a high BMI). • Quantitative measures of the perfusion defect size have become more widely available as diagnostic and prognostic markers with the introduction of solid- state detector CZT technology. • Dynamic imaging enables compartmental modelling and provides absolute measures of myocardial ischemia, thereby bringing SPECT closer to PET as the reference standard. **PET** • PET is the clinical reference standard for the quantification • of myocardial perfusion. • Challenges of PET use include limited visual assessment of quantitative 15O- water PET and the lower spatial resolution of PET compared with CT or MRI perfusion imaging. • Small or 13N- ammonia cyclotrons, as well as the availability of 18F- labelled tracers, could improve the cost- effectiveness of cardiac PET imaging, as well as logistics and dissemination. • Quantitative measures of myocardial ischemia are provided with the addition of the measurement of viability and functional parameters during a single scan.

Contributing Organization **Year** ***Document Title***	**Consensus**
	• Hybrid imaging combining PET perfusion imaging with coronary CT angiography data might provide comprehensive assessment, especially in patients with multivessel disease.
Society of Nuclear Medicine and Molecular Imaging & ASNC[169] 2018 ***Clinical Quantification of Myocardial Blood Flow Using PET: Joint Position Paper of the SNMMI Cardiovascular Council and the ASNC***	**Assessment of Myocardial Blood Flow (MBF) and Myocardial Flow Reserve (MFR) using PET** • A relationship between the severity of epicardial coronary artery stenoses and PET measures of both peak hyperemic stress MBF and MFR has been established for more than 2 decades. • Though initially established using 15O-water, this finding was quickly replicated using 13N-ammonia and more recently using 82Rb. • The application of stress MBF and MFR for improving the diagnostic accuracy of PET MPI with clinical protocols has been investigated by many groups with both 13N-ammonia and 82Rb. • Although these studies have consistently demonstrated improved diagnostic sensitivity, at least 2 large studies have raised concerns about potential for decreased specificity, possibly due to the contributions of diffuse atherosclerosis and microvascular disease to stress MBF and MFR measurements. • Consequently, the positive predictive value of even severely depressed (<1.5) MFR is only modest. • Conversely, preserved MFR (>2.0) has an excellent negative predictive value for high-risk CAD (i.e., left main and 3-vessel disease), and high-risk disease is extremely uncommon with an MFR of more than 2.5.
Myocardial CT Perfusion	
Society of Cardiovascular Computed Tomography[188] 2020 ***Society of cardiovascular computed tomography expert consensus document on myocardial computed tomography perfusion imaging***	**Absolute contraindications to pharmacologic stress myocardial CT perfusion** • High-risk unstable angina • Decompensated or inadequately controlled CHF • Uncontrolled hypertension (BP > 200/110) • Hypotension (SBP<90 mm Hg) • Known contrast allergy, unless pre-treated • Allergy to stress agent • Uncontrolled cardiac arrhythmias

Contributing Organization Year *Document Title*	Consensus
	• Severe symptomatic aortic stenosis. • Bronchospastic Lung Disease (avoid adenosine and dipyridamole; regadenoson may be considered unless active wheezing) • Acute pulmonary embolism. • Active CVA • Acute myocarditis or pericarditis. • Acute aortic dissection. • Severe pulmonary hypertension. • Acute myocardial infarction. • Acutely ill for any reason. • Severe renal Insufficiency (GFR<30mi/min/BSA) • High-degree (AV) block. • Unable to cooperate with breath hold instructions. • Any caffeine, theophylline, or chocolate consumption in the last 12 hours **Relative contraindications to pharmacologic stress myocardial CT perfusion** • Known left main coronary stenosis >50% • Hypertrophic obstructive cardiomyopathy or other forms of outflow tract obstruction • Electrolyte abnormalities • Significant tachyarrhythmias or bradyarrhythmia • Recent stroke • Recent seizure • Heart rate >100, and cannot be treated with beta blockers • Moderate renal insufficiency (GFR 30-60mi/min/BSA) • Morbid Obesity (BMI>40) **Key Consensus Statements for Myocardial CT Perfusion** 1. We recommend that myocardial CTP may be added to coronary CTA when there is a high likelihood of ischemic heart disease, known CAD, prior coronary intervention, or significant calcifications, Additionally, CTP may be added when there is a known stenosis of indeterminate functional significance. In such cases, myocardial CTP is

Contributing Organization Year *Document Title*	Consensus
	recommended if knowledge regarding the presence and severity of ischemia would impact patient management and CTP is feasible. 2. Myocardial CTP imaging with pharmacologic stress testing requires supervision by a trained medical provider who is experienced in the administration of pharmacologic stress agents and stress testing. 3. Continuous 12-lead ECG monitoring may be performed using radiolucent electrodes and leads. Alternatively, 12-lead ECG monitoring can be interrupted during scan acquisition while continuous rhythm is still being recorded and monitored by the scanner console. Upon the completion of imaging, a 12 lead ECG should be performed to ensure there are no significant changes from baseline suggestive of post-stress myocardial ischemia or injury. 4. If an automated bolus-tracking algorithm is utilized, a region of interest should be defined in either the proximal-ascending or mid-descending thoracic aorta. The automated trigger should be set to a Hounsfield Unit (HU) threshold that is ~80-100HU above the baseline HU of the selected reference area immediately prior to the contrast injection. After the scanner is triggered, a short pause (~5 seconds) is required to allow for breath-hold instructions to be given. Contrast dose and flow rate is typically ~60–70ml injected at 5–6ml/sec. 5. The optimal sequence of scans (rest first versus stress first) has not been determined and either sequence has advantages and disadvantages. Our committee suggests assessment of factors that could impair exclusion of obstructive CAD on coronary CTA (e.g. significant coronary calcium, prior coronary event or coronary revascularization, high pre-test probability of obstructive CAD) prior to decision to perform CTP. Those patients with a high likelihood or known significant coronary disease or severe amount of CAC may undergo stress myocardial perfusion imaging first; whereas, patients who lack the above features may undergo coronary CTA first. 6. A delay of 10–20 minutes between the rest and stress CT acquisitions is recommended to minimize myocardial contrast agent contamination and to eliminate the potential adverse interaction of pharmacologic stress agents and nitroglycerin administration. 7. There is no consensus about whether imaging should be performed at end-systole or during diastasis although most larger trials to date have selected diastole. A

Contributing Organization **Year** ***Document Title***	**Consensus**
	multiphase acquisition which includes phases from both systole and diastole can be considered so that the phase with the least amount of artifact can be selected for analysis retrospectively. 8. For optimal image interpretation, images may be reconstructed from multiple phases of the cardiac cycle, typically at 5–10% intervals of the R-R image acquisition window and raw CTA and CTP data files should be retained until image interpretation is complete. 9. In static visual CTP interpretation, myocardial images are typically arranged using three standard orthogonal views - the short axis, vertical long axis, and horizontal long axis. CTP images usually use a narrow window width of ~200–300 and level setting of ~100–150 with an average slice thickness of 5–8 mm. Images may be viewed in minimal intensity projection (MinIP) or average intensity projections 10. Perfusion defects should be described in terms of size, transmurally, and reversibility in the context of the degree of stenosis in the supplying coronary artery.
Echocardiography	
Quantitative Cardiac Imaging Study Group[53] 2020 ***Clinical quantitative cardiac imaging for the assessment of myocardial ischemia***	**Echocardiography** • Echocardiography is most commonly applied for cardiac function imaging but is increasingly also being used for the assessment of myocardial perfusion and can be performed at the bedside. • The challenges of echocardiography include the common presence of noise and artefacts, lack of reproducibility, variable image quality and time- consuming manual analysis. • High frame rate echocardiography allows the estimation of myocardial blood velocity as a semiquantitative measure of myocardial ischemia with improved image quality. • Artificial intelligence solutions using machine learning for automated myocardial segmentation promise automated and fast segmentation and perfusion quantification. • Evaluation of patients with suspected acute coronary syndrome at the bedside is the primary strength of echocardiography when performed by experienced operators.

BMI = body mass index, CABG = coronary artery bypass graft, CAC = coronary artery calcium, CAD = coronary artery disease, CHF = congestive heart failure, CT = computed tomography, CTA = computed tomography angiogram, CTP = computed tomography perfusion, ECG = electrocardiogram, FFR = fractional flow reserve, MDCT = multi-detector

computed tomography, mm = millimeter, MPI = myocardial perfusion imaging, MRI = magnetic resonance imaging, PET = positron emission tomography, TEE = transesophageal echocardiogram.

2.11 Medicare and Representative Private Insurer Coverage Policies

Table 10. Summary table of payer policies for CCTA (including FFR)

Payer (year)	Evidence Base	Covered	Not Covered
CMS (2021) National Coverage Determination (NCD) for Noninvasive Fractional Flow CT *No other NCD was determined to be appropriate at this time*	2 SRs of diagnostic accuracy 5 diagnostic accuracy studies 1 prospective observational cohort 3 retrospective observational studies 1 registry study	FDA-approved FFRct technology may be considered reasonable and necessary in the management of patients with symptomatic, stable ischemic heart disease (SIHD) when the CCTA analysis is completed and demonstrates one of the following criteria: 1. Left main disease with intermediate coronary stenosis (lumen diameter reduction of 30-50%); **OR** 2. Proximal and mid-left anterior descending (LAD) coronary artery disease with intermediate stenosis (lumen reduction 40-70%); OR Proximal and mid-left circumflex disease with intermediate coronary stenosis (lumen reduction 40-70%; (considered equivalent to two-vessel disease); OR 3. Proximal two- or three-vessel disease with intermediate coronary stenosis in at least two vessels; OR 4. Right coronary disease with intermediate (lumen reduction 40-70%) coronary stenosis This service should be performed in patients with stable coronary symptoms. It should not be performed until after the base study (CCTA) has been completed and interpreted. If higher grade stenoses (i.e., >70%) are present, this study is not medically necessary, as the patient should proceed to catheterization. Similarly, low-grade stenoses (< 30%) do not require additional confirmatory data. If more than two intermediate risk coronary lesions are identified, the clinical situation is considered high risk, and the patient should proceed directly to catheterization.	FFRct is not considered reasonable in the following clinical circumstance: 1. Severe obesity (BMI > 39 kg/m2) 2. Prior placement of prosthetic valves 3. Known severe aortic stenosis 4. Prior placement of grafts in coronary bypass surgery 5. Suspicion of acute coronary syndrome (where MI or unstable angina have not been ruled out) 6. Intracoronary metallic stent 7. Status post-heart transplantation 8. Recent MI (30 days or less) 9. Prior pacemaker or defibrillator lead placement 10. Newly diagnosed systolic heart failure, with no prior left heart catheterization 11. Left main coronary artery disease with Intermediated Coronary Stenosis (lumen reduction less than or equal to 30%) 12. Non-obstructing stenosis (<50% of all major epicardial vessels) on CTA or catherization in the past twelve months, in the absence of a new symptom complex

Payer (year)	Evidence Base	Covered	Not Covered
Aetna (2019)	See Appendix N for references	Using 64-slice or greater, medically necessary for the following indications: A. Rule out obstructive coronary stenosis in persons with a low or intermediate pre-test probability of coronary artery disease or atherosclerotic cardiovascular disease by Framingham risk scoring, Pooled Cohort Equations, or by American College of Cardiology (ACC) criteria (see Appendix) who: i. Are symptomatic ii. Have a positive (i.e., greater than or equal to 1 mm ST segment depression) stress test C. Evaluation of asymptomatic persons at an intermediate pre-test probability of coronary heart disease or atherosclerotic cardiovascular disease by Framingham risk scoring or Pooled Cohort Equations who have an equivocal or uninterpretable exercise or pharmacological stress test or have resting electrocardiogram (ECG) changes (such as left bundle branch block (LBBB), pathologic q-waves, or right bundle branch block (RBBB) with left anterior fascicular block (LAFB) in which coronary artery disease (CAD) is a possible etiology. Note: Current guidelines from the American Heart Association recommend against routine stress testing for screening asymptomatic adults. D. Pre-operative assessment of/for: i. Persons scheduled to undergo 'high-risk" non-cardiac surgery, where an imaging stress test or invasive coronary angiography is being deferred unless absolutely necessary. The ACC defines high-risk surgery as emergent operations, especially in the elderly, aortic and other major vascular surgeries, peripheral vascular surgeries, and anticipated prolonged surgical procedures with large fluid shifts and/or blood loss involving the abdomen and thorax. ii. Planned non-coronary cardiac surgeries including valvular heart disease, congenital heart disease, and pericardial disease, in lieu of cardiac catheterization as the initial imaging study, in persons with low or intermediate pretest	Experimental and investigational for persons with any of the following contraindications to the procedure because its effectiveness above has not been established: • Body mass index (BMI) greater than 40 (except when 3rd generation Dual-Source CT (DSCT) 120-kv tube voltage is utilized). • Inability to image at desired heart rate (under 80 beats/min), despite beta blocker administration. • Person with allergy or intolerance to iodinated contrast material • Persons in atrial fibrillation (except when rate-controlled and 3rd generation Dual-Source CT (DSCT) 120-kv tube voltage is utilized) or with other significant arrhythmia. • Persons with extensive coronary calcification by plain film or with prior Agatston score greater than 1000. • for screening of asymptomatic persons, evaluation of atherosclerotic burden, evaluation of persons at high pre-test probability of coronary artery disease, evaluation of stent occlusion or in-stent restenosis, evaluation of persons with an equivocal PET rubidium study, identification of vulnerable plaques, monitoring of atheroma burden,

Payer (year)	Evidence Base	Covered	Not Covered
		risk of obstructive CAD. F. Detection and delineation of suspected coronary anomalies in young persons (less than 30 years of age) with suggestive symptoms (e.g., angina, syncope, arrhythmia, and exertional dyspnea without other known etiology of these symptoms in children and adults; dyspnea, tachypnea, wheezing, periods of pallor, irritability (episodic crying), diaphoresis, poor feeding and failure to thrive in infants). G. Calculation of fractional flow reserve (HeartFlow FFR) for persons who have a coronary CTA that has shown coronary artery disease of uncertain functional significance, or is non-diagnostic.	and for all other indications (e.g., atrial angiosarcoma). Note: The selection of CT angiography should be made within the context of other testing modalities such as stress myocardial perfusion images or cardiac ultrasound results so that the resulting information facilitates the management decision and does not merely add a new layer of testing. • Aetna considers coronary CT angiography experimental and investigational for assessment of coronary atherosclerosis in asymptomatic diabetics who do not otherwise meet the above criteria for CT coronary angiography because of insufficient evidence.
BCBS of NC Corporate Medical Policy (2018)	See Appendix N for references	The use of CT Coronary Angiography (CCTA), with or without Fractional Flow Reserve assessed by CT (FFR-CT) may be covered when accompanied by pre-test considerations as well as supporting clinical data and prerequisite information based on the following diagnostic indications: A. Indications where FFR-CT will not be required in conjunction with CCTA: i. Congenital coronary artery anomalies • For evaluation of suspected congenital anomalies of the coronary arteries. B. Indications where FFR-CT may be appropriate but is not a required capability of the performing imaging facility: i. Congestive heart failure/cardiomyopathy/LV dysfunction • For exclusion of coronary artery disease in patients with	The use of CT Coronary Angiography (CCTA), with or without Fractional Flow Reserve assessed by CT (FFR-CT) is considered investigational for all other indications.

Payer (year)	Evidence Base	Covered	Not Covered
		left ventricular ejection fraction <55% and low to moderate coronary heart disease risk (using standard methods of risk assessment, such as SCORE risk calculation) in whom CAD had not been excluded as the etiology of the cardiomyopathy. • Patients with high coronary heart disease risk should undergo cardiac catheterization. ii. Pre-operative evaluation for patients undergoing non-coronary cardiac surgery • Evaluation of symptomatic* or asymptomatic patients at moderate coronary heart disease risk (using standard methods of risk assessment, such as the SCORE risk calculation) to avoid an invasive angiogram, where all the necessary pre-operative information can be obtained using cardiac CT. • Procedures include open and percutaneous valvular procedures or ascending aortic surgery iii. Suspected coronary artery disease in symptomatic* patients who: • Have *not had evaluation* of coronary artery disease (MPI, cardiac PET, stress echo, CCTA or cardiac catheterization) within the preceding 60 days a. When both of the following apply: 1. Patient has low or moderate coronary heart disease risk (using standard methods of risk assessment such as the SCORE risk calculation) AND 2. During testing the patient had exercise-induced chest pain, ST segment change, abnormal BP response or complex ventricular arrhythmias • Have *had equivocal MPI or SE* within the past 60 days a. When both of the following apply: 1. Patient has low or moderate coronary heart disease risk (using standard methods of risk	

Payer (year)	Evidence Base	Covered	Not Covered
		assessment such as the SCORE risk calculation)AND 2. The imaging portion of the study is neither clearly normal nor clearly abnormal • Have had *abnormal MPI or stress echo* within the past 60 days a. When both of the following apply: 1. Abnormal MPI or stress echo is suspected to be false positive on the basis of low coronary heart disease risk (using standard methods of risk assessment such as the SCORE risk calculation) AND 2. The imaging portion of the study is abnormal • Have abnormal resting EKG • Have not had a recent CAD evaluation (MPI, cardiac PET, stress echo, CCTA or coronary angiography) within the preceding 60 days C. Indications where FFR-CT may be appropriate and is a required capability of the imaging facility i. Suspected CAD in symptomatic* patients who have abnormal resting EKG • When resting EKG abnormalities (left bundle branch block, electronically paced ventricular rhythm, left ventricular hypertrophy with repolarization abnormalities, resting ST segment depression 1 mm or more, digoxin effect or pre-excitation syndrome) would render an exercise treadmill test (without imaging) uninterpretable ii. Suspected CAD in symptomatic* patients who have not had recent CAD evaluation • When no CAD imaging evaluation (MPI, cardiac PET, stress echo, CCTA or coronary angiography) has been performed within the preceding sixty (60) days	

Payer (year)	Evidence Base	Covered	Not Covered
Cigna 2020	See Appendix N for references	A. Symptomatic individuals who have a 'low' or 'intermediate' pretest probability of CAD* B. 'Low' or 'intermediate' pre-test probability of coronary disease with persistent symptoms after a stress test. C. Replace performance of invasive coronary angiogram in individuals with low risk of CAD (i.e. Pre-op non-coronary surgery). D. For symptomatic individuals, evaluate post-CABG graft patency when only graft patency is a concern and imaging of the native coronary artery anatomy is not needed, such as in early graft failure. Additional Indications: E. Re-do CABG F. Evaluate coronary artery anomalies and other complex congenital heart disease of cardiac chambers or great vessels. G. Anomalous coronary artery(ies) suspected for diagnosis or to plan treatment and less than age 40 with a history that includes one or more of the following : i. Persistent exertional chest pain and normal stress test, ii. Full sibling(s) with history of sudden death syndrome before age 30 or with documented anomalous coronary artery, iii. Resuscitated sudden death and contraindications for conventional coronary angiography. iv. Prior nondiagnostic coronary angiography in determining the course of the anomalous coronary artery in relation to the great vessels, origin of a coronary artery or bypass graft location. H. Unexplained new onset of heart failure. I. Evaluation of newly diagnosed congestive heart failure or cardiomyopathy. i. No prior history of coronary artery disease, the ejection fraction is less than 50 ii. percent, and low or intermediate risk on the pre-test probability assessment, and iii. No exclusions to cardiac CT angiography.	NR

Payer (year)	Evidence Base	Covered	Not Covered
		iv. No cardiac catheterization, SPECT, cardiac PET, or stress echocardiogram has been performed since the diagnosis of congestive heart failure or cardiomyopathy. J. Ventricular tachycardia (6 beat runs or greater) if CCTA will replace conventional invasive coronary angiography. K. Equivocal coronary artery anatomy on conventional cardiac catheterization. L. Newly diagnosed dilated cardiomyopathy. M. Preoperative assessment of the coronary arteries in individuals who are going to undergo surgery for aortic dissection, aortic aneurysm, or valvular surgery if CCTA will replace conventional invasive coronary angiography. N. Vasculitis/Takayasu's/Kawasaki's disease O. Cardiac Trauma Indications for FFR-CT A. To further assess CAD seen on a recent CCTA that is of uncertain physiologic significance	
Wisconsin Physicians Service Insurance Corporation (2017) Local Coverage Determination States covered: Iowa, Kansas, Missouri, Nebraska, Indiana, Michigan.	None cited.	A. Alternative to invasive angiography and stress testing. For patients with anginal symptoms, patients with unclear stress tests results, patients in whom the stress test result contradicts the clinical assessment, to determine the patency of coronary artery bypass grafts, as an alternative when cardiac catheterization is impossible or carries a high risk, to rule out stenosis before non-coronary cardiac surgery such as valve replacement or resection of tumors, and clarifying unclear finding after invasive angiography. B. Assess patients suspected of having a congenital coronary anomaly of great vessels, cardiac chambers and valves. It is often used after an anomaly has been identified following a different test such as prior invasive coronary angiogram. CCTA is used to decide if surgery is indicated and for surgical planning. C. Evaluate acute chest pain in the emergency department (ED). The rationale is to quickly triage patients in order to rule out coronary artery disease as a possible cause of symptoms. Many will present	A. The test is never covered for screening, i.e., in the absence of signs, symptoms or disease. B. The test will be considered not medically necessary if the anticipated results are not expected to provide new, additional information to that already previously obtained from other tests (such as stress myocardial perfusion images or cardiac ultrasound). New or additional information should facilitate the management decision, not merely add a new layer of testing. C. The test will be considered not

Payer (year)	Evidence Base	Covered	Not Covered
		with a normal electrocardiogram and myocardial enzymes. D. Assess coronary or pulmonary venous anatomy. Coronary mapping is primarily for pre-surgical planning such as pacemaker lead placement in the lateral coronary vein to resynchronize cardiac contraction in patients with heart failure, or guiding biventricular pacemaker placement. Pulmonary vein anatomy can vary from patient to patient. Pulmonary vein mapping is primarily for catheter ablation which can isolate electrical activity from the pulmonary veins and allow for the elimination of recurrent atrial fibrillation, or help eliminate procedural complications. E. Assess etiology with new onset heart failure for evaluation of coronary arteries.	medically necessary if pretest evaluation indicates that the patient would require invasive cardiac angiography for further diagnosis or for therapeutic intervention. D. The test may be denied, on post-pay review, as not medically necessary when used for cardiac evaluation if there were pre-test knowledge of sufficiently extensive calcification of the suspect coronary segment that would diminish the interpretive value. (e.g., angina decubitus, unstable angina, Prinzmetal angina, etc.) E. Coverage is limited to devices that process thin, high resolution slices (1mm or less). The multi-detector scanners must have at least 64 slices per rotation capability. F. The administration of beta blockers and the monitoring of the patient during MDCT/CCTA by a physician experienced in the use of cardiovascular drugs is included as part of the test and is not a separately payable service. G. All studies must be ordered by the physician/qualified non-physician practitioner treating the H. patient and who will use the results of the test in the management of the patient. I. The test must be performed under

Payer (year)	Evidence Base	Covered	Not Covered
			the direct supervision of a physician, similar to the stress myocardial perfusion imaging. J. This LCD does not address electron beam tomography (EBT) technology or Ultrafast CT for coronary artery examination. There is no extension of coverage of EBT based on this policy. K. Quantitative calcium scoring is not a covered service and will be denied as not medically necessary. Calcium scoring reported in isolation is considered a screening service. When performed in association with CT angiography, there is neither separate nor additional included reimbursement for the calcium scoring. L. Atrial fibrillation or atrial flutter alone is not an indication; atrial fibrillation or atrial flutter with planned ablation therapy is allowed.
National Government Services, Inc. (2016) Local Coverage Determination Covered States: Connecticut, Illinois, Maine, Massachusetts, Minnesota, New Hampshire, New York	See Appendix N for references	A. **Patient presenting with chest pain syndrome.** These tests may be used in lieu of an imaging stress test. The clinician must have a high degree of suspicion that CAD is high on the differential diagnosis of the symptoms. B. **To facilitate the management decision of a patient with an equivocal stress test.** These tests might be chosen in select patients who have an equivocal stress (or stress imaging) test. The rationale is that a noninvasive coronary anatomic test (CCTA) allows an alternate method of assessing the coronary arteries, which would limit the number of negative invasive coronary angiograms.	A. These tests are never covered for screening, i.e., in the absence of signs, symptoms or disease. B. These tests will be considered not medically necessary if the anticipated results are not expected to provide new, additional information to that already previously obtained from other tests (such as stress myocardial perfusion images or cardiac ultrasound). New or additional

Payer (year)	Evidence Base	Covered	Not Covered
(Entire state, Downstate, Upstate, Queens), Rhode Island, Vermont, Wisconsin		C. **When the recurrence of symptoms in patients with known coronary artery disease may be related to progression/exacerbation of underlying disease.** The use of these tests in this setting would be to evaluate the extent of previously diagnosed coronary artery disease. Patients with known disease may have had remote invasive angiography and/or stress testing to evaluate prior events or symptoms. New or recurrent symptoms may relate to a change in the coronary anatomy that can be assessed with these tests. D. **When patients with prior bypass surgery or intracoronary artery stent placement present with chest pain or dyspnea.** Coronary bypass grafts are relatively well seen with these tests. The rationale for the tests would be to determine the patency and severity of possible graft stenoses that may be the source of chest pain. Patients with prior intracoronary stents often present with recurrent chest pain. The rationale for these tests as an alternative to invasive angiography is to rule out in-stent restenosis as the cause of symptoms. (Accurate assessment of in-stent restenosis may be limited by the artifact caused by the stent material itself and the quality of the scan and scanner). E. **Suspected congenital anomalies of the coronary circulation.** These tests are used to assess patients suspected of having a congenital coronary anomaly. The cross-sectional nature of this technique allows one to determine accurately both the presence and possible future harm that could result from the anomaly. It is often used after an anomaly has been identified following a different test such as prior invasive coronary angiogram. These tests are used to decide if surgery is indicated and for surgical planning. F. **The assessment of coronary or pulmonary venous anatomy.** This application of the tests for the coronary and pulmonary veins is primarily for pre-surgical planning. Coronary venous anatomy can be useful for the cardiologist who needs to place a pacemaker lead in the lateral coronary vein in order to resynchronize cardiac	information should facilitate the management decision, not merely add a new layer of testing. C. These tests will be considered not medically necessary if it is anticipated that the patient would require invasive cardiac angiography for further diagnosis or for therapeutic intervention. (e.g., angina decubitus, unstable angina, Prinzmetal angina, etc.) D. These tests may be denied, on post-pay review, as not medically necessary when used for cardiac evaluation if there were pre-test knowledge of sufficiently extensive calcification of the suspect coronary segment that would diminish the interpretive value. E. The administration of beta blockers and the monitoring of the patient during MDCT/CCTA by a physician experienced in the use of cardiovascular drugs is included as part of the test and is not a separately payable service. CCTA must be performed under the direct supervision of a physician. H. This LCD does not address electron

Payer (year)	Evidence Base	Covered	Not Covered
		contraction in patients with heart failure. This may be helpful to guide biventricular pacemaker placement. Pulmonary vein anatomy can vary from patient to patient. Pulmonary vein catheter ablation can isolate electrical activity from the pulmonary veins and allow for the elimination of recurrent atrial fibrillation. The presence of a pulmonary venous anatomic map may help eliminate procedural complications and allow for the successful completion of the procedure. G. **The patient undergoing non-coronary artery cardiac surgery.** - Certain patients who have non-coronary artery cardiac surgery (valve or ascending aortic surgery) may need a pre-operative invasive coronary angiogram. The surgical planning may also depend upon the exact location of the coronary arteries. The rationale for the use of CCTA in these patient subsets is to avoid potentially unnecessary invasive testing and still provide appropriate pre-surgical information. - The test may be medically necessary in patients presenting to the emergency room with complaints consistent with cardiac ischemia, but without diagnostic electrocardiography (ECG) or enzymes. - The test may be considered medically necessary in patients status post revascularization procedures who present with recurrent symptoms not clearly identifiable as ischemic. H. **FFRCT -** this test may be considered medically necessary when CCTA shows CAD of uncertain functional significance, or is non-diagnostic and where the addition of functional information provided by FFRCT can help the physician determine which patient may require invasive evaluation and / or treatment.	beam tomography (EBT) technology or Ultrafast CT for coronary artery examination. There is no extension of coverage of EBT based on this policy. I. Quantitative calcium scoring (CPT 75571) is not a covered service and will be denied as not medically necessary. Calcium scoring reported in isolation is considered a screening service. When performed in association with CT angiography, there is neither separate nor additional included reimbursement for the calcium scoring.
Noridian Healthcare Solutions, LLC (2020) Local Coverage	See Appendix N for references	FDA-approved FFRct technology may be considered reasonable and necessary in the management of patients with symptomatic, stable ischemic heart disease (SIHD), when the CCTA analysis is completed and demonstrates one of the following criteria:	FFRct is not considered reasonable in the following clinical circumstances: 1. Prior placement of prosthetic valves 2. Extensive coronary calcification

Payer (year)	Evidence Base	Covered	Not Covered
Determination Covered States: Alaska, Idaho, Oregon, Washington, Arizona, Montana, North Dakota, South Dakota, Utah, Wyoming		1. Left main disease with intermediate coronary stenosis (lumen diameter reduction of 30-50%); OR 2. Proximal left anterior descending (LAD) coronary artery disease with intermediate coronary stenosis (lumen reduction 50-70%); OR 3. Proximal left dominant circumflex disease with intermediate (lumen reduction 50-70%) coronary stenosis (considered equivalent to two-vessel disease); OR 4. Proximal two- or three vessel disease with intermediate coronary stenosis in at least 2 vessels.	3. Known severe aortic stenosis 4. Known severe 3-vessel disease 5. Prior placement of venous grafts in coronary bypass surgery 6. Suspicion of acute coronary syndrome 7. Severe obesity (BMI > 35 kg/m2)

CABG = coronary artery bypass graft, CAD = coronary artery disease, CCTA = coronary computed tomography, CT = computed tomography, ECHO = echocardiography, EKG = electrocardiogram, FFR = fractional flow reserve, MDCT = multi-detector computed tomography, MPI = myocardial perfusion imaging, PET = positron emission tomography, SPECT = single photon emission computed tomography.

* For the purposes of this guideline, a patient is considered to be "symptomatic" when one of the following (A-D) applies:

A. Chest pain

- With intermediate or high pretest probability of CAD; OR
- With low or very low pretest probability of CAD and high risk of CAD (SCORE)

B. Atypical symptoms: syncope, shortness of breath (dyspnea), neck, jaw, arm, epigastric or back pain, or sweating (diaphoresis)

- With moderate or high risk of CAD (SCORE)

C. Other symptoms; palpitation, dizziness, lightheadedness, near syncope, nausea, vomiting, anxiety, weakness, fatigue etc.

- With high risk of CAD (SCORE)

D. Patients with any cardiac symptom who have diseases/conditions with which coronary artery disease commonly coexists such as:

- Diabetes mellitus; OR
- Abdominal aortic aneurysm; OR
- Established and symptomatic peripheral vascular disease; OR
- Prior history of cerebrovascular accident (CVA), transient ischemic attack (TIA) or carotid endarterectomy (CEA) or high grade carotid stenosis (>70%); OR
- Chronic renal insufficiency or renal failure

Table 11. Summary table of payer policies for PET

Payer (year)	Evidence Base	Covered	Not Covered
CMS (2002)	• **Positron Emission Tomography (Australia , 2000):** This review of PET literature focused on the added value of PET in patients who have already had SPECT. The review found that PET seems more sensitive and specific than SPECT but that the two tests disagree on a relatively small number of patients. Only one study was correctly designed to determine the incremental value of PET over SPECT. Of the patients with discordant results, PET was overall the better predictor of myocardial recovery, with almost all PET results correct and SPECT results incorrect predictors. • **Functional Diagnostic Imaging in the Assessment of Myocardial Viability (Alberta, Canada, 1999):** This is a comprehensive review of many different functional diagnostic imaging tests including PET, SPECT anLLd dobutamine echo. This report found that there are few good data on the influence of any of the tests on patient management. Overall, the sensitivity of PET, SPECT and dobutamine echo was similar. The specificity of PET and dobutamine echo was similar, and both were better than SPECT. • **INAHTA summary (1999):** This summary of 11 different technology assessments found a general agreement on the "comparable or superior performance of PET to other myocardial perfusion imaging alternatives, particularly thallium-201 SPECT" but with no clear conclusions about the extent of the improvement due to PET. The summary notes that PET is more costly than other alternatives and that consideration should be given to the most overall cost-effective approach	On December 15, 2000, CMS published a Decision Memorandum on a request for broad coverage of PET for all oncological indications, heart disease, and neurological disorders. The December 15th decision memorandum stated that CMS had insufficient evidence to support coverage for the indication of myocardial viability except for the decision to cover the service following an inconclusive SPECT. CMS intends to revise the NCD at CIM 50-36 to state that: 1. Both SPECT or FDG PET are reasonable and necessary as a primary or initial diagnostic study for determining myocardial viability prior to revascularization 2. PET continues to be reasonable and necessary following an inconclusive SPECT 3. The greater specificity of PET makes using SPECT following an inconclusive PET of no added value and	NR

Payer (year)	Evidence Base	Covered	Not Covered
		thus not reasonable and necessary.	
Aetna (2020)	Not specified.	A. Evaluation of Coronary Artery Disease PET scans using rubidium-82 (Rb-82) or N-13 ammonia done at rest or with pharmacological stress are considered medically necessary for non-invasive imaging of the perfusion of the heart for the diagnosis and management of members with known or suspected coronary artery disease, provided such scans meet either one of the two following criteria: i. The PET scan is used in place of, but not in addition to, a single photon emission computed tomography (SPECT), in persons with conditions that may cause attenuation problems with SPECT (obesity (BMI	NR

Payer (year)	Evidence Base	Covered	Not Covered
		greater than 40), large breasts, breast implants, mastectomy, chest wall deformity, pleural or pericardial effusion); or ii. The PET scan is used following an inconclusive SPECT scan (i.e., the results of the SPECT are equivocal, technically uninterpretable, or discordant with a member's other clinical data). • In these cases, the PET scan must have been considered necessary in order to determine what medical or surgical intervention is required to treat the member.

	clear conclusions about the extent of the improvement due to PET. The summary notes that PET is more costly than other alternatives and that consideration should be given to the most overall cost effective approach		
Aetna (2019)	Not specified.	Aetna considers SPECT medically necessary for the diagnosis of coronary artery disease and for the assessment of prognosis in persons with coronary artery disease except as outlined in "exclusion criteria" below."	Aetna considers SPECT experimental and investigational for all other cardiac indications because its effectiveness for indications other than the ones listed above has not been established. Exclusion criteria: Aetna considers SPECT myocardial perfusion imaging experimental and investigational for the following indications for which the study is considered “inappropriate” according to appropriateness criteria from the American College of Cardiology (ACC): A. As a routine screening evaluation after a percutaneous transluminal coronary angioplasty (PTCA) with or without stenting or coronary artery bypass surgery (CABG) prior to discharge from the acute care setting; *or* B. As a routine screening evaluation after a re-vascularization procedure (PTCA with stenting or CABG) at an interval of less than 2 years from the procedure if there is no worsening in the members symptomatology and if the member had symptoms prior to the intervention, and there is no history of congestive heart failure. **Note**: If there is a history of congestive heart failure and the member is status post re-vascularization,

Payer (year)	Evidence Base	Covered	Not Covered
			repeat nuclear imaging as frequently as annually may be medically necessary; *or* C. Assessment of vulnerable plaque; *or* D. Evaluation of a member with an acute coronary event and hemodynamic instability, shock, or mechanical complications of the event; *or* E. In the setting of acute chest pain or equivalent symptoms with a high likelihood of being acute coronary syndrome, when there has been a diagnosis of acute myocardial infarction, in the immediate post-thrombolytic period, or when there is a high pre-test likelihood of significant coronary disease as demonstrated by marked ST segment elevation on the ECG; *or* F. Prior to high-risk surgery when the member is asymptomatic and there was a normal cardiac catheterization, coronary intervention (PTCA, stenting, CABG), or normal nuclear stress test less than 1 year before the surgical date; *or* G. Prior to intermediate-risk non-cardiac surgery if the member is capable of, and has no contraindication to standard stress testing**; *or* H. Prior to low-risk non-cardiac surgery for risk assessment; *or* I. Re-evaluation of members without chest pain or equivalent symptoms, without known coronary disease, at high-risk for coronary disease (based upon the Framingham score greater than 10)*, who have an initial negative radionuclear imaging study, when it has been less than 2 years since the last radionuclear

Payer (year)	Evidence Base	Covered	Not Covered
			study; *or* J. Re-evaluation of members without chest pain or equivalent symptoms or with stable symptoms, with known coronary disease as determined by prior abnormal catheterization or SPECT cardiac study (but without prior infarction), when it has been less than 1 year since the last radionuclear study. Note: if the member has worsening symptoms or if the member had silent ischemia, more frequent imaging or other diagnostic testing or interventions may be medically necessary; *or* K. Screening of members with chest pain or chest pain equivalent symptoms when there is a low probability of coronary disease (Framingham score less than 10)*, no history of diabetes, and there are no impediments or contraindications to non-nuclear stress testing; *or* L. Screening of members without chest pain or equivalent symptoms when there is a low probability of coronary disease (Framingham score less than 10)* and no history of diabetes

CABG = coronary artery bypass graft, FDG = Fludeoxyglucose, PET = positron emission tomography, PTCA = percutaneous transluminal coronary angioplasty, SPECT = single photon emission computed tomography.

3 The Evidence

3.1 Methods of the Systematic Literature Review

3.1.1 Objectives

The aim of this report is to evaluate the clinical impact, safety and cost-effectiveness of the three primary noninvasive imaging methods of diagnosing CAD, namely CCTA (including use of FFR), CT perfusion imaging, stress nuclear imaging and stress echocardiography. This review updates the 2008 CCTA HTA and 2013 nuclear imaging HTA and adds evaluation of stress echocardiography.

3.1.2 Contextual Questions

Prior to addressing research questions related to the impact of cardiac imaging on clinical outcomes ***the diagnostic accuracy (validity)*** of these modalities compared with invasive coronary angiography (the usual reference standard) will be briefly summarized for context, given the clinical maturity of these imaging modalities.

In patients with known or suspected CAD who are *symptomatic:*

1. What is the diagnostic accuracy of *CCTA* for anatomical confirmation of obstructive CAD? Is there evidence of differential test accuracy for specific subpopulations (e.g., women, patients with comorbidities, the elderly)?

2. What is the diagnostic accuracy of *CCTA with determination of fractional flow reserve (FFR)* for the diagnosis of CAD? Is there evidence of differential test accuracy for specific subpopulations (e.g., women, patients with comorbidities, the elderly)?

3. What is the diagnostic accuracy of *stress CCTA* for the diagnosis of CAD? Is there evidence of differential test accuracy for specific subpopulations (e.g., women, patients with comorbidities, the elderly)?

4. What is the diagnostic accuracy of *stress nuclear imaging*? Is there evidence of differential test accuracy for specific subpopulations (e.g., women, patients with comorbidities, the elderly)?

5. What is the diagnostic accuracy of *stress echocardiography*? Is there evidence of differential test accuracy for specific subpopulations (e.g., women, patients with comorbidities, the elderly)?

3.1.3 Research Key Questions

The scope of this report and final key questions were refined based on input from clinical experts. Clinical expert input was sought to confirm critical outcomes on which to focus. Draft Key Questions and PICOTS scope were published on the HCA website for public comment. None were received. Public comments as well as those from clinical experts and peer-reviewers were considered for finalization of this report.

The following Key Questions focus on ***the impact on clinical outcomes*** for the use of CCTA, stress nuclear imaging, and stress echocardiography to diagnose CAD **in patients with known or suspected CAD who are *symptomatic.***

1. What is the comparative effectiveness of noninvasive cardiac anatomic or functional imaging modalities (CCTA, stress nuclear imaging, stress echocardiography) in leading to improved *clinical outcomes* (e.g., MI, mortality)?

2. What is the comparative effectiveness of noninvasive cardiac anatomic or functional imaging modalities (CCTA, stress nuclear imaging, stress echocardiography) with respect to *clinical decision-making* including additional testing and treatments?

3. What is the comparative effectiveness of noninvasive cardiac anatomic or functional imaging modalities (CCTA, stress nuclear imaging, stress echocardiography) with regard to *harms or adverse events* which may result directly from testing or additional, downstream testing?

4. Does effectiveness (in terms of clinical outcomes) or safety of noninvasive cardiac anatomic or functional imaging (CCTA, stress nuclear imaging, stress echocardiography) differ in *special populations* (e.g., women, those with comorbidities, the elderly)?

5. What is the *cost-effectiveness* of noninvasive cardiac anatomic or functional imaging modalities (CCTA, stress nuclear imaging, stress echocardiography) for clinical outcomes?

3.1.4 Inclusion/Exclusion Criteria

Table 13 below provides a summary of the inclusion and exclusion criteria. Briefly, included studies met the following requirements with respect to participants, intervention, comparators, outcomes, and study design:

- **Population**: Adults with (1) symptoms of suspected (previously undiagnosed) CAD who present with stable (nonemergent) typical or atypical symptoms suspicious for CAD or suspected acute coronary syndrome (ACS) in emergency departments, or (2) known/established CAD.

- **Intervention:** CCTA (including use of FFR and pharmacologic stress with 64 slice or higher CT), stress nuclear imaging and stress echocardiography.

- **Comparators:** No testing, usual care, comparison of the above interventions with each other, and invasive coronary angiography.

- **Outcomes:** Primary clinical outcomes are 1) myocardial infarction (MI), 2) cardiac death, and 3) all-cause mortality. Clinical Decision-Making outcomes are 1) referral for treatment and 2) referral for additional testing. Safety outcomes include harms of testing (e.g., adverse events related to contrast agents, medication for pharmacologic stress testing), vascular complications (e.g., stroke) and risks and consequences of testing (radiation exposure, psychological

consequences of diagnosis, ramifications of additional testing, other). [redacted]

- **Studies:** The focus was on high quality (low risk of bias) comparative studies (e.g., randomized controlled trials, comparative cohort studies with concurrent controls) for Key Questions 1-3. Comparative cohort studies that were designed specifically to evaluate safety or comprehensive systematic reviews specifically on safety were considered for inclusion. For Key Question 4, RCTs that stratified on baseline patient characteristics and evaluated effect modification were included. Full, comparative, formal economic studies (i.e., cost-effectiveness, cost-utility, cost-minimization, and cost-benefit studies) were sought for Key Question 5; studies using modeling may be used to determine cost-effectiveness.

Table 13. Summary of inclusion and exclusion criteria

Study Component	Inclusion	Exclusion
Patients	Adult patients (≥18 years of age) with symptoms of suspected (previously undiagnosed) CAD who present with • Stable (nonemergent) typical or atypical symptoms suspicious for CAD (e.g., chest pain, chest tightness, chest burning, shoulder pain, palpitations, jaw pain, or non-chest pain symptoms, such as dyspnea or worsening effort tolerance) • Suspected acute coronary syndrome (ACS) in emergency departments. Symptomatic adults with known/established CAD including those who have had prior MI and/or revascularization. For all questions, data on special populations and circumstances including the following will be evaluated: • Women • Patients with atypical symptoms • Elderly patients • Patients with comorbidities (including renal insufficiency, DM), LBBB)	• Asymptomatic patients • Patients presenting for evaluation of cardiac pathologies other than CAD (e.g., congenital abnormalities, valvular disease, evaluation of cardiomyopathy etiology, CHF) • Patients with STEMI
Intervention	• Coronary CT Angiography (including use of FFR) and CT perfusion imaging (pharmacologic stress) with 64 slice or higher CT • Stress nuclear imaging (including PET, SPECT) • Stress echocardiography	• CACS • Screening • Novel uses of any of these tests • MRI/MRA • Comparisons of technical

Study Component	Inclusion	Exclusion
		performance parameters or variations of a testing modality (e.g., comparison different CT techniques) • Outdated equipment or methods
Comparator(s)	• No testing • Usual care* • Comparison of the above interventions with each other • Invasive coronary angiography	
Outcomes	Clinical health outcomes (PRIMARY) • MI, cardiac death, all-cause mortality Clinical decision making • Referral for treatment • Referral for additional testing Harms, risks and consequences of testing (initial testing and subsequent testing) • Harms of testing (e.g., adverse events related to contrast agents, medication for pharmacologic stress testing), vascular complications (e.g., stroke) • Risks and consequences of testing (radiation exposure, psychological consequences of diagnosis, ramifications of additional testing, other†) Economic: Incremental cost-effectiveness or similar outcome	• Intermediate outcomes
Timing	• Emergent or non-emergent • Any point in the diagnostic workup	• none
Setting(s)	• Emergency department • Non-emergent settings	• none
Studies	• Focus will be on studies with the least potential for bias. Focus will start with RCT evidence; in the absence of RCTs, high quality comparative observational studies that control for potential confounding will be considered. Observational studies will primarily be considered for test-related harms. • Studies published in English in peer-reviewed journals, technology assessments or publicly available FDA reports. • Full (comparative) economic studies • Studies published after 2000 (except for stress	• Non-comparative studies • Modeling studies for prediction • Prognostic studies • Costing studies • Studies evaluating the incremental benefit of adding a test to another. • Studies published prior to 2000 (except for stress echocardiography)

Study Component	Inclusion	Exclusion
	echocardiography)	

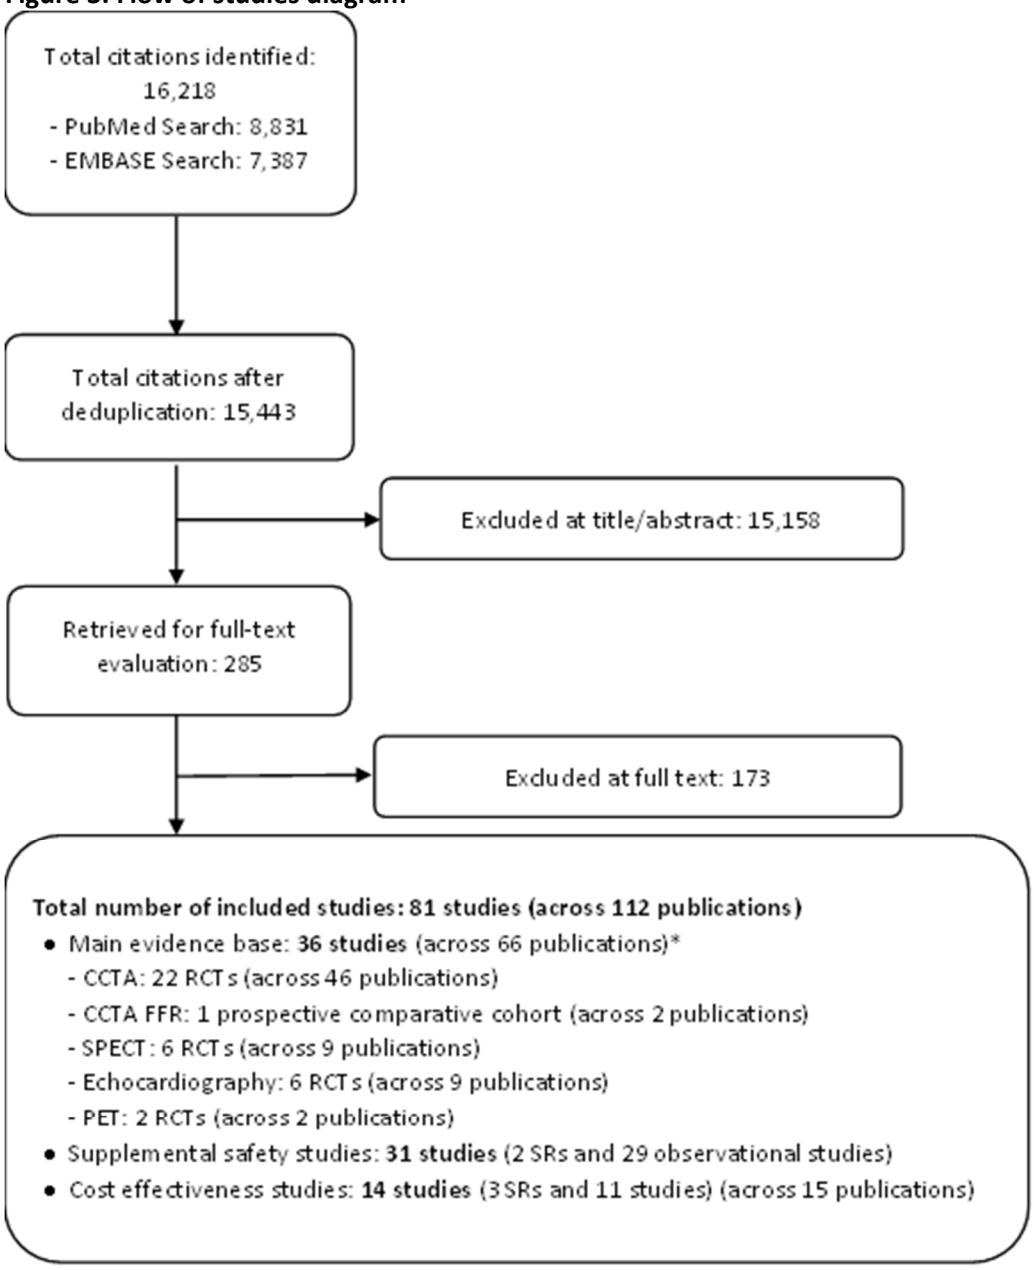
CACS = coronary artery calcium scoring; CAD = coronary artery disease; CHF = congestive heart failure; CT = computed tomography; DM = diabetes mellitus; FFR = fractional flow reserve; LBBB = left bundle branch block; RCT = randomized controlled trials; MI = myocardial infarction; PET = positron emission tomography; SPECT = single photon emission computed tomography; STEMI = ST-segment elevation myocardial infarction.
*Usual care typically includes no treatment/nothing if low pretest probability, "watchful waiting", or medical treatment if high pretest probability.
†Other may include impact on patients such as days lost from work, procedures cancelled (waiting for tests), vacations cancelled, etc.

3.1.5 Data Sources and Search Strategy

We searched electronic databases from January 1, 2000 to March 23, 2021 (for PubMed) and from database inception to March 23, 2021 (for all other databases) to identify publications assessing the capabilities of CCTA, stress nuclear imaging and stress echocardiography as diagnostic tests for CAD to direct patient management and improve patient outcomes that had been published since the prior reports. A formal, structured systematic search of the peer-reviewed literature was performed across a number of databases including PubMed, the Cochrane Central Register of Controlled Trials, and the Cochrane Database of Systematic Reviews (see Appendix B for full search strategy) to identify relevant peer reviewed literature as well as other sources (ClinicalTrials.gov, ECRI Guidelines Trust, Center for Reviews and Dissemination Database) to identify pertinent clinical guidelines and previously performed assessments. We also hand searched the reference lists of relevant studies and the bibliographies of systematic reviews.

The clinical studies included in this report were identified using the algorithm shown in Appendix A. The process involves four stages. The first stage of the study selection process consisted of the comprehensive electronic search and bibliography review. We then screened all possible relevant articles using titles and abstracts in stage two. This was done by two individuals independently. Those articles that met a set of *a priori* retrieval criteria were included for full-text review. We excluded conference abstracts, non-English-language articles, duplicate publications that did not report different data or follow-up times, white papers, narrative reviews, preliminary reports, and incomplete economic evaluations. Any disagreement between screeners that were unresolved resulted in the article being included for the next stage. Stage three involved retrieval of the full text articles remaining. The final stage of the study selection algorithm consisted of the review and selection of those studies using a set of *a priori* inclusion criteria, again, by two independent investigators. Discrepancies were resolved through discussion and if necessary, adjudicated by a third investigator. A list of excluded articles along with the reason for exclusion is available in Appendix C. The remaining articles form the evidence base for this report.

Figure 3. Flow of studies diagram



CCTA = coronary computed tomography angiography; FFR = fractional flow reserve; PET = positron emission tomography; RCT = randomized control trial; SPECT = single photon emission tomography; SR = systematic review
* One trial (CECaT trial) provided data for both SPECT and Stress Echocardiogram.

3.1.6 Data Extraction

Reviewers extracted the following data from the clinical studies: study design, setting, country, source of funding, sample size, inclusion and exclusion criteria, study population characteristics, follow-up time, noninvasive testing protocol, definition of a positive test, study outcomes and adverse events. For economic studies, data related to sources used, economic parameters and perspectives, results, and sensitivity analyses were abstracted. An attempt was made to reconcile conflicting information among multiple reports presenting data from the same study. Detailed study and patient characteristics and results are available in Appendices F–L.

3.1.7 Quality Assessment: RoB, QHES Evaluation, and Overall SOE

The method used by Aggregate Analytics, Inc. (AAI) for assessing the quality of evidence of individual studies as well as the overall strength of evidence (SOE) are based on established methods for systematic reviews. Included studies reporting on primary outcomes of interest were critically appraised independently by two reviewers evaluating the methodological quality, study limitations and potential for bias based on study design as well as factors which may bias studies using defined templates and pre-specified criteria. Assessment of RCTs followed appropriate criteria based on methods described in *the Cochrane Handbook for Systematic Reviews of Interventions*[40,104] and guidance from the Agency for Healthcare Research and Quality (AHRQ) *Methods Guide for Effectiveness and Comparative Effectiveness Reviews.*[1] In keeping with the AHRQ methods and the 2016 report on non-invasive imaging for CAD[230], each study was given a final rating of “good”, “fair”, or “poor” quality as described below. Discrepancies in ratings between reviewers were resolved through discussion and consensus. Criteria are detailed in Appendix D.

Table 14. Criteria for grading the quality of individual studies

Rating	Description and Criteria
Good	• Low risk of bias; study results generally considered valid • Employed valid methods for selection, inclusion, and allocation of patients to treatment; report similar baseline characteristics/key risk factors for testing groups being compared; clearly describe attrition and have low attrition; use appropriate means for preventing bias (e.g., blinded outcomes assessment); and use appropriate analytic methods (e.g., intention-to-test analysis); full reporting on pre-specified outcomes. • For studies of testing, pre-specification of thresholds for a positive test,
Fair	• Study is susceptible to some bias but not enough to necessarily invalidate results • May not meet all criteria for good quality, but no flaw is likely to cause major bias; the study may be missing information making it difficult to assess limitations and potential problems • This category is broad; studies with this rating will vary in strengths and weaknesses; some fair-quality studies are likely to be valid, while others may be only possibly valid
Poor	• Significant flaws that imply biases of various kinds that may invalidate results; the study contains "fatal flaws" in design, analysis or reporting; large amounts of missing information; discrepancies in reporting or serious problems with intervention or test delivery • Study results are at least as likely to reflect flaws in the study design or execution as the true difference between the compared interventions • Considered to be less reliable than higher quality studies when synthesizing the evidence, particularly if discrepancies between studies are present

Risk of bias was not assessed for case series (single arm studies); all case series were considered to be at high risk of bias. Economic studies were evaluated according to The Quality of Health Economic Studies (QHES) instrument developed by Ofman et al. in conjunction with consideration of epidemiologic principles that may impact findings.[182] Systematic reviews included as primary evidence were assessed using the AMSTAR-2tool.[224,225] Based on these quality criteria, each comparative study chosen for inclusion for a Key Question was given a risk of bias (RoB) (or QHES) rating; details of each rating are available in Appendix E. For contextual questions, general risk of bias was assessed for systematic reviews of diagnostic accuracy and reliability based on AMSTAR-2.[224,225] Individual reliability studies were assessed as described in Appendix D. Individual studies for diagnostic accuracy were not assessed.

SOE was assessed by two researchers following the principles for adapting GRADE (Grades of Recommendation Assessment, Development and Evaluation)[89,92,93] as outlined by the Agency for Healthcare Research and Quality (AHRQ).[7] The strength of evidence was based on the highest quality evidence available for the primary outcomes.

In determining the strength of body of evidence regarding a given outcome, the following domains were considered:

- **Risk of bias**: the extent to which the included studies have protection against bias
- **Consistency:** the degree to which the included studies report results that are similar in terms of effect sizes, range and variability.
- **Directness**: describes whether the evidence is directly related to patient health outcomes or comparisons of interventions are direct (head to head).

- **Precision:** describes the level of certainty surrounding the effect estimates.
- **Publication or reporting bias:** is considered when there is concern of selective publishing or selective reporting. This is difficult to assess particularly for nonrandomized studies.

Bodies of evidence consisting of RCTs are initially considered as High SOE. In general, the GRADE and AHRQ methodologies initially consider nonrandomized studies as Low SOE as such studies typically are at higher risk of bias due to lack of randomization and inability of investigators to control for critical confounding factors. The SOE could be downgraded based on the limitations described above. There are also situations where studies (particularly observational studies) could be upgraded if the study had large magnitude of effect (strength of association) or if a dose-response relationship is identified and there are no downgrades for the primary domains listed above and confounding is not a concern. Publication and reporting bias are difficult to assess, particularly with fewer than 10 RCTs and for observational studies.[25,213] Publication bias was unknown in all studies and thus this domain was eliminated from the strength of evidence tables. The final SOE was assigned an overall grade of high, moderate, low, or insufficient, which are defined as follows:

- High - Very confident that effect size estimates lie close to the true effect for this outcome; there are few or no deficiencies in the body of evidence; we believe the findings are stable.
- Moderate – Moderately confident that effect size estimates lie close to the true effect for this outcome; some deficiencies in the body of evidence; we believe the findings are likely to be stable but some doubt remains.
- Low – Limited confidence that effect size estimates lie close to the true effect for this outcome; major or numerous deficiencies in the body of evidence; we believe that additional evidence is needed before concluding that findings are stable or that the estimate is close to the true effect.
- Insufficient – We have no evidence, are unable to estimate an effect or have no confidence in the effect estimate for this outcome; OR no available evidence or the body of evidence has unacceptable efficiencies precluding judgment.

Assessing the SOE for studies performing subgroup analysis for evaluation of differential effectiveness or safety requires additional considerations discussed below. Methods for determining the overall quality (strength) of evidence related to economic studies have not been reported, thus the overall strength of evidence for outcomes reported in Key Question 5 was not assessed.

3.1.8 Analysis

Evidence was summarized qualitatively and quantitatively. Risk ratio (RR) and 95% confidence intervals were used for dichotomous outcomes to evaluate the presence of an association between testing and the outcome. Risk differences (RD) and 95% CIs were calculated if an association was seen for “hard” outcomes that might be reliably measured (e.g., death). Risk differences were not calculated for observational studies as causality cannot be inferred. In the absence of adjusted effect size estimates, for dichotomous outcomes, crude risk ratios (RR) and 95% confidence intervals (CI) were calculated using either STATA 14.0[235] or Rothman Episheet.[3] For instances with fewer than five observations per cell, exact methods were employed. Where effect estimates that were adjusted for confounding were

reported by study authors, they were preferred and reported. For continuous variables, mean differences (MD) and associated 95% CIs were calculated if the outcomes were reported using the same scale, and standardized mean difference (SMD) and 95% CI were used when the outcomes were reported in different scale

Meta-analyses were conducted as appropriate in order to summarize primary outcome data from multiple studies and to obtain more precise and accurate estimates using STATA 14.0. [235]To determine the appropriateness of meta-analysis, we considered clinical and methodological diversity and assessed statistical heterogeneity. To determine the appropriateness of meta-analysis, we considered clinical and methodological diversity and assessed statistical heterogeneity. Statistical heterogeneity among the studies was assessed using Cochran's χ^2 test and the I^2 statistic.[105] To combine trials, we used a random effects model based on the profile likelihood method which provides a more conservative effect estimate. In the case of non-convergence with profile likelihood, the Der Simonian and Laird estimates were reported.[97] For continuous variables, differences in mean follow-up scores between treatments were analyzed to determine mean differences as an effect size. Methods for calculating the standard deviations and for imputing missing standard deviations followed the recommendations given in The Cochrane Handbook 7.7. Where no events occurred in one arm of a study, a value of 0.50 was used for that arm in accordance with Cochrane methods. Studies in which no events occurred in either study arm did not contribute to effect estimates (0% weight) but were retained in some plots for visual effect and completeness. Sensitivity analyses were conducted excluding poor-quality studies, outlying data and clinically heterogeneous trials where there were sufficient data. Given the limitations of ETT as a functional test, sensitivity analyses comparing CCTA with functional imaging tests only were also conducted. Tests for interaction related to study populations were done. Given that patients with acute symptoms presenting to the ED may have different need for and timing of hospitalization, we did not pool data for this outcome. Outcomes are detailed in the evidence tables in the appendices and/or the body of the report. Where results were reported at different time frames, we stratified by timing to evaluate results at the time of index test (primarily in studies in an ED setting) and then along common follow-up times as reported in included studies.

We did not conduct analyses to evaluate potential markers for publication bias given the substantial heterogeneity in study designs, programs, length of follow-up and patient populations and small number of trials available for some analyses in specific populations.[174,226]

To evaluate differential efficacy and safety (heterogeneity of effect, interaction), we focused on RCTs as they have the least potential for bias and confounding thus allowing for causal inference. Further, only RCTs that formally tested for interaction between subgroups were reported for Key Question 4. SOE for these studies is based on consideration of the overall study risk of bias (study quality) as well as whether subgroup variables and analyses were specified a priori, the hypothesized impact of a subgroup on the outcome/effect and sample size as evaluation of interaction requires greater sample size. Such analyses should be interpreted cautiously and consider the biologic plausibility of differential efficacy or safety. Such analyses are generally considered hypothesis generating, and additional confirmatory evidence should be sought.[185,239,252]

4 Contextual Questions

Diagnostic tests are recommended when evaluating the severity of a condition or predicting therapeutic response. However, for testing to be of value, results must lead to meaningful action that improve an individual's wellbeing. They must be accurate and reliable while minimizing harms, including those related to downstream testing. They must also impact the process of care and impact key patient outcomes. For years CCTA, stress nuclear imaging, and stress echocardiography as diagnostic tests for coronary artery disease (CAD) have been investigated for their abilities to direct patient management and improve patient outcomes, as well as for their cost-effectiveness. These tests are the most common modalities for CAD diagnosis in symptomatic patients other than ECG and ECG treadmill testing.

In the past decade, a growing number of randomized control trials have provided additional evidence to describe the impact of noninvasive imaging on clinical outcomes. Two prior reports published over a decade ago focused mostly on diagnostic accuracy. With more published data comes increased clinical evidence available for most modalities. In the last decade in particular, there is much more clinical evidence related to CCTA. However, it is still critical to consider the reliability and accuracy of available tests.

In recent years, the technologies and their application have evolved, and due to clinical maturity, we are now focusing on clinical characteristics of the tests, while simultaneously providing important context for accuracy, particularly compared with the historical referent of invasive angiography. Diagnostic accuracy and validity are addressed via the contextual questions below. Contextual questions represent issues in a review for which a valid, but not necessarily systematic, summary of current research is needed to provide important context. The contextual questions will provide important background information on diagnostic validity and reliability for the included tests.

In patients with known or suspected CAD who are *symptomatic:*

1. What is the diagnostic accuracy of CCTA for anatomical confirmation of obstructive CAD? Is there evidence of differential test accuracy for specific subpopulations (e.g., women, patients with comorbidities, the elderly)?
2. What is the diagnostic accuracy of CCTA with determination of fractional flow reserve (FFR) for the diagnosis of CAD? Is there evidence of differential test accuracy for specific subpopulations (e.g., women, patients with comorbidities, the elderly)?
3. What is the diagnostic accuracy of stress CCTA for the diagnosis of CAD? Is there evidence of differential test accuracy for specific subpopulations (e.g., women, patients with comorbidities, the elderly)?
4. What is the diagnostic accuracy of stress nuclear medicine imaging? Is there evidence of differential test accuracy for specific subpopulations (e.g., women, patients with comorbidities, the elderly)?
5. What is the diagnostic accuracy of stress echocardiography? Is there evidence of differential test accuracy for specific subpopulations (e.g., women, patients with comorbidities, the elderly)?

4.1 Terms and definitions

Diagnostic test performance measures were used in this report. Briefly for the contextual questions:

- **True positive (TP):** patients who test positive and who have the disease
- **False positive (FP):** patients who test positive but do not have the disease
- **False negative (FN):** patients who test negative but do have the disease
- **True negative (TN):** patients who test negative and do not have the disease
- **Sensitivity** (true positive rate) measures the ability of a diagnostic test to correctly identify patients with the disease, and can be calculated as follows: TP/(TP + FN) usually expressed as % of patients with the disease who test positive
- **Specificity** (true negative rate) measures the ability of a diagnostic test to minimize false positives, and can be calculated as follows: TN/ (FP + TN) usually expressed as % of patients who do not have disease who test negative
- Note that sensitivity and specificity are negatively correlated with one another: if the threshold of a positive test is set higher to maximize sensitivity, specificity will be lower, and vice versa.
- **Negative Predictive Value (NPV):** % of patients with negative test who do not have the disease; depends on prevalence can be calculated one of two ways: TN/(TN+FN) or

$$\text{NPV} = \frac{\text{specificity x (1-prevalence)}}{\text{(1-sensitivity) x prevalence + sp1ecificity x (1-prevalence)}}$$

- **Positive Predictive Value (PPV):** % of patients with positive test who have the disease; depends on prevalence; can be calculated one of two ways: TP/(TP+FP) or

$$\text{PPV} = \frac{\text{sensitivity x prevalence}}{\text{sensitivity x prevalence + (1-specificity) x (1-prevalence)}}$$

- **1 – negative predictive value (NPV).** The negative predictive value is the % of patients with a negative test who do not have the disease so 1- NPV is the percent of patients with a negative test who *do* have the disease.
- **Positive Likelihood Ratio (LR+):** how much odds of disease increase with a positive test; depends on sensitivity and specificity; can be calculated as follows: sensitivity/(1-specificity)
- **Negative Likelihood Ratio (LR-):** how much odds of disease decrease with a negative test; depends on sensitivity and specificity; can be calculated as follows: (1-sensitivity)/specificity)
- **Kappa statistic:** represents the extent to which the agreement observed exceeds that which would be expected by chance alone, and can be calculated as follows:

$$\text{Kappa} = \frac{\text{(\% agreement observed) – (\% agreement expected by chance alone)}}{\text{100\% – (\% agreement expected by chance alone)}}$$

4.2 Results for Diagnostic Accuracy

To provide a general overview of the diagnostic accuracy of the included noninvasive tests in the target population of symptomatic patients with suspected or known CAD in emergent or non-emergent settings, a targeted search of the literature was done to identify moderate- to high-quality systematic reviews (based on a modified AMSTAR-2 checklist[51,225]) that compared noninvasive tests included in this report with the historic gold standard of ICA in terms of traditional diagnostic test performance measures (i.e., sensitivity, specificity, positive/negative predictive value, positive/negative likelihood ratio). Where relevant, we included data on noninvasive tests compared with fractional flow reserve. Noninvasive tests included CT angiography, stress nuclear imaging, and stress echocardiography. Most studies reported 50% or greater stenosis in ICA, however some reported diagnostic accuracy of the test relative to a higher threshold or stenosis of 70%, see tables for details. ICA is an anatomic test, so accuracy for anatomic tests such as CCTA may differ from functional tests such as stress nuclear imaging or stress echocardiography when compared with ICA; a strict correspondence between ICA and functional tests is not expected.

The diagnostic test characteristics of all the included tests compared with the test results from ICA are summarized below in Table 15 through Table 25, with more specific details available in Appendix L**.** The values of the various diagnostic test characteristics in these tables were taken from or calculated from the values reported in the included systematic reviews. Generally, authors did not describe the disposition or proportion of uninterpretable tests or account for them in the calculation of diagnostic accuracy parameters. [redacted].[184] This method assumes that clinicians refer non-diagnostic and indeterminate tests to ICA for further non-invasive testing, and conservatively estimates such cases to ultimately be false positive. This approach therefore may underestimate specificity and PPV because measures take into account false positives in their calculations.

Overall, evidence on diagnostic accuracy was available from five government-related reports[2,100,183,184,230] and nine systematic reviews[6,86,94,132,194,234,264] published in the peer review literature. The overall quality of systematic reviews published in the peer reviewed literature was moderate based on modified AMSTAR-2 ratings. Unfortunately, many studies were graded lower due to methodological issues, particularly a lack of rationale or listing of excluded studies and issues related to publication bias. The summary below provides information for each modality compared with the usual referent of ICA. Additional information for other comparators is found in Appendix L. Summary bullets are across the two ICA threshold of 50% or 70% stenosis, see tables for details. No studies focusing on specific subpopulations were identified. Additionally, key questions included considering differential accuracy based on specific populations, however included studies did not provide this.

<u>For the diagnostic accuracy in patients with stable symptoms in outpatient settings</u>:

- The diagnostic accuracy of **CCTA for anatomic imaging compared with ICA** across sources had the following ranges. Among these, Haase[94] investigated diagnostic accuracy using individual patient data.

  - Sensitivity (93.4% to 98%), specificity (72% to 84.4%)
  - PPV (58% to 93%), NPV (89% to 99%)
  - LR+ (3.43 to 5.98), LR- (0.02 to 2.64)
  - Prevalence of CAD (24.2% to 75.5%)
- The diagnostic accuracy of **CT myocardial perfusion compared with ICA** across sources had the following ranges
  - Sensitivity (54% to 66%), specificity (98% to 100%)
  - PPV (96% to 100%), NPV (66% to 100%)
  - LR+ (33.00 to 54.00), LR- (0.45 to 0.47)
  - Prevalence of CAD (NR)
- The diagnostic accuracy of **stress SPECT compared with ICA** across sources had the following ranges
  - Sensitivity (76% to 87%), specificity (70% to 78%)
  - PPV (32% to 95%), NPV (47% to 97%)
  - LR+ (2.88 to 3.68), LR- (0.24 to 2.33)
  - Prevalence of CAD (14.1% to 86%)
- The diagnostic accuracy of **stress PET compared with ICA** across sources had the following ranges
  - Sensitivity (90% to 91%), specificity (85% to 86%)
  - PPV (78% to 91%), NPV (84% to 94%)
  - LR+ (5.87 to 6.50), LR- (0.10 to 0.12)
  - Prevalence of CAD (36.5 to 62.5%)
- The diagnostic accuracy of **stress echocardiography compared with ICA** across sources had the following ranges
  - Sensitivity (64% to 90%), specificity (73% to 90%)
  - PPV (72% to 98%), NPV (36% to 97%)
  - LR+ (3.21 to 6.40), LR- (0.14 to 2.95)
  - Prevalence of CAD (35.1% to 90.8%)

For the diagnostic accuracy in patients with suspected or known CAD in outpatient settings:

- The diagnostic accuracy of **CCTA for anatomic imaging compared with ICA** across sources had the following ranges
  - Sensitivity (98.2% to 100%), specificity (81.6% to 89%)
  - PPV (90.5% to 93%), NPV (99%)
  - LR+ (9.20), LR- (0.00)
  - Prevalence of CAD (58% to 59.9%)
- The diagnostic accuracy of **stress SPECT compared with ICA** across sources had the following ranges
  - Sensitivity (83% to 85%), specificity (77% to 85%)
  - PPV (72% to 85%), NPV (79% to 85%)
  - LR+ (3.56 to 5.13), LR- (0.18 to 0.22)
  - Prevalence of CAD (41% to 50%)
- The diagnostic accuracy of **stress PET compared with ICA** across sources had the following ranges
  - Sensitivity (82% to 91%), specificity (82% to 91%)

    - PPV (93% to 96%), NPV (53% to 84%)
    - LR+ (4.97 to 8.89), LR- (0.11 to 0.21)
    - Prevalence of CAD (63% to 80%)
- The diagnostic accuracy of **stress echocardiography compared with ICA** across sources had the following ranges
    - Sensitivity (84% to 88%), specificity (72% to 89%)
    - PPV (85% to 93%), NPV (69% to 80%)
    - LR+ (3.08 to 8.35), LR- (0.13 to 0.21)
    - Prevalence of CAD (64% to 68%)

In addition to CCTA for anatomic imaging in particular, two systematic reviews[6,86] and one government report[100] describe diagnostic accuracy for the inclusion of FFRct to evaluate function. It is important to note that the government report was not a full systematic review, but a rapid response review that included two systematic reviews and one primary study.

For the diagnostic accuracy of FFRct in patients with suspected or known CAD in outpatient settings:

- The diagnostic accuracy of **FFRct compared with FFR via ICA** across sources had the following ranges
    - Sensitivity (84% to 91%), specificity (55% to 84%)
    - PPV (58% to 100%), NPV (0% to 90%)
    - LR+ (2.02 to 3.70), LR- (0.16 to 0.23)
    - Prevalence of CAD (32% to 100%)

Only one systematic review[114] reported on diagnostic accuracy across patients in an emergent setting. The patient population included those with suspected or known CAD, and the authors only reported sensitivity, specificity, positive and negative likelihood ratios. However, this study was done in patients with non-ST segment elevation myocardial infarction and without troponin, therefore the population is of lower risk of CAD. The prior ICER[184] study also included studies in emergency department settings but pooled all data across emergent and non-emergent settings. 3 prospective cohort studies[108,120,207] were identified from that report and data was abstracted.

For the diagnostic accuracy in patients with suspected or known CAD, presenting with or without ACS, or with possible ischemic chest pain in emergency departments:

- The diagnostic accuracy of **CCTA for anatomic imaging compared with ICA** across one systematic review and across three primary studies[108,120,207] from the prior ICER report had the following ranges
    - Sensitivity (93% to 100%), specificity (77% to 92%)
    - PPV (47% to 87%), NPV (91% to 100%)
    - LR+ (4.08 to 12.50), LR- (0.00 to 0.08)
    - Prevalence of CAD (NR)
    - The percentage of patients with a negative test that do have the disease (0% to 9%)
- The diagnostic accuracy of **stress SPECT compared with ICA** across sources had the following estimates

  - Sensitivity (85%), specificity (92%)
  - PPV (NR), NPV (NR)
  - LR+ (10.48), LR- (0.19)
  - Prevalence of CAD (NR)
- The diagnostic accuracy of **stress echocardiography compared with ICA** across sources had the following estimates
  - Sensitivity (75%), specificity (96%)
  - PPV (NR), NPV (NR)
  - LR+ (18.67), LR- (0.25)
  - Prevalence of CAD (NR)

In general, compared with FFR via ICA in the stress tests, sensitivity was similar or somewhat less while specificity was usually less than tests compared to the gold standard of ICA. Details are found in Tables 22-25.

Table 15. Summary of systematic review findings on diagnostic accuracy of coronary computed tomography angiography compared with invasive coronary angiography

Author, year AMSTAR-2	Population	Sensitivity	Specificity	PPV	NPV	LR +	LR -	CAD prevalence

4.3 Results for Reliability

To provide a general overview of reliability of the included non-invasive tests, we performed a search of the literature to identify studies that included assessments of intra- and interobserver agreement using Cohen's Kappa. Cohen suggests that Kappa results be interpreted as follows: values ≤0 as indicating no agreement, 0.01 to 0.20 as none to slight agreement, 0.21 to 0.40 as fair, 0.41 to 0.60 as moderate, 0.61 to 0.80 as substantial, and 0.81 to 1.00 as almost perfect agreement.

Intraobserver reliability in CCTA ranged from substantial agreement to almost perfect agreement (k=0.72 to 0.96) in 3 studies.[137,205,258] Between observer reliability was investigated in six studies[31,90,109,137,205,258] and ranged from moderate agreement to almost perfect agreement (k=0.58 to 0.94). Intraobserver reliability was investigated in two studies[41,80] for FFRct and found fair to almost perfect agreement (k=0.40 to 0.97), but no studies were found on interobserver agreement. CT perfusion was only investigated in one study[43] and found interobserver reliability ranging from substantial to almost perfect agreement (k=0.72 to 0.86).

SPECT studies found almost perfect agreement across one intraobserver[70] and two interobserver studies[43,70] (k=0.96 and k=0.91 to 0.95 respectively). Similarly, one study[258] investigating PET found almost perfect agreement for both intra- and interobserver reliability (k=0.94 and k=0.82 respectively).

Reliability studies on stress echocardiography included both exercise and dobutamine for inducing stress. In general, three intraobserver studies[70,75,102] all found almost perfect agreement for stress echocardiography (k=0.81 to 0.90). Meanwhile, between observer reliability ranged from moderate to almost perfect agreement across 5 studies[70,74,75,102,130] (k=0.56 to 0.87).

Although ICA is commonly considered the gold standard for identifying CAD, there are well known limitations regarding variability, reliability, and image distortion in its use. Nevertheless, one study that we identified for CCTA also investigated the interobserver reliability of ICA and found substantial agreement between observers (k=0.79).[31]

Risk of bias was assessed using the following criteria: 1) Broad spectrum of persons with expected conditions, 2) Adequate methods description for replication, and 3) Blinded performance of tests/interpretations. A good-quality study includes all three criteria and drops one level for each violation. Our assessment found that study quality ranged from poor to good, with the majority of studies rated as good quality (Appendix E).

Table 26. Summary of intraobserver reliability studies for each test modality

Study, year Risk of Bias*	Test modality and criteria	Intraobserver Cohen's Kappa interpretation (k, 95% CI)
Computed Tomography (CCTA, FFRct)		
Lehman 2009 Good quality	CCTA (Stenosis NR)	Almost perfect agreement (k=0.95, 95% CI: NR)
Rinehart 2010 Good quality	CCTA (Stenosis NR)	Degree of stenosis: Almost perfect agreement (k=0.96, 95% CI: NR) Plaque classification: Almost perfect agreement (k=0.96, 95% CI: NR)
Williams 2017 Good quality	CCTA (>50% stenosis)	Substantial agreement (k=0.72, 95% CI: NR)
Ghaemian 2020 Moderate quality	FFRct (<0.80)	Whole population: Fair agreement (k=0.40, 95% CI: NR) True SPECT: Almost perfect agreement (k=0.97, 95% CI: NR)†
Collet 2018 Good quality	FFRct (<0.80)	Almost perfect agreement (k=0.82, 95% CI: 0.73 to 0.90) ‡
Stress Nuclear Imaging (SPECT, PET)		
Ferro 2007 Good quality	SPECT (Stenosis NR)	Almost perfect agreement (k=0.96, 95% CI: NR)
Williams 2017 Good quality	PET (Stenosis NR)	Almost perfect agreement (k=0.94, 95% CI: NR)
Stress Echocardiography		
Ferro 2007 Good quality	Dobutamine stress echo (Stenosis NR)	Almost perfect agreement (k=0.81, 95% CI: NR)
Hernandez-Gonzalez 2015 Moderate quality	Dobutamine stress echo (≥70% stenosis)	Almost perfect agreement (k=0.81, 95% CI: NR)
Gaibazzi 2010 Good quality	Wall motion stress echo (>70% stenosis)	Almost perfect agreement (k=0.90, 95% CI: NR)

CCTA = computed coronary tomography angiography; CI = confidence interval; DSE = dobutamine stress echocardiography; FFR = fractional flow reserve; FFRct = computed tomography derived fractional flow reserve; ICA = invasive coronary angiography; NR = not reported; PET = positron emission tomography; SPECT = single-photon emission computed tomography; WM = wall motion; WMS = wall motion scoring.

* Based on Risk of Bias for Diagnostic Reliability Studies (Appendix D). The three criteria include 1) Broad spectrum of persons with expected conditions, 2) Adequate methods description for replication, and 3) Blinded performance of tests/interpretations. A good-quality study includes all three criteria, and drops one level for each violation.

† Whole population = concordance between FFR and SPECT in patient population as a whole; True SPECT = concordance between FFR and SPECT in patients in whom SPECT was truly positive and truly negative.

‡ Compares agreement concerning recommendation of revascularization strategy between FFRct and ICA

Invasive Coronary Angiography		
Butler 2007 Good quality	ICA (>50% stenosis)	Substantial agreement (k=0.79, 95% CI: NR)

CCTA = computed coronary tomography angiography; CI = confidence interval; DSE = dobutamine stress echocardiography; FDG = F-18-fluoro-2-deoxyglucose; FFR = fractional flow reserve; FFRct = computed tomography derived fractional flow reserve; ICA = invasive coronary angiography; IHP = International Harmonization Project; NR = not reported; PET = positron emission tomography; PET-CT = positron emission tomography-computed tomography; SPECT = single-photon emission computed tomography; WM = wall motion; WMS = wall motion scoring.

* Based on Risk of Bias for Diagnostic Reliability Studies (Appendix D). The three criteria include 1) Broad spectrum of persons with expected conditions, 2) Adequate methods description for replication, and 3) Blinded performance of tests/interpretations. A good-quality study includes all three criteria, and drops one level for each violation.

† The number of reversible defects was calculated as the number of segments with positive differences (stress score rest score) for segments with a stress score >1. A subject was determined to be ischemic if ≥2 segments had reversible defects according to the median count across the 3 readers.

‡ The segment was considered fixed if the segment was scored >1 and was equal at both rest and stress. A subject was determined to have the presence of fixed defects if ≥1 segment had a fixed defect according to the median count across the 3 readers.

5 Key Questions Results Overview

5.1 Number of studies retained

From 15,443 unique citations identified via systematic data base searching, 81 studies across 112 publications were retained (Figure 3). A total of 36 studies (in 66 publications) (35 RCTs and 1 prospective comparative cohort)[5,17,36,37,47,48,52,57-60,83-85,88,91,96,109,111,117,126,135,138-146,148,149,151,153,159-161,163,168,171,175,176,180,186,187,189,192,204,209-211,215,217,218,220,223,237,238,241,245,246,248,256,257,262] comprised the primary evidence base for Key Questions 1–4 and an additional 31 studies (2 SRs and 29 nonrandomized observational studies)[4,13,15,20,23,24,33,45,64,66,69,72,76,77,81,87,119,122,124,125,134,155,158,164-166,181,191,193,200,229] provided supplemental data on safety (Key Question 3; see Appendix Tables O23-O25 for details). For cost-effectiveness (Key Question 5), 14 studies across 15 publications (3 systematic reviews and 11 formal economic analyses) were included.[8,26,27,82,91,116,123,136,147,162,196,197,243,249,263]

5.1.1 Primary evidence base for Key Questions 1–4

A total of 35 trials (in 64 publications) [5,17,36,37,47,48,52,58,59,83-85,88,91,96,109,111,117,126,135,138-146,148,149,151,153,159-161,163,168,171,175,176,180,186,187,189,192,204,209-211,215,217,218,220,223,237,238,241,245,246,248,256,257,262] and one prospective comparative cohort study (in 2 publications)[57,60] that met inclusion criteria were identified and comprise the primary the evidence base for evaluation of efficacy and safety in this report. The bulk of the new trials evaluated CCTA. Most trials were considered fair (17 RCTs) with 11 considered good and seven considered poor quality (see Appendix E for details).

Although we sought studies in the three symptomatic populations of interest (i.e., patients with unknown but suspected CAD, those with known/established CAD and those with suspected ACS), only 1 trial (which evaluated PET) was specifically in patients with known CAD.[189] Populations in 13 trials[36,52,59,88,126,153,163,209,211,215,223,238,262] and one prospective comparative cohort[60] were predominately (≥80%) those with unknown/suspected CAD presenting to in an outpatient setting and are described as stable outpatients in the results. Five trials enrolled a mixed population of known and suspected CAD.[48,117,168,210,220] Sixteen trials were in patients presenting acutely to the ED or similar setting with suspected ACS (unstable angina or NSTEMI).[37,47,84,85,96,109,138,140,142,144,145,161,171,180,192,248] Studies in patients with STEMI were excluded. There was heterogeneity across trials regarding how pre-test risk was determined and reported. Given this heterogeneity it was not possible to stratify results by this variable. Appendix M provides information as reported by trial authors, and patient and study characteristics can be found in Appendix Q.

Table 28 below provides an overview of the included studies by test and comparator as well as population.

Table 28. Overview of included studies comprising the primary evidence base for Key Questions 1–4 arranged by test and comparator as well as population of interest.

Test	Comparator	Population					Total
		Stable, OP			Acute, ED/similar setting		
		Suspected CAD only	Mixed suspected or known CAD	Known CAD	Suspected ACS only	Mixed suspected or known CAD	
CCTA	**Any functional testing**	*Low to intermediate pre-test risk:* 1. Douglas 2015 (PROMISE)[59]			*Low pre-test risk:* 1. Dedic 2016 (BEACON)[47] *Low to intermediate pretest risk:* 2. CCTA = coronary computed tomography angiography; ETT ECG = exercise treadmill test with electrocardiography; FFR = fractional flow reserve; ICA = invasive coronary angiography; PET = positron emission tomography; Pro CC = prospective comparative cohort; RCT = randomized controlled trial; SPECT = single photon emission computed tomography; Stress Echo = stress echocardigraphy

* **McKavanagh 2015 (CAPP)**: Low risk: 43%; Intermediate risk: 24%; High risk: 34%.
Sabharwal 2007: Low risk: 16%; Intermediate risk: 61%; High risk: 23%.

Chang 2008: Low risk: 37%; Intermediate risk: 42%; High risk: 21%.
Lim 2013: unclear distribution
Zacharias 2017: Low risk: 41%; Intermediate risk: 34%; High risk: 25%.

† 85% of patients in the CCTA arm also received ETT ECG so this is not a true CCTA vs. ETT ECG comparison.

‡ From Supplemental material, CE-MARC 2 trial: "In essence, the guidelines recommend invasive angiography as the most cost-effective first test if the likelihood of CHD is 61-90%, non-invasive functional testing (SPECT, stress echocardiography or stress CMR) if the likelihood of CHD is 30-60%, CT scanning (with 64 slices or above) if the likelihood of CHD is 10-29% or no further testing if the likelihood of CHD is low (<10%)."

§ 6-hour observation period followed by hospital admission if deemed (by ED physician) high to intermediate risk for ACS (by the ED physician) or discharge (discharged patients followed-up at the cardiology clinic within 2 weeks). Further investigations (i.e., ICA or non-invasive cardiac function testing—including stress echocardiography, SMPI, or exercise ECG testing) performed at discretion of the attending cardiologist either during index hospitalization or on an outpatient basis (32% had MPI or stress echo; 24% had stress ECG only; 11% had ICA).

****** Hospitalized until a positive or negative diagnosis was reached according to local protocols without imposing any time constraints on investigators. The final diagnosis was achieved using clinical judgment only without performing additional diagnostic examinations in 39 cases (71%), using stress echo in 6 (11%), using EET in 7 (13%), and using coronary angiography in 3 (5%).

A total of 22 trials across 46 publications evaluated CCTA (see Appendix Table O34 for a list of the index trial and its affiliated publications). Twenty trials compared CCTA with functional testing.[59,126,153,163,215,238] Of these, six trials evaluated stable patients with suspected CAD[59,126,153,163,215,238] and 14 trials evaluated patients with suspected ACS.[37,47,84,85,96,109,138,140,144,145,161,171,192,248] Two RCTs compared CCTA versus direct referral to ICA in patients with suspected CAD (known CAD was an exclusion criteria)[36,52] One prospective nonrandomized comparative cohort compared CCTA plus Fractional Flow Reserve (FFR) versus any non-invasive testing and versus ICA in patients with suspected CAD treated on an outpatient basis.[57,60] Of the 22 RCTs, seven were considered good quality[47,52,59,84,126,215,238], 12 fair quality[36,37,96,109,138,140,144,145,153,171,192,248] and three poor quality[85,161,163]; the prospective comparative cohort was considered good quality[57,60] (see Appendix E for details).

A total of six trials evaluated SPECT. Two trials compared SPECT imaging with stress echocardiography in mixed populations of patients with suspected or known CAD, one in stable and one in acute patients.[210,220,241] Two trials compared SPECT with exercise ECG in stable outpatients with suspected CAD (known CAD was an exclusion criteria).[209,223] One trial compared SPECT imaging versus clinical assessment only in acute patients with suspected ACS presenting to the ED.[142]

One trial compared SPECT with NICE guideline-directed care in stable outpatients with suspected CAD.[88] Lately, one trial compared SPECT with ICA in stable patients with suspected or known CAD.[220,241] This latter trial also compared SPECT with exercise ECG. Of the six RCTs, two were considered good quality[88,220,241] and four fair quality[142,209,210,223] (see Appendix E for details).

A total of six, primarily older trials (2009 or earlier) evaluated stress echocardiography. Five trials compared stress echocardiography with exercise ECG, two in stable outpatients with suspected CAD (known CAD was an exclusion criteria)[91,211,262] and three in patients with acute symptoms presenting to the ED or hospital[48,117,180]. One trial compared stress echocardiography with "standard care" in low-risk patients with suspected ACS presenting to the ED.[180] One trial compared stress echocardiography with direct referral to ICA in stable patients with suspected or known CAD.[220,241] One of these trials included both an exercise ECG and a standard care comparison arm.[180] Of the six RCTs, two were considered good quality[91,220,241,262], one fair quality[48] and three poor quality[117,180,211] (see Appendix E for details).

A total of two trials evaluated PET and both compared PET with SPECT in outpatient settings. One poor-quality trial included stable patients with a mixed of suspected or known CAD[168] and the second good-quality trial included stable patients with known CAD presenting with new or worsening symptoms.[189]

See Appendix E for study quality details.

5.1.2 Evidence base for Key Question 5

In addition to the trials evaluating efficacy and safety, a total of three systematic reviews[243,249,263] and 11 primary studies were included that formally evaluated cost-effectiveness. Eight of the studies (in nine publications) were in stable outpatients with suspected CAD,[8,26,27,91,116,123,136,147,162] and three were in patients with suspected ACS.[82,196,197] Formal economic studies identified for inclusion primarily

compared combinations of testing strategies involving CCTA, stress nuclear imaging (primarily SPECT), stress echocardiography, exercise ECG treadmill testing and invasive coronary angiography, with only few directly comparing one specific test to another. Given the complexity of interpreting these studies, all cost-effectiveness data is summarized under section 6.1.5 under the CCTA heading. Across the studies, scores on the Quality of Health Economic Studies (QHES), the instrument used to systematically assess the quality of each study, ranged from 50 to 94 out of 100 (See Appendix E for details).

5.2 Comparison with the 2008 and 2013 reports

CCTA

The 2008 review of CCTA primarily focused on diagnostic accuracy (34 for the 41 included studies) for 64 slice or higher resolution equipment and most included patient already scheduled for ICA. A variety of scenarios were modeled for clinical impact and cost-effectiveness of CCTA related to CAD prevalence. Only one RCT[85] measured the impact of CCTA on patient outcomes was identified. The report included patients with acute chest pain presenting in an ED setting (7 studies, total N=496) and patients with stable chest pain at low to intermediate CAD risk presenting to outpatient settings (34 studies, total N 3349, CAD prevalence range 2–40%); most reported on diagnostic accuracy. Approximately two-thirds of studies excluded patients with known CAD or revascularization.

Primary findings from the 2008 report include:

- Based on ICER's modeling, Integrated Evidence Rating method and assuming a CCTA reimbursed price of $466:
    - For the triage of patients with acute chest pain at low to intermediate risk of ACS in an ED setting, CCTA was considered to be of comparative clinical effectiveness versus usually care/other diagnostic strategies and of high value based on their economic modeling.
    - In outpatients with or without signs and symptoms of unstable chest pain and at low to intermediate risk of significant CAD, the comparative clinical effectiveness of CCTA was rated as "unproven but with evidence of potential net benefit" (limited confidence of small or moderate-large net health benefit) and reasonable or comparable value.
- CCTA was considered highly sensitive with moderately high specificity (See Executive Summary and other tables in this report).
- Data on clinical outcomes and decision making not synthesized across studies; all but one study was observational.
- For triage of ED patients, their models suggested that ICA may be reduced if CCTA were to be employed compared with usual care.
- Regarding safety, CCTA was considered safe with risks similar to other tests employing contrast media. A range of CCTA-related radiation exposure values was reported (2 mSv to 14 mSv). As noted, small but definite risks may exist related to radiation exposure. Incidental/extra cardiac findings requiring further evaluation was reported to range from 5 to 20% of patients. Authors note the need to consider incidental findings in economic analyses.

Comparison with this update:

Since 2008, 19 additional RCTs (43 publications, total N >20,000 patients) comparing CCTA with functional testing have been published and are included in this re-review and constitute the primary evidence base for CCTA effectiveness and safety. This update reports on an expanded evidence base of higher quality studies. Thus, this update focused on the impact of CCTA on clinical outcomes and decision making with information regarding diagnostic accuracy summarized for contes making direct comparison to the 2008 report challenging

- In general, for CCTA compared with functional imaging in particular, there were no clear differences in clinical outcomes (MI, all-cause mortality), use of additional testing or hospitalization for patients presenting to the ED or for stable outpatients. (See Executive Summary and full report for details).
- In contrast to modeling done in the 2008 report, data synthesized across more recent RCTs suggests that ICA is more common (as is PCI) with CCTA versus functional imaging
- Safety findings in this update are overall consistent with the 2008 report. Continued improvement in methods for reducing test-related radiation exposure are noted.
- Definitive conclusions for cost-effectiveness of CCTA specifically from published included studies were not possible.

Cardiac nuclear imaging

The key questions for 2013 review of cardiac nuclear imaging differed from this review evaluation and the prior review included screening of asymptomatic patients. The review included 34 studies, 26 of which evaluated clinical outcomes. Nine studies were comparative cohort studies comparing different protocols and 12 were case series. The 2013 report included patients with known CAD, including asymptomatic patients, who receive nuclear imaging test for prognostic purposes such as risk stratification, treatment selection or follow-up monitoring. Most studies were in "mixed" populations which included symptomatic and asymptomatic patients, those with suspected and known CAD. Most studies of symptomatic patients were in higher risk patients.

Primary findings of the 2013 report relevant to this update:

- For diagnostic accuracy, the report compared PET and SPECT with ICA-derived fractional flow reserve and summarized accuracy data from systematic reviews for the comparison with ICA. (See report and Executive Summary Tables).
- Overall, based on ICER's modeling, Integrated Evidence Rating method for symptomatic patients at low to intermediate CAD risk,
    - Clinical effectiveness of SPECT was considered to be comparable or better versus ETT and based on HCA payment schedules, was more costly as an initial test, but that a 2-stage strategy of ETT followed by SPECT may provide cost savings but the comparative value was considered to be low.
    - SPECT and stress echo were considered to provide similar diagnostic and prognostic performance and SPECT was rated as "reasonable/comparable" for both clinical effectiveness and value.
    - In symptomatic patients with known CAD, SPECT and stress echo were considered comparable in clinical effectiveness and they expected it to be of "reasonable/comparable" value based on one RCT. Evidence comparing SPECT with ETT was considered to be insufficient as no studies were identified.

  - SPECT and PET were considered to be safe, but lack of comparative effectiveness evidence was noted. AEs were generally considered to be insignificant and due to exercise or pharmacologic stressors. Effective radiation does for SPECT (7–30 mSv) and PET (2–14 mSV) were reported.
- Evidence for PET was considered to be insufficient for all populations

- Evidence related to differential effectiveness or safety for key subgroups was considered insufficient.

Comparison with this update:

Our update focuses on the clinical impact of stress nuclear imaging (SPECT and PET).

- This update does not include asymptomatic patients based on clinical input at the time of topic development, nor does it include patients at high CAD risk or studies of prognosis.
- A total of six RCTs (including three from the prior report) for SPECT and two RCTs for PET (including one from the previous report. RCTs comparing SPECT with NICE guideline directed care and clinical assessment where part of this update as was one RCT comparing it with ICA which were not part of the 2013 report. (Please see full report and executive summary)
- For SPECT compared with other functional test (ETT, stress echo), there were no differences in all-cause mortality, ICA referral, hospitalization, subsequent ED visits (SOE low for all) or revascularization (SOE Moderate). Findings and conclusions regarding safety are similar to the prior report.
- For PET, was insufficient for all clinical outcomes. There was no difference in ICA or revascularization between PET and SPECT based on the newly identified RCT in patients with known CAD with new or worsening symptoms (SOE Low).
- Definitive conclusions for cost-effectiveness of CCTA specifically from published included studies were not possible.

Given that stress echocardiography is an established modality for evaluating cardiac function, based on clinical input it is included in this HTA.

6 Coronary Computed Tomography Angiography (CCTA) Results

6.1 CCTA versus Any Functional Testing

A total of 20 trials comparing CCTA with functional testing that met inclusion criteria were identified.[59,126,153,163,215,238] Six trials evaluated stable patients with suspected CAD[59,126,153,163,215,238] and 14 trials evaluated patients with suspected ACS.[37,47,84,85,96,109,138,140,144,145,161,171,192,248]

Since studies of patient with STEMI were excluded, ACS for included studies pertains to patients with unstable angina or NSTEMI as described in the studies. Some studies focused on patients with normal ECG and negative troponins. No studies specifically in patients with known CAD were identified.

CCTA vs. functional testing in stable patients with suspected CAD

Six randomized control trials (across 23 publications)[5,58,59,115,126,135,146,148,149,151,153,163,175,176,186,187,215,217,218,237,238,256,257] compared CCTA with functional testing in patients with suspected CAD in the outpatient setting. (See Appendix Q for details). All trials used a 64-slice (or higher) CT scanner for CCTA imaging and four[153,163,215,238] reported the use of iodinated contrast agents. Two trials[153,215] included CACS imaging as part of their CCTA protocol and three trials[59,163,238] did not. In one trial,[126] 3% of patients randomized to the CCTA arm received CACS. Specific functional tests included SPECT in three trials [126,163,238](across 4 publications, N=1,533), exercise ECG in two trials[153,215] (across 7 publications, N=4,646), and any functional testing in one trial[59] (across 12 publications, N=10,003). In the latter trial, most patients (63%) underwent nuclear stress testing as their index test, though patients could have received CACS, stress echocardiography, exercise ECG, ICA, or no testing at index visit. In one trial, the SCOT-HEART trial,[215] 85% of *all* patients in the CCTA arm had exercise treadmill tests (ETT) (as standard care) and the function testing arm was predominately ETT making this trial more of an adjunctive comparison.

Across all six trials, sample sizes ranged from 180 to 10,003 (total N=16,182). Mean patient age ranged from 57 to 61 years and the proportion of females ranged from 44% to 53%. Less than a third of participants were non-white (range, 22% to 29%) across the three trials reporting race.[59,126,238] Five trials specifically excluded patients with known CAD[59,126,153,163,238] and four trials excluded patients with prior revascularizations.[59,126,163,238] Patients' pre-test risk for CAD was low to intermediate one trial,[59] intermediate in one trial,[126] intermediate to high in one trial,[163] mixed in two trials,[153,215] and not reported in one trial.[238] Across all six trials, the proportion of patients reporting chest pain ranged from 73% to 100% (four trials reported on the specific sub-type of chest pain: typical [range, 12% to 35%] atypical [7% to 78%] and non-anginal [11% to 40%][59,153,163,215]); hypertension, from 31% to 65%; diabetes, from 11% to 28%; and smoking (past or current), from 15% to 53%. None of the trials reported on the proportion of patients with unstable angina. The proportion of patients presenting with dyspnea was reported by two trials (range, 10% to 15%)[59,126] and hyperlipidemia by three trials (range, 57% to 68%).[59,126,163] Duration of follow-up ranged from 2 months to 5 years. See Appendix Q for details.

Three trials were conducted in the United States,[59,163,238] two trials in the United Kingdom,[153,215] and one trial in multiple countries (Brazil, Czech Republic, India, Mexico, Slovenia, and Turkey).[126] Investigators

received funding from the government in four trials,[153,215,238] industry in one trial,[238] and an international organization in one trial.[126]

Four trials were rated good quality,[59,126,215,238] one fair quality,[153] and one poor quality.[163] The major methodological limitations in the fair-quality trial were unclear allocation concealment methods and unclear blinding of outcome assessors. In the poor-quality trial, limitations included unclear randomization and allocation concealment methods, failure to blind outcomes assessors, differences in key CAD risk factors at baseline between groups, it was unclear if follow-up times were comparable between groups.

CCTA vs. functional testing among patients with suspected ACS

Fourteen randomized control trials[37,47,84,85,96,109,138,140,144,145,161,171,192,248] (across 21 publications) compared CCTA with functional testing in patients with suspected ACS. (See Appendix Q for details). Ten trials took place in the Emergency Department,[37,47,84,85,96,109,138,145,161,248] three trials in the inpatient setting,[140,171,192] and one trial in the outpatient setting.[144] All trials used a 64-slice (or higher) CT scanner for CCTA imaging and nine reported the use of iodinated contrast agents.[37,84,85,96,109,140,171,192,248] Seven trials[84,85,109,140,145,161,171] included CACS imaging as part of their CCTA protocol and six trials[37,47,96,138,144,192] did not. In one trial,[248] 1% of patients randomized to the CCTA arm received CACS. Specific functional tests included SPECT in four trials[84,85,140,171] (across 5 publications, N=1,944), stress echocardiography in three trials[138,192,248] (across 4 publications, N=1,014), exercise ECG in one trial (across 1 publication, N=562),[96] and any functional testing in six trials[37,47,109,144,145,161] (across 11 publications, N=3,818).

Across all 14 trials, sample sizes ranged from 60 to 1,392 (total N=7,338). Mean patient age ranged from 49 to 64 years and the proportion of females ranged from 39% to 63%. A large majority of the patients identified as non-white (range, 33% to 95%) across the 7 trials reporting race.[109,138,140,145,161,171,248] Eight trials specifically excluded patients with known CAD,[85,96,109,138,140,161,171,248] and in two trials, 14% and 15% of patients had known CAD.[37,144] The remaining four trials did not report on patient's CAD status.[47,84,145,192] Two trials reported excluding patients with prior revascularizations[109,161] and one trial reported excluding patients with prior MI.[109] In two trials, 1% of patients had a prior MI.[84,145] The remaining trials did not report on patients' history of MI or revascularizations. Patients' pre-test risk for CAD was very low to low in one trial,[85] low in one trial,[47] low to intermediate in eight trials,[84,96,138,144,145,161,171,192] intermediate in two trials,[109,140] mixed in one trial,[37] and not reported in one trial.[248] In the trial including patients with varied risk statuses, 37% were low risk, 42% were intermediate risk, and 21% high risk.[37] All patients in all trials reported having chest pain (four trials reported on the specific sub-type of chest pain; typical [range, 12% to 90%] atypical [10% to 39%] and non-anginal [2% to 49%][109,140,144,192]). One trial reported that 1% of patients had unstable angina.[84] Two trials reported the proportion of patients with dyspnea (range, 2% to 49%),[109,248] 13 trials reported the proportion of patients with hypertension (range, 17% to 72%),[37,47,84,85,96,109,138,140,144,145,171,192,248] 12 trials reported the proportion of patients with diabetes (range, 6% to 32%),[37,84,85,96,109,138,140,144,145,171,192,248] 11 trials reported the proportion of patients with hyperlipidemia (range, 25% to 52%),[37,84,85,96,109,138,140,144,145,171,248] and 13 trials reported the proportion of smokers (past or current) (range, 14% to 49%).[37,47,84,85,96,109,138,140,144,145,171,192,248] Duration of follow-up ranged from 1 month to 4.7 years.

Nine trials were conducted in the United States,[84,85,109,138,140,145,161,171,248] one trial in Australia,[96] one trial in Denmark,[144] one trial in the Netherlands,[47] one trial in South Korea,[37] and one trial in Spain.[192] Investigators received funding from the government in four trials,[47,109,145,161] industry in two trials,[84,85] and non-profit foundations in four trials.[96,138,140,144] One trial reported receiving no funding[248] and three trials provided no information on funding.[37,171,192]

Two trials were rated good quality,[47,84] 10 trials were rated fair quality,[37,109,138,140,144,145,171,192,248] and two were rated poor quality.[85,161] The major methodological limitations in the fair-quality trials were unclear randomization and allocation concealment methods and failure to blind outcomes assessors. Other methodological shortcomings in the poor-quality trials included difference in key CAD risk factors between groups at baseline which were not controlled for and no prespecified definition for a positive test in one trial.

6.1.1 Key Question 1: Primary Outcomes (MI, all-cause mortality, cardiac death)

6.1.1.1 <u>Summary of results for primary outcomes</u>

There were 17 RCTs comparing CCTA with functional testing, six RCTs[59,126,153,163,215,238] in stable patients with suspected CAD and 11 RCTs (12 publications)[37,47,84,85,96,109,111,138,143,145,192,248] in patients with suspected ACS that reported primary clinical outcomes. Functional testing included imaging tests (stress nuclear, stress echocardiography and ETT. Given the limitations of ETT as a functional test, sensitivity analyses comparing CCTA with functional imaging tests only were conducted. There was no statistical interaction between the patient populations for any outcome.

Across studies that include stable patients with suspected CAD and patients with suspected ACS presenting to an emergency department or similar setting:

- There is no clear difference in the frequency of MI between CCTA and functional imaging tests (SOE Moderate).
    - Three smaller RCTs, one in stable patients and two in those with suspected ACS, reported no MI in either testing arm.
    - CCTA was associated with lower MI risk compared with functional testing based on pooled estimates across the 14 remaining RCTs (14 RCTs, pooled RR 0.70, 95% CI 0.56 to 0.89, I^2=0%), however, the RD (0.4, 95% CI 0.1 to 0.8 per 100 patients) was small. The association was no longer clearly significant following exclusion of one RCT in stable patients with suspected CAD in which 85% of all patients had ETT in addition to CCTA (13 RCTs, pooled RR 0.75, 95% CI 0.57 to 0.99, I^2=0). This pattern was seen across RCTs of stable patients when the one trial was excluded. Across 10 RCTs in patients with suspected ACS, there was no difference in the frequency of MI between CCTA and functional testing at any time.
- There was no association between CCTA and reduction in all-cause mortality compared with functional testing (SOE Moderate).
    - Six RCTs reported no mortality in either testing arm (1 RCT in stable patients, 5 RCTs in suspected ACS patients).

  - There was no difference in all-cause mortality between CCTA and functional testing across the remaining 11 RCTs (pooled RR 0.99 95% CI 0.40 to 2.68, I^2=0%). There was also no difference in all-cause mortality when the populations were considered separately.
- Cardiac death was rare in both patient populations, with six total cardiac deaths reported in patients receiving CCTA and 13 reported in patients receiving functional testing (SOE Insufficient).
- It is possible that smaller trials in particular may have been underpowered to detect differences in MI, all-cause mortality, and cardiac death between CCTA and functional testing given that many trials enrolled patients with low or low to intermediate pre-test risk.

Detailed results

6.1.1.2 Myocardial infarction

Across populations, 17 RCTs (N=22,238) reported on myocardial infarction; six RCTs[59,126,153,163,215,238] were in stable patients with suspected CAD and 11 RCTs (12 publications)[37,47,84,85,96,109,111,138,143,145,192,248] were in patients with suspected ACS presenting to an emergency department or similar setting. Across trials, the cumulative incidence of MI was 1.5 per 100 patients, with 3 smaller trials (N=667), two in the stable, suspected CAD population[126,163] and one in the suspected ACS population[85], reporting no MI in either testing arm. CCTA was associated with CCTA was associated with lower MI risk compared with functional testing based on pooled estimates across the 14 remaining RCTs (14 RCTs, pooled RR 0.70, 95% CI 0.56 to 0.89, I^2=0%)[37,47,59,84,96,109,111,143,145,153,192,215,238,248] however the RD (0.4, 95% CI 0.1 to 0.8 per 100 patients, I^2=19%) was small. Only one RCT (SCOT-HEART)[215] in a population of stable patients with suspected CAD at intermediate pre-test risk reported a statistically significant decrease in MI favoring CCTA over ETT. However, 85% of *all* patients had ETT (as standard care) and the function testing arm was predominately ETT in this trial, raising concern regarding substantial clinical heterogeneity compared with other RCTs where stress echocardiography and SPECT were more common in the functional testing arm. Exclusion of this trial did not impact statistical heterogeneity, (no change in I^2) however, the confidence interval for the pooled estimate across the remaining RCTs the null value of 1.0 suggesting no clear association between CCTA and reduced MI (13 RCTs RR 0.75, 95% CI 0.57 to 0.99). Exclusion of two poor-quality studies[85,163] did not affect pooled estimates as both had reported that no MI occurred (Figure 4, Table 29). There was no statistical interaction between the stable and suspected ACS populations (p = 0.23).

In stable outpatients with suspected CAD, MI was evaluated in six RCTs (N= 16,154)[59,126,153,163,215,238] comparing CCTA with functional testing in stable outpatients. Two smaller RCTs, one poor-quality (N= 173) with 55 days follow-up[163] in intermediate to high-risk patients and one good-quality RCT (N = 297)[126] in intermediate risk patients reported no MI in either testing arm. Four RCTs reported occurrence of MI. CCTA was associated with lower risk of MI compared with functional testing across six RCTs reporting various lengths of follow-up (4 RCTs, pooled RR 0.64, 95% CI 0.44 to 0.87, I^2=0%)[59,153,215,238] after testing in stable outpatients

suspected of CAD across time frames ranging from 12 to 58 months. The risk difference was small however across trials (pooled RD 1, 95% CI –1 to 0 per 100 people I^2=42%). Only one RCT (SCOT-HEART)[215] in a population that appears to have enrolled patients at intermediate pre-test risk of CAD reported a statistically significant decrease in MI favoring CCTA over ETT, however 85% of *all* patients had ETT and the function testing arm was predominately ETT (as standard care) in this trial, raising concern regarding substantial clinical heterogeneity compared with other RCTs where stress echocardiography and SPECT were more common in the functional testing arms. Exclusion of this trial did not impact statistical heterogeneity, (no change in I^2) however. The impact of the longer follow-up time (58 months) than reported for other trials is unknown. Results were no longer statistically significant based on sensitivity analysis excluding the SCOT-HEART trial (3 RCTs, pooled RR 0.69, 95% CI 0.27 to 1.14 I^2=0%).[59,153,238]

In patients with suspected ACS *presenting to an emergency room or similar acute care setting*, seven trials evaluated MI at or shortly after index visits (N=4584).[37,47,85,96,109,145] There was no difference in MI frequency between CCTA and functional testing at time of index testing (6 trials, pooled RR 0.8, 95% CI 0.53 to 1.19, I^2=21.6%). One smaller (N= 197) poor-quality trial in very low risk patients reported no MI occurred in either testing arm.[85] At 1 to 6.5 months, there were also seven trials that reported on MI.[37,84,85,96,109,144,145] No MI was reported for any testing arm when CCTA was compared with either SPECT (two RCTs)[84,85] or ETT (one RCT)[96]. Across the four other trials of CCTA versus any type of functional test the difference between tests on the occurrence of MI failed to reach statistical significance (4 trials, pooled 0.28, 95% CI 0.07 to 1.09 I^2= 0%). Similarly at time frames ≥12 months, there was no difference in MI between CCTA and functional testing (5 trials, pooled RR 1.22 (95% CI 0.51 to 2.74 I^2=0%)[111,138,143,192,248] There was little or no statistical heterogeneity in the analyses. In some trials, patients were only randomized to index testing after normal ECG and normal serum biomarkers were obtained and/or the tests were performed after the time of the index visits.

6.1.1.3 All-cause mortality and cardiac mortality

Across populations, seventeen RCTs (N= 21,680) reported on all-cause mortality; five RCTs[59,126,153,163,215] were in stable patients with suspected CAD and 12 were in patients with suspected ACS.[37,47,84,85,96,109,111,138,140,143,145,192,248] Across trials, the cumulative incidence of all-cause mortality was 1.3 per 100 patients. There was no difference in all-cause mortality between CCTA and functional testing (1.2 versus 1.3 per 100 patients). No mortality was observed in six trials (n=2746) including one RCT in stable patients[163] and five RCTs in patients with suspected ACS.[84,85] Across the remaining 11 RCTs reporting events (N=18,935), there was no association between CCTA and mortality compared with functional testing (11 RCTs, pooled RR 0.99 95% CI 0.40 to 2.68, I^2=0%). Figure 5. Exclusion of SCOT-HEART or poor-quality RCTS did not impact effect size estimates, heterogeneity or conclusions (Table 29). There was no statistical interaction between the stable and suspected ACS populations (p=0.985).

ACS = acute coronary syndrome; CCTA = coronary computed tomography angiography; CI = confidence interval; ECHO = stress echocardiography; ED = emergency department; ETT = exercise treadmill test; SPECT = single photon emission computed tomography.

Evidence was insufficient to draw conclusions regarding the impact of CCTA versus functional testing on cardiac mortality. The pre-test CAD probability across most studies was low to intermediate and cardiac

death was rare; studies may not have been adequately powered to detect cardiac death. Cardiac mortality was evaluated in 13 RCTs, four RCTs in stable patients[153,163,238] (N=5854) and nine RCTs in patients with suspected ACS (N= 5793).[84,85,96,109,111,138,143,145,171,248] Ten RCTs reported no cardiac deaths in either testing arm. Individual study sample sizes ranged from N=173 to N=4146.

Across populations, six cardiac deaths in those receiving CCTA and 13 in those receiving functional testing were observed in three RCTs.[111,143,215] In stable patients, cardiac death occurred in 0.24% (5/2073) CCTA patients and 0.28% (12/2073) of ETT patients RR 0.42, 95% CI 0.15 to 1.18) in one RCT.[215] In patients with suspected ACS, across two RCTs (N= 1942), only two cardiac deaths were reported, one in each study arm (RR 0.72, 95% CI 0.04 to 13.3) in each trial.[111,143]

***In stable outpatients with suspected CAD*,** there were no differences between CCTA and functional testing in in all-cause mortality across five individual trials (N= 15,107)[59,126,153,163,215] from 55 days up to 58 months after testing. No mortality was seen in either testing arm in one smaller (N= 173) poor-quality trial.[163] Across trials in which death occurred, there was no difference between CCTA and functional testing (4 trials, pooled RR 1.0, 95% CI 0.76 to 1.3, I^2=0%)[59,126,153,215]. Exclusion of the SCOT-HEART comparing CCTA with ETT did not change the effect estimate, statistical heterogeneity or conclusions. (3 trials, RR 1.0, 95% CI 0.61 to 1.89, I^2=0%).[59,126,153,163] One trial also comparing CCTA with ETT in a mixed risk population (N= 488) (McKavanagh) in which 38% of patients were at higher risk reported only one death in each arm.

Four RCTs (N= 5854)[153,163,215,238] reported on cardiac death. Three reported that no cardiac deaths occurred in either testing arm; there was no difference between CCTA (0.2%, 5/2073) and ETT (0.58% 12/2073), in the one RCT in which cardiac death occurred RR 0.42, 95% CI 0.15 to 1.18). To the extent that cardiac death is rare in these populations, individual studies may have been underpowered to detect cardiac death or differences in cardiac death.

In patients with suspected ACS *presenting to an emergency room or similar acute care setting,* there was no difference in all-cause mortality across 13 RCTs (N= 7941)[37,47,84,85,96,109,111,138,140,143,145,192,248] comparing CCTA to functional tests and time frames ranging from one-month post ED/observational unit discharge to 56 months. No deaths were observed in six[37,84,85,109,145,248] of the 13 trials (N= XXX) . Across the seven trials reporting one or more deaths, there was no different between testing arms (pooled RR 1.0, 95% CI 0.40 to 2.69, I^2= 11%).[47,96,111,138,140,143,192]

There was no difference in cardiac mortality across 10 RCTs (N=7163)[84,85,96,109,111,138,140,143,145,248] comparing CCTA to functional tests and time frames ranging from one-month post ED/observational unit discharge to 56 months. Eight of the trials found no cardiac mortality. Across the two other trials, no difference was seen between testing arms, RR 0.72, 95CI 0.4 to 13.3 I^2= 0%. Pre-test risk in patient populations across studies were most generally low[47,84] or low to intermediate[96,138,144,145,161,171,192], with one reporting very low pre-test probability.[85] Two trials focused on patient with intermediate risk.[109,140] To the extent that cardiac death is rare in these populations, individual studies may have been underpowered to detect cardiac death or differences in cardiac death.

6.1.1.4 Other clinical outcomes

See Appendix O for summary tables.

Acute coronary syndrome, unstable angina (Appendix O, Tables O29 and O30)

No trials in stable outpatients reported on the frequency of ACS. Across five trials in *patients with suspected ACS*[37,47,96,109,111,143-145], there was no difference between CCTA and functional testing in the cumulative frequency ACS (as defined by the authors). There was no difference between testing arms in the cumulative frequency of unstable angina (UA) across nine RCTs, one in stable outpatients[153] and eight in patients with suspected ACS[37,47,84,85,96,109,143,144,248]. One RCT, in stable outpatients, reported that at 12 months there was no difference in UA between testing arms at 12 months, but more CCTA patients had UA at a median of 25 months compared with functional testing (1.2% vs. 0.8%, p=0.045).

Nonfatal stroke, cardiac arrest, continued chest pain, recurrent ischemia

Across populations, stroke and cardiac arrest were rare, occurring in ≤ 1% of any testing arm. No differences in cumulative frequency of these was see between testing arms were reported at any time frame. Five RCTs reported on nonfatal stroke,[59,138-140,175,215,238] one RCT reported on cardiac arrest[138,139], Many trials may have been underpowered to detect these events or evaluate differences between arms.

The cumulative frequency of continued chest pain varied substantially across trials (0.8% to 28%).

> ***In stable outpatients***, CCTA was associated with lower frequency of revisit to the ED with chest pain compared with ETT in one RCT (0.8 vs 6.9%) within 12 months[153], but a second larger RCT[175] reported no difference (3.7% vs. 3.3%) at a median of 1.7 years.
>
> ***In patients with suspected ACS***, across four RCTs[85,143,144,171,192] there were no difference between testing arms in the cumulative frequency of continued or recurrent chest pain at any time frame, however one RCT reported that CCTA was associated with a higher frequency compared with stress echocardiography (28% vs. 19%) at one month.[138] There was no difference between CCTA and SPECT in the cumulative frequency of recurrent ischemia in one trial of stable outpatients.[126] One RCT in patients with suspected ACS reported that recurrent ischemia occurred in 10% of those who had functional testing but no data for the CCTA arm were provided.[143,144]

Composite outcomes (MACE)

Across populations composite outcomes (MACE) were the primary endpoint(s) in many trials. Components of the composites varied across trials and within trials, different combinations of components were used. The PROMISE trial[59] reported on four different composite outcomes in stable outpatients. Appendix O, Table O31 summarizes the findings for the composites. In general, across trials, there were no statistically significant differences between CCTA and functional testing for various composite outcomes in stable outpatients or in patients with suspected ACS. There were two exceptions. The PROMISE trial[59] reported a marginally insignificant association between CCTA and

slightly lower occurrence of their primary MACE (which included all-cause mortality, nonfatal MI, hospitalization for UA, or major procedural complication) plus catheterization showing no obstructive CAD at 12 months, based on adjusted hazard ratios, but the risk differences were small (RD –0.4 per 100 patients). Their composite of mortality or nonfatal MI was similarly marginally insignificant with a small RD. The SCOT-HEART trial[175,215] compared CCTA with ETT (although 85% of CCTA patients also receive ETT). CCTA was associated with reduction of both composite outcomes evaluated.

Health status (Seattle Angina Questionnaire)

Four RCTs[59,153,163,256], ***all in stable outpatients*** administered the Seattle Angina Questionnaire (SAQ). The SAQ scores range from 0 to 100 and assess the following domains: Physical Limitation (9 items), Angina Stability (1 item), Angina Frequency (2 items), Treatment Satisfaction (4 items), and Quality of Life(QOL) (3 items). For the QOL domain (scale 0–100) higher scores indicate increased QOL, fewer symptoms and better health status. None of the RCTs in patients with suspected ACS reported on this outcome. There were no differences between CCTA and functional tests for the physical limitation or treatment satisfaction domains in any RCT. Results across trials for the other domains were inconsistent with only one or two of the four RCTs finding an association with the testing strategy. Results for the remaining domains are summarized as follows:

- Anginal stability: In three RCTs, there was no difference between testing groups on this domain at any time frame[59,163,215]; one RCT reported that CCTA was associated with less angina at 3 and 12 months.[153]
- Anginal frequency: Three trials reported no difference between testing groups for this domain at any time frame.[59,163,215] One RCT reported that CCTA was associated with less frequent angina at 6 months, but there was no difference at six weeks from index testing compared with ETT.[256]
- QOL: Two RCTs, including the largest (PROMISE) reported no difference in the QOL domain at any time frame.[59,163] One RCT reported that CCTA was associated with improved QOL at 6 months but not at 6 weeks[256]; another reported an association between CCTA and improved QOL at both 3 and 12 months.[153]

6.1.2 Key Question 2: Clinical decision making

6.1.2.1 Summary of results

The majority of RCTs comparing CCTA with functional testing which reported one or more of the following outcomes in either stable patients with suspected CAD or patients presenting emergently with suspected ACS: Referral for ICA (19 RCTs, N=22,335), any additional noninvasive testing (17 RCTs, N=11,595), referral for any revascularization (19 RCTs, N=23,124) and referral for PCI specifically (12 RCTs, N=18,960). There was no statistical interaction between the patient populations for any outcome.

Summary of results across populations

Across studies that include stable patients with suspected CAD and patients with suspected ACS presenting to an emergency department or similar setting:

- **ICA referral:** CCTA was associated with more frequent ICA referral compared with functional testing (19 RCTs, 14.4 vs. 12 per 100 patients, pooled RR 1.25, 95% CI 1.09 to 1.47, I^2=67%, RD 2.7, 95% CI 1 to 4 per 100, I^2=59%) (SOE Moderate).
    - **In stable outpatients**, ICA referral was more frequent following CCTA), but the association bordered the null and there was substantial heterogeneity. However, exclusion of SCOT-HEART increased the effect size and strengthen the association between CCTA and ICA referral compared with functional testing and substantially reduced the heterogeneity (4 RCTS pooled RR 1.57, 95% CI 1.21 to 1.65, I^2=0%, RD 4.1, 95% CI 3.0 to 5.2 per 100 patients).
    - **In patients with suspected ACS**, ICA referral (cumulative) was also more frequent following CCTA compared with functional testing but was less than the frequency seen in stable outpatients. Referral for ICA was highest at the index evaluation.
- **Referral for any additional noninvasive testing** was not different between CCTA and functional testing groups across populations (17 RCTs, 7.2 versus 7.6 per 100, pooled RR 0.82, 95% CI 0.53 to 1.28, I^2=83%) (SOE Low) or when populations were considered individually. Type of additional testing was inconsistently reported but appears to be primarily stress imaging.
- **Revascularization:** CCTA was associated with more frequent revascularization (9.5 per 100 patients) compared with functional testing (7.1 per 100 patients), 19 RCTs, pooled RR 1.52, 95% CI 1.26 to 1.90 I^2=66%, RD 2.4, 95% CI 1.4 to 3.3 per 100) (SOE Moderate). Again, this was also true when the populations were considered individually.
- **PCI for revascularization:** CCTA was associate with higher frequency of PCI as a revascularization procedure compared with functional testing (12 RCTs, 8.2 vs. 6.0 per 100 patients, pooled RR 1.63, 95% CI 1.22 to 2.35, I^2=74%, RD 2.4, 95% CI 1.3 to 3.6 per 100 patients) across populations (SOE Moderate).
    - In stable outpatients with suspected CAD, PCI was more common with CCTA, but the association failed to reach statistical significance (pooler RR 1.16, 95% CI 0.96 to 2.99).
    - In patients with suspected ACS the association between CCTA and PCI was seen at index testing but there was no difference between CCTA and functional testing at 1 to 6.5 months or ≥ 12 months.
- **Hospitalization**:
    - **In stable outpatients t**here was no difference in hospitalization between CCTA and functional testing across 4 RCTs (SOE Moderate).
    - **In patients with suspected ACS**,
        - At index testing, across comparators with CCTA there is substantial heterogeneity and results are mixed. While 4 RCTs comparing CCTA with any functional test suggest that hospitalization is less common with CCTA, large studies of CCTA vs echo and SPECT suggest that hospitalization may be more with CCTA (SOE Insufficient).
        - There was no difference in hospitalization between CCTA and functional testing across studies, regardless of comparator, at 1 to 6.5 months after index testing (9 RCTs, 3.0 vs. 3.9 per 100 patients, pooled RR 0.76, 95% CI 0.49 to 1.1, I^2=18%) (SOE High). Similarly, there was no difference between testing arms at ≥12

months (6 RCTs 14.9 vs. 17.4 per 100 patients, pooled RR 0.90, 95% CI 0.77 to 1.03, I^2=0%) (SOE High).

- **Subsequent ED visits:** In patients with suspected ACS there was no difference in emergency department visits after index testing between CCTA and functional testing across studies, regardless of comparator, at 1 to 6.5 months (7 RCTs, pooled RR 0.84, 95% CI 0.66 to 1.06, I^2=0%) or at ≥12 months (5 RCTs, pooled RR 1.06, 95% CI 0.93 to 1.56, I^2=16%) (SOE High for both time frames).

Medication: CCTA was not consistently associated with initiation of, discontinuation of or changes in medications and results for many mediations were mixed. Evidence is insufficient to draw firm conclusions about the impact of testing on medication use (SOE insufficient).

Detailed results

6.1.2.2 Additional testing (ICA, other noninvasive testing)

Referral for ICA was reported in 19 RCTs, of which 14 were in patients with suspected ACS [37,47,84,85,96,111,138,140,143,145,161,171,192,248] and five were in stable patients with suspected CAD.[59,126,153,163,215] Five RCTs were considered good quality,[47,59,84,126,215] three were considered poor [85,161,163] and the remaining 10 were considered fair.[37,96,109,111,138,140,143,145,153,171,192,248]

Across populations, CCTA was associated with higher frequency of ICA referral (14.4 per 100 patients) compared with functional testing (12 per 100 patients) across 19 RCTs (pooled RR 1.25, 95% CI 1.09 to 1.47, I^2=67%, RD 2.7, 95% CI 1 to 4 per 100, I^2=59%). (Figure 6) There was no statistical interaction between the stable and suspected ACS populations (p= 922). Exclusion of the SCOT-HEART trial[215] had no substantial impact on effect size or conclusions but did decrease heterogeneity from I^2 of 67% to 45%. Effect sizes and heterogeneity were similar following exclusion of three poor-quality trials[85,161,163] and exclusion of one outlier trial.[248] (Table 29)

ACS = acute coronary syndrome; CCTA = coronary computed tomography angiography; CI = confidence interval; ECHO = stress echocardiography; ED = emergency department; ETT = exercise treadmill test; ICA = invasive coronary angiography; SPECT = single photon emission computed tomography.

In stable outpatients with suspected CAD, ICA referral was more frequent following CCTA, compared with functional testing (15.9 vs. 13.0 per 100), but the association bordered the null and there was substantial heterogeneity (5 RCTs, pooled RR 1.24, 95% CI 1.00 to 1.61, I^2=86, RD 2.0, 95% CI –0.3 to 5.8 per 100 patients).[59,126,153,163,215] Exclusion of one poor-quality trial[163] had no impact on effect size, the association or heterogeneity (4 RCTs, 1.23, 95% CI 0.94 to 1.6, I^2=89%). However, exclusion of SCOT-HEART[215] increased the effect size and strengthen the association between CCTA and ICA referral and substantially reduced the heterogeneity (4 RCTS pooled RR 1.57, 95% CI 1.21 to 1.65, I^2=0%, RD 4.1, 95% CI 3.0 to 5.2 per 100 patients).

In patients with suspected ACS *presenting to an emergency room or similar setting,* ICA referral (cumulative) was also more frequent following CCTA compared with functional testing, (11.5 vs. 9.5 per 100 patients, 14 RCTS pooled RR 1.27, 95% CI 1.04 to 1.58, I^2= 51%, RD 2.8, 95%VI 0.6 to 5.0 per 100 patients),[37,47,84,85,96,109,111,138,140,143,145,161,171,192,248] but was less than the frequency seen in stable outpatients. Exclusion of two poor-quality trials[85,161] did not impact effect estimates

and slightly increased heterogeneity (12 RCTs, pooled RR 1.26, 95% CI 1.01 to 1.60, I^2= 58%). Referral for ICA was highest at the index evaluation (10.6 and 10.7 per 100 patients) and ≥12 months (6.5 vs. 5.5 per 100 patients) for CCTA and functional testing respectively with only 1.4 vs. 1.6 per 100 patients receiving ICA between 1 and 6.5 months. Pooled estimates at individual time frames however were not statistically significant; Index evaluation (8 RCTs, pooled RR 1.11, 95% CI 0.87 to 1.48),[37,47,84,85,109,144,145,192] 1 to 6.5 months (7 RCTs pooled RR 0.96, 95% CI 0.57 to 1.67),[47,84,85,109,145,161,171] ≥12 months (6 RCTS, pooled RR 1.45, 95% CI 0.87 to 2.69).[96,111,138,140,143,248] Exclusion of one outlying trial[248] for the ≥12-month time frame, slightly decreased effect size (3 RCTs, pooled RR 1.34, 95% CI 0.76 to 2.54) but did not change conclusions.

Referral for any additional noninvasive testing was reported in 17 RCTs (N=11,595), of which four were in stable patients[126,153,163,215] and 13 were in patients with suspected ACS.[37,47,84,85,96,109,111,138,140,143,145,161,192,248]

Across populations referral for additional noninvasive testing was not different between CCTA and functional testing groups (7.2 versus 7.6 per 100, pooled RR 0.82, 95% CI 0.53 to 1.28, I^2=83%), however substantial heterogeneity was noted. (Figure 7) Exclusion of two outlier RCTS resulted in a slight increase in the pooled RR (15 RCTS RR 0.94, 95% CI 0.68 to 1.25, I^2=69.3%) and reduced heterogeneity, but conclusions of no association did not change. Exclusion of three poor-quality trials[85,161,163] also resulted in the same slight increase in effect size but heterogeneity was similar. Exclusion of SCOT-HEART, in which 85% of patients received ETT, did not impact effect size, heterogeneity, or conclusions across the populations. Exclusion of two outliers[37,153] resulted in a larger effect size and reduced heterogeneity (15 RCTS, pooled RR 0.94, 95% CI 0.68 to 1.25 I^2=69%) but no difference in conclusions. (Table 29)

ACS = acute coronary syndrome; CCTA = coronary computed tomography angiography; CI = confidence interval; ECHO = stress echocardiography; ED = emergency department; ETT = exercise treadmill test; SPECT = single photon emission computed tomography.

In stable outpatients with suspected CAD, there was no association between CCTA and referral for any additional noninvasive testing (4 RCTs, pooled RR 0.54, 95% CI 0.09 to 3.38, I^2=94%), but heterogeneity was substantial. Exclusion of one poor-quality RCT[163] slightly increased the effect size and exclusion SCOT-HEART decreased the effect size estimate, but neither of these exclusions impacted heterogeneity or conclusions. Exclusion of an outlier trial[153] resulted in a higher effect estimate and decreased heterogeneity, however the conclusion of no association remained.

Referral for additional stress imaging specifically in general and stress imaging that involved additional radiation was rarely described across trials. The evidence is sparse and conflicting and may be related to the comparator for CCTA. CTTA was associated with referral for additional stress imaging within 6 months of initial evaluation in one small good-quality RCT (RR 3.60, 95% CI 1.6 to 8.1)[126] compared with SPECT (16.9 vs. 4.7 per 100 patients, RD 11, 95% CI 4 to 18 per 100). Stress imaging involving radiation was done 23 of the 25 patients in the CCTA group (15.5 per 100 patients in the group) and in all seven patients in the SPECT group. At ≥12 months one

trial reported that CCTA was associated with less frequent referral for stress imaging compared with ETT (RR 0.08, 95% CI 0.03 to 0.18, RD –29, 95% CI –35 to –22).[153] All six patients in the CCTA group received additional stress imaging involving radiation as did 76 of the 77 patients in the ETT group (31 per 100 patients in the ETT group). Another larger trial which compared CCTA to ETT reported no association between CCTA and use of additional noninvasive testing (RR, 0.83, 95% CI 0.25 to 2.73).[215] This may in part be due to use of ETT across 85% of the enrolled patients in this trial. Authors do not report whether additional stress imaging involved radiation. (APPENDIX P)

In patients with suspected ACS *presenting to an emergent setting,* again, no association between CCTA and additional noninvasive testing was observed (13 RCTS, pooled RR 0.94, 95% CI 0.69 to 1.23, I^2=68%). Exclusion of an outlier trial[37] or two poor-quality trials[85,161] did not change effect size, heterogeneity, or conclusions. Similarly, no differences in referral for any additional noninvasive testing between testing groups was seen at < 6 months after index testing (7 RCTs, pooled RR 0.82, 95% CI 0.51 to 1.41)[37,47,85,109,145,161,171] or ≥12 months (7 RCTs, pooled RR 1.05, 95% CI 0.74 to 1.39.[96,111,138,140,143,192,248] Removal of one outlying trial[37] at the < 6 month time frame slightly increased effect size, but did not change conclusions.

Referral for additional stress imaging specifically in general and stress imaging that involved additional radiation was inconsistently described across trials. Across time frames after index testing (< 6 months and ≥ 12 months after index test), there was no difference between CTTA and functional tests in referral for stress imaging (11 RCTs, pooled RR 0.97, 95% CI 0.73 to 1.19, I^2=38%). Similarly, there was no difference between CCTA and functional tests regarding referral for additional noninvasive stress testing involving radiation (10 RCTs, pooled RR 0.68, 95% CI 0.37 to 1.04, I^2=54%), however, these findings should be interpreted cautiously as authors were vague about which specific tests were performed. (APPENDIX P)

6.1.2.3 Treatment

Referral for any revascularization was reported in 19 RCTS (N= 23,124), six were in stable outpatients with suspected CAD[59,126,153,163,215,238] and 13 were in patients with suspected ACS.[37,47,84,85,96,109,111,138,140,143,145,161,192,248] There was no statistical interaction between the patient populations for any outcome.

Across patient populations, CCTA was associated with more frequent revascularization (9.5 per 100) compared with functional testing (7.1 per 100), pooled RR 1.52, 95% CI 1.26 to 1.90 I^2=66%, RD 2.4, 95% CI 1.4 to 3.3 per 100). (Figure 8) Exclusion of the SCOT-HEART resulted in a slight increase the effect estimate but heterogeneity decreased substantially (1.63, 95% CI 1.33 to 1.98, I^2=31%) and exclusion of three poor-quality RCTs[85,161,163] resulted in a slight diminution of the effect size but did not impact heterogeneity (RR 1.48, 95% CI 1.22 to 1.83, I^2=68%). (Table 29)

ACS = acute coronary syndrome; CCTA = coronary computed tomography angiography; CI = confidence interval; ECHO = stress echocardiography; ED = emergency department; ETT = exercise treadmill test; SPECT = single photon emission computed tomography.

In stable outpatients with suspected CAD the association between CCTA and more frequent revascularization versus functional testing (11.2 vs. 8.4 per 100) was seen across RCTs (6 RCTs, N=16,115, pooled RR 1.5, 95% CI 1.08 to 2.16, I^2=86%, RD 2.8, 95% CI 1.4 to 4.2) but there was substantial heterogeneity. Exclusion of one poor-quality trial,[163] which also an outlier, had little impact on the effect size or heterogeneity (5 RCTs, pooled RR 1.46, 95% CI 1.02 to 2.04, I^2=88%). Exclusion on of the SCOT-HEART[215] resulted in a larger effect size and substantially reduced heterogeneity but did not alter overall conclusions (5 RCTs, pooled RR 1.8, 95 %CI 1.37 to 2.24, I^2=31%, RD 2.2, 95% CI 0.9 to 3.4 per 100 patients).

Similarly, *in* ***patients with suspected ACS***, CCTA was associated with more frequent revascularization compared with functional testing (13 RCTS, 5.7 vs 3.9 per 100, pooled RR 1.52, 95% CI 1.19 to 2.10, I^2=25%, RD 2.4, 95% CI 0.7 to 4.2 per 100 patients). Exclusion of two poor-quality trials[85,161] slightly decrease effect size (11 RCTs, pooled RR 1.48, 95% CI 1.16 to 2.02, I^2=29%).

Type of revascularization

PCI was more commonly performed (8 per 100 patients) than CABG as a revascularization procedure in both stable outpatients with suspected CAD and in those with suspected ACS presenting to an emergent setting. Surprisingly it was more common in stable outpatients versus those presenting with suspected ACS (8.0 vs 4.0 per 100 patients)

Across patient populations, CCTA was associated with higher frequency **of PCI** as a revascularization procedure compared with functional testing across (12 RCTs, 8.2 vs. 6.0 per 100, pooled RR 1.63, 95% CI 1.22 to 2.35, I^2=74%, RD 2.4, 95% CI 1.3 to 3.6 per 100),[47,59,84,85,96,109,138,143,153,161,215,248] (Figure 9). Exclusion of two poor-quality RCTs[85,161] or exclusion of one outlier trial,[248] had little impact on effect estimates or heterogeneity. Exclusion of SCOT-HEART,[215] however, increased effect size and reduced heterogeneity by 49% (11 RCTs, pooled RR 1.89, 95% CI 1.3 to 4.0, I^2=36%). The impact of CCTA combined with ETT in this trial on the need for revascularization is unclear (Table 29).

ACS = acute coronary syndrome; CCTA = coronary computed tomography angiography; CI = confidence interval; ECHO = stress echocardiography; ED = emergency department; ETT = exercise treadmill test; PCI = percutaneous coronary intervention; SPECT = single photon emission computed tomography.

In stable outpatients with suspected CAD, the overall frequency of **PCI** was 8 per 100 patients. PCI was more commonly performed following CCTA (8.4 per 100 patients) compared with functional testing (6.9 per 100 patients) and the association approached statistical significance, but substantial heterogeneity was noted (3 RCTS, pooled RR 1.61, 95% CI 0.96 to 3.00, I^2=93%; Figure 9).[59,153,215] Exclusion of the SCOT-HEART[215] substantially increased the effect size and reduced heterogeneity to 0% and resulted in a stronger association between CCTA and PCI, (2 RCTS, pooled RR 2.04, 95% CI 1.57 to 2.87, I^2=0%). The impact of CCTA combined with ETT in this trial on the need for revascularization is unclear.

In contrast, **CABG** was performed in 1.7 per 100 patients across testing arms and was more common following CCTA versus functional testing (2.0 vs. 1.5 per 100) but there was no association with CCTA compared with functional testing based on the pooled estimate (3 RCTs, pooled RR 1.39, 95% CI 0.85 to 2.23, I^2=53%). The largest trial[59] did however show an association (RR 1.90, 95% CI 1.28 to 2.81) comparing CCTA with any functional testing but the other two trials comparing CCTA with ETT did not[153,215]; in the largest of these trials,[215] however 85% of patients in the CCTA arm received ETT. The pretest risk across these trials appears to primarily be low to intermediate, which may partially explain less frequent use of CABG. See Appendix P for figure.

In patients with suspected ACS presenting to an emergency setting, **PCI** frequency overall was 4 per 100 patients, with greater cumulative frequency following CCTA compared with functional testing (9 RCTs, 5.0 vs. 2.8 per 100, pooled RR 1.65, 95% CI 1.08 to 2.93, I^2=43%; Figure 9).[47,84,85,96,109,138,144,161,248] With regard to timing, at index testing, CCTA was associated with more frequent PCI use compared with functional testing (4 RCTs, 5.0 vs. 2.6 per 100 patients, pooled RR 1.89, 95% CI 1.02 to 3.48, I^2= 19%).[84,85,109,144] There was, however, no differences between testing arms at 1 to 6.5 months (5 RCTs, pooled RR 1.65, 95% CI 0.83 to 3.31, I^2= 0%)[47,84,85,109,161] or ≥12 months after index testing (4 RCTs, pooled RR, 1.43, 95% CI 0.54 to 7.83, I^2= 71%).[96,138,140,248] Exclusion of one outlying trial[248] for this later time frame reduced the effect estimate and heterogeneity but did not impact conclusions (3 RCTS, pooled RR 1.04, 95% CI 0.45 to 3.12, I^2=51%).[96,138,140]

CABG was less commonly performed than PCI in patients with suspected ACS. There was no association between CCTA and CABG related to timing of the index test (4 RCTs, pooled RR I^2=). At >1 month following index testing, four of the nine RCTs reported that no patients received CABG and pooled estimates across the remaining trials, showed no difference between testing arms (5 RCTs, pooled RR 1.27, 95% CI 0.26 to 6.20, I^2=51%).[47,96,138,140,248] Less frequent use of CABG may in part be due to the low to intermediate pre-test risk of CAD in patients across these trials. See Appendix P for figure.

6.1.2.4 Hospitalization

Four RCTs in stable outpatients with suspected CAD[59,153,163,215] and 14 RCTs in patients with suspected ACS[37,47,84,85,96,109,111,138,140,143,145,161,171,192,248] reported on hospitalization. In theory the need for and timing of hospitalization may be different in these populations, thus, we did not pool data for this outcome across them.

Across populations, in general across time frames, there were no differences in hospitalization between CCTA and functional testing. However, there was heterogeneity within populations, so each will be addressed separately.

In stable outpatients with suspected CAD, across four RCTs, there was no difference in hospitalization between CCTA and functional testing (4.3 vs. 4.5 per 100 patients, pooled RR 1.00, 95% CI 0.29 to 1.75, I^2=77%). Heterogeneity is likely related to one RCT[153] which reported that CCTA was associated with lower risk of hospitalization compared with ETT (RR 0.12, 95% CI 0.03 to 0.51) (Figure 10).

Figure 10. Comparison of CCTA and functional testing: Hospitalization in stable outpatients with suspected CAD

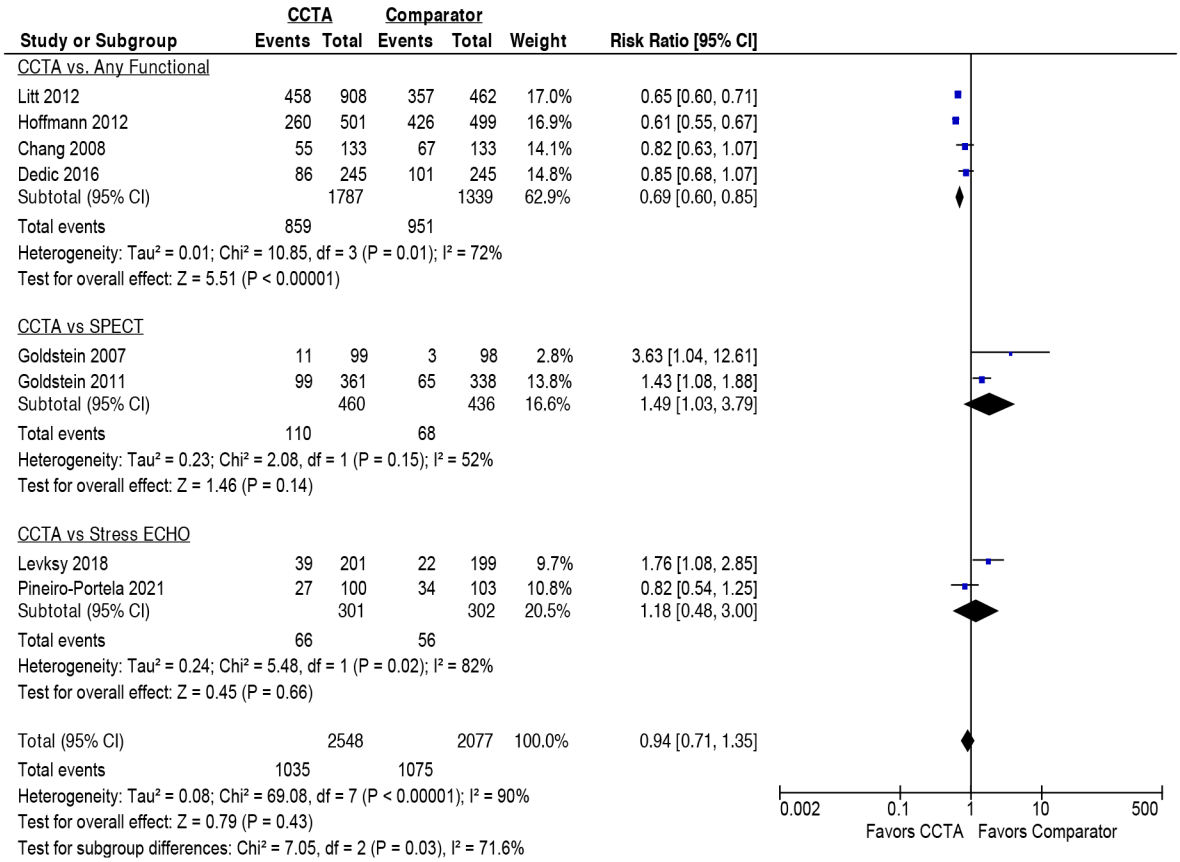
CAD = coronary artery disease; CCTA = coronary computed tomography angiography; CI = confidence interval; ETT = exercise treadmill test; SPECT = single photon emission computed tomography.

In patients with suspected ACS *presenting to an emergency setting*, at the time of index testing, CCTA was not associated with hospitalization across all functional testing comparators, but substantial heterogeneity was noted (8 RCTs, pooled RR 0.94, 95% CI 0.70 to 1.35, I^2=90%) and the test for interaction suggests that there may be differences based on comparators. (Figure 11) Across four fair-quality RCTs comparing CCTA with any (unspecified) functional testing, CCTA was associated with lower risk of hospitalization (4 RCTS 48 vs. 71 per 100 patients, pooled RR 0.69, 95% CI 0.60 to 0.85, I^2= 93.2, RD –19.6 per 100, 95% CI –31.7 to –7.5 per 100) with the two largest RCTs reaching statistical significance.

In contrast, two RCTs[84,85] individually found an association between CCTA and increased risk of hospitalization compared with use of SPECT, although the pooled estimate was not statistically significant (pooled RR 1.49, 95% CI 1.03 to 3.79). In the larger good-quality RCT (N= 699) in low pre-test risk patients,[84] 27 per 100 patients in the CCTA group were hospitalized versus 19 per 100 patients who received SPECT (RR 1.43, 95% CI 1.08 to 1.88). Across two fair-quality RCTs comparing CCTA with stress echo, hospitalization was overall more common in patients who received CCTA (21.9 vs. 18.5 per 100 persons).[138,192] However, again the pooled estimate showed no association (pooled RR 1.18, 95% CI 0.48 to 3.00). The largest RCT (N=400) found an association between increased in hospitalization and CCTA (RR 1.76, 95% CI 1.08 to 2.85) compared with stress echo.[138] In some trials, patients were only randomized to index testing after ruling out ACS, after normal ECG and normal serum biomarkers, were obtained and/or the tests were performed after the time of the index visits. In addition, not all patients received functional testing.

Figure 11. Comparison of CCTA and functional testing: Hospitalization in patients with suspected ACS at time of index ED visit



ACS = acute coronary syndrome; CCTA = coronary computed tomography angiography; CI = confidence interval; ECHO = echocardiography; ED = emergency department; ETT = exercise treadmill test; SPECT = single photon emission computed tomography.

In patients with suspected ACS, there was no difference in hospitalization between CCTA and functional testing across studies, regardless of comparator, at 1 to 6.5 months after index testing (9 RCTs, 3.0 vs. 3.9 per 100 patients, pooled RR 0.76, 95% CI 0.49 to 1.1, I^2=18%).[37,47,84,85,109,143,145,161,171] Similarly, there was no difference between testing arms at ≥12 months (6 RCTs 14.9 vs. 17.4 per 100 patients, pooled RR 0.90, 95% CI 0.77 to 1.03, I^2=0%),[96,111,138,140,143,248] (Figure 12 and Figure 13).

6.1.2.5 Subsequent emergency department visits in patients with suspected ACS

In patients with suspected ACS, there was no difference in emergency department visits after index testing between CCTA and functional testing across studies, regardless of comparator, at 1 to 6.5 months after index testing (7 RCTs, 5.9 vs.6.7 per 100 patients, pooled RR 0.84, 95% CI 0.66 to 1.06, I^2=0%).[47,84,85,109,145,161,171] Exclusion of two poor RCTs[85,161] had little impact on the effect estimates (5 RCT, pooled RR 0.86, 95% CI 0.62 to 1.11). Similarly, at there was no difference between testing arms ≥12 months (5 RCTs, 30.5 per 30.8 per 100 patients, pooled RR 1.06, 95% CI 0.93 to 1.56, I^2=16%),[96,111,138,140,192] (Figure 14 and Figure 15).

6.1.2.6 Medication changes (Appendix O, Table O27 and O28)

Across populations and within populations, CCTA was not consistently associated with initiation of, discontinuation of or changes to medications. Results across trials for mediations were mixed. Evidence is insufficient to draw firm conclusions about the impact of testing on medication decisions.

In stable outpatients, initiation, discontinuation or change in medication use are briefly outlined below

- **Aspirin, statin, and beta-blocker use**: One large, good-quality RCT[135] reported that CCTA was associated with changes in use of these medications compared with functional testing with a higher proportion of CCTA recipients initiating them by 60 days. There

didn't appear to be differences in discontinuation. Another small, poor-quality RCT found no differences.[163]

- **ACE inhibitors, ARBs, non-statins**: There were no differences between CCTA and functional tests for the following medications: ACE inhibitors, (Angiotensin converting enzyme inhibitor) or ARBs (Angiotensin receptor blockers) in two RCTs,[135,163] calcium channel blockers or non-statin lipid-lowering mediations.[163]
- **Other medical management**: Two RCTs reported that CCTA was associated with more patients initiating medical management (unspecified) compared with ETT.[115,153,215] The largest of the two RCTs reported that CCTA was associated with both initiation and discontinuation of medications (unspecified) and antianginal medications at 6 weeks and through a median of 4.8 years follow-up.[115,215] (Confidence intervals for discontinuation were large indicating substantial variation.)
- **Lifestyle changes:** The same large good-quality RCT reported no differences between testing groups related to smoking cessation, exercise or changes in overweight/obese status based on changes in BMI.[135]

In patients with suspected ACS, results for initiation, continuation or change in medications are briefly outlined below.

- **Aspirin:** across five RCTs were mixed. Three RCTS found no differences use between CCTA and functional tests[111,138,140,145] while two reported that CCTA was associated with initiation of aspirin (after index visit)[144] or change in use (at median of 48 hours after index).[248]
- **Statins or lipid prescription**: Three trials reported no differences between CCTA and functional tests.[140,143,248] CCTA was associated with higher continued use of statins at 12 months compared with functional testing in the fourth trial[111,145] and with new or increased dose of a lipid prescription in a fifth trial.[138]
- **Antiplatelet drugs**: Only one trial found that CCTA was associated with initiation of antiplatelet therapy following the index visit[143,144] compared with functional testing however a second larger trial found no difference between testing groups for initiation or continuation of such medications at any time frame (up to 12 months following index).[111,145] Two other RCTs comparing CCTA with stress echo also found no differences between testing groups for initiation of or change in these medications.[138,248]
- **Beta-blockers:** Two RCTs reported no difference in initiation or change in use of beta blockers between testing arms.[143,144,248] In contrast, one trial reported that CCTA was associated with initiation of beta blockers compared with stress echo at a median of 2 years follow-up.[138,139]
- **Nitrate**s: Initiation of nitrates was more common following index testing with CCTA versus functional testing in one RCT,[143,144] but there was no difference between testing arms in another trial evaluating change in use.[248]
- **Anti-hypertensive drugs:** CTTA was associated with fewer changes in use in one RCT within 49 hours of index testing compared with stress echo (10% vs. 18%).[248]
- **Diuretics:** These were initiated more frequently following CCTA and the time of index test compared with functional tests in one trial.[143,144]
- **Diabetes medications**: There were no differences between CCTA and stress echo in the percent changes in either insulin or oral hypoglycemics in one trial.[248]

6.1.3 Key Question 3: Safety

6.1.3.1 Test-related Adverse Events

Fourteen trials (across 18 publications; N=21,446)[36,37,47,52,59,83,85,109,111,126,138,140,145,149,153,215,238,257] assessing CCTA provided information on adverse events related to index testing (Table 29). Trials have been previously described and detailed information about each trial can be found in Appendix Q. Briefly, patients had suspected CAD in 7 trials[36,52,59,126,149,153,215,238,257] (N=17,311) and suspected ACS in 7 trials[37,47,83,85,109,111,138,140,145] (N=4,135). Comparator tests included any functional testing in 5 trials [37,47,59,109,111,145,149], SPECT in 4 trials[83,85,126,140,238], exercise ECG in 2 trials[52,215,257], ICA in 2 trials[36,52], and stress echocardiography in 1 trial [138]. In addition, data from one case series was included.[23]

See Appendix F, Table F3 for detailed abstraction of safety-related outcomes by trial.

6.1.3.1.1 Summary of results for test-related adverse events

- Major or serious test-related adverse events/harms are rare for all modalities. Complications reported across studies were minor. For stress testing most reported symptoms are expected responses to the pharmacologic agents used.
- No major complications were observed across three RCTS at time of index test or within 24 hours (SOE Low). The largest RCT in stable outpatients also reported no test-related hospitalization in the CCTA arm and 0.1% (5/4837) in the functional testing arm (SOE Low).
- Minor complications at time of index test or within 24 hours was <4% across treatment arms across five RCTs in stable outpatients and five RCTs in patients with suspected ACS. Two other trials in patients with suspected ACS reported on a broader range of minor complications, one finding that 24% of patients in each testing arm experienced them and the other that 14% of CCTA patients and 6.4% experienced minor complications (1 RCT, RR 2.16, 95% CI 1.12 to 4.14) (SOE Low).
    - Contrast-related events related to CCTA occurred in ≤3% of patients at time of index testing as reported in six RCTs and one case series. Transient creatinine elevation not requiring dialysis were reported in two trials as 0.2% and 1% (SOE Low) and a third RCT reported that no contrast-induced nephropathy occurred (SOE Insufficient). Mild contrast reaction occurred in 0.5% to 2.1% of patients across six RCTs (SOE Low).
    - CCTA was associated with lower risk of chest pain, shortness of breath, or palpitations at the time of index testing compared with stress SPECT (1 RCT, 0.5% vs. 16% RR 0.03, 95% CI 0.004 to 0.24, p<0.001) and stress echo (1 RCT, 0% vs. 3%, p=0.03) in patients with suspected ACS (SOE Low). The symptoms are likely consistent with inducing cardiac stress with pharmacologic agents. One large RCT in stable outpatients reported much lower risk of symptoms related to nuclear stress testing (0.1%) and events related to dipyridamole or adenosine (0.2%) (SOE Low).
    - Arrythmias occurred in ≤ 0.2% in all testing arm across testing arms (SOE Insufficient).

Detailed Results

6.1.3.1.2 Any major or minor test-related complications (Table 30)

No major test-related complications were observed in one RCT[59,149] in stable outpatients (N=9470) with suspected CAD or in two RCTs (N= 800) in patients with suspected ACS[83,138,140] that compared CCTA with functional testing at time of index testing or within 24 hours of index testing. The RCT[59,149] in stable outpatients defined major complications as death, renal failure requiring dialysis, or anaphylaxis requiring emergency respiratory and/or circulatory support within 24 hours of index test. Hospitalization related to testing complications was rare (<1%), occurring in none of patients receiving CCTA and total of 4 patients receiving stress imaging. In supplemental material, authors of this trial report that within 72 hours of index testing, the following occurred in CCTA vs. functional testing groups: stroke 0.02% (1/4996) vs. 0.04% (2/5007), major bleeding in 0.06% (3/4996) vs. 0.06% (3/5007) and no anaphylaxis or renal failure requiring dialysis in either group. It is unclear if these later events were directly related to testing or subsequent treatment. Stroke and cardiac arrest were considered major adverse events as part of MACE in the other two RCTs.[83,138,140]

Test-related complications considered to be minor by trial authors were described in five RCTs[59,126,149,153,215,238,257] in stable outpatients and seven RCTs[37,47,83,85,109,111,138,140,145] in patients with suspected ACS that compared CCTA with functional testing. Examples of complications considered minor included transient elevation of creatinine levels, contrast extravasation, minor contrast reactions (e.g., hives, rash), dizziness, vasovagal reaction, headache, nausea, shortness of breath, and others. Arrhythmias including tachycardia, bradycardia and atrial fibrillation were reported in some trials and occurred in < 0.5% of patients. Description of specific events varied across trials. Complications are listed by trial in Appendix F, Table F3. Commonly described individual minor complications are summarized below and in Table 30. Some of the minor complications reported are specific to the testing modality. For example, those related to iodinated contrast material are specific the CCTA, those related to pharmacologic stress agents are specific to stress echo or stress SPECT. Patients may have experienced more than one minor event. Given these factors, no direct comparisons between testing arms can be made. This, combined with the heterogeneity of outcomes reported precluded pooling across trials.

Risk of any minor test-related complication at time of index test or within 24 hours was <4% across treatment arms across five RCTs[59,126,149,153,215,238,257] in stable outpatients and five RCTs[37,47,85,109,111,145] in patients with suspected ACS. In the largest trial in stable outpatients, CCTA was associated with having a minor complication compared with functional testing but the absolute risks for both testing arms were low (0.8% vs. 0.5%, RR 1.76, 95% CI 1.04 to 2.87). [59,149] Two trials in patients with suspected ACS, however, reported much higher risk of any minor complication and appear to have included a broader range of potential events. One trial[83,140] comparing CCTA with SPECT reported that 24% of patients in each testing arm experienced one or more minor complication, most commonly headache, nausea, dizziness or feeling of warmth. The other trial from the same author group[138], reported that 14% of CCTA patients and 6.4% of stress echo patients had complaints or adverse reactions to imaging (RR 2.16, 95% CI 1.12 to 4.14). They report 17 CCTA (9%) and 6 stress echo (3%) recipients complained about

examination length or positional discomfort and that none of the CCTA group but 3% of the stress echo group complained about shortness of breath or chest pain during imaging.

*6.1.3.1.3 Individual test-related adverse events (*Table 30*)*

Contrast-related adverse events occurring with CCTA occurred in ≤3% of patients at time of index testing as reported in six RCTs[37,47,59,109,149,215,257] and one case series[23]. Transient creatinine elevation not requiring dialysis were reported in two trials as 0.2%[109] and 1%[47] and a third RCT reported that no contrast-induced nephropathy occurred.[37] Extravasation of contrast occurred in 2%[47] to 3%[59,149] of patients in another. Mild contrast reaction occurred in 0.5% to 2.1% of patients across three trials[59,126,149,215,257] in stable outpatient and in 1% to 1.5% of patients across three trials in patients suspected ACS (skin rash, pruritus). [37,47,83,140] Contrast-related allergic reactions were reported in 1.7% of patients in the case series[23] (N=232).

CCTA was associated with lower risk of **chest pain, shortness of breath, or palpitations** at the time of index testing compared with stress SPECT (1RCT, 0.5% (1/186) vs. 16% (30/188), RR 0.03, 95% CI 0.004 to 0.24, p<0.001)[83,140] and stress echo (1 RCT, 0% vs. 3% (5/188). p=0.03)[138] in patients with suspected ACS. Similarly, in one RCT[59,149] in stable outpatients, **dipyridamole or adenosine-related events** were seen in patients receiving nuclear stress testing as were unspecified stress-induced symptoms, however the risks were small (0.2%, [5/3263] and 0.1% [5/3263] respectively). These responses are expected effects of the stressors and not likely minor adverse events. **Arrythmias, hypotension and hemodynamic instability** were rare across testing arms (≤0.2%). (Table 30)

Table 30. Summary table of test-related adverse events reported by CCTA trials

Outcome	Author, year/Trial name	Intervention vs. comparator	F/U	CCTA % (n/N)	Comparator % (n/N)	Effect size or p-value

ACS = acute coronary syndrome, CAD = coronary artery disease, CCTA = coronary computed tomography angiography, ECG = electrical echocardiogram, ICA = invasive coronary angiography, NR = not reported, SPECT = single photon emission computed tomography

* 404 patients had no testing and 29 had ICA as a first test; these patients are not included in the as tested population.

† In the PROMISE trial, for both CCTA and functional testing, major complications were defined as death, renal failure requiring dialysis, or anaphylaxis requiring emergency respiratory and/or circulatory support.

‡ In the CONSERVE trial, only major bleeding was reported as an adverse event. Of the four major bleeds in the ICA group of this trial, one also required major transfusion.

§ Of the minor procedural complications in the CCTA group, four occurred after coronary angiography and two after CCTA. The p-value for the difference between groups for all complications, including those from procedures, was 0.014. Only those related to CCTA are reported in the table above.

** Neither the PROSPECT trial nor Levsky 2018, defined major complications. Both trials simply stated that no patients had serious complications from imaging.

†† Of patients in each testing arm experienced one or more minor complication, most commonly headache, nausea, dizziness or feeling of warmth.

‡‡Authors report this as complaints or adverse reactions to imaging; 17 CCTA and 6 stress echo patients complained about examination length or positional discomfort; None of the CCTA group but 3% of the stress echo group complained about shortness of breath or chest pain during imaging

§§ 3 events were rated as possibly due to testing, 1 rated as unlikely to be due to testing

6.1.3.2 Radiation exposure

Sixteen trials[36,37,47,52,59,83,84,96,109,126,138,140,143,144,149,153,163,171,215,257] (across 20 publications; N=21,627) assessing CCTA provided information on radiation exposure. Trials have been previously described and detailed information about each trial can be found in Appendix Q. Thirteen trials[36,37,59,83,84,96,126,138,140,143,144,149,153,163,171,215,257] (N=19,787) provided information on effective radiation dose for the index test only (**Table 31**). Of these 13 trials, 6 trials[36,59,126,149,153,163,215,257] were in patients with suspected CAD (N=16,210) and 7 trials[37,83,84,96,138,140,143,144,171] were in patients with suspected ACS (N=3,577). Ten trials[47,52,59,83,109,126,138,140,143,144,149,163,171] (N=14,324) reported on the cumulative radiation dose from all tests (**Table 32**). Of these 10 trials, 4 trials[52,59,126,149,163] were in patients with suspected CAD (N=10,826) and 6 trials[47,83,109,138,140,143,144,171] were in patients with suspected ACS (N=3,498).

6.1.3.2.1 Summary of results for radiation exposure

Data reported in **Table 31** for the PROMISE trial[59,149] are among the subgroup intended for nuclear stress testing before randomization (n=3146 vs. 3203 as tested); this was the only group with radiation data available for index test only. Additionally, one trial[52], comparing CCTA with ICA reported on radiation from follow-up procedures (ICAs and revascularizations), in addition to testing.

- **Radiation from index tests**: Across six RCTs comparing CCTA specifically with SPECT radiation exposure at index tended to be lower with CCTA (SOE Low). Five RCTs reported that CCTA was associated with a lower effective radiation dose for the index test; a sixth trial reported that CCTA was associated with slightly higher radiation (estimated difference 1.8 mSv). Rough estimates of difference between tests ranged from approximately 1.30 mSv to 11.9 mSv. Stress echocardiography and ETT do not involve ionizing radiation (SOE Low).
- **Cumulative radiation**: Across nine RCTs, results are somewhat mixed, but suggest that cumulative radiation may be higher when CCTA is the initial test (SOE Low). Good- or fair-quality RCTs found that CCTA was associated with higher cumulative radiation compared with functional testing with rough estimates of differences ranging from 1.9 mSv to 9.0 mSv in these trials. It is unclear from included RCTs what tests (e.g., SPECT, ICA) or procedures (e.g., PCI) were included in the estimates. Stress echocardiography does not involve ionizing radiation. It is unclear if some of the differences between arms would impact clinical decision making. CCTA was associated with lower cumulative radiation versus SPECT in two RCTs (estimated range 6 mSv to 15 mSv) and no statistical difference between CCTA and SPECT was reported in a third smaller poor-quality RCT.

Detailed results

6.1.3.2.2 Index test radiation

Three RCTs[59,126,149,163] in stable outpatients and three RCTs[83,84,140,171] in patients with suspected ACS compared index test effective radiation dose for CCTA with SPECT or any nuclear stress testing. Radiation doses in the CCTA arms of these trials ranged varied substantially across trials (means range 10.4 mSv to 12.7 mSv, median ranges 5.0 mSv to 11.5 mSv) (Table 31). Radiation doses in the SPECT/nuclear stress testing arms also varied (means range 10.9 mSv to 14.1 mSv, median ranges 9.3 mSv to 27 mSv). Across five RCTS, CCTA was associated with a lower effective radiation dose than SPECT (or other nuclear stress test) at index test. One large good-quality RCT (N=6,348) in stable outpatients reported a mean difference (MD –3.7 ,95% CI –3.9 to –3.5).[59,149] In contrast index CCTA was associated with higher effective radiation dose in one smaller fair-quality RCT[171] (N=598) in patients with suspected ACS (MD 1.8, 95% CI 0.89 to 2.7) (Table 31). It is unclear whether some of the differences would impact clinical decision making.

The other RCTs either did not report radiation dose for functional tests[37,143,144] or compared CCTA with tests that do not involve ionizing radiation (i.e., ETT or stress echo).[96,138,153,215,257] Across this group of RCTs, the means ranged from 5.1 mSv to 12.5 mSv and medians ranged from 3.8 mSv to 6.4 mSv (Table 31).

ACS = acute coronary syndrome; CCTA = coronary computed tomography angiography; CI = confidence interval; ECG = electrocardiography; ED = emergency department; ETT = exercise treadmill test; IQR = interquartile range; MD = mean difference; mSv = millisievert; NR = not reported; SPECT = single photon emission computed tomography; Stress Echo = stress echocardiography.

Differences between trials regarding how exposure was reported (means or medians) combined with the substantial heterogeneity across studies precluded pooling of data, however, Figure 16 and Figure 17 provides rough estimates of differences between testing arms and provides a visual representation of the data for studies that reported comparative data. Two of the studies compared CCTA functional tests that do not use ionizing radiations, one with ETT[153] the other with stress echocardiography.[138]

6.1.3.2.3 Cumulative Radiation

Three RCTs[59,126,149,163] in stable outpatients and 6 trials[47,83,109,138,140,143,144,171] in patients with suspected ACS compared cumulative radiation dose by CCTA versus functional testing as initial testing strategies. It is assumed that the cumulative does includes additional downstream testing. Six RCTs[47,59,109,138,143,144,149,171] found that CCTA was associated with higher cumulative radiation compared with functional testing. CCTA was associated with lower cumulative radiation versus SPECT in two

RCTs[83,126,140] and no statistical difference between CCTA and SPECT was reported in a third smaller poor-quality RCT,[163] (Table 32).

Differences between trials regarding how exposure was reported (means or medians) combined with the substantial heterogeneity across studies precluded pooling of data. Figure 18 and Figure 19 provide rough estimates of differences between arms for a visual overview of differences between testing arms. It is unclear if some differences may impact clinical decision making.

Figure 18. Visual overview of cumulative radiation exposure in stable outpatients

Study or Subgroup	Follow-up	CCTA Effect	CCTA SD	CCTA Total	Comparator Effect	Comparator SD	Comparator Total	Effect Difference [95% CI]

CCTA vs SPECT								
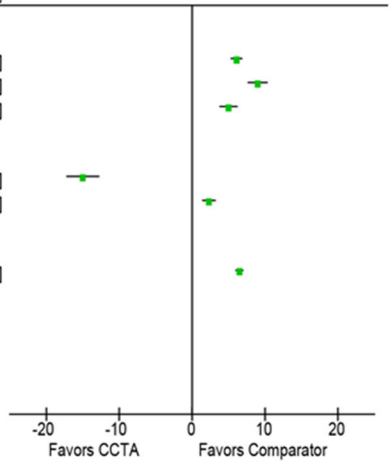
PROSPECT Trial	12 month	12	14.52	200	27	5.93	200	-15.00 [-17.17, -12.83]
Nabi 2016*	6.5 months	13.3	5.8	288	11	4.6	310	2.30 [1.46, 3.14]
CCTA vs ECHO								
Levksy 2018	12 months	6.5	3.26	201	0	0	199	6.50 [6.04, 6.96]



CCTA = coronary computed tomography angiography; CI = confidence interval; ECHO = stress echocardiography; SD = standard deviation; SPECT = single photon emission computed tomography.

In stable outpatients, the largest, good-quality RCT (N=10,003 as randomized, 9470 as tested) CCTA was associated with slightly higher cumulative radiation exposure compared with any functional testing within 3 months of testing (MD 1.90 mSv (95% CI 1.6 to 2.2 mSv).[59,149] In contrast, one smaller (N=303) good-quality RCT[126] reported that CCTA was associated with slightly lower cumulative radiation compared with SPECT at 12 months and one small (N=180) poor-quality RCT found no statistically significant difference between CCTA and SPECT (medians 7.3 mSv vs. 13.3 mSv) at a mean of 55 days. [163] (Table 32)

In patients with suspected ACS, in five[47,109,138,143,144,171] of the six RCTs, CCTA was associated with higher cumulative radiation compared with functional testing in general. The largest, fair-quality RCT (N=1000) reported a mean difference of 9mSv (95% CI 7.7 to 10.3 mSv) at 1 month, one good-quality trial[47] (N=500) reported a mean difference of 4.7 mSv (95% CI 3.5 to 5.9) at 1 month and the mean difference in a third fair-quality trial[171] (N=598) was 2.30mSv (95% CI 1.5 to 3.1mSv) at approximately 6.5 months. Median ranges for cumulative radiation reported in the remaining two fair-quality RCTs[138,143,144] were 6.1 to 6.5mSv for CCTA and 0 for functional testing (IQR 0 to 5.7). One of these RCTs compared CCTA with stress echocardiography.[138]

In contrast, in one fair-quality RCT (N=400), CCTA was associated with substantially lower cumulative radiation compared with SPECT at 12 months (median 12mSv vs. 27 mSv) and at a median of approximately 40 months (median 13mSv vs. 27mSv)[83,140] (Table 32).

Table 32. Summary table of cumulative radiation from all tests reported by CCTA trials

Author Year	N	Intervention test (n)	Comparator test (n)	Follow-up time	Intervention group; cumulative radiation from all tests	Comparator group; cumulative radiation from all tests	MD (95% CI), p-value Author provided p-value for Medians
Suspected CAD

				Median: 24 months	Median (IQR): 6.5 (5.5 to 10.0) mSv	Median (IQR): 0 (0 to 0)	p<0.001

ACS = acute coronary syndrome, CAD = coronary artery disease, CCTA = coronary computed tomography angiography, CI = confidence interval; ECG = electrical echocardiogram, ICA = invasive coronary angiography, IQR = interquartile range, MD = mean difference, mSv = millisievert, N/A = not applicable, NR = not reported, SD = standard deviation, SPECT = single photon emission computed tomography.

* All PROMISE subjects who had functional testing or CCTA as their first test were included in the as tested population. Patients who had no test or who had invasive coronary angiography (ICA) as their first test were excluded. Computed tomography (CT) protocols commonly include a non-contrast CT for assessment of coronary artery calcium score before contrast-enhanced CCTA to assess coronary artery stenosis. Some sites chose not to proceed with CCTA in patients with a high calcium score; these participants were excluded as the radiation dose from calcium score CT alone is substantially lower than for CCTA.
† Includes radiation from ICAs and revascularizations, in addition to testing.

6.1.3.3 Incidental findings

Four trials[59,83,140,149,215,238,257] (across 7 publications; N=12,671) assessing CCTA reported on incidental and/or extra cardiac findings found on index test (Table 33). Trials have been previously described and detailed information about each trial can be found in Appendix Q. Three trials[59,149,215,238,257] (N=12,295) were in patients with suspected CAD and 1 trial[83,140] was in patients with suspected ACS (N=376). Comparators consisted of SPECT MPI in 2 trials [83,140,238], exercise ECG in 1 trial[215,257], and any functional testing in 1 trial[59,149].

In addition to the four CCTA trials reporting on incidental findings, 2 systematic reviews[72,125] and 4 retrospective single arm studies[24,66,124,200] provided additional information on extracardiac findings found on CCTA (Table 34). One systematic review included 11,703 patients with suspected CAD (unclear if symptomatic or asymptomatic) across 13 studies. The other systematic review included 15,877 mostly with suspected CAD across 19 studies. Karius 2014 included 9 studies that were not included in the Flor 2013 systematic review, and Flor 2013 included 3 studies that were not included in Karius 2014. Across the 4 additional single arm studies, which all included patients with suspected CAD, sample sizes ranged from 1,383 to 3,898 (Total N=9,090). Focus was on total extracardiac findings, clinically significant or major extracardiac findings, malignant extracardiac findings, and the top 5 most commonly reported extracardiac findings in each study.

6.1.3.3.1 Summary of results

- Incidental findings are common with CCTA (28% to 44%) across included RCTs, systematic reviews and nonrandomized studies with pulmonary findings being most common. The proportion that were considered “potentially significant”, “clinically significant” or “required follow-up” ranged from 4.9% to 16% (SOE Low).

Detailed Results

Incidental and/or extra cardiac findings at index testing were commonly seen and variably defined across four CCTA trials[59,83,140,149,215,238,257] that reported on this. Pulmonary-related findings (nodules, masses, granuloma, emphysema or other parenchymal changes) were most commonly reported across trials. (Table 33) In stable outpatients, “potentially significant” incidental findings occurred in 11.6% of patients in the CCTA group versus 0.7% of those receiving stress nuclear testing or 1.9% of patients receiving stress echocardiography ($p<0.001$ for CCTA vs. any functional test) in the largest trial. [59,149] Two other trials in stable outpatients reported frequencies of any incidental findings of 38.1%[215,257] and 32.8%[238], however additional imaging was required in fewer patients, 7.5% and 11.4% respectively. In one trial in patients with suspected ACS incidental findings occurred in 83.4% of patients; 156 of 187 patients had a total of 386 incidental findings.[83,140] The most common were pulmonary (63%), non-coronary cardiac (37%), gastrointestinal (26%) and hepatobiliary (22%) findings. Findings the authors considered potentially serious or life threatening were pericardial effusion (6.4%), aortic dilatation (3.2%), pulmonary embolism (2.1%), pneumonia (1.6%) and congestive heart failure (1.6%).

Across two systematic reviews[72,125], one retrospective database study[124] and three large retrospective case series[24,66,200], the overall frequency of extracardiac findings (ECFs) ranged from 28.4% to 44%. (Table 34) Again, pulmonary findings were most common. The two systematic reviews[72,125] report a pooled prevalence of 16% (95% CI range 9% to 24%) for clinically significant or major ECFs. The frequency of ECFs major and/or requiring follow-up ranged from 2.4% to 6.8% in three retrospective studies[24,66,124] with the fourth study[200] reporting that 4.9% of ECFs were considered significant. The pooled prevalence of acute life-threatening ECFs was 2.2% in one systematic review[125] and the prevalence of ECFs requiring urgent attention was 0.4%in the retrospective database study[124] by the same author group. The prevalence of malignant ECFs ranged from 0.1% to 0.7% across two systematic reviews[72,125], the database study[124] and two case series[24,200].

Resources required to follow-up incidental findings and use of additional testing involving radiation were not described in these studies. The impact of incidental findings and their follow-up on patients (anxiety, cost, time from work, etc.) was not described.

Table 33. Summary table of incidental findings on index test reported by CCTA trials

Outcome	Author, year (trial name)	Intervention vs. comparator	CCTA; % (n/n)	Comparator test; % (n/N)	Effect Size or p-value

ACS = acute coronary syndrome, CAD = coronary artery disease, CCTA = coronary computed tomography angiography, ECG = electrical echocardiogram, ICA = invasive coronary angiography, NR = not reported, SPECT = single photon emission computed tomography.

* Across the trials, incidental findings were defined as "potentially significant incidental findings" (PROMISE trial), "non-cardiac findings" (SCOT-HEART trial), "non-cardiac findings" (RESCUE trial), and "incidental findings" (PROSPECT trial).

† In the functional testing arm, abnormal breast uptake of radiotracer (0.3%, 11/3263) on nuclear stress testing, and mitral regurgitation (1.0%, 11/1083) on stress echocardiography were the most common incidental findings.

‡ In addition, there were 28.2% (501/1778) other cardiac findings identified.

§ To include: anterior mediastinal mass, arteriovenous malformation, Bochdalek hernia, broncocele, duplication cyst, elevated left hemidiaphragm, gallstones, hamartoma, pericardial cyst, sclerotic vertebrae, syndesmophytes, subclavian vein stenosis, splenomegaly, splenic artery aneurysm, vertebral wedge fractures.

** Considered to be potentially serious or life threatening.

Table 34. Summary of extracardiac findings (ECF) identified by CCTA

Author Year	Study design	N	Population	Incidental findings
Karius 2014	SR	11,703 (across 13 studies)*	Suspected CAD (unclear if symptomatic or asymptomatic)	• Pooled prevalence of overall ECFs: 41% (95% CI 27% to 56%), p<0.0001 [Overall ECF were identified in 3794 of 11,186 participants] • Pooled prevalence of clinically significant ECFs: 16.0% (95% CI 9% to 24%, p<0.0001) [Clinically significant ECF were detected in 1989 of 11,703 patients] • Pooled prevalence of acutely life-threatening ECFs in relation to the study cohort: 2.2% (95% CI 1.9% to 2.5%), p<0.0001 • Pooled prevalence of malignant ECFs in relation to the study cohort: 0.3% (95% CI 0.2% to 0.4%), p<0.0001 • Top 5 most commonly reported ECFs in relation to the total number of clinically significant ECFs: - Suspicious pulmonary nodules: 26.6% (575/2160) - Hiatal hernia: 20.8% (450/2160) - Aortic abnormalities: 10.8% (233/2160) - Emphysema: 8.6% (186/2160) - Pulmonary infiltration: 5.5% (11/2160)
Flor 2013	SR	15,877 (across 19 studies)*	Mixed (suspected CAD, healthy subjects, AFIB)	• Pooled prevalence of overall ECFs: 44% (95% CI 35% to 54%), p=0.275 • Pooled prevalence of major ECFs: 16% (95% CI 14% to 20%), p<0.001 • Pooled prevalence of malignant ECFs: 0.7% (95% CI 0.5% to 1.0%), p=NR *Individual event types were not reported by this study.*
Karius 2019	Retrospective database	3,898 (with 4,209 CCTAs performed)	CCTA examinations performed with an indication to rule out CAD. Patients without significant CAD (coronary stenosis < 50%) on CCTA were included.	• Proportion of patients with an ECF: 30.2% (1117/3898) • Proportion of patients with an ECF with a recommended for follow-up: 2.4% (95% CI 2.0% to 2.9%) (94 patients) • Proportion of patients with an urgent ECF: 0.4% (95% CI 0.3% to 0.7%) (16 patients) • Proportion of patients with a malignant ECF: 0.1% (95% CI 0.0% to 0.2%) (3 patients) • Top 5 most commonly reported ECFs in relation to the total number of patients included in the study: - Chronic changes of lung parenchyma and bronchial system: 12.9% (501/3898) - Extensive atherosclerosis: 5.4% (209/3898) - Pulmonary nodule/consolidation: 4.3% (167/3898) - Extensive spinal degradation: 4.1% (159/3898) - Aortic dilation: 2.9% (112/3898)

Bendix 2011	Retrospective case series	1,383	Suspected CAD	• Proportion of patients with an ECF: 28.4% (393/1383) (with 482 ECFs total) • Proportion of patients with a major ECF requiring follow-up: 6.7% (94/1383) (with 1030 ECFs total) • Proportion of patients with a malignant ECF: 0.3% (4/1383) (with 4 ECFs total) • Top 5 most commonly reported ECFs in relation to the total number of ECFs identified: - Adenopathy: 18.0% (87/482) - Hepatic cyst: 12.2% (59/482) - Atelectasis: 8.5% (41/482) - Emphysema: 8.3% (40/482) - Pleural plaque: 5.4% (26/482)
Ramanathan 2019	Retrospective case series	1,713	Suspected CAD†	• Proportion of patients with an ECF: 35.0% (600/1713) (with 812 ECFs total) • Proportion of ECFs that were considered significant: 4.9% (39/812) • Proportion of patients with a malignant ECF: 0.2% (4/812) • Top 5 most commonly located ECFs in relation to the total number of patients included in the study (actual ECF types are NR): - Lungs: 13% (222/1713) - Liver: 11% (189/1713) - Mediastinum: 5% (85/1713) - Bone: 4% (68/1713) - Great vessels: 3% (51/1713)
Erol 2014	Retrospective case series	2,096	Suspected CAD‡	• Proportion of patients with an ECF: 8.1% (170/2096) (with 174 ECFs total) • Proportion of patients with an ECF requiring further follow-up: 6.8% (142/2096) • Top 5 most commonly reported ECFs in relation to the total number of patients included in the study: - Fusiform dilatation of the ascending aorta: 3.2% (67/2096) - Left atrial diverticula: 1.2% (25/2096) - Massive mitral valve annulus calcification: 0.9% (19/2096) - Bicuspid aortic valve: 0.57% (12/2096) - Acute pulmonary embolism: 0.29% (6/2096) - Secundum-type atrial septal defect: 0.29% (6/2096)

AFIB = atrial fibrillation, CAD = coronary artery disease, CAD = coronary artery disease, CCTA = coronary computed tomography, CI = confidence interval, ECF= extra cardiac finding, SR = systematic review.

* Karius 2014 includes 9 studies that are not included in the Flor 2013 SR, and Flor 2013 includes 3 studies that are not included in Karius 2014

† Indications for CCTA included: Acute and chronic chest pain (44%), Dyspnea (8%), Hypertension (15%), Diabetes mellitus (12%), Abnormal or equivocal stress test (8%), Abnormal ECG (3%), Palpitations (2%), Congestive heart failure (30%), Pre operative: assessment (4%)

‡ Indications for CCTA were atypical chest pain, angina pectoris, coronary artery anomalies, and determination of the patency of bypass grafts or stents.

6.1.4 Key Question 4: Differential Efficacy or Safety

6.1.4.1 Summary of results

Three large RCTs comparing CCTA with functional testing reported tests for interaction between subgroups on efficacy and/or safety outcomes. Two RCTs were in stable outpatients (N = 10,003[59] and 4146[215] respectively) and one RCT was in patients with suspected ACS (N=1000)[109]. These trials are described in previous sections. Only one of these pre-specified subgroup analyses and consider this in sample size determinations. All performed multiple analyses for multiple outcomes, including multiple composite outcomes. None of the RCTs specified all outcomes evaluated. None specified hypotheses to be tested or expected direction.

- **Clinical outcomes**: Only one RCT reported on the primary clinical outcomes of interest for this HTA. At a median of 3.2 years, the effect of CCTA did not appear to vary based on anginal classification (non-anginal chest pain, possible anginal chest pain) for MI (SOE Low), all-cause mortality (SOE Insufficient) or death due to CAD (SOE Insufficient). As many of these outcomes appear to be rare, it is possible that this trial was not sufficiently powered to effectively evaluate interaction. The factors, outcomes and hypothesized direction do not appear to have been specified a priori.
- **Downstream testing:** One RCT in patients with suspected ACS found no significant variation in use of downstream testing with CCTA based on sex or race at either the index visit, or 28 day follow up. Downstream testing did vary by diabetes status; more downstream testing occurred with CCTA in patients with diabetes at index visit and by 28-day follow-up (interaction p-values 0.001 and 0.002 respectively). The factors, outcomes and hypothesized direction do not appear to have been specified a priori in this fair-quality trial (SOE Low).
- **ICA referral:** Across two RCTs, one in stable outpatients and the other in patients with suspected ACS the effect of CCTA versus functional testing on ICA referral did not vary by diabetes status (SOE Low). Similarly, there was no effect modification in the trial in patients with suspected ACS by sex or race at index visit or by 28-day follow-up (SOE Low).
- **Revascularization**: Across two RCTs, one in stable outpatients and the other in patients with suspected ACS the effect of CCTA versus functional testing on revascularization did not vary by diabetes status (SOE Low). The effect of CCTA versus functional testing on revascularization was not modified by either sex (1 RCT) or angina classification (1 RCT) (SOE Insufficient).
- **Radiation exposure:** In stable outpatients, CTTA cumulative radiation may vary based on baseline heart rate. Patients with ≥75 beats-per-minute may have higher cumulative radiation with CCTA compared with functional testing. Tests for interaction by age, sex and BMI were not significant (SOE Insufficient). In patients with suspected ACS, there was insufficient evidence to confidently make conclusions about how radiation dose may vary by sex, diabetes status or race for CCTA versus functional testing index testing or within 28 days (SOE insufficient).

Detailed results

Three large RCTs comparing CCTA with functional testing reported tests for interaction between subgroups on efficacy and/or safety outcomes.[5,146,148,175,186,187,204,217,218,245,246] All three reported on multiple patient characteristics or factor for multiple outcomes (Table 35). This section will focus on the primary outcomes of interest to this HTA (MI, all-cause death, cardiac death, stroke, ICA and revascularization referral, safety-related); we will briefly describe analyses on other outcomes, including the various definitions of MACE. Summary tables detail results for factors and outcomes evaluated in these studies are found in greater detail in Appendix O, Tables O7 through O22. Only select tables will be included here.

In stable outpatients, the largest, RCT described pre-specified subgroup analyses and took this into account for sample size determination and during the randomization process[58] based on their protocol. Authors created three cohorts based on specific functional tests (e.g., SPECT, stress echo, ETT) for the pre-specified analyses; in each, half was randomized to the pre-specified functional test and half to CCTA to form paired CCTA-functional test subgroups. The goal was to evaluate subgroups where anatomic testing might be particularly advantageous, or where the question of a benefit from CTA is particularly relevant. While the subgroups/factors were prespecified, the use of multiple composite outcomes for the analyses do not appear to have been. For the other RCT in stable outpatients (N=4146), neither the protocol[176] nor the primary publication[215] specify subgroup analysis in terms of factors or outcomes. Subgroup analyses were reported in a later publication.[5] Multiple composite outcomes were evaluated. Similarly, the fair-quality trial **in patients with suspected ACS** (N=1000) does not specify subgroup analysis in the protocol or primary publication.[109] Their primary trial endpoint was length of stay.

Table 35. Overview of RCTs evaluating differential efficacy and safety

Trial, (N) Quality (ROB)	Factors specified *a priori or not*	Hypothesis direction	Outcome(s)
Stable Outpatients			
PROMISE (Douglas 2015) N=10,003 Good quality	**Specified a priori:** Age, sex, race, comorbidity, cardiovascular risk factors, pre-randomization choice of functional test, and characteristics precipitating symptoms	NR	• Composite (cardiovascular death, MI) • Composite (cardiovascular death, myocardial infarction, and unstable angina hospitalization) • Composite (death from any cause, nonfatal myocardial infarction, hospitalization for unstable angina, or major procedural complication • Composite of the above plus ICA without obstructive CAD • ICA referral • Any revascularization PCI referral • Medication use • test positive rate (≥70% stenosis in at least one epicardial artery or ≥50% stenosis in the left main
SCOT-HEART (2018) N=4146	**Not specified a priori;** Age, sex, 10 year risk,	NR	• MI (fatal, non-fatal, separately, and together) • Composite (MI, stroke)

Trial, (N) Quality (ROB)	Factors specified *a priori or not*	Hypothesis direction	Outcome(s)
Good quality	previous CAD, Diabetes, NICE classification (angina, nonanginal chest pain)		• Composite (Death from CAD or nonfatal MI) at 5 years • All-cause mortality • Cardiac death (CAD) • CABG
Suspected ACS			
ROMICAT-II (Hoffman) N=1000 Fair quality	**Not specified a priori:** Sex, diabetes, race	NR	• MACE (not defined) • Downstream testing • Repeat ED visit or hospitalization for chest pain • ICA • Revascularization, PCI • Index radiation dose • Mean cumulative radiation does • Administrative/Utilization (direct ED discharge, LOS (hours), hospital admission)

CABG = coronary artery bypass graft; CAD = coronary artery disease; ED = emergency department; ICA = invasive coronary angiography; LOS = length of stay; MACE = major adverse cardiac events; MI = myocardial infarction; NICE = National Institute for Health and Care Excellence; PCI = percutaneous coronary intervention; RCT = randomized controlled trial.

6.1.4.2 Primary clinical outcomes

Only one, fair-quality RCT[5] in stable outpatients with suspected CAD reported sub analyses with tests for interaction for the primary clinical outcomes of interest for this HTA. At a median of 3.2 years there was no evidence of differential test effectiveness based on NICE classification of chest pain as non-anginal or possibly anginal for MI, non-fatal stroke, all-cause mortality or death due to CAD. As many of these outcomes appear to be rare, it is possible that this trial was not sufficiently powered to effectively evaluate interaction. The factors, outcomes and hypothesized direction do not appear to have been specified a priori (Table 36).

Table 36. Analyses for impact of NICE classification of chest pain on primary outcomes

Trial name	Follow-up	Subgroup (N)	CCTA, % (n/N))	Exercise ECG, % (n/N)	Author reported HR (95% CI)	Author reported interaction p-value
MI (fatal and nonfatal)						
SCOT-HEART, 2018	Median 3.2 years	NICE classification of non-anginal chest pain*	1.0% (7/712)	1.5% (11/735)	0.65 (0.25 to 1.69)	0.836
		NICE classification of possible anginal chest pain*	1.9% (22/1174)	3.2% (37/1149)	0.58 (0.34 to 0.99)	
Non-fatal stroke						
SCOT-HEART, 2018	Median 3.2 years	NICE classification of non-anginal chest pain*	0.1% (2/712)	0.7% (5/735)	0.21 (0.02 to 1.8)	0.200
		NICE classification of possible anginal chest pain*	0.5% (6/1174)	0.5% (6/1149)	1.01 (0.32 to 3.12)	
All-cause mortality						

SCOT-HEART, 2018	Median 3.2 years	NICE classification of non-anginal chest pain*	1.0% (7/712)	0.5% (4/735)	1.81 (0.53 to 6.18)	0.200
		NICE classification of possible anginal chest pain*	1.5% (18/1174)	1.9% (22/1149)	0.82 (0.44 to 1.53)	
Coronary heart disease death						
SCOT-HEART, 2018	Median 3.2 years	NICE classification of non-anginal chest pain*	0% (0/712)	0.3% (2/735)	0 (0 to Infinity)	0.998
		NICE classification of possible anginal chest pain*	0.3% (3/1174)	0.3% (4/1149)	0.78 (0.17 to 3.48)	

CCTA = coronary computed tomography angiography; CI = confidence interval; ECG = electrocardiography; HR = hazard ratio; MI = myocardial infarction; NICE = National Institute for Health and Care Excellence.
* Participants with non-anginal chest pain had the lowest event rates. Patients with possible angina had a higher and time-varying event rate with increased early hazards. Additionally, study reports third group of patients with known CAD that were already on established preventative therapies which were not reported in this data.

Two trials in stable outpatients reported sub analyses with tests for interaction for composite outcome of cardiovascular death or MI.[175,217,218] Both evaluated whether the presence of diabetes modified the effect of testing for this outcome. Results from the largest trial suggest that diabetes may modify testing for the composite outcome of MI or cardiovascular death, however the other, smaller trial reported no interaction (Table 37).

Table 37. Analyses for impact of diabetes on the composite outcome of MI and cardiovascular death

Trial name	Timing	Subgroup (N)	CCTA, % (n/N)	Comparator, % (n/N)	Author reported effect estimate	Author reported interaction p-value
PROMISE trial	Median follow-up: 25 months	With diabetes (N=NR)	1.1% (10/936)	Any functional test: 2.6% (25/972)	Adj. HR 0.38, 95% CI 0.18 to 0.79*	0.020
		Without diabetes (N=NR)	1.4% (50/3564)	Any functional test: 1.29% (45/3494)	Adj. HR 1.03, 95% CI 0.69 to 1.54*	
SCOT-HEART, 2018	Median 4.8 year follow-up	Diabetes (N=NR)	2.2% (41/1850)	Exercise ECG: 3.5% (64/1852)	HR 0.63 (95% CI 0.43 to 0.94)	0.40
		No diabetes (N=NR)	3.1% (7/223)	Exercise ECG: 7.7% (17/221)	HR 0.36 (95% CI 0.15 to 0.87)	

CI = confidence interval; ECG = electrocardiography; HR = hazard ratio; MI = myocardial infarction; NICE = National Institute for Health and Care Excellence; NR = not reported.

There was no evidence of interaction from additional subanalyses on this composite outcome in the SCOT-HEART trial for any of the following factors (see Appendix O for tables): Age (< 65, ≥65 years), sex, 10-year cardiovascular risk (<15%, ≥15%), previous coronary heart disease, NICE anginal classification (non-anginal, anginal).

Results for other composite outcomes are also found in Appendix O. In general, there was no evidence of differential effectiveness (interaction p-values were not significant) by sex.

6.1.4.3 Downstream testing

In one fair-quality trial[246] in patients with suspected ACS, testing effect appears to be modified by the presence or absence of diabetes. While downstream testing was more common in the CCTA arm for both those with and without diabetes compared with functional testing, those with diabetes had differentially higher rates of downstream testing with CCTA. Neither sex nor race modified the effect of testing (Table 38).

Table 38. Subgroup analyses for any downstream testing in patients with suspected ACS

Trial name	Timing	Subgroup (N)	CCTA, % (n/N)	Functional Testing, % (n/N)	Author reported effect estimate	Author reported interaction p-value
ROMICAT-II trial	Index Visit	Females (N=NR)	16% (37/239)	10% (22/229)	NR	0.08
		Males (N=NR)	30% (79/262)	12% (31/270)	NR	
	28 day follow-up	Females(N=NR)	20% (47/239)	24% (11/229)	NR	0.23
		Males (N=NR)	33% (86/262)	13% (86/270)	NR	
	Index Visit	With diabetes (N=NR)	38% (33/86)	5% (4/87)	NR	0.001
		Without diabetes (N=NR)	20% (83/415)	12% (49/412)	NR	
	28 day follow-up	With diabetes (N=NR)	42% (36/86)	7% (6/87)	NR	0.002
		Without diabetes (N=NR)	23% (97/415)	13% (54/412)	NR	
	Index Visit	White (N=NR)	24% (80/330)	13% (42/329)	NR	0.16
		Black (N=NR)	22% (/141)	6% (9/140)	NR	
	28 day follow-up	White (N=NR)	29% (95/330)	15% (48/329)	NR	0.18
		Black (N=NR)	23% (32/141)	6% (9/140)	NR	

CCTA = coronary computed tomography angiography; NR = not reported.

6.1.4.4 Test positivity rate of index test

Sex and BMI (<35, ≥35) appear to modify the effect of testing on the test positive rate (≥70% stenosis in at least one epicardial artery or ≥50% stenosis) in one trial[186,187] in stable outpatients, based on test for interaction across functional tests. Tests for interaction for age and diabetes status were not significant (Table 39).

Table 39. Subgroup analyses for test positive rate (≥70% stenosis in at least one epicardial artery or ≥50% stenosis in the left main)

Trial name	Timing	Subgroup (N)	CCTA % (n/N)	Comparator % (n/N)	Author reported adjusted OR (95% CI)*	Author reported interaction p-value
PROMISE trial	Index test	Male (N=NR)	16.1% (350/2168)	Any functional test: 14.0% (290/2078)	1.23 (1.04 to 1.47)	CCTA vs. any functional test: <0.001[†]
				Nuclear Stress: 16.9% (230/1362)	1.03 (0.85 to 1.25)	
				Stress Echo: 7.7% (36/465)	2.10 (1.45 to 3.04)	
				Ex ECG: 9.6% (24/251)	1.79 (1.15 to 2.80)	
		Female (N=NR)	7.9% (184/2332)	Any functional test: 11.5% (274/2388)	0.67 (0.55 to 0.82)

				Stress Echo: 7.4% (58/785)	NR	
				Ex ECG: 13.3% (47/354)	NR	

CCTA = coronary computed tomography angiography; CI = confidence interval; Ex ECG = exercise electrocardiography; NR = not reported; OR = odds ratio; Stress Echo = stress echocardiography.
* Adjusted for age, race, body mass index, coronary artery disease (CAD) equivalent, Framingham risk score, ASCVD score, 2011 Diamond and Forrester score, hypertension, dyslipidemia, diabetes, family history of premature CAD, sedentary lifestyle, smoking, typicality of chest pain, and physician's estimation of likelihood of significant CAD.
† All other tests: p=NR.

6.1.4.5 ICA referral

For ICA referral, there was no evidence of modification/interaction of testing by sex, race or diabetes status across two RCTs, one in stable outpatients[217,218] and the other in patients with suspected ACS[204,245,246] (Table 40).

Table 40. Subgroup analyses for ICA

Trial name	Timing	Subgroup (N)	CCTA, % (n/N)	Functional testing, % (n/N)	Author reported effect estimate	Author reported interaction p-value
PROMISE trial (Stable outpatients)	Within 90 days of index test	With diabetes (N=NR)	15.1% (141/936)	10.2% (99/972)	Adj. OR 2.12 (95% CI 1.50 to 3.00)*	0.596
		Without diabetes (N=NR)	10.9% (388/3564)	7.6% (265/3494)	Adj. OR 1.90 (95% CI 1.56 to 2.33)*	
ROMICAT-II trial (Patients with suspected ACS)	Index Visit	With diabetes (N=NR)	19% (16/86)	6% (5/87)	NR	0.06
		Without diabetes (N=NR)	9% (38/415)	8% (31/412)	NR	
	28 day follow-up	With diabetes (N=NR)	20% (17/86)	7% (6/87)	NR	0.08
		Without diabetes (N=NR)	10% (42/415)	8% (34/412)	NR	
	Index Visit	Females (N=NR)	5% (12/239)	5% (12/229)	NR	0.15
		Males (N=NR)	16% (42/262)	9% (24/270)	NR	
	28 day follow-up	Females (N=NR)	5% (13/239)	5% (12/229)	NR	0.24
		Males (N=NR)	18% (46/262)	10% (28/270)	NR	
	Index Visit	White (N=NR)	13% (44/330)	9% (30/329)	NR	0.83
		Black (N=NR)	5% (7/141)	3% (4/140)	NR	
	28 day follow-up	White (N=NR)	15% (48/330)	10% (34/329)	NR	0.68
		Black (N=NR)	6% (8/141)	3% (4/140)	NR	

ACS = acute coronary syndrome; CCTA = coronary computed tomography angiography; CI = confidence interval; ICA = invasive coronary angiography; NR = not reported; OR = odds ratio.
* Adjusted model controls for noninvasive testing results (positive vs. negative), sex, and age.

6.1.4.6 Revascularization

Diabetes did not modify the effect of testing on revascularization across two RCTs, one in in stable outpatients[217,218] and the other in patients with suspected ACS[245,246]. NICE classification did not modify the testing effect on revascularization in stable outpatients[5] (Table 41). Similarly there was no modification by sex or diabetes status[245,246] or NICE angina classification for the use of PCI[5] or for NICE angina classification for CABG[5] (see Appendix O).

Table 41. Subgroup analyses for any revascularization

Trial name	Timing	Subgroup (N)	CCTA, % (n/N)	Comparator (n/N)	Author reported effect estimate	Author reported interaction p-value
PROMISE trial (Stable outpatients	Within 30 days of ICA	With diabetes (N=NR)	55.7% (78/140)	Any functional test: 38.0% (38/100)	Adj. OR 1.51 (95% CI 0.65 to 3.49)*	0.372
		Without diabetes (N=NR)	49.2% (191/388)	Any functional test: 38.7% (103/266)	Adj. OR 0.95 (95% CI 0.55 to 1.65)*	
ROMICAT-II trial (Suspected ACS)	28 day follow-up	With diabetes (N=NR)	8% (7/86)	Any functional test: 2% (2/87)	NR	0.26
		Without diabetes (N=NR)	6% (25/415)	Any functional test: 4% (18/412)	NR	
ROMICAT-II trial (Suspected ACS)	28 day follow-up	Females (N=NR)	3% (7/239)	Any functional test: 1% (2/229)	NR	0.33
		Males (N=NR)	10% (25/262)	Any functional test: 7% (18/270)	NR	
SCOT-HEART, 2018 (Stable outpatients)	Median 3.2 year follow-up	NICE classification of non-anginal chest pain	2.2% (16/712)	Exercise ECG: 1.0% (14/735)	RR 1.2 (95% CI 0.59 to 2.46)	0.938
		NICE classification of possible anginal chest pain	18.7% (220/1174)	Exercise ECG: 16.5% (170/1149)	RR 1.16 (95% CI 0.95 to 1.41)	

CCTA = coronary computed tomography angiography; CI = confidence interval; ECG = electrocardiography; ICA = invasive coronary angiography; NR = not reported; OR = odds ratio; SD = standard deviation.
* Adjusted model controls for noninvasive testing results (positive vs. negative), sex, and age

6.1.4.7 Medication use

The effect of testing on use of aspirin, statins, beta blockers or angiotensin-converting enzyme inhibitor/angiotensin receptor blockers was not modified by the presence of diabetes in one large trial in stable outpatients (Appendix O).

6.1.4.8 Administrative outcomes in patients with suspected ACS

One fair-quality RCT reported subanalyses for sex, diabetes status and race for administrative outcome. The effect of testing on these outcomes was not modified by diabetes status (Appendix O).

While sex did not appear to modify the testing effect on direct discharge from the emergency department at time of index testing or the composite of repeat ED visit or hospitalization within 28 days of index testing, sex may modify the testing effect for length of stay and hospital admission at the index visit. (Table 42). Race did not modify testing effect for any of the outcomes in the table below (see full tables in Appendix O), with the possible exception of repeat ED visit or hospitalization within 28 days of index testing, where the p-value for the interaction test was 0.049.

Table 42. Subgroup analyses for administrative outcomes

Trial name	Timing	Subgroup (N)	CCTA, % (n/N) or Mean (SD)	Any functional test, % (n/N) or Mean (SD)	Author reported effect estimate	Author reported interaction p-value
Direct ED discharge						
ROMICAT-II trial	Index Visit	Females (N=NR)	55% (132/239)	14% (33/229)	NR	0.22
		Males (N=NR)	41% (107/262)	12% (33/270)	NR	
Hospital length of stay (hours)						
ROMICAT-II trial	Index Visit	Females (N=NR)	17.0 (24.5)	30.7 (24.1)	NR	0.006
		Males (N=NR)	28.8 (44.7)	31.0 (30.9)	NR	
Hospital admission						
ROMICAT-II trial	Index Visit	Females (N=NR)	33% (14/239)	25% (57/229)	NR	0.005
		Males (N=NR)	29% (75/262)	26% (69/270)	NR	
		White (N=NR)	23% (75/330)	25% (82/329)	NR	0.31
		Black (N=NR)	18% (25/141)	26% (36/140)	NR	
Repeat ED visit or hospitalization for chest pain						
ROMICAT-II trial	28 day follow-up	Females (N=NR)	3% (6/239)	1% (2/229)	NR	0.11
		Males (N=NR)	3% (9/262)	6% (17/270)	NR	
		White (N=NR)	2% (8/330)	5% (16/329)	NR	0.049
		Black (N=NR)	4% (6/141)	1% (2/140)	NR	

ED = emergency department; NR = not reported; SD = standard deviation.

6.1.4.9 Safety

Two RCTs comparing CCTA with functional testing reported tests for interaction between subgroups for the outcome of radiation exposures (Table 43).

One large RCT in stable outpatients did not find that the effect of CCTA varied by age (<65 years vs. ≥65 years), sex, or BMI (<30 (<30 kg/m^2 vs. ≥30 kg/m^2), in patients for whom nuclear stress testing was intended at randomization. However, CTTA cumulative radiation may vary based on baseline heart rate. Patients with ≥75 bpm may have higher cumulative radiation with CCTA. In one RCT in patients with suspected ACS, radiation dose at index varied by sex as did mean cumulative radiation dose; doses were higher for men at each time period for CCTA. Mean cumulative radiation dose also varied diabetes status with patients with diabetes receiving higher doses with CCTA. The effect of CCTA on radiation dose did not vary by race.

Table 43. Subgroup analyses for radiation exposure

Trial name	Timing	Outcome	Subgroup	CCTA % (n/N) or Mean (SD)	Functional Test % (n/N) or Mean (SD)	Interaction p-value
PROMISE trial	≤90 days	Cumulative radiation effective dose among those patients intended for nuclear stress testing	<65 years	12.2 (8.1) (N=2178)	15.3 (6.9) (N=2159)	0.072
			≥65 years	12.6 (8.9) (N=968)	15.0 (6.7) (N=1044)	
			Male	13.7 (9.0) (N=1452)	160 (7.4) (N=1694)	0.82
			Female	11.2 (7.5) (N=1694)	14.6 (6.3) (N=1786)	
			Not Obese (<30 kg/m2)	11.1 (8.0) (N=1556)	14.9 (6.9) (N=1537)	0.10
			Obese (≥30 kg/m2)	13.6 (8.5) (N=1570)	15.5 (6.7) (N=1638)	
			Heart rate <75 bpm*	11.9 (8.4)	15.3 (6.9)	0.042
			Heart rate ≥75 bpm*	13.0 (8.3)	15.0 (6.6)	
ROMICATT-II	Index test only	Radiation Dose During the Index Visit	Female	10.8 (8.7)	4.7 (8.1)	0.003
			Male	14.2 (11.2)	4.7 (8.7)	
	28 days	Mean (SD) cumulative radiation dose (mSv)	Female	11.0 (8.9)	6.0 (8.2)	0.002
			Male	14.7 (12.0)	5.6 (10.7)	
			With diabetes	18.4 (14.7)	6.6 (10.4)	0.04
			Without diabetes	13.4 (9.8)	5.1 (9.5)	
			White	Median (IQR) 12.0 (7.9	Median (IQR) 0.0 (0.0 to	0.60

* Baseline resting heart rate was recorded at the enrollment physical examination.

6.1.5 Key Question 5: Cost-Effectiveness

Economic studies identified for inclusion primarily compared combinations of testing strategies involving CCTA, stress nuclear imaging (primarily SPECT), stress echocardiography, exercise ECG treadmill testing and invasive coronary angiography, with only few directly comparing one specific test to another. [redacted]. A total of three systematic reviews[243,249,263] and 11 primary studies were included. Eight of the studies (in nine publications) were in stable outpatients with suspected CAD,[8,26,27,91,116,123,136,147,162] and three were in patients with suspected ACS.[82,196,197] Of these, two studies in stable outpatients[123,162] and three studies in patients with suspected ACS were conducted in the United States.[82,196,197] Industry funding was noted and/or author ties to related industries were described in three studies.[82,123,162] Studies reporting changes in risk as the benefit to testing, those comparing different pharmacologic stressors or older versus newer technology were excluded. No full economic studies specific to stress PET imaging were identified.

Full economic studies of diagnostic testing are complex, challenging to perform and challenging to interpret. A variety of assumptions and estimates from diverse sources (which may vary in quality) provide input into any economic model and impact the results of that model. There are a number of additional factors that need to be considered in modeling of the cost-effectiveness of diagnostic testing.[68,131,179,203] Such factors include: the disease prevalence in the population, the pre-test likelihood of disease and spectrum of disease in patients included in the testing strategy (and model estimates), the diagnostic accuracy of index tests, the role of indeterminate tests and follow-up of false positives, consideration of the role of a given test (e.g., as a triage test, add-on test), whether tests are sequential (in what sequence and what is the impact of this on accuracy), the clinical decision-making leading to additional testing or treatment based on test results, treatment options and their impact on patient outcomes. Diagnostic testing's impact on patient clinical outcomes (e.g., MI) is **indirect.** Such outcomes are impacted by the clinical decisions made about treatment(s) and the effectiveness of the treatments. The estimates of treatment provision, adherence and success may be challenging to model and impact the results of any model.

For the diagnosis of CAD specific factors related to the above should be considered when putting the results of cost-effectiveness studies for non-invasive imaging for CAD into context. First, there are multiple scenarios and options for non-invasive testing including index tests, follow-up testing and the sequence of testing in both clinical practice and as recommended by ACC/AHA clinical guidelines. Thus, modeling of a given sequence or pathway may or may not be generalizable to different settings and accuracy of testing in sequential testing may be different from stand-alone testing. A proportion of all non-invasive imaging tests, particularly in low-risk patient populations will be false positives and a proportion of tests will be indeterminant; both situations may require additional testing. Similarly, some tests, particularly CCTA may reveal incidental findings that may or may not require follow-up. The impact of the above on both cost and effectiveness was generally not modeled. The historic "gold standard" for evaluating accuracy of cardiac diagnostic testing has been ICA, however, as described elsewhere, its accuracy is not 100% as assumed in the models. In addition, CCTA as an anatomic test may show better accuracy than functional tests as ICA alone does not provide functional information. As noted in the background, an observation of vessel obstruction does not always correspond to either symptoms or diminished function. Some tests are operator-dependent and/or require special expertise for performance and/or interpretation. This is difficult to model. Finally, various assumptions regarding the effectiveness of treatment were employed across models.

Summary of results:

Most economic models described in the systematic reviews and the primary studies compared testing strategies (i.e., different scenarios for index test and subsequent sequential tests) not individual tests, making it difficult to draw definitive conclusions for specific tests. The results below attempt to focus on findings for specific tests. Variation across studies in data sources, estimation of model parameters, clinical pathways for test sequencing and decision making leading to additional testing and/or treatment make comparison across studies challenging. Evidence was mixed for demonstrating a definitive cost-effective diagnostic approach.

- Results across studies (including systematic reviews) were somewhat mixed.
- Cost-effectiveness and ICERs varied based on testing sequencing, pre-test likelihood of CAD, assumed accuracy of tests across populations. These key drivers were also identified in the prior HTAs.
- In stable outpatients with suspected CAD
    - The U.S. studies generally found CCTA to be the dominant initial testing strategy against comparators/other strategies, which included ICA and functional tests. FFRct in addition to CCTA was consider cost-effective in one industry-funded study.
    - Stress echocardiography and SPECT were found to be cost-effective compared to ICA.
    - Two systematic reviews suggest that stress echo or nuclear stress testing may be more cost-effective than comparators in some settings depending on patient prior probability of CAD and prevalence of CAD. Stress echo may be more cost-effective than SPECT in patients with low to intermediate probability.
- In patients presenting with suspected ACS in an emergency setting

  - CCTA was compared with standard of care (variably defined), ETT, expert consensus based on ACC/AHA guidelines and "do nothing" strategies. CCTA was the dominant or cost-effective approach in most all comparisons.
  - In one poor-quality review of seven studies in patients with acute chest pain. Stress nuclear testing was cost-effective versus traditional strategies involving ECG. However, authors note that stress nuclear testing in the acute setting may not often used in 'real life', due to logistical challenges.
- Common limitations across studies include
  - The assumption that ICA has 100% sensitivity and specificity.
  - Extrapolation of data to lifetime time horizon particularly when RCT data is only available for approximately 2 years for many of the studies. Results from short-term time horizons may differ from those seen at longer term.
  - Lack of or insufficient modeling of indeterminate tests, false positive and false negative results, accuracy based on sequencing of tests, potential adverse events and incidental findings.
  - Some modeled strategies (e.g., some "do nothing" strategies) may not be consistent with clinical practice. Modeling of appropriate "no test" strategies was not done.
  - Models assume the availability of all tests and competence in performing and interpreting them across clinical settings.
  - Lack of information on the potential impact of radiation exposure for index and downstream testing.

Detailed results

6.1.5.1 Outpatients with Stable Chest Pain

The cost-effectiveness of using coronary CT angiography (CCTA), stress nuclear imaging and stress echocardiography (ECHO) for the diagnosis of CAD was considered. A total of three systematic reviews[243,249,263] and eight primary economic studies (in nine publications) met the inclusion criteria.[8,26,27,91,116,123,136,147,162]

Evidence was mixed for demonstrating a definitive cost-effective diagnostic approach; however, multiple studies report common findings and indications for cost-effective alternatives while also delineating areas for further research. Table 44 provides an overview of primary findings.

Eight studies of patients with stable chest pain that analyzed the cost-effectiveness of CCTA, ECHO and SPECT against various comparators (including ICA, ETT and "no imaging") met the inclusion criteria.[8,26,27,91,116,123,136,147,162] The Quality of Health Economic Studies (QHES) instrument was used to systematically assess the quality of each study. Scores ranged from 50 to 94 out of 100. Data for clinical parameters based on government funded clinical studies in some reports. The funding support from government agencies was reported for some studies or in two cases was not reported.[91,116] Of the

remaining six, three appear to have had at least partial industry funding and/or author ties to industry.[82,123,162]

Generally, six of the seven studies that investigated CCTA reported it to be a cost-effective, if not the dominant strategy, against various comparators including ETT and ICA.[8,26,27,123,136,147,162] Of the four studies that reported results for stress ECHO versus ETT or ICA,[26,27,116,147,162] three studies indicated that stress ECHO was the cost-effective approach.[26,27,147,162] In each case, for both the CTTA and ECHO comparisons, the contradicting results came from the same study and that study notably had the lowest QHES score. In general, when SPECT was compared with ICA it was found to be cost-effective, however, CCTA tended to be the preferred alternative. Beyond the base-case results, the primary drivers of cost-effectiveness were the pretest likelihood of CAD, test accuracy and how post-test care was defined. Administering more aggressive post-test care also tended to decrease a test's cost-effectiveness. Detailed data abstraction is found in Appendix K.

Many of the primary studies reviewed drew attention to the large number of influential variables and the intricacy of modeling the cost-effectiveness of diagnostic testing. Consequently, the optimal strategy remained difficult to define. There were several notable limitations that further complicated a conclusive strategy. A high level of variability within studies, as well as between studies, led to uncertainty, which often failed to be thoroughly analyzed in a comprehensive sensitivity analysis. The majority of studies used a model based on a "payer" perspective rather than a more complete societal perspective. A common assumption made to facilitate the analysis was to grant ICA 100% sensitivity and that all positive diagnostic tests resulted in ICA. Studies generally did not consider modeling the impact of indeterminate tests or follow-up of false positive results. Furthermore, some studies had short time horizons or were underpowered to detect significant results. Given that the majority of the studies reviewed were performed outside the United States, the implementation of testing, care provided and relative costs were prone to variability.

Systematic reviews

Three systematic reviews investigated the cost-effectiveness of diagnostic testing for CAD.[243,249,263] Two of the reviews were very poor quality and were narrative in nature.[243,263] They will be only briefly described. The findings of which were consistent with the majority of individual, primary studies reviewed.

The most comprehensive systematic review by van Waardhuizen et al. 2016 included 70 economic studies published between January 1995 to December 2015 (20 years).[249] Confidence in this review was considered moderate based AMSTAR-2 appraisal. Some studies in this review were published prior to the previous HTAs and assumed to have been considered in them. Thirteen studies from our search were included in this SR and will not be described individually. They are listed in Appendix K with the data abstraction. Authors critically appraise included articles; 54% were considered to be at high or moderate risk of bias. Heterogeneity prevented the authors from completing a quantitative meta-analysis. Overall, in patients with low to intermediate prior probability, the optimal diagnostic imaging strategy from a cost-effectiveness perspective was not definitive. However, collectively the studies

revealed several patterns that led the reviewers to conclude that CCTA may be the best as an initial "gatekeeper" test for patients with stable chest pain and low-to-intermediate likelihood of CAD. van Waardhuizen et al. further went on to suggest that ECHO or SPECT to be cost-effective strategies if functional testing is needed in patients with an intermediate prior probability of CAD. When compared directly, ECHO was considered cost-effective versus SPECT in patients with low to intermediate probability. An in-depth assessment of the sensitivity analyses carried out in the 70 studies reviewed highlighted the primary factors determining the cost-effectiveness of the tests. The most common influencing factor was the prior probability of CAD. Of the 51 sensitivity analyses, 26 of them indicated the prior probability of CAD as the most important influence. Testing sensitivity was the next most frequent factor followed by the cost of the diagnostic test, particularly the cost of CCTA testing. In addition to identifying the drivers of cost-effectiveness, the reviewers also noted that many of the studies exhibited similar limitations, which also appeared in the individual studies reviewed here. The main limitation was the heterogeneity of the studies, the range of assumptions and variability of input parameters of the models. Next, the diversity of the country of origin of the studies often made direct comparisons unfeasible (only 13 of the 70 were performed in the U.S. or Canada). Furthermore, the perspectives (healthcare payer or healthcare provider) of many of the analyses were too limited in scope to make fully informed decisions. Short-term time horizons and not reporting the willingness-to-pay threshold were other common limitations.

Another poor-quality systematic review by Zeb et al 2014 looked at the cost-effectiveness of only CCTA and included 42 articles with the goal of assessing CCTA as a "gatekeeper" to ICA.[263] Although authors report a systematic approach to searching for economic studies, inclusion/exclusion criteria were vague, and neither a full list of included studies nor a list of excluded studies with rationale was provided. The narrative description of selected studies and summary tables do not account for all 42 articles. No critical appraisal of individual studies was done and limited data on cost-effectiveness parameters (e.g. ICERs) were provided. Confidence in this review was considered critically low based on AMSTAR-2 appraisal. It is not clear that all studies were full economic studies. Of the 42 articles, 20 looked at CE of CCTA and subsequent downstream testing in stable chest pain patients, 18 articles in patients with acute chest pain presenting to ED and 4 at the cost-effectiveness of CACS as an initial test. The authors found the optimal strategy was dependent on CAD prevalence. CCTA was cost-effective when CAD prevalence was assumed to be between 10% to 50%. When CAD prevalence exceeded 70% ICA was cost-effective.

A third poor-quality review focused on evaluation cost-effectiveness of nuclear stress testing in both patients with stable chest pain, described below and patients presenting with acute chest pain which are discussed with the primary studies for this population.[243] Although authors report using a systematic approach to searching for economic studies, many components of the systematic review were not described, and critical appraisal of individual studies was not done. It was more narrative in nature. A total of 57 studies were reportedly included, however formal lists of included and exclude studies were not provided. Confidence in this review was considered critically low based on AMSTAR-2 appraisal. This is the only review to focus on cost-effectiveness of nuclear stress testing (MPI with SPECT or PET). The review reports findings for three comparisons with MPS in patients with stable chest pain; ETT, ICA and other noninvasive tests. When comparing MPS versus ETT the review assessed 25 studies and found MPS to be more cost-effective than ETT in patients with intermediate likelihood of CAD. The review

included one study that compared initial MPS with selective ICA and direct ICA. MPS reduced the number of ICA by 30% to 41%. MPS was cheaper and equally effective when compared with strategies not using MPS. Lastly, the authors compared MPS with other noninvasive tests. 16 complete studies were included along with four ongoing studies. The results of the cost-effectiveness of MPS over other non-invasive tests, such as CTCA, stress echocardiography, PET, and CMR were conflicting and inconclusive. In patients with suspected stable CAD, ETT was found to be cost-effective as a first line test in patients with low likelihood. However, at higher pretest likelihoods, non-invasive imaging including MPS is more cost-effective than ETT due it its increased accuracy. Overall, MPS was a cost-effective gatekeeper to ICA.

Individual primary studies published subsequent to prior reports and systematic reviews

The individual, primary cost-effectiveness studies, not already included in the systematic reviews, had comparable findings. Two high-quality studies based in the United States were identified. Because of their more direct relevance to this HTA, they will form the focus of the results below. Additional data from these studies and studies outside of the U.S. are found in Appendix K. A summary of the primary findings for all studies in Table 44.

US-Based Studies

Two high-quality studies based in the United States published subsequent to the van Waardhuizen 2016 review are described below.[123,162]

Karady et al. 2020[123]

Overview and Design:

A high-quality study of low-risk, stable chest pain patients that compared CCTA and CCTA combined with CT-derived FFR (FFRct) with functional tests, primarily SPECT as initial tests for diagnosis of CAD A Markov decision-analytic model was populated based on observed outcomes from the PROMISE trial was used as a primary source to simulate changes in health states over time. PROMISE data were combined with assumptions from clinical guidelines, registry data and other sources regarding referral for ICA and treatment options (e.g., medication, PCI) as well as the progression of obstructive and nonobstructive CAD. Data were collected at 6 months and 2 years and costs for testing and subsequent procedures, including ICA with or without revascularization, were recorded. ICERs were calculated for a lifetime time horizon with costs discounted at a rate of 3% to 2014 USD. A societal perspective was stated, however data on indirect costs and other factors usually considered in such analyses were not described; only cost of care appears to have been delineated. Pre-planned subgroup analyses were done based on age and sex. Sensitivity analyses included a probabilistic sensitivity analysis as well as a number of one-way sensitivity analyses ranging from gender to adherence to statin therapy. Authors considered adherence to medical therapy in their modeling. Authors validated their model by comparing it to outcomes as reported in the PROMISE trial through its 2-year follow-up. This economic study was industry-funded (HeartFlow) and multiple authors report relationships with industries related to this study. The PROMISE trial was government-funded. The study scored 90/100 using the QHES.

Key Assumptions:

A mean 53.3% pretest likelihood of CAD was incorporated into the model with an average patient age of 60-years-old; 52.7% of the patients were female and 77.7% white. Diagnostic sensitivity of ETT, CCTA and SPECT were 45-50%, 95-99% and 63-87% respectively while specificity was 85-90%, 64-83% and 63-87% respectively. 25.3% of the sample population had a CAD risk equivalent and 67.6% of patients had a 10-year risk of events of at least 7.5%. FFRct was reportedly done in 31.4% of patients who had 30% to 69% stenosis on CCTA. Models assumed that CCTA and CCTA with FFRct led to more effective selection of patients for ICA and that higher costs for CCTA with FFRct were offset by lower rates of ICA and revascularization compared with CCTA alone.

Results:

[redacted]

[redacted]. Modeling over a patient's lifetime a total of 6 months of good health were gained. The models in this cost-utility analysis for CCTA and functional strategies differ in the proportion of patients requiring additional downstream testing. Meta-analyses across RCTs in this HTA suggest that referral for ICA was associated with CCTA and an initial test but that there were no differences in the use of additional non-invasive testing between CCTA and functional testing strategies.

Driving these improved outcomes was the assumed overall better diagnostic accuracy for obstructive and nonobstructive CAD, which led to greater statin use for those in the anatomic group versus the function group 85.4% and 67.0% respectively. CCTA continued to be cost-effective in both women and men as well as in both older and younger patients [redacted]. CCTA FFRct combined with CCTA was cost-effective in men [redacted] and dominant for all other subgroups explored.

Authors also report sensitivity analysis involving a "do nothing" strategy in which only medical therapy is provided based on their risk-factor profile. As one would expect, the "do nothing" strategy had the lowest costs associated with it and also yielded the fewest quality adjusted life years when compared

with the other strategies. [redacted].

Limitations:

Assumptions regarding diagnostic accuracy were an essential element to the model results, however, uncertainty surrounding these assumptions was a limitation for this study. Furthermore, the authors note gaps in how major adverse cardiovascular events were accounted for and the extent of the effects of medical therapy. Author's objective was to model the cost-effectiveness of patients at low risk of CAD. The population modeled had a substantial cardiovascular risk factor burden and estimated pre-test likelihood of obstructive CAD of 53.3%; it is unclear if results may apply to patients with lower pre-test risk. Modeling of the CCTA strategy appears to assume that only SPECT is used for additional testing in patients with a moderate abnormality on CTTA. Given that costs for stress echocardiography may be less than for SPECT, the impact of modeling of stress echocardiography (and or ETT) may be important to consider. Currently, FFRct is not routinely performed and requires special analysis methods based on CT data. Its role, accuracy and value do not appear to be widely established yet and high-quality evidence of impact on clinical outcomes is sparse.[100] Another potential bias exists when comparing CCTA plus FFRct as some patients were unable to receive FFRct causing a potential imbalance in baseline characteristics across the two groups. Two years of results from the PROMISE trial were available; the model extrapolates to a lifetime. Lastly, the grouping of various functional tests and presentation of results made it difficult to make direct comparisons between specific tests.

Min et al. 2017[162]

Overview and Design:

A well-conducted, but complex study of stable CP patients that explored twelve testing pathways and reported results assuming multiple levels of CAD prevalence. CCTA, ECHO and stress nuclear testing (MPS) were measured against ETT and ICA (among other comparisons). Primary sources for clinical components were from published literature. For modeling treatment, data based on the COURAGE and SYNTAX RCTs were used. The study partially funded by industry, a cardiac imaging institute and reports on data from government-funded research. The lead author reports receiving support from industry. Sensitivity analyses include varying pretest likelihoods from 20% to 50% and to 80% as well as varying post-test treatment plans. A Markov model was used to estimate the costs and assess each test's impact on patients' quality of life from a payer's perspective. The time horizon of the model was over a patient's lifetime. All costs were discounted at a rate of 3%, however, the costing year was not reported. Incremental cost-effectiveness ratios were the primary cost-effectiveness outcome measure. The study scored a 94/100 using the QHES. Funding for this economic study is somewhat unclear; clinical data appear to come from government funding sources. Other funding listed includes the Dalio Institute of Cardiovascular Imaging and an unrestricted educational grant from GE.

Key Assumptions:

The study population consisted of patients of intermediate risk but no prior CAD. A hypothetical cohort of 55-year-old males was considered in the model. The diagnostic sensitivity of ETT, CCTA and ECHO were modeled as 68.0%, 93.7% and 86.7% respectively and specificity ranged from 77% to 84%. Authors provide thresholds for test positivity and categorization of disease. ETT was assumed to be indeterminate 62% of the time while CCTA and ECHO were assumed to be indeterminate in 7% of the tests and depending on the strategy, were referred for either additional downstream non-invasive testing or ICA. All positive test results from noninvasive tests were referred for ICA.

Results:

While the authors found that overall, in patients without known CAD presenting with stable chest pain, a sequence of imaging tests to be the most cost-effective (ETT, followed by ECHO, followed by ICA), [redacted]

This study also investigated the role of varying post-test care as part of the cost-effectiveness modeling. Given the long-term time horizon, slight variability in assumptions regarding the type of care showed a significant impact on both costs and effectiveness. Min et al. report that the cost-effectiveness of each test depends largely on patient characteristics and how treatment approaches are tailored to patient care based upon test findings. Therefore, in addition to the base-case analysis, they also report results for "conservative" post-test care (defined as medical therapy alone for patients with 1–2 vessel CAD and PCI for all patients with 3-vessel or left main CAD) and "aggressive" post-test care (using PCI for all patients with 1–2 vessel CAD and coronary artery bypass surgery for all patients with 3-vessel CAD). When comparing CCTA versus ICA, CCTA changes from being the dominant strategy in conservative cases to ICA being cost-effective [redacted] when more aggressive treatments are employed. Varying post-test treatment approach showed cost-effectiveness contingent on follow-up care post-test. The authors discuss how this serves to underscore the complexity of evaluating the cost-effectiveness of diagnostic testing.

Limitations:

A potential limitation of this study was that all positive diagnostic tests resulted in ICA, which was assumed to have perfect sensitivity and specificity. The impact of false-positive tests was not modeled. It

appears that positive tests at any stage were referred to ICA, including false positives. Authors left some ambiguity surrounds how patients transition between health states within the model. Limited data for some sensitivity analyses were described. PET was not considered in any testing strategy. It remains unclear how reliably or appropriately the sources used for the model inputs can be extended over the course of the model's lifetime time horizon. Additionally, the sensitivity analysis was limited in scope and did not fully explore potential biases or discuss in detail its own potential limitations.

Studies based outside of the U.S.

In addition to the two studies conducted in the United States six international studies not included in the van Waardhuizen systematic review were identified. Three of these were based in Europe and the remainder was comprised of a diverse geographic, socio-economic range from South Korea, Brazil and Iran. Given the differences in healthcare systems between the US and other countries, these studies will only be briefly summarized. Additional detail is found in Appendix K.

Agus et al. 2016[8]

A study conducted alongside an RCT in Northern Ireland and it investigated the cost-effectiveness of CCTA vs ETT. (QHES 64) CCTA was found to be the dominant strategy for patients when a pretest likelihood of less than 30% was assumed. [redacted].

The interpretation of the final results was made difficult because the baseline characteristics across groups were different. Notably, there was imbalanced CAD prevalence across groups, which has been seen as a driving factor for cost-effectiveness in the other studies. Missing data was also an issue when building the model and determining the input parameters. Beyond that, the outcome assessment was not fully blinded from investigators. Also, the sample population excluded BMI greater than 35% and included a low number of diabetic patients. Therefore, it may not be a representative sample. Lastly, the study had a relatively short follow-up time and may not have allowed for all costs and outcomes to occur.

Gurunathan et al 2018[91]

This study was also conducted along with a RCT. It was a relatively poor-quality study (QHES 50/100) carried out in the UK, evaluated the predictive value and costs of stress ECHO and ETT. Its measure of cost-effectiveness was a simple sum of costs and a comparison of the positive predictive value of each test. Authors found ECHO to have a 20% reduction in cost and less downstream testing, hospital visits. ETT yielded a 64% positive predictive value in determining a flow-limiting disease on angiography. Meanwhile, ECHO achieved 100% positive predictions. The cost of ECHO and ETT were £631 and £796 respectively.

A significant limitation from the outset for this study was that it was underpowered to detect most clinical outcomes. It also used an overly simplistic analytic model in which it did not validate or pursue any subgroup or sensitivity analyses.

Lorenzoni et al. 2019[147]

A moderately well-conducted (QHES 84/100) Italian study evaluated several testing strategies. [redacted]. ECHO and SPECT approaches were both found to be a less expensive alternative but yielded fewer correct diagnoses.

Heterogeneity in data relating to sourcing from multiple countries with variation in practices and costs was an issue in this study. It also unrealistically assumed that anyone not receiving ICA was a true negative test result. Adding to that, authors also assumed perfect accuracy of ICA.

Bertoldi et al. 2016/2017[26,27]

A Brazilian study where CCTA appeared to be a cost-effective approach for CAD in this well-conducted study (QHES 94/100). [redacted] SPECT testing strategies were dominated by the other test options. Additionally, sensitivity analysis showed that procedural costs and test sensitivity were significant factors in determining cost-effectiveness.

Many of the potential comparisons were not reported. Furthermore, the authors assumed ICA to have 100% sensitivity and specificity.

Lee et al. 2015[136]

A moderately well-designed study (QHES 77/100) conducted in South Korea that explored the diagnostic accuracy of CCTA and SPECT followed by a brief cost-utility analysis. Its measure of cost-effectiveness was a cost per correct diagnosis. CCTA was shown to be the more accurate, effective and less expensive alternative in the majority of cases. Therefore, CCTA dominated SPECT. For every 1000 patients, CCTA accurately diagnosed 835 while SPECT accurately diagnosed 779 patients. Subgroup analysis by pretest likelihood showed SPECT to perform slightly better with lower pretest probability but CCTA remained cost-effective with the most accepted willingness to pay thresholds.

The baseline characteristics of groups were different, which causes results difficult to interpret. For instance, the SPECT group had significantly older and had a higher pretest likelihood probability. There were also issues with procedural implementation. The CCTA data derived from 2006 when techniques may not have been as developed in Korea.

Jafari et al. 2020[116]

A relatively poorly conducted study (QHES 62/100) conducted in Iran compared several testing options including CCTA, ECHO and SPECT against ETT and ICA among others. It reported its results against a strategy using a combination of tests (that it had found to be optimal). Results reported here are individual testing strategies with stand-alone ETT and ICA testing. The cost-effectiveness measure reported was the cost per diagnosis. In general, it found ETT and ICA to perform better than CCTA and ECHO. [redacted]

[redacted].

The cost data used in this study seems difficult to reconcile to a US setting. Furthermore, there was poor description of patient characteristics with no reporting of demographic information or CAD pretest likelihood. It was also assumed ICA 100% sensitive. Lastly, given the uncertainty involved in the results the sensitivity analysis was very limited.

Table 44. Overview of reported cost-effectiveness (CE) stratified by pretest likelihood, stable CP, assuming a willingness-to-pay WTP of $100,000

Pretest Risk %	Origin	CCTA	ECHO	SPECT
<30%	USA	Min 2017 CCTA dominates ICA	Min 2017 ECHO is CE vs ICA	Min 2017 MPS is CE vs ICA
	Foreign	Lorenzoni 2019 CCTA dominates "no imaging" Bertoldi 2017 CCTA $1420/diagnosis vs ETT Jafari 2020 ETT dominates CCTA Lee 2015 CCTA dominates SPECT	Lorenzoni 2019 ECHO costs €3316/diagnosis vs. "no imaging" Bertoldi 2017 ETT dominates ECHO Jafari 2020 ETT dominates ECHO	Lorenzoni 2019 SPECT costs €2111/diagnosis vs. "no imaging" Bertoldi 2017 CCTA, ECHO dominated SPECT Jafari 2020 SPECT costs $46.74/ diagnosis relative to ETT SPECT costs $11.51/diagnosis relative to ICA
30-60%	USA	Min 2017 CCTA is CE vs ICA Karady 2020 CCTA costs additional [redacted] vs. functional tests	Min 2017 ECHO is CE vs. ICA	Min 2017 MPS is CE vs. ICA

Pretest Risk %	Origin	CCTA	ECHO	SPECT
	Foreign	Agus 2016 CCTA dominates ETT Bertoldi 2017 CCTA costs [redacted] vs. ETT	Gurunathan 2018 ECHO dominates ETT Bertoldi 2017 ECHO [redacted] vs. ETT	Bertoldi 2017 CCTA, ECHO dominated SPECT Lee 2015 SPECT costs additional [redacted] vs. CCTA
>60%	**USA**	Min 2017 CCTA is CE vs. ICA	Min 2017 ECHO is CE vs. ICA	Min 2017 MPS is CE vs. ICA
	Foreign	Bertoldi 2017 CCTA $790/diagnosis vs ETT Lee 2015 CCTA dominates SPECT	Bertoldi 2017 ECHO costs $890/diagnosis vs. ETT	Bertoldi 2017 CCTA, ECHO dominated SPECT

CCTA = coronary computed tomography angiography; CE = cost-effective; ECHO = stress echocardiography; ETT = exercise treadmill test; ICA = invasive coronary angiography; MPS = myocardial perfusions scan; [redacted]; SPECT = single photon emission computed tomography.

6.1.5.2 Patients with suspected ACS (Acute Chest Pain)

One poor-quality review[243] and three US-based economic studies[82,196,197] evaluated the cost-effectiveness of various imaging strategies in patients with suspected ACS or acute chest pain presenting to an emergency department or observational unit.

One systematic review focused on evaluating the cost-effectiveness of nuclear stress testing in both stable chest pain, (described above) and patients presenting with acute chest pain which are discussed here.[243] Authors report that MPI was evaluated in 7 studies of patients with acute chest pain. The review found that MPS was cost-effective when compared with traditional strategies involving ECG. However, authors note that MPS in the acute setting is not very often used in 'real life', due to logistical challenges.

Primary studies published subsequent to prior reports and systematic reviews

Three primary economic studies evaluated testing strategies for patients in emergency departments or observatory units were include and are described below.[82,196,197] Their QHES scores ranged from 69 to 90 out of 100. Table 45 provides an overview of primary findings.

Goehler 2020[82]

Overview and Design:

A study using a well-constructed model of short, intermediate and long-term cost-effectiveness carried out in the United States. CCTA performance was analyzed against three strategies: standard of care, expert consensus following AHA/ACD guidelines and expedited ED discharge with further testing done in an outpatient setting. A Markov model was used to model the cost-effectiveness of the interventions over time. The hypothetical cohort was designed drawing primarily from finding of the ROMICAT II trial, which was subsequently validated using the same trial. Utility values for various chest discomfort classifications were derived from published literature. Initial cost data came from a micro-costing assessment at each ROMICAT-II clinical site while outpatient costs were based on Medicare reimbursements. Long-term cost approximations came from RedBook. Authors assessed outcomes at 28 days, 1 year, 3 years, 10 years and overall lifetime of patients. [redacted] Though not explicitly stated, the perspective assumed was most consistent with a payer's perspective. Costs were discounted at a rate of 3%, however, the costing year was not clearly stated. The trial data used to for the model's parameters ended in 2012 USD. Funding came from grants provided by National Heart, Lung, and Blood Institute, National Institute of Health and the American Heart Association, however, authors also report ties with related industry (imaging companies). Sensitivity analyses looked at varying medical compliance over time and tested the confidence interval bounds of relative risks across interventions. Testing diagnostic sensitivity and specificity were also varied and ICERs recalculated. The study scored 90/100 using the QHES.

Key Assumptions:

A population of emergency department patients with suspected ACS was considered with a mean age of 54.2 years and 53% male. Patients comprised of low-intermediate risk of ACS having an average of 7.5% prevalence of ACS. Diagnostic sensitivity ranged from 85% to 100% while the specificity varied from 50% to 100%. Baseline characteristics of the hypothetical cohort assumed 50.7% of patients had no CAD, 43.0% of patients had non-obstructive CAD and 6.3 presented obstructed CAD.

Results:

Short-term results found CCTA to be both more costly and required more revascularization procedures than all other comparators. Notably, revascularization rates for CCTA were 5.2% versus 2.6 to 3.7% for other strategies. However, in the long-term model, CCTA became cost-effective. Lower mortality (5.06% for CCTA versus 5.21% to 5.36% for other strategies after 10 years) led CCTA to dominate standard of care and ACC/AHA guidelines [redacted] when compared with expedited ED discharge. CCTA was the most effective at identifying obstructive CAD (98% accurate), followed by

expert consensus (75%) and standard of care (69%). Expedited discharged was only 46% accurate at identifying obstructive CAD. Initial costs found CCTA was the most expensive at $2,692. Standard of care costed $2,535, expert consensus following AHA/ACD Guidelines costed $2,501 while expedited ED discharge was the least costly at $1,891. [redacted].

[redacted].

Limitations:

While overall well conducted, there were some limitations. Pretest likelihood of CAD is often a major determining factor to a test's cost-effectiveness. The authors did not incorporate that key aspect. Also not included in the model were repeated visits to the emergency department or the cost of litigation for missed detection of CAD. Additionally, some model input parameters were sourced from older studies which may not reflect current healthcare settings. With regards to presenting the results some useful information was not included such as what scope of the perspective assumed and the costing year that estimates were discounted to.

Powell et al. 2012[196]

Overview and Design:

A moderately well-conducted study comparing CCTA, standard of care and "do nothing" strategies in an observation unit setting. A decision-analytic model was used. The patient population and the strategies' characteristics were derived from data obtained from published literature and from a retrospective cohort review. The time horizon of the model was not made clear. The costing data was reported in 2009 USD and discounted using the Consumer Price Index. [redacted] The source study's funding was not reported. The study scored 69/100.

Key Assumptions:

The study considered patients in an observation unit for the evaluation of low-risk chest pain. Patients were found to have either indeterminate or positive-stress test results. The mean age was 50-year-old and 54% were male. The assumed sensitivity of CCTA 98.9% while the specificity for CCTA was 84%. Given an abnormal stress test result, the probability of that the patient has no CAD was assumed to be 69.5%. The probability of an indeterminate CCTA test was 3.8%.

Results:

Authors found CCTA to have similar effectiveness as the standard of care while being approximately 20% less expensive. The "do nothing" approach was the cheapest, however, also the least effective. [redacted] The marginal cost-effectiveness of standard-of-care as compared with CTCA was $352,651. (CCTA cheaper but marginally less effective).

[redacted]

The standard of care strategy becomes preferable only at extremely high willingness to pay thresholds because it has a slight effectiveness advantage. The do-nothing strategy was preferable at only a very low WTP ($8,306).

Limitations:

The "do-nothing strategy" in which all patients were discharged home after positive- or indeterminate-stress tests without further testing analyzed in this study is likely an unrealistic scenario and does not provide a very valuable comparison. Furthermore, like many other studies, the authors here assumed that ICA 100% sensitive, which also may not be a realistic assumption. It is not entirely clear which costs the authors included in the analysis. They do note that the study does not consider startup costs of a CCTA or additional ED revisits. Additionally, the time horizon of the study is not reported, which potentially has significant implications for interpreting the results. Lastly, given the complexity of the model and degree of uncertainty the scope of the sensitivity analysis was limited.

Priest et al. 2011[197]

Overview and Design:

A fairly well-designed cost-effectiveness study that investigated several testing options in and emergency department including a strategy of doing an initial CCTA followed by confirmatory SPECT for indeterminate CCTA results, CCTA alone, stress ECHO, stress SPECT and ETT. A decision model was implemented with a 12-month time horizon. Estimates were discounted using the Consumer Price Index to 2010 USD. Sensitivity analyses were conducted to compare the differences in the type of stress-based test used (specifically in terms of diagnostic accuracy) and also explore the effect that the rate of incidence of adverse events as well as the costs associated with each test. A payer's perspective was assumed for costs. The study was funded by the National Health and Medical Research Council The study scored 75/100 using the QHES.

Key Assumptions:

Several testing strategies were compared in an emergency department setting with patients having a CAD prevalence of 2–30%. Published literature and a meta-analysis were used to build the model. The sensitivity and specificity of CCTA 2were assumed to be 100% and 80% respectively. The sensitivity and specificity of ETT were assumed to be 67% and 72% respectively. For both ECHO and SPECT, the

estimates varied by to the stress was induced. For stress ECHO, the sensitivity ranged from 72% to 83% while its specificity ranged from 84% to 95%. For stress SPECT, the sensitivity ranged from 84% to 91% while its specificity ranged from 69% to 81%. The procedural costs for ETT, SPEC, ECHO and CCTA were $144, $461, $290, and $374 respectively.

Results:

CCTA with "confirmatory SPECT" was considered the most cost-effective strategy at all prevalence thresholds investigated compared with all other strategies explored. The CCTA with SPECT strategy also had the lowest average cost per patient diagnosed based on the evaluation of diagnostic accuracy. Using the results reported it was possible to compare CCTA, ECHO and SPECT against ETT. ETT was consistently dominated by all three alternative tests at varying levels of CAD prevalence. As the prevalence increase, however, the dominance be narrower. The total 12-month costs with a 5% prevalence of CAD for ETT, SPECT, ECHO, CCTA and CCTA the SPECT were $10,430, $10,799, $7,539, $4,862 and $3,464 respectively. [redacted].

Limitations:

A major limitation found in this study is the short follow-up time. Goehler et al found the comparison of tests' cost-effectiveness to be reversed from the short-term follow-up to the longer-term follow-up. Beyond the insufficient time horizon, when compared to other studies on the topic the model presented is relatively simple and authors indicate a lack of available data to specify the parameters necessary for a more complex model. Specifically, revisits to the emergency department and other complications were not considered. The model also does not include the likely benefits of revascularization or distinguish between varying levels of stenosis. Lastly, as with many other studies, the potential risks and costs associated with radiation exposure from CCTA and SPECT were not factored into the analysis.

Table 45. Overview of reported cost-effectiveness (CE) stratified by pretest likelihood, Acute/ED patients, assuming a willingness-to-pay WTP of $100,000

6.2 CCTA versus ICA

Two randomized control trials compared CCTA with ICA in patients with suspected CAD (N=1,951). (See Appendix F for details.) One trial was conducted exclusively in the outpatient setting[36] and in the other trial,[52] 43% of patients were treated in the outpatient setting and 57% in the inpatient setting. One trial[36] used a 64-slice CT scanner for CCTA imaging and the other trial[52] did not report on this information. Both trials used iodinated contrast agents. One trial included CACS imaging as part of their CCTA protocol.[52]

In both trials, the mean patient age was 60 years and the proportion of females ranged from 44% to 49%. In the one trial reporting race, 87% of patients identified as non-white. Both trials excluded patients with prior MIs and/or revascularizations. One trial excluded patients with known CAD,[36] and in the other trial,[52] 6% of patients had known CAD. In one trial,[52] 100% of patients had chest pain (specific chest pain sub-types included atypical angina in 44% of patients, non-anginal chest pain in 54% of patients, and other chest discomfort in 2% of patients. In the other trial, 72% of patients presented with chest pain (specific sub-types included atypical angina in 40% of patients, typical angina pain in 31% of patients, and non-anginal chest pain in 2% of patients).[36] Eleven percent of patients in the latter trial

were asymptomatic. Neither of the trials reported on the proportion of patients with unstable angina. Across both trials, the proportion of patients reporting diabetes ranged from 28% to 71%; hypertension ranged from 34% to 53%; and current smoking ranged from 14% to 23%. In one trial, 58% of patients had hypertension and 17% presented with dyspnea.[215] Duration of follow-up ranged from 1 to 3.3 years.

One trial was conducted in Germany[52] and the other trial was conducted across multiple countries in North America, East Asia, Europe, and India.[36] One trial received funding from the government[36] and the other trial received funding from a non-profit agency. [52]

One trial was rated good quality[52] and the other was rated fair quality[36] In the good quality trials, blinding of outcome assessors was unclear. Other methodological shortcomings in the fair-quality trial included unclear allocation concealment methods and higher than acceptable attrition at 12 months.

6.2.1 Summary of results (Key questions 1, 2 and 3)

- There was no difference in the risk of all-cause mortality or MI in CCTA versus ICA group at 12 and a median 40 months across one good- and one fair-quality RCT (SOE Low for both). Cardiac mortality was rare (SOE Insufficient).
- Compared with direct referral to ICA, CCTA was associated with a reduced risk of ICA without obstructive CAD (2 RCTs, N=1,019; 22 versus 65 per 100 patients; pooled RR 0.32, 95% CI 0.18 to 0.51, I^2=0%; pooled RD –48.0%, 95% CI –67.0% to –29.2%, I^2=73%) (SOE Moderate) and any revascularization (2 RCTs, N=1,832; 13 vs. 18 per 100 patients; pooled RR 0.71, 95% CI 0.55 to 0.96, I^2=0%; pooled RD –5.0%, 95% CI –8.0% to –2.0%, I^2=0%) (SOE Moderate) to include PCI but not CABG procedures, but an increased risk of additional downstream noninvasive testing (1 fair-quality RCT, N=1,503; 53 vs. 27 per 100 patients; RR 1.96, 95% CI 1.71 to 2.25; RD 26.0%, 95% CI 21.1% to 30.7%) (SOE Moderate). This latter trial found no difference between tests in the risk of cardiac hospitalization (4 vs. 4 per 100 patients) over 12 months (SOE Moderate).
- No major complications were reported in one good-quality trial and only one major complication was reported in the second fair-quality trial, major bleeding, which occurred in two patients (0.4%) in the ICA group; one patient (0.1%) required transfusion (SOE Low).

Detailed results

6.2.2 Key Question 1: Primary Outcomes (MI, all-cause mortality, cardiac death)

Myocardial infarction, all-cause mortality and cardiac death

There were no differences between CCTA and ICA in the incidence of MI (0.3 vs. 0.2 per 100 patients; pooled RR 1.26, 95% CI 0.24 to 6.67, I^2=0%) and all-cause mortality (0.2 vs. 0.2 per 100 patients; pooled RR 1.03, 95% CI 0.06 to 11.08, I^2=0%) across 2 RCTs (N=1,832) with follow-up periods of 12 months and a median 40 months (Figure 20).[36,52] One cardiac-related death was reported over a median of 40 months in one trial and it occurred in the ICA group; this death was also counted under all-cause mortality[52].

Other Outcomes

There were no differences between CCTA and ICA in the incidence of unstable angina, stroke, or MACE across both RCTs (Table 46).

Table 46. Secondary outcomes in trials comparing CCTA vs. ICA in patients with suspected CAD

Outcome	Author, year RCT	Time point	CCTA	ICA	Risk Ratio (95% CI)*

Chang: death, acute non-fatal MI, UA, cardiac hospitalization, or stroke

6.2.3 Key Question 2: Clinical decision making

Additional testing

Compared with a diagnostic strategy of direct referral to ICA, only 14 per 100 patients (24/167) patients randomized to CCTA in one good-quality trial[52] and 23 per 100 patients (179/784) in one fair-quality trial[36] underwent subsequent ICA over median follow-ups of 12 and 40 months. One of the trials reported that 30 patients in the ICA group (n=719) underwent a second ICA during follow-up[36] (4 per 100 patients). The proportion of patients without obstructive CAD on ICA was significantly lower in patients randomized to index CCTA compared with those randomized to direct ICA in both trials (total N=1,019)[36,52]: 22 versus 65 per 100 patients; pooled RR 0.32 (95% CI 0.18 to 0.51), I^2=0%; pooled RD –48.0% (95% CI –67.0% to –29.2%), I^2=73% (Figure 20). One trial, in mixed stable and acute patients with

atypical chest pain, reported that ICA led to revascularization of obstructive CAD in more CCTA patients (16/24) than ICA patients (23/162) (67 vs. 14 per 100 patients; RR 4.70, 95% CI 2.93 to 7.53; RD 52.5%, 95% CI 32.9% to 72.1%).[52]

Additional downstream noninvasive testing was twice as common following index CCTA compared with direct referral to ICA in one fair-quality trial evaluating stable patients (53 vs. 27 per 100 patients; RR 1.96, 95% CI 1.71 to 2.25; RD 26.0%, 95% CI 21.1% to 30.7%) but there was no difference between groups in the frequency of these tests that required stress testing with imaging or that required radiation (Figure 20).[36] Additional testing (in order of most to least common) included rest echocardiography, exercise ECG, nuclear perfusion, stress echocardiography and CCTA. More CCTA patients underwent subsequent rest echocardiography compared with ICA patients (36 vs. 13 per 100 patients; RR 2.71, 95% CI 2.20 to 3.34; RD 22.6%, 95% CI 18.5% to 26.8%); the frequency of all other tests was similar between groups.

Treatment

When data were pooled across both trials, CCTA was associated with fewer revascularization procedures compared with ICA over median follow-up periods of 12 and 40 months (2 RCTs, N=1,832; 13 vs. 18 per 100 patients; pooled RR 0.71, 95% CI 0.55 to 0.96, I^2=0%; pooled RD –5.0%, 95% CI –8.0% to –2.0%, I^2=0%), Figure 20. Individually, only the larger fair-quality trial (N=1,503) in stable outpatients reported a statistically significant difference between groups over 12 months: 13 versus 18 per 100 patients, RR 0.71 (95% CI 0.55 to 0.90), RD –5.0% (95% CI –9.0% to –2.0%). Results were similar when the frequency of PCI was considered separately but there were no differences in the frequency of CABG between groups (Figure 20). In the trial evaluating both stable and acute patients with atypical chest pain, most patients underwent revascularization following the index visit with similar proportions (re)revascularized more than 2 months after randomization (6/167 vs. 5/162, 4 vs. 3 per 100 patients; adjusted HR 0.89, 95% CI 0.27 to 2.90).[52]

Hospitalization and ED visits

Hospitalization for cardiac causes occurred with similar frequency between the CCTA and ICA groups over a median follow-up of 12 months in one trial evaluating stable patients treated on an outpatient basis: 4 vs. 4 per 100 patients, RR 0.98 (95% CI 0.60 to 1.58)[36]; Figure 20. The other trial, in a mixed stable and acute population with atypical chest pain, did not report hospitalization rates but did report that for those patients hospitalized, CCTA was associated with a shorter hospital length of stay compared with ICA: median 30 (IQR 3.5 to 77.3) versus 52.9 (IQR 49.5 to 76.4) hours.[52]

6.2.4 Key Question 3: Safety

The good-quality trial evaluating both stable and acute patients with atypical chest pain reported that no major complications occurred, i.e., complications that prolonged hospital stay by 24 hours or more.[52] Minor procedural complications were less frequent following CCTA compared with ICA (4 vs. 11 per 100 patients), primarily driven by the rate of hematoma at the puncture site (1 vs. 9 per 100 patients), Table 47. In one fair-quality trial evaluating stable outpatients, only one major complication was reported,

major bleeding, which occurred in two patients (0.4%) in the ICA group; one patient (0.1%) required transfusion[36] (Table 47).

Table 47. Safety data for RCTs comparing CCTA vs. ICA in patients with suspected CAD

Author, year RCT Timepoint	Adverse event	CCTA	ICA	Estimate (95% CI)*
Dewey, 2016* ***CAD-Man*** ≤48 hours after last procedure related to CCTA or ICA	**Any complications prolonging hospital stay by ≥ 24 hours**	0% (0/165)	0% (0/162)	NC, p=NS

‡Patients with stable angina treated on an outpatient basis

6.2.5 Key Question 4: Differential Effectiveness or Safety

No trials reported on differential effectiveness or safety.

6.2.6 Key Question 5: Cost-Effectiveness

Given the complexities in how cost-effectiveness was reported in the included studies, cost-effectiveness related to CCTA versus is covered in section 6.1.5 under the comparison of CCTA versus any functional testing.

6.3 CCTA with Fractional Flow Reserve (FFR)

One prospective comparative cohort (across 2 publications), the PLATFORM study, compared CCTA plus Fractional Flow Reserve (FFR) versus any non-invasive testing (N=204) and versus ICA (N=380) in the outpatient setting in patients with suspected CAD who had an intermediate risk of coronary disease.[57,60] Patients were subdivided into two consecutive cohorts based on the evaluation plan decided upon before enrollment (any non-invasive testing or ICA). (See Appendix J for details.) The decision to send patients for noninvasive or invasive testing prior to enrollment was made by the patients' physicians; it is unclear what criteria were used to make this decision, though it is assumed that those patients who were being sent directly to ICA were higher risk than those being sent for noninvasive testing. Among patients originally planned to receive non-invasive testing, 104 were allocated to CCTA (with 64% also receiving FFR) and 100 were allocated to any non-invasive test. Among patients originally planned to receive ICA, 193 were allocated to CCTA (with 69% also receiving FFR) and 187 were allocated to ICA. FFR analyses were performed centrally using HeartFlow when requested by the site (recommended if the CTA revealed ≥30% stenosis or if the patient was referred to ICA), thus not all patients received FFR as indicated previously. CCTA was complete with a 64 slice or greater CT scanner and contrast was used but the type and dose were not reported. CACS was not performed in any patient. For those allocated to the any non-invasive testing arm, tests included stress echocardiogram, SPECT, CMR, CCTA, and other (not further specified).

Patients in the planned ICA cohort were somewhat older than those in the planned non-invasive cohort (mean 62 vs. 59 years); within the planned ICA cohort, patients allocated to receive CCTA with FFR were younger than those allocated to ICA (61 vs. 63 years), Appendix J. The proportion of females ranged from 38% to 40% across the two cohorts. Less than 2% of all patients identified as a racial or ethnic minority. The study excluded patients with previously diagnosed CAD and did not report information on prior revascularizations, myocardial infarctions, or the proportion of patients with dyspnea. Most patients presented with atypical angina (74%); in the planned noninvasive test cohort, fewer patients who were allocated to CCTA with FFR had at atypical angina compared to those who received noninvasive testing (77% vs. 91%). Across all patients, the proportion with hypertension, diabetes, and hyperlipidemia was 54%, 13%, and 71%, respectively, and 54% smoked in the past or presently. In the planned non-invasive test cohort, more patients who were allocated to CCTA with FFR had hypertension (55% vs. 38%) and were taking aspirin (43% vs. 29%) compared with those who received other noninvasive testing. In the planned ICA cohort, fewer patient allocated to CCTA with FFR were taking aspirin (47% vs. 62%). All patients had intermediate likelihood of CAD; mean pretest risk was 45% in the planned noninvasive test cohort and 50.5% in the planned ICA cohort based on the Diamond-Forrester risk model. Follow-up occurred at 3, 6, and 12 months. The study was conducted at 11 sites in Europe and one site in the United States. Authors received funding from industry (HeartFlow, Inc.).

The study quality was rated as good. There were some differences in key characteristics between arms at baseline; however, the authors performed a sensitivity analysis of their primary outcome using propensity score matching (based on age, sex, diabetes, smoking status, and type of angina) to control for these imbalances and the unrandomized nature of the test allocation.

6.3.1 Summary of Results

CCTA with FFR vs. any NIT (planned NIT cohort)

- There was no difference between groups in any outcome over 12 months (SOE Insufficient for all outcomes).
- One MI occurred in the any noninvasive test group (0 vs. 1 per 100 patients). There were no deaths or hospitalizations with urgent revascularization in either group. Given that these are rare events, the study may not have been sufficiently powered to detect a difference.
- Risk of ICA was 21 vs. 16 per 100 patients; of ICA without obstructive CAD was 13 vs. 6 per 100 patients (at 3 months); and of any revascularization was 10 vs. 7 per 100 patients, respectively.

CCTA with FFR vs. ICA (planned ICA cohort)

- There were no differences between groups over 12 months in the risk of MI (1 vs. 1 per 100 patients), all-cause death (0 vs. 1 per 100 patients) or hospitalization with urgent revascularization (1 vs. 0 per 100 patients). Given that these are rare events, the study may not have been sufficiently powered to detect a difference (SOE Insufficient).
- Compared with direct referral to ICA, patients who underwent CCTA with FFR were referred to ICA significantly less often (51 vs. 100 per 100 patients; RR 0.51, 95% CI 0.45 to 0.59) and importantly, there were no events in the 61% of CCTA with FFR patients in whom ICA was cancelled in the planned ICA cohort. The risk of ICA without obstructive CAD was also significantly reduced following CCTA with FFR (39 vs. 100 per 100 patients; RR 0.39, 95% CI 0.33 to 0.47) (SOE Insufficient).
- There was no difference between groups in the risk of any revascularization (SOE Insufficient).

Key Question 3, Safety

- There was one mild contrast reaction from CCTA testing; no other information was provided (SOE Insufficient).
- Patients who received CCTA with FFR had significantly greater cumulative radiation exposure over 12 months compared to those who received any noninvasive test (planned noninvasive test cohort): 9.6 vs. 6.4 mSv, MD 3.1 (95% CI, 0.6 to 5.7); there was no difference for CCTA with FFR versus direct referral to ICA (planned ICA cohort) (SOE Low).

Detailed Results

6.3.2 Key Question 1: Primary clinical outcomes (MI, all-cause mortality, cardiac death)

For both the planned noninvasive test cohort (CCTA with FFR vs. any noninvasive test) and the planned ICA cohort (CCTA with FFR vs. ICA), there were no differences between testing arms in the risk of nonfatal MI (≤1 per 100 patients across all arms) or all-cause mortality (0 per 100 patients in the noninvasive test cohort and <1 per 100 patients in the ICA cohort, across both arms), as well as in the risk of the composite outcomes of MACE or MACE plus vascular complications across 12 months of follow-up (Table 48).[57,60] Importantly, there were no events in the 61% of CCTA with FFR patients in whom ICA was cancelled in the planned ICA cohort. Cardiac mortality was not reported.

6.3.3 Key Question 2: Clinical Decision-making outcomes

Additional testing

In the planned noninvasive cohort, the risk of ICA, as well as the risk of ICA without obstructive CAD, was similar between patients who received CCTA with FFR versus any noninvasive test over 12 months (Table 48).[57,60] In the planned ICA cohort, allocation to CCTA with FFR was associated with a 50% reduction in the risk of ICA over 12 months compared with direct referral to ICA (51 vs. 100 per 100 patients; RR 0.51, 95% CI 0.45 to 0.59; RD –48.7% 95% CI –41.7% to –55.8%). The risk of ICA without obstructive CAD was also significantly reduced in patients who received CCTA with FFR compared with ICA as measured at 3 months (12 vs. 73 per 100 patients; RR 0.17, 95% CI 0.12 to 0.25; RD –60.8%, 95% CI –53.0% to –68.7%). Results from the propensity score matching analysis (n=148 in each arm) were similar (12 vs. 72 per 100 patients).

Over the 12 months after enrollment, in the planned noninvasive testing cohort, CCTA with FFR was associated with fewer total referrals for stress echocardiography (2 vs. 29 per 100 patients) and stress nuclear scans (8 vs. 17 per 100 patients) but a similar frequency of stress ECG and cardiac MRI compared with any noninvasive testing; 62% of patients allocated to the noninvasive testing arm received CCTA over the study duration (Table 48).[57,60] In the noninvasive testing arm, it was unclear which tests patients received at index visit so we could not calculate the proportion of additional noninvasive tests required post-index testing making it difficult to draw conclusions regarding the risk of additional downstream testing for this cohort. In the planned ICA cohort, there was no difference between patients who received CCTA with FFR versus ICA in additional noninvasive testing to include stress ECG, stress echocardiography, stress nuclear, cardiac MRI and CCTA (Table 48).

Additional treatment and hospitalization

There were no differences between test arms in risk of any revascularization or of hospitalization with urgent revascularization over 12 months for both the planned noninvasive test cohort (CCTA with FFR vs. noninvasive testing) and the planned ICA cohort (CCTA with FFR vs. direct referral to ICA), Table 48.[57,60]

Changes in medication use (i.e., aspirin, statins and $P2Y1_{12}$ inhibitors) over 12 months were similar in the two arms of both cohorts except for $P2Y1_{12}$ inhibitors (i.e., clopidogrel, prasugrel, and ticagrelor) in the planned ICA cohort which were greater in the CCTA with FFR arm compared with the ICA arm.[57,60] It is unclear what medication changes were made (e.g., dose increase or decrease, initiation or discontinuation).

ACP = acute chest pain; ACS = acute coronary syndrome; CABG = coronary artery bypass graft; CI = confidence interval; ICA = invasive coronary angiography; MD = mean difference; MI = myocardial infarction; NA = not applicable; NS = not statistically significant; OP= outpatient; PCI = percutaneous coronary intervention; RCT = randomized controlled trial; RR = risk ratio; SD = standard deviation.

*It is unclear what patients received at index testing.

†MACE includes all-cause mortality, non-fatal MI, hospitalization with urgent revascularization.

‡Known/history of CAD was an exclusion criterium.

§Requested in 67 but not completed in 7 due to poor image quality or inadequate acquisition.

6.3.4 Key Question 3: Safety

There was one reported adverse event from CCTA testing, a mild contrast reaction. The authors did not provide any other information or report on any other test-related adverse events.[57,60]

In the planned noninvasive test cohort, CCTA with FFR was associated with greater cumulative radiation exposure compared with the any noninvasive testing arm at both 3 months (8.8 vs. 5.8 mSv; mean difference 3.0, 95% CI 0.6 to 5.4) and 12 months (9.6 vs. 6.4 mSv; mean difference 3.1, 95% CI 0.6 to 5.7). In the planned ICA cohort, there was no difference in cumulative radiation exposure between the CCTA with FFR group and the ICA group (9.9 vs. 9.4 mSv at 3 months and 10.7 vs. 10.4 mSv at 12 months, respectively).

6.3.5 Key Question 4: Differential Effectiveness and Safety

Authors performed analyses on predefined subgroups (age, sex, race, diabetes, pretest risk of CAD) and evaluated interaction to explore differential effects of testing on the finding of no obstructive CAD on ICA within 90 days.[57,60] There was no evidence of differential effectiveness (interaction p-values not statistically significant) by any subgroup for the outcome of ICA without obstructive CAD within 90 days in either the cohort originally planned to receive noninvasive testing or the higher CAD risk cohort originally planned to receive ICA with one exception. In the higher risk cohort, there was a statistically significant test for interaction between subgroups based on pre-test probability of CAD (<50% versus ≥50%) (Appendix O). It appears that the analyses were done on raw data from the respective cohorts that were not adjusted for potential confounding or selection bias. Confounding and selection bias are primary factors which threaten the validity of non-randomized observational studies and causal inference is not possible. Thus, there is insufficient information to draw firm conclusion from these analyses.

6.3.6 Key Question 5: Cost-Effectiveness

Given the complexities in how cost-effectiveness was reported in the included studies, cost-effectiveness related to CCTA with FFR is covered in section 6.1.5 under the comparison of CCTA versus any functional testing.

7 Single Photon Emission Computed Tomography (SPECT) Results

Six trials (across 7 publications) evaluated the effectiveness and/or safety of SPECT compared with stress echocardiography (2 RCTs)[220,241], exercise ECG (2 RCTs)[209,223], clinical assessment only (1 RCT)[142], NICE-guideline directed care (1 RCT)[88], and ICA (1 RCT)[220,241]. One trial included both a stress echocardiography and an ICA comparison arm.[220,241]

7.1 SPECT versus Stress Echocardiography and versus Exercise ECG

Given that the results across the four trials comparing SPECT with stress echocardiography and exercise ECG showed similar results in general, they are summarized together in the bullet points below, in the strength of evidence table, and their results are presented together in the same plots/figures. However, each comparison is described in detail separately in the sections that follow. All figures corresponding to the meta-analyses can be found after the section comparing SPECT versus exercise ECG.

7.1.1 Summary of results

- There was no difference in the risk of MI (SOE Insufficient), all-cause mortality (SOE Low) or cardiac mortality (SOE Insufficient) between SPECT and stress echocardiography (2 trials) or exercise ECG (2 trials) across four trials (N=1,908) with varying populations and follow-up periods. The absolute risk was <2 per 100 patients across all testing arms for all outcomes over follow-up periods ranging from 1 to 24 months. Given that these are rare events, trials may not have been sufficiently powered to detect a difference.
- There was no difference in the risk of ICA (4 trials, N=1,908) (SOE Low) or additional noninvasive testing (N=3 trials, N=1,679) (SOE Insufficient) for SPECT versus stress echocardiography or exercise ECG across all four trials over follow-up periods ranging from 1 to 24 months, however, there was substantial heterogeneity. Individually, only the trials comparing SPECT versus exercise ECG reported statistically significant differences which favored SPECT for both ICA (1 trial) and additional noninvasive testing (2 trials); however, for the latter, the estimates across trials were inconsistent and imprecise. Differences in testing protocols, patient populations and/or pretest risk, and follow-up periods may have played a role in these findings.
- There was no difference in the risk of revascularization (4 trials, N=1,908) (SOE Moderate) or hospitalization (3 RCTs, N=1,451) (SOE Low) between SPECT and stress echocardiography or exercise ECG, or ED visits in 1 trial (N=229) of SPECT vs. echocardiography through 24 months of follow-up (SOE Low).

7.1.2 SPECT versus Stress Echocardiography

Two trials (total N=679)[210,220,241] compared Tc-99m sestamibi SPECT imaging with stress echocardiography in a mixed population of patients with suspected or known CAD, one in stable patients and one in acute patients (See Appendix Q). One trial enrolled patients with stable CAD referred for outpatient angiography (mean age 62 years, 30% female, 27% with prior MI/known CAD). Referral to angiography was based on the results of an exercise ECG complete within 1 month of enrollment, the

results of which were not available to the trial personnel. Patients were considered high risk (69%) or low risk (31%) according to the Pryor risk assessment. Baseline cardiac risk factors included prior cerebrovascular accident (6%), peripheral vascular disease (9%), diabetes (12%), family history of CAD (25%), hypertension (58%), hyperlipidemia (78%), and smoking (43%). Patients were on a variety of cardiovascular related medications at baseline including antiplatelets, statins, and beta-blockers primarily as well as ACE inhibitors, calcium channel blockers, nicorandil, nitrates, diuretics, and angiotensin-II receptor antagonists. The second trial enrolled patients with acute chest pain presenting to the ED[210] and subsequently hospitalized (mean age 57 years, 54% female, 24% known CAD). Baseline cardiac risk factors included prior MI (15%), cerebrovascular disease (8%), diabetes (39%), hypertension (76%), hyperlipidemia (48%), and COPD (10%). Patients were on a variety of cardiovascular related medications at baseline including antihypertensives (beta blockers and other), aspirin, and lipid-lowering medication primarily, as well as diabetes medication, warfarin and clopidogrel. SPECT was performed using adenosine as the stress agent in one trial (the stable outpatient population) and dipyridamole (73%) or treadmill exercise (27%) as the stressor in the other (acute ED population). Stress echocardiography was performed using dobutamine in the stable population and either dobutamine (58%) or exercise (42%) stress in the acute ED population; both trials used contrast to enhance the images. Follow-up was 30 days in the acute ED trial and up to 72 months in the stable outpatient trial. One trial was conducted in the United States and was funded by industry (GE Healthcare)[210] and the other was conducted in the United Kingdom and funded by the National Institute for Health Research.

One trial was considered good quality[220,241] and the other fair quality[210]. The only methodological shortcoming in the good-quality trial was unclear blinding of outcome assessors; in the fair-quality trial, limitations included unclear allocation concealment methods and between-group differences at baseline on a CAD risk factor. See Appendix D for details regarding study quality determination.

Detailed results

7.1.2.1 Key Question 1: Primary Outcomes (MI, all-cause mortality, cardiac death)

Myocardial infarction

Across both trials, the frequency of MI following SPECT versus stress echocardiography was 0.6 versus 1.8 per 100 patients. No events occurred within 30 days in the fair-quality trial evaluating patients hospitalized with acute chest pain.[210] In the good-quality trial evaluating stable outpatients at higher pretest risk, two patients who received SPECT were admitted for acute MI with 18 months of randomization compared with six patients who received dobutamine stress echocardiography; the difference was not statistically significant: 0.9 versus 2.7 per 100 patients; RR 0.34 (95% CI 0.07 to 1.65)[220], Figure 21.

All-cause mortality and cardiac mortality

There was no difference in all-cause mortality between SPECT and stress echocardiography across the two trials, both individually and when pooled (2 RCTs, N=679, 2.4 vs. 3.2 per 100 patients; RR 0.71, 95% CI 0.22 to 4.58, I^2=0%), Figure 22. The good-quality trial in stable outpatients at higher pretest risk

reported a total of seven and 11 deaths, respectively, over 72 months of follow-up (3.1 vs. 4.9 per 100 patients)[241]. The fair-quality trial in acute ED patients reported one death in the SPECT arm over 30 days (0.9 vs. 0 per 100 patients).[210] Cardiac mortality was reported in five SPECT patients and one echocardiography patient at 18 months in the trial evaluating stable outpatients (2.2 vs. 0.4 per 100 patients; RR 5.04, 95% CI 0.59 to 42.84)[220], Figure 23.

Other Outcomes

There was no difference between SPECT and Echo for the composite outcomes of any nonfatal event (admission for chest pain, admission for acute MI, unplanned PCI, unplanned CABG, or other) (10.7 vs. 13.7 per 100 patients; RR 0.78, 95% CI 0.47 to 1.29) and any fatal plus nonfatal event (12.9 vs. 16.4 per 100 patients; RR 0.79, 95% CI 0.50 to 1.24) over 18 months in the good-quality trial evaluating stable outpatients referred for ICA.[220] In this same trial here was no difference in the proportion of patients achieving a clinically significant improvement in CCS angina class at 18 months (42 vs. 34 per 100 patients). Similarly, there were no differences between groups for mean scores on all subscales of the Seattle Angina Questionnaire at 6 and 18 months (See Appendix O for all secondary outcomes).

7.1.2.2 Key Question 2: Clinical decision making

Additional testing

There was no difference in the frequency of ICA between SPECT and stress echocardiography across the two trials, both individually and when pooled (2 RCTs, N=679, 52.1 vs. 51.3 per 100 patients; RR 1.04, 95% CI 0.77 to 1.24, I^2=33%), Figure 24. The good-quality trial in stable outpatients at higher pretest risk reported that 175 and 169 patients, respectively, were referred for ICA over 18 months of follow-up (78 vs. 75 per 100 patients; RR 1.04, 95% CI 0.94 to 1.16)[220] while the fair-quality trial in acute ED patients reported that two and five patients received subsequent ICA within 30 days (1.7 vs. 4.4 per 100 patients; RR 0.39, 95% CI 0.08 to 1.97).[210] In the good-quality trial, one patient in the SPECT arm received additional noninvasive testing (repeat SPECT) compared with no patient in the echocardiography arm (0.4 vs. 0 per 100 patients; RR 3.03, 95% CI 0.12 to 73.90)[220]; the timing of additional noninvasive testing was unclear (Figure 25).

Treatment

There was no difference in the risk of any revascularization for SPECT compared with stress echocardiography across both trials (2 RCTs, N=679, 29 vs. 36 per 100 patients; RR 0.82, 95% CI 0.53 to 1.16, I^2=0%), Figure 26. Individually, the larger, good-quality trial evaluating stable outpatients at higher pretest risk showed an association favoring SPECT (lower risk) over 36 months of follow-up: 43.8 versus 53.5 per 100 patients, RR 0.82 (95% CI 0.67 to 0.99)[241], RD –9.8% (95% CI –19.0% to –0.6%); however, the estimate was just barely statistically significant. The fair-quality trial in acute ED patients reported no difference between diagnostic strategies over 30 days, with only one patient in the stress echocardiography arm undergoing revascularization (PCI) (0 vs. 0.9 per 100 patients).[210] Differences in populations and the length of follow-up periods may have played a role in these findings. When

considered separately, there were no difference between test groups in the risk of PCI (Figure 27) or CABG (Figure 28), though both trials tended to favor SPECT with regarding to PCI (lower risk).

Hospitalization and ED visits

There was no difference in the frequency of hospitalizations due to cardiac causes between SPECT and stress echocardiography across the two trials, both individually and when pooled (2 RCTs, N=679, 7.1 vs. 9.1 per 100 patients; RR 0.76, 95% CI 0.39 to 3.19, I^2=32%), Figure 29. Except for eight acute MIs requiring hospitalization (2 in the SPECT and 6 in echocardiography arm) in the good-quality trial evaluating stable outpatients at higher pretest risk[220], all hospitalizations were due to chest pain. The rate of cardiac hospitalization in the good-quality trial was 9.4 versus 13.3 per 100 patients (RR 0.71, 95% CI 0.42 to 1.20)[220], respectively, over 18 months and in the fair-quality trial evaluating acute ED patients was 2.6 versus 0.9 per 100 patients (RR 2.92, 95% CI 0.31 to 27.68)[210] over 30 days. In the latter trial, three patients (3 per 100) in each group returned to the ED within 30 days. There was no difference between groups in the length of hospital stay in this same trial (Appendix O).

7.1.3 SPECT versus Exercise ECG

Two trials (total N=1,281) compared Tc-99m sestamibi SPECT imaging with exercise ECG in stable patients with suspected CAD (known CAD was an exclusion criteria) treated on an outpatient basis[209,223] (See Appendix Q). Mean patient age was 60 to 63 years. One trial[223] enrolled only women (78% postmenopausal) who were 87% Caucasian while the second trial included 44% women and the population was 52% Caucasian and 40% Indian-subcontinent origin. Most patients across both trials were at intermediate to high pretest risk (100% in the trial enrolling women only[223] and 84% in the other trial[209]); the remaining 16% in the one trial were considered low risk. Regarding cardiac risk factors, there was a similar proportion of patients with hypertension (50% and 53%), diabetes (13% and 17%) and family history of CAD (43% and 47%) in both trials but a greater proportion of patients with smoking history (45% and 14%) in the trial enrolling women only. In the latter trial, presenting symptoms included typical angina (60%), atypical angina (9%), nonspecific angina (28%) and dyspnea (51%). In addition, medications at baseline in this trial included aspirin (35%), statins (32%), gastrointestinal drugs (27%) (39% had coexisting esophageal reflux) primarily as well as beta-blockers, antidepressants, ACE inhibitors, NSAIDs, angiotensin receptor blockers and others. The other trial did not report presenting symptoms (other than chest pain, 100%) or baseline medication use. In the trial enrolling only women, patients in both diagnostic testing arms received exercise stress testing according to Bruce protocol. In the other trial, 62% of patients in the SPECT arm underwent exercise treadmill testing and 38% had pharmacological stressors (dipyridamole or dobutamine) while all patients in the ECG arm underwent exercise using the symptom-limited modified Bruce protocol. Follow-up periods were similar, 24 months and a mean 20 months. One trial was conducted in the United States and the other in the United Kingdom. Both were funded by industry; the United Kingdom trial also received research grants.

Both trials were considered fair quality. The primary methodological shortcoming in both trials included unclear allocation concealment methods and in one, unclear blinding of outcome assessors. See Appendix D for details regarding study quality determination.

Detailed results

7.1.3.1 Key Question 1: Primary Outcomes (MI, all-cause mortality, cardiac death)

Myocardial infarction

Across both trials there were a total of four MIs. One trial reported no difference between SPECT and exercise ECG in the frequency of MI over 24 months (N=457, 0 vs. 0.5 per 100 patients, RR 0.28, 95% CI 0.01 to 6.74)[209]; this was a fatal MI (Figure 21). The other trial reported that there were three nonfatal MIs (0.4 per 100 patients) over a mean of 20 months but did not specify the group to which the patients were randomized.[223]

All-cause mortality and cardiac mortality

There was no difference in all-cause mortality between SPECT and exercise ECG across the two fair-quality trials, both individually and when pooled (2 RCTs, N=1,229, 0.9 vs. 0.7 per 100 patients; RR 1.38, 95% CI 0.27 to 6.44, I^2=0%), Figure 22. There was a total of two cardiac deaths across both RCTs: one fatal MI in the exercise ECG group in one trial (0 vs. 0.5 per 100 patients; RR 0.28, 95% CI 0.01 to 6.74) Figure 23) and one sudden cardiac death (0.1 per 100 patients) in the second trial that enrolled only women, however the authors did not report to which group the patient was randomized.[223]

Other Outcomes

In the trial enrolling women only, the frequency of MACE (composite of cardiac death, nonfatal MI, or hospital admission for an ACS or heart failure) was similar between the SPECT and exercise ECG over 24 months (N=772, 2.3 vs. 1.7 per 100 patients; RR 1.14, 95% CI 0.44 to 2.92).[223] No difference in the frequency of MACE was seen for SPECT versus ECG when women with normal test results and those with abnormal test results were considered separately. Heart failure was reported in one woman (0.1 per 100 patients) and acute coronary syndrome in 12 (1.6 per 100 patients) all of which required hospitalization, but they did not report to which arms the patients were randomized (this data is repeated below in Key Question 2 under Hospitalization). The proportion of women who were angina-free (65 vs. 60 per 100 patients at 24 months) and the median scores across all subscales of the Seattle Angina Questionnaire (data not provided) were also similar between groups during follow-up. The second trial did not report on any secondary outcomes.

7.1.3.2 Key Question 2: Clinical decision making

Additional testing

In one trial, SPECT was associated with an almost 3-fold reduction in referral for ICA compared with exercise ECG over a mean follow-up of 20 months: 16.4 versus 47.3 per 100 patients; RR 0.35 (95% CI 0.25 to 0.47[209]; RD –30.9%, 95% CI –39.2% to –22.7%). The other trial which enrolled only women reported no difference in ICA rates between diagnostic strategies over 24 months (5.5 vs. 6.7 per 100 patients, respectively; RR 0.82, 95% CI 0.47 to 1.43).[223] When the two trials were pooled the difference was not statistically significant and there was substantial heterogeneity (2 RCTs, N=1,229, 9.8 vs. 20.8

per 100 patients; RR 0.50, 95% CI 0.19 to 1.47, I^2=86%), Figure 24. Difference in populations, testing protocols, and treatment algorithms may partially explain the heterogeneity.

In both trials, SPECT was associated with significantly fewer downstream noninvasive tests compared with exercise ECG. In the trial enrolling only women, the risk of subsequent noninvasive testing was 9.4 versus 18.6 per 100 patients, respectively, over 24 months (RR 0.51, 95% CI 0.35 to 0.73), almost all of which were SPECT (9.1 vs. 17.8 per 100 patients); only one SPECT patient and two exercise ECG patients had additional exercise ECG (0.3 vs. 0.5 per 100 patients). In the second trial, no patients randomized to SPECT underwent additional noninvasive testing while 23.2% of patients in the exercise ECG arm received subsequent stress (pharmacological) echocardiography (0 vs. 23.2 per 100 patients; RR 0.01, 95% CI 0.00 to 0.14)[209] over a mean of 20 months. However, when results were pooled across the two trials there was no difference between the two test groups (5.7 vs. 20.0 per 100 patients; RR 0.11, 95% CI 0.00 to 8.87, I^2=93%), likely due to the substantial heterogeneity across the trials (Figure 25).

Treatment

In one trial, SPECT was associated with fewer revascularization procedures compared with exercise ECG over a mean follow-up of 20 months: 10.8 vs. 17.9 per 100 patients, RR 0.60 (95% CI 0.38 to 0.96)[209], RD –7.1% (95% CI –13.6% to –0.6%); however, the difference was only marginally significant. The other trial which enrolled only women reported no difference in revascularization rates between diagnostic strategies over 24 months (2.1 vs. 1.1 per 100 patients, respectively; RR 2.02, 95% CI 0.61 to 6.66).[223] When the two trials were pooled the difference was not statistically significant, however heterogeneity was high (2 RCTs, N=1,229, 5.5 vs. 6.9 per 100 patients; RR 0.71, 95% CI 0.29 to 3.78, I^2=71%), Figure 26. Difference in populations, testing protocols, and treatment algorithms may partially explain the heterogeneity.

More patients randomized to SPECT versus exercise ECG started aggressive medical therapy (not defined) as a result of the test (83.6 vs. 30.4 per 100 patients; RR 2.75, 95% CI 2.22 to 3.40) in one trial.[209] The other trial enrolling only women reported similar rates of new use or discontinuation of nitrates, beta-blockers, statins and antidepressants between groups (no data provided, p=0.20).[223]

Hospitalization and ED visits

There was no difference between SPECT versus exercise ECG in the frequency of hospitalization for chest pain symptoms over 24 months in the trial enrolling only women (N=772, 3.9 vs. 3.1 per 100 patients; RR 1.26, 95% CI 0.60 to 2.66)[223], Figure 29. This same trial also reported one hospitalization for heart failure (0.1 per 100 patients) and 12 hospitalizations for acute coronary syndrome (1.6 per 100 patients) but they did not report to which arms the patients were randomized (this data is repeated above for Key Question 1 under Other Outcomes).

7.2 SPECT versus Clinical Assessment Alone and versus NICE Guideline-Directed Care

Given that the results across the two trials comparing SPECT with clinical assessment alone and with NICE guideline-directed care showed similar results in general, they are summarized together in the bullet points below, in the strength of evidence table, and their results are presented together in the same plots/figures. However, each comparison is described in detail separately in the sections that follow. All figures corresponding to the meta-analyses can be found after the section comparing SPECT versus NICE guideline-directed care.

7.2.1 Summary of results

- There was insufficient evidence to draw conclusions regarding the risk of MI and all-cause mortality in one RCT in stable outpatients (SPECT vs. NICE guideline-directed care) with a median follow-up of 16 months and cardiac death across both RCTs, one in stable and one in acute patients (follow-up range, 1 to median 16 months). The absolute risk was ≤1.3 per 100 patients across both test arms in both trials for all outcomes. Given that these are rare events, the trials may not have been sufficiently powered to detect a difference (SOE Insufficient).
- SPECT was associated with a decreased risk of ICA across both trials (10.2 vs. 21.1 per 100, pooled RR 0.49, 95% CI 0.26 to 0.95, I^2=85%; pooled RD –11.1%, 95% CI –14.4% to –7.8%) (SOE Low); the association was stronger in the trial comparing SPECT versus NICE guideline-directed care, likely due the direct referral to ICA of patients with high pretest risk per the NICE guideline algorithm, and could account for much of the heterogeneity in the pooled estimate. SPECT was also associated with a decreased risk of ICA showing no obstructive CAD (1 RCT, SPECT vs. clinical assessment alone: 21.9 vs. 39.3 per 100 patients; RR 0.56, 95% CI 0.32 to 0.96; RD –17.4%, 95% CI –33.3% to –1.4%) and unnecessary ICA (1 RCT, SPECT vs. NICE guideline-directed care: 7.1 vs. 28.8 per 100 patients; RR 0.25, 95% CI 0.17 to 0.36; RD –21.7%, 95% CI –27.9% to –15.5%) (SOE: Low for both).
- There was no difference between SPECT and clinical assessment alone or NICE guideline-directed care in the risk of any revascularization (2 RCTs, 5.9 vs. 7.0 per 100 patients; RR 0.85, 95% CI 0.57 to 1.28, I^2=0%) (SOE Low).
- SPECT was associated with decreased risk of additional downstream NIT over 12 months (12.1 vs. 68.3 per 100 patients; RR 0.18, 95% CI 0.15 to 0.21; RD –56.2%, 95% CI –60.7% to –51.7%) and hospitalization at the index visit (10.2 vs. 18.5 per 100 patients; RR 0.55, 95% CI 0.42 to 0.71; RD –8.3%, 95% CI –12.2% to –4.4%) compared with clinical assessment alone in one trial (SOE Low for both).

7.2.2 SPECT versus Clinical Assessment Alone

One trial (N=1,508)[142] compared Tc-99m tetrofosmin SPECT imaging (n=1,004) with clinical assessment only (n=504) in acute patients with suspected ACS presenting to the ED (See Appendix Q). All patients first underwent standard observation (continuous 12-lead ECG monitoring and cardiac biomarkers) over

a 6-hour period; only those who had a negative 6-hour observation received their randomly assigned protocol. Mean patient age was 52 years, 41% were female, and 69% were Chinese. A small number of patients had known CAD (4%) or had suffered a prior MI (1%). Patients had the following cardiac risk factors: hypertension (42%), smoker (32%) and diabetes (18%). Stress SPECT was performed using exercise (preferred) or dipyridamole or dobutamine if pharmacological stressors were required. Patients in the clinical assessment group were assessed for the likelihood of ACS by the emergency medicine physician based on patients' characteristics and cardiac risk factors and ECG results; 82% were considered intermediate or high risk and 18% were considered low risk. Patients considered to be at intermediate or high risk per physician assessment were admitted to the hospital. Pretest risk was not reported for those randomized to SPECT. The follow-up period was 12 months. This trial was conducted in Singapore and received government grants.

This trial was considered fair quality; it was unclear if outcome assessors were blinded and attrition at 12 months was unclear. See Appendix D for details regarding study quality determination.

Detailed results

7.2.2.1 Key Question 1: Primary Outcomes (MI, all-cause mortality, cardiac death)

Cardiac mortality

Over 12 months of follow-up, three cardiac deaths were reported, and all occurred in the SPECT arm after 30 days (0.3 vs. 0 per 100 patients), Figure 30. The trial did not report the outcomes of MI and all-cause mortality.

Other outcomes

The incidence of cardiac events (composite outcome defined as cardiac-related death, ventricular fibrillation, MI, cardiogenic shock, or acute pulmonary oedema requiring endotracheal intubation) was similar between SPECT and clinical assessment alone at the end of follow-up (0.7 vs. 1 per 100 patients; RR 0.70, 95% CI 0.22 to 2.20); most events occurred within 30 days (0.4 vs. 0.8 per 100 patients; RR 0.5, 95% CI 0.13 to 2.0).

7.2.2.2 Key Question 2: Clinical decision making

Additional testing

SPECT was associated with fewer referrals for ICA compared with clinical assessment over 12 months: 7.3 versus 11.1 per 100 patients, RR 0.65 (95% CI 0.47 to 0.91), RD –3.8% (95% CI –7.0% to –0.7%), Figure 31. For those who underwent ICA, fewer patients in the SPECT group did not show significant CAD compared to the clinical assessment group: 21.9 versus 39.3 per 100 patients; RR 0.56 (95% CI 0.32 to 0.96), RD –17.4% (95% CI –33.3% to –1.4%). SPECT was also associated with less additional noninvasive testing of any type over 12 months (12.1 vs. 68.3 per 100 patients; RR 0.18, 95% CI 0.15 to 0.21; RD –56.2%, 95% CI –60.7% to –51.7%) as well as noninvasive stress testing requiring imaging (2.6 vs. 32.3 per 100 patients; RR 0.08, 95% CI 0.05 to 0.12; RD –29.8%, 95% CI –34.0% to –25.6%) and requiring radiation

(1.6 vs. 23.8 per 100 patients; RR 0.07, 95% CI 0.04 to 0.11; RD –22.2%, 95% CI –26.0% to –18.4%). The majority of additional testing was resting echocardiography in the SPECT group and equal proportions of SPECT and exercise ECG in the clinical assessment group.

Treatment

There was no difference between the SPECT and clinical assessment groups in the rate of any revascularization procedure over 12 months (4.8 vs. 6.2 per 100 patients; RR 0.78, 95% CI 0.50 to 1.21), Figure 32.

Hospitalization

SPECT was associated with an almost 50% reduction in hospitalization at index testing compared with clinical assessment (10.2 vs. 18.5 per 100 patients; RR 0.55, 95% CI 0.42 to 0.71; RD –8.3%, 95% CI –12.2% to –4.4%). In the clinical assessment arm, 94% of patients admitted to the hospital were considered intermediate or high risk for ACS according to the attending physician. The frequency of subsequent hospitalization following the index visit was not reported.

7.2.3 SPECT versus NICE guideline-directed care

One good-quality trial (N=721)[88] compared Tc-99m tetrofosmin or sestamibi SPECT (n=481) imaging versus NICE guideline-directed care (n=240) in stable patients with suspected CAD treated on an outpatient basis (See Appendix Q). A history of prior MI and prior revascularization were exclusion criteria. Mean patient age was 56 years, 47% of patients were female, and 92% were Caucasian. Patients presented with atypical (67%) and typical angina (33%) and had the following cardiac risk factors: former or current smoker (58%), family history of CAD (55%), dyslipidemia (41%), hypertension (39%), diabetes (13%), cerebrovascular disease (3%) and peripheral vascular disease (3%). Group allocation was stratified by the pretest likelihood of CAD (as well as age, sex, and center) which was determined according to NICE guidelines CG95; the pretest risk was 10% to 29% in 26%, 30% to 60% in 38%, and 61% to 90% in 36% of the population. Patients randomized to the NICE guideline group received specific diagnostic tests based on their pretest risk: those at a pretest risk of 10% to 29% received cardiac CT; 30% to 60% received SPECT; and 61% to 90% proceeded directly to ICA. In the SPECT group, stress imaging was performed using treadmill exercise as the default, with adenosine stress for those who could not exercise. Follow-up was a median 16 months (12 months minimum). This trial was conducted in the United Kingdom and received professional research grants.

See Appendix D for details regarding study quality determination.

Detailed results

7.2.3.1 Key Question 1: Primary Outcomes (MI, all-cause mortality, cardiac death)

Myocardial infarction, all-cause mortality and cardiac mortality

There were no differences between the SPECT and NICE guideline-directed care groups in the incidence of MI (0.4 vs. 0.8 per 100 patients; RR 0.50, 95% CI 0.07 to 3.52), all-cause mortality (0.6 vs. 1.3 per 100 patients; RR 0.50, 95% CI 0.10 to 2.45), and cardiac mortality (0.6 vs. 0.4 per 100 patients; RR 1.50, 95% CI 0.16 to 14.31; Figure 30) over a median follow-up of 16 months.

Other Outcomes

There were no differences between the SPECT and NICE guideline-directed care groups in the incidence of MACE, a composite outcome of cardiovascular death, MI, unplanned revascularization or hospital admission for cardiac causes (3.1 vs. 2.5 per 100 patients; RR 1.24, 95% CI 0.49 to 3.17), heart failure (0.8 vs. 0 per 100 patients), stroke or TIA (0.2 vs. 0 per 100 patients), and arrhythmia (0.6 vs. 0.8 per 100 patients; RR 0.75, 95% CI 0.13 to 4.45) over a median follow-up of 16 months.

7.2.3.2 Key Question 2: Clinical decision making

Additional testing

SPECT was associated with a decreased incidence of ICA compared with NICE guideline-directed care up to 12 months of follow-up: 16.2 versus 42.5 per 100 patients; RR 0.38, 95% CI 0.30 to 0.49; RD –26.3%, 95% CI –33.4% to –19.2% (Figure 31). Unnecessary ICA (as described by the authors) was also less common following SPECT versus NICE guideline-directed care: 7.1 versus 28.8 per 100 patients; RR 0.25, 95% CI 0.17 to 0.36; RD –21.7%, 95% CI –27.9% to –15.5%. The primary reasons cited for an unnecessary ICA included a negative noninvasive test overruled by the attending physician (4.4 per 100 patients) and a false-positive test (2.5 per 100 patients) in the SPECT group, and direct referral to ICA (per algorithm) for patients with high pretest likelihood in the guideline-directed care group (24.6 per 100 patients). This trial did not report on additional noninvasive testing.

Treatment

The frequency of any revascularization procedure over 12 months was similar between the SPECT and NICE guideline-directed care groups, respectively, (8.3 vs. 8.8 per 100 patients; RR 0.95, 95% CI 0.57 to 1.57), Figure 32, as was the frequency of PCI (5.6 vs. 5.8 per 100 patients; RR 0.96, 95% CI 0.51 to 1.80) and CABG (2.7 vs. 2.9 per 100 patients; RR 0.93, 95% CI 0.37 to 2.29) specifically. In both groups 0.8% of patients had an unplanned PCI over a median follow-up of 16 months (RR 1.0, 95% CI 0.18, to 5.41). There were no unplanned CABGs performed.

Hospitalization and ED visits

This trial did not report hospitalization or ED visits.

7.3 SPECT versus ICA

One good-quality trial (N=446)[220,241] compared SPECT versus invasive coronary angiography (ICA) in patients with suspected or known (25% with prior MI) stable CAD referred for outpatient angiography (See Appendix Q). Referral to angiography was based on the results of an exercise ECG complete within 1 month of enrollment, the results of which were not available to the trial personnel. Patients in the SPECT arm were randomized to undergo rest and stress 99m Tc sestamibi SPECT with adenosine (or dobutamine if adenosine was contraindicated) while those randomized to the control arm underwent ICA as originally planned. Mean patient age was 61 years, and 69% were male. Patients were considered high-risk (69%) or low-risk (31%) according to the Pryor risk assessment and randomization was stratified based on pretest risk. Baseline cardiac risk factors included prior cerebrovascular accident (5%), peripheral vascular disease (9%), diabetes (12%), family history of CAD (26%), hypertension (56%), hyperlipidemia (75%), and smoking (44%). Patients were on a variety of cardiovascular related medications at baseline including antiplatelets, statins, and beta-blockers primarily as well as ACE inhibitors, calcium channel blockers, nicorandil, nitrates, diuretics, and angiotensin-II receptor antagonists. The primary follow-up period was 18 months. The secondary publication by Thom et al. (focused on cost-effectiveness) provided mortality data out to 72 months and post-index revascularization rates out to 32 months. This trial was conducted in the United Kingdom and funded by the National Institute for Health Research.

See Appendix D for details regarding study quality determination.

7.3.1 Summary of results

- There was insufficient evidence to draw conclusions regarding the risk of MI, all-cause mortality and cardiac mortality between groups. Over 18 months, the absolute risk was ≤2 per 100 patients across both test arms for all outcomes; at 72 months, the absolute risk of all-cause mortality was 3 per 100 patients. Given that these are rare events, the trial may not have been sufficiently powered to detect a difference (SOE Insufficient).
- Compared with ICA, SPECT was associated with a decreased risk of any revascularization after the index visit through 36 months (43.8 vs. 53.2 per 100 patients; RR 0.82, 95% CI 0.68 to 0.99; RD –9.4%, 95% CI –18.6% to –0.2%) (SOE Low). There was no difference in the risk of any hospitalization for chest pain (SOE Low).
- There was insufficient evidence to draw conclusions regarding impact of testing strategies on additional downstream NIT (SOE Insufficient).

Detailed results

7.3.2 Key Question 1: Primary Outcomes (MI, all-cause mortality, cardiac death)

Myocardial infarction, all-cause mortality and cardiac mortality

Two patients randomized to SPECT compared with no patient randomized to ICA were admitted for acute MI over the 18-month follow-up (0.9 vs. 0 per 100 patients; p=0.16)[220], Table 49. There were no differences in the incidence of all-cause (1.8 vs. 1.8 per 100 patients) or cardiac (2.2 vs. 1.4 per 100 patients) mortality between diagnostic strategies by 18 months[220] or for all-cause mortality through 72 months (3.1 vs. 3.2 per 100 patients; RR 0.99, 95% CI 0.35 to 2.78)[241].

Other clinical outcomes

There was no difference between diagnostic strategies for the composite outcomes of any nonfatal event and any fatal plus nonfatal event at 18 months, or in the proportion of patents achieving a clinically significant improvement in Canadian Cardiovascular Society angina class (Table 49). There were no differences between SPECT and ICA on all subscales of the Seattle Angina Questionnaire or on the SF-36 health-related quality of life questionnaire at 6 and 18 months (Appendix Table O6).

7.3.3 Key Question 2: Clinical decision making

Additional testing

Most patients (78%) in the SPECT arm went on to get subsequent ICA during the 18-month follow-up. No patient in the ICA arm required repeat ICA. SPECT was associated with less additional noninvasive testing compared with ICA (0.4 vs. 3.6 per 100 patients; RR 0.12, 95% CI 0.02 to 0.98; RD –3.2%, 95% CI –5.8% to –0.6%)[220], Table 49; all but one additional test was SPECT imaging. The timing of additional noninvasive testing was unclear.

Treatment

Similar proportions of patients received revascularization following index testing with stress echocardiography versus ICA (30.4 vs. 34.2 per 100 patients, respectively; RR 0.89, 95% CI 0.68 to 1.16), to include rates of PCI and CABG.[220] However, SPECT was associated with a lower cumulative rate of revascularization over 36 months versus ICA (43.8 vs. 53.2 per 100 patients; RR 0.82, 95% CI 0.68 to 0.99; RD –9.4%, 95% CI –18.6% to –0.2%)[241], Table 49.

Hospitalization

There was no difference in the proportion of patients admitted for chest pain over 18 months in the stress echocardiography arm versus the ICA arm: 8.5 versus 6.3 per 100 patients, RR 1.35 (0.69 to 2.62)[220], Table 49.

Table 49. SPECT vs. ICA: Summary of primary and clinical decision making outcomes

Author, year RCT	Outcome	Timepoint	SPECT	ICA	Risk Ratio (95% CI)
Sharples 2007 Thom 2014 CECaT Suspected and known CAD Low (21%) and high (69%) risk.	**Admission for acute MI**	18 months	0.9% (2/224)	0% (0/222)	NC, p=0.16
	All-cause mortality	18 months	1.8% (4/224)	1.8% (4/222)	0.99 (0.25 to 3.91)
		72 months	3.1% (7/224)	3.2% (7/222)	0.99 (0.35 to 2.78)
	Cardiac mortality	18 months	2.2% (5/224)	1.4% (3/222)	1.65 (0.40 to 6.83)

		18 months	42% (87/224)	32% (65/222)	1.33 (1.02 to 1.72)

ACP = acute chest pain; ACS = acute coronary syndrome; Adj = adjusted statistically; CABG = coronary artery bypass graft; CCCS = Canadian Cardiovascular Society; CI = confidence interval; ICA = invasive coronary angiography; MD = mean difference; MI = myocardial infarction; PCI = percutaneous coronary intervention; RCT = randomized controlled trial; SD = standard deviation; SF-36 = Short-Form 36 quality of life questionnaire.
*Includes admission for chest pain or acute MI, unplanned PCI or CABG, and other (other for the SPECT group = 1 post-CABG wound infection, 1 admission for breathlessness, 1 admission for ICD implant, 1 admission for suspected MI found to be muscular pain, 1 seen in A&E with chest pain in SPECT; and for the ICA group = 1 CVA post-ICA, observed overnight).

7.3.4 Key Question 3: Safety

Summary of results

- Test-related complications appear to be rare following SPECT in one good-quality trial (SOE Low).
- Data from one fair-quality trial was insufficient to draw conclusions regarding radiation exposure (SOE Insufficient). Mean exposure following SPECT was 14 mSv; exercise ECG does not use radiation.
- Adverse events from stress agents are relatively common and ranged from 2% to 13% of patients (5% to 37% of events) for dipyridamole and from 4% to 53% for regadenoson; the most

common events included headache, dyspnea, GI upset/nausea and dizziness or lightheadedness (SOE Low). Most reported symptoms are expected responses to the pharmacologic agents used.

Safety data were poorly reported by the included RCTs evaluating SPECT imaging as a first line diagnostic test. One fair-quality trial comparing SPECT with exercise ECG in a population of only women with stable angina and suspected CAD reported mean ionizing radiation exposure following index SPECT testing which was 14 mSv.[223] A second, good-quality trial comparing SPECT with NICE-guideline directed care reported that five test-related medical complications occurred, but none were following SPECT imaging.[88] The complications included one case of mild urticarial reaction following cardiac MRI, one vasovagal episode following cardiac CT, and one each of ventricular tachycardia, pseudo-aneurysm and popliteal deep venous thrombosis, and right coronary artery spasm and transient ST elevation following ICA. No further information was provided.

Given the lack of safety data reported by the included RCTs, additional studies reporting test-specific adverse events related to SPECT were evaluated for inclusion and are summarized below. See Appendix O for detailed results tables.

Adverse events related to Regadenoson and Dipyridamole

Three studies were identified that evaluated regadenoson or dipyridamole as stressor agents for SPECT MPI in patients with suspected or known CAD: two case series (one of regadenoson[134] and one of dipyridamole[158]) and one retrospective comparative cohort study comparing regadenoson versus dipyridamole.[13] For the purposes of this report, each arm of the comparative cohort was treated as a case series.

Across the two studies[13,158] reporting AEs following dipyridamole use for SPECT (N=284 patients in one study and N=604 adverse events in the other), the most common events included headache (13% of patients in one study; 37% of all AEs in the other), gastrointestinal upset/nausea (8% of patients; 11% of all AEs), chest pain (4% of patients; 12% of all AEs), dizziness or lightheadedness (6% of patients; 5% of all AEs), flushing (4% of patients; 8% of all AEs), and dyspnea (2% of patients; 5% of all AEs).

Across the two studies[13,134] reporting AEs following regadenoson use for SPECT (N=96 and 284), the most common events included dyspnea (30% and 53%), gastrointestinal upset/nausea (28% and 3%), chest pain (9% and 16%), dizziness or lightheadedness (8% and 13%), headache (7% and 12%), and flushing (4% and 6%).

Most reported symptoms are expected responses to the pharmacologic agents used. All reported side effects can be found in Appendix O, Table O26.

7.3.5 Key Question 4: Differential Effectiveness and Safety

None of the included trials evaluating SPECT versus stress echocardiography, exercise ECG, clinical assessment alone or NICE-guideline directed care reported safety or differential effectiveness or safety.

8 Positron Emission Tomography (PET) Results

8.1 PET versus SPECT

Two trials (total N=540) evaluated the effectiveness of PET compared with SPECT across different patient populations.

One trial (N=210)[168] randomized stable patients with a mixed of suspected (70%) or known (30%) CAD to initial diagnostic testing with PET versus SPECT in an outpatient setting. The mean patient age was 64 years, and 50% of patients were female. Presenting symptoms included any chest pain in 37%, shortness of breath in 16% and atypical angina in 15%. Baseline risk factors included high blood pressure in 49%, a family history of CAD in 19%, high cholesterol in 13% and congestive heart disease in 3%; in addition, 13% had undergone prior coronary angiography and 11% had a prior MI. PET imaging was performed using Rb-chloride for the radioactive tracer; all patients received dipyridamole as the stressor. SPECT imaging was performed using TI-chloride and Tc-labeled Sestamibi for radioactive tracers (dual-isotope technique); 94% of patients received dipyridamole as the stressor and 6% received dobutamine. Follow-up was a mean of 9 months (range, 6 to 12 months). This trial was conducted in the United States and funding was provided, in part, by industry (Bracco Diagnostics, Positron Corporation). This trial was rated as poor quality. Methodological limitations included unclear randomization and allocation concealment methods, lack of independent or blinded outcomes assessment, difference in sex (a key CAD risk factor) at baseline between treatment groups, and it was unclear whether there was comparable follow-up time between treatment groups.

The second trial (N=322)[189] randomized stable patients with known CAD presenting with new or worsening symptoms to receive PET versus SPECT in an outpatient setting. History of CAD was defined as presence of prior MI or prior coronary revascularization. The mean age of patients was 66 years, and 36% were female. Presenting symptoms included typical chest pain in 33%, atypical chest pain in 27%, non-anginal chest pain in 21%, and shortness of breath in 68%. Baseline cardiac risk factors included hyperlipidemia (99%), hypertension (90%), family history of cerebrovascular disease (43%), diabetes (28%), peripheral vascular disease (27%), smoking (18%), and prior cerebrovascular accident (15%). Sixteen percent of patients had atrial fibrillation. Regarding baseline medications, 89% of patients were taking aspirin, 78% were on 3 or more antianginal medications, 77% were on beta-blocker therapy, and 77% were on a statin. Both PET and SPECT imaging was performed using Tc-99m Sestamibi, RB-82 for the radioactive tracer and all patients in both groups received dipyridamole or regadenoson as the stressor. Follow-up was 12 months. This trial was conducted in the United States and funding was provided by Blue Cross Blue Shield. This trial was considered good quality.

8.1.1 Summary of results

- In the good-quality trial in patients with known CAD and new or worsening symptoms, the absolute risks of MI and all-cause mortality were ≤1 per 100 patients across both the PET and SPECT arms over 12 months, however the evidence was considered insufficient to draw conclusions (SOE Insufficient). There was no difference in the risk of ICA (29 vs. 28 per 100

patients); of diagnostic failure, defined as unnecessary ICA or additional confirmatory noninvasive testing within 2 months (2.0 vs. 2.5 per 100 patients); of any revascularization (16 vs. 15 per 100 patients); and of escalation in antianginal therapy (26 vs. 23 per 100 patients) (SOE Low for all).
- The only outcome reported by the older, poor-quality trial evaluating a mixed population of suspected and known CAD was cardiac mortality (absolute risk 3 vs. 4 in 100 patients over a mean 9 months) (SOE Insufficient).
- Neither trial reported on test safety or on differential effectiveness or safety.

Detailed results

Across both trials, there were no difference in any of the reported outcomes for patients randomized to PET versus SPECT (Table 50).

8.1.2 Key Question 1: Primary Outcomes (MI, all-cause mortality, cardiac death)

In the good-quality trial in patients with known CAD and new or worsening symptoms, the absolute risks of MI and all-cause mortality were ≤1 per 100 patients across both the PET and SPECT arms over 12 months.[189] The only outcome reported by the older, poor-quality trial evaluating a mixed population of suspected and known CAD was cardiac mortality (absolute risk 3 vs. 4 in 100 patients over a mean 9 months).[168] See **Error! Reference source not found.** for data.

8.1.3 Key Question 2: Clinical decision making

Over 12 months, the risk of ICA was 29 versus 28 per 100 patients; of any revascularization was 16 versus 15 per 100 patients; and of escalation in antianginal therapy was 26 versus 23 per 100 patients, for PET versus SPECT, respectively, in the good-quality trial.[189] The risk of diagnostic failure, defined as unnecessary ICA or additional confirmatory noninvasive testing within 2 months, was 2.0 versus 2.5 per 100 patients. See Table 50 for data. There was no difference on any of the SAQ subscales or in the Rose Dyspnea Score between test arms (Appendix H).

Table 50. Summary of primary clinical and decision-making outcomes for comparison of PET with SPECT

Study	Outcome	F/U	PET % (n/N)	SPECT % (n/N)	RR (95% CI)*
Mullani 2000 Mixed suspected or known CAD	Cardiac mortality†	Mean 9 (range 6-12) months	3% (3/105)	4% (4/105)	RR 0.75 (0.17, 3.27)

	Obstructive disease on angiography‡	3 months	15.5% (25/161)	10.6% (17/161)	RR 1.47 (0.83, 2.62)
	Diagnostic failure§	2 months	1.9% (3/161)	2.5% (4/161)	RR 0.75 (0.17, 3.30)
	Revascularization (PCI/CABG)	3 months	11.2% (18/161)	9.9% (16/161)	RR 1.13 (0.60, 2.13)
		6 months	12.4% (20/161)	11.8% (19/161)	RR 1.05 (0.58, 1.90)
		12 months	15.5% (25/161)	14.9% (24/161)	RR 1.04 (0.62, 1.74)
	Late revascularization after 3 months**	3 months	4.3% (7/161)	5.0% (8/161)	RR 0.88 (0.32, 2.36)
	Escalation in anti-anginal therapy††	3 months	25.5% (41/161)	23.0% (37/161)	RR 1.11 (0.75, 1.63)

CAD = coronary artery disease; MI = myocardial infarction; NC = not calculable; PET = positron emission tomography; RR = risk ratio; SPECT = single photon emission computed tomography
*Calculated unless otherwise indicated.
†2 of the deaths occurred in patients with prior history of CAD (3% [1/31] PET vs. 3% [1/31] SPECT), whereas 5 deaths occurred in patients with no prior history of CAD (3% [2/74] PET vs. 4% [3/73] SPECT).
‡Defined as stenosis of ≥ 50% of the left main coronary artery or ≥ 70% of a major epicardial or branch vessel or ≥ 70% of a graft vessel with occluded flow by native circulation for patients with history of coronary bypass graft surgery.
§Defined as unnecessary coronary angiography (i.e. absence of ≥ 50% stenosis in ≥1 vessels should the patient have undergone angiography) or additional confirmatory non-invasive testing such as repeat MPI, stress echo, of CCTA within 60 days of the baseline MPI
**Defined as the cumulative number of patients that had revascularization after 3 months.
††Defined as addition of another anti-anginal medication class or increase in dose or frequency of one or more of existing anti-anginal medications within 3 months post baseline MPI

8.1.4 Key Question 3: Safety

Neither trial reported on adverse events related to the diagnostic tests or radiation exposure.

8.1.5 Key Question 4: Differential Effectiveness and Safety

Neither trial reported differential effectiveness or safety.

9 Stress Echocardiography Results

Six trials (across 8 publications) evaluated the effectiveness and/or safety of stress echocardiography compared with exercise ECG (5 RCTs)[48,91,117,180,211,262], "standard care" (1 RCT)[180], and ICA (1 RCT)[220,241]. One trial included both an exercise ECG and a standard care comparison arm[180].

9.1 Stress Echocardiography versus Exercise ECG

Among the five trials comparing stress echocardiography with exercise ECG, two (total N=543) included stable patients with suspected CAD (known CAD was an exclusion criteria) treated on an outpatient basis (See Appendix Q). Mean patient age was 54 years in both trials. One trial enrolled only women[211] while in the second trial most of the population was male (68%). In the latter trial, patients' pre-test risk was considered low (41%), intermediate (34%), and high (25%); the other trial did not report pre-test risk. Regarding cardiac risk factors, there was a similar proportion of patients with diabetes in both trials (8% and 9%) but a greater proportion of patients with hypertension (49% and 18%), smoking history (21% and 8%), and family history of CAD (23% and 13%) in the trial enrolling women only. The latter trial, 42% of patients had hyperlipidemia and 76% were postmenopausal. Neither trial reported baseline pharmacological treatments. In one trial, patients in both arms underwent treadmill exercise using the standard Bruce protocol; in the echocardiography arm, intravenous contrast (Sonovue) was used as needed in technically difficult patients.[91,262] In the second trial, both treadmill exercise and pharmacological stressor (dobutamine) was used in the echocardiography arm depending on patient capability with no mention of whether contrast was used; treadmill exercise was used in the ECG arm. Mean follow-up periods were 28 and 36 months. One trial was conducted in the United Kingdom and the other in Canada. Both were funded by clinical research grants.

The remaining three trials (total N=854) comparing stress echocardiography with exercise ECG included patients with acute symptoms presenting to the ED or hospital (See Appendix Q). One RCT included low-risk patients with suspected ACS[180], one included patients with suspected or known CAD (27% with known ischemic heart disease) at primarily low (21%)-to-intermediate (69%) pretest risk[117], and the third (COSTAMI-II) included patients presenting with uncomplicated acute MIs.[48] Mean patient age ranged from 51 to 60 years across the trials. The majority of patients in all trials were male, with considerably more males in the trial evaluating those with uncomplicated MIs (57% to 61% vs. 87%). Regarding cardiac risk factors, the proportion of patients with prior MI ranged from 3% to 15%, prior revascularization from 3% to 25% (PCI, 2%–14% and CABG, 1%–11% in the 2 trials that reported it), hypertension from 36% to 66%, diabetes from 9% to 24%, and smoking from 44% to 63%. Pharmacological treatment at baseline varied across the populations. In the trial of low-risk patients with suspected ACS, 20% were taking antiplatelets, 13% beta-blockers, 11% calcium channel blockers, and 9% nitrates.[180] In the trial of low-to-intermediate risk patients with suspected or known CAD, 82% were taking aspirin, 52% statins, 41% beta-blockers and clopidogrel, 34% ACE inhibitors, and 23% calcium channel blockers.[117] The trial of uncomplicated MI patients did not report baseline medications. Two trials used dobutamine/atropine in the echocardiography arm while the third used either dobutamine or exercise as the stressor. Treadmill exercise was used in the ECG arms. Follow-up periods

ranged from 2 to 24 months. Two trials were conducted at multiple hospitals across several European countries[117,180] and one was conducted in the United Kingdom. One trial received support from professional societies[48] and the remaining two did not report any sources of funding.

One trial was considered good quality[91,262], one fair-quality[48] and three poor quality.[117,180,211] Methodological shortcomings in the fair quality trial included unclear allocation concealment methods, lack of blinding of outcome assessors and unclear attrition. Additional limitations in the poor-quality trials included unclear randomization sequence, between group differences at baseline on key CAD risk factors, and lack of a prespecified definition for a positive test in one trial. Both good-quality trials were in stable patients with suspected CAD. See Appendix D for details regarding study quality determination.

9.1.1 Summary of results

- There was insufficient evidence to draw conclusions regarding the risk of MI, all-cause mortality and cardiac mortality following stress echocardiography versus exercise ECG across the five trials. The absolute risks of MI and all-cause mortality across four trials were 1.3 vs. 0.9 and 0.6 vs. 0.9 per 100 patients, respectively, across follow-up periods ranging from 2 to 36 months. The absolute risk of cardiac mortality in one RCT was 0.5 vs. 0 at 36 months. Given that these are rare events, the trial may not have been sufficiently powered to detect a difference (SOE Insufficient).
- In stable patients with suspected CAD, stress echocardiography was associated with a reduced risk of ICA (1 good-quality RCT; 6.3 vs. 13.4 per 100 patients; RR 0.47, 95% CI 0.24 to 0.90; RD –7.1%, 95% CI –13.0 to –1.2%) (SOE Low) and additional downstream NIT (2 RCTs, 1 good and 1 poor quality; 5.8 vs. 42.7 per 100 patients; pooled RR 0.15, 95% CI 0.06 to 0.28, I^2=0%; pooled RD –31.6 (95% CI –49.3% to –14.0%, I^2=84%) (SOE Low) compared with exercise ECG over 28 to 36 months. Across the three trials in acute patients with a mix of known or suspected CAD, there was no difference between groups in either outcome, though one fair-quality trial tended to favor echocardiography for ICA (lower risk); heterogeneity was high possibly due to differences in populations, pretest risk and follow-up times (SOE Low for ICA; SOE Insufficient for additional NIT).
- Across trials in both stable (1 RCT) and acute patients (3 RCTs) with varying pretest risks of CAD, there were no differences between testing arms in the risk of revascularization (4 RCTs, 1 good, 2 fair and 1 poor quality) or (re)hospitalization (3 RCTs, 1 good, 1 fair and 1 poor quality) over follow-up periods ranging from 2 to 36 months (SOE Moderate for both).

Detailed results

9.1.2 Key Question 1: Primary Outcomes (MI, all-cause mortality, cardiac death)

9.1.2.1 Suspected CAD (stable, non-emergent, outpatient)

Myocardial infarction

One nonfatal MI occurred in both the stress echocardiography and the exercise ECG arms over a mean follow-up of 36 months in one good-quality trial[91,262] (N=385): 0.5% vs. 0.5 per 100 patients, RR 1.02 (95% CI 0.06 to 16.12), Figure 33. In the other poor-quality trial (n=158), which enrolled only women, there was also a total of two MIs (1.3 per 100 patients) over a mean follow-up of 28 months, however the authors did not report the incidence by study arm.[211]

All-cause and cardiac mortality

The good-quality trial[91,262] reported mortality, with a total of five all-cause deaths, one in the stress echocardiography arm versus four the exercise ECG arm: 0.5 vs. 2.1 per 100 patients; RR 0.25 (95% CI 0.03 to 2.25), Figure 34. The one death in the echocardiography arm was considered a cardiac death since evidence of coronary atherosclerosis was evident at autopsy (but no evidence of MI or acute coronary thrombosis). This patient was initially discharged based on a negative stress echocardiogram, re-admitted for urgent noncardiac surgery, and later died at home.

Other Outcomes

Both trials reported the incidence of MACE, with no difference between the stress echocardiography and the exercise ECG arms, respectively (Table 51). One good-quality RCT (N=385) defined MACE as death, nonfatal MI, late revascularization (>6 months), and hospitalization for chest pain [10.5 vs. 13.4 per 100 patients, mean follow-up 36 months][91,262] and the other poor-quality trial (N=158), in women only, did not define specific clinical events [7.7 vs. 7.4 per 100 patients, mean follow-up 28 months].[211] In the latter trial, the incidence of several other outcomes were reported for the overall population but not by test arm: unstable angina (1.3 per 100 patients), defined as prolonged or accelerating chest pain with EKG changes but no enzyme rise diagnostic of infarction; composite MI or unstable angina (2.5 per 100 patients overall); and acceleration of chest pain syndrome (9.5 per 100 patients), defined as symptoms not fulfilling criteria for MI or UA but resulted in frequency presentation to the clinic or ED. (See Appendix O, Tables O1 and O2 for other outcomes.)

9.1.2.2 Suspected or known CAD and suspected ACS (acute chest pain, ED/similar setting)

Myocardial infarction

There was no difference in the risk of MI across three trials[48,117,180] reporting various lengths of follow-up, both individually and when pooled (3 RCTs, N=707, 1.7 vs. 1.1 per 100 patients, pooled RR 1.52, 95% CI 0.18 to 8.52, I^2=8%), Figure 33. All MIs occurred in the two trials that included patients with either suspected or known CAD. In the poor-quality trial with 27% of patients with known ischemic heart

disease[117], there was one MI in the echocardiography group compared with two in the exercise ECG group over a mean follow-up period of 8.5 months. In the fair-quality trial evaluating uncomplicated MIs[48], nonfatal reinfarction occurred in five versus two patients, respectively, over 12 months (3.8 vs. 1.5 per 100 patients; RR 2.46, 95% CI 0.49 to 12.46). Of note, in the latter trial, four of the five MIs in the echocardiography group and both MIs in the exercise ECG group occurred following negative tests. The third, poor-quality trial in low-risk patients with suspected ACS which reported no MIs followed patients for only 2 months.[180]

All-cause mortality

There was no difference in the risk of all-cause mortality across three trials reporting various lengths of follow-up, both individually and when pooled (3 RCTs, N=707, 0.6 vs. 0.3 per 100 patients, pooled RR 1.60, 95% CI 0.13 to 21.89, I^2=0%)[48,117,180], Figure 34. All deaths occurred in the two trials that included patients with either suspected or known CAD. In the poor-quality trial with 27% of patients with known ischemic heart disease[117], there was one death in each group over a mean follow-up period of 8.5 months. In the fair-quality trial evaluating uncomplicated MIs[48], only one death occurred over 12 months and was in the echocardiography arm (0.8 vs. 0 per 100 patients; RR 2.95, 95% CI 0.12 to 71.88). The causes of death were not reported in either trial. The third, poor-quality RCT in low-risk patients with suspected ACS that reported no deaths followed patients for only 2 months.[180]

Cardiac mortality

None of the trials evaluating patients presenting to the ED or hospital with known or suspected CAD or suspected ACS reported on cardiac mortality.

Other Outcomes

There was no difference between stress echocardiography and exercise ECG in the frequency of MACE across two trials that included patients with either suspected or known CAD (Table 51). In the poor-quality trial with 27% of patients with known ischemic heart disease[117], the rate of the composite outcome of death, MI or revascularization, respectively, was 12.7 versus 16.6 per 100 patients (RR 0.77, 95% CI 0.44 to 1.34) and of death or MI was 1.4 versus 2.0 per 100 patients (RR 0.71, 95% CI 0.12 to 4.18) over a mean follow-up period of 8.5 months. In the fair-quality trial evaluating uncomplicated MIs[48], the frequency of death, nonfatal MI or unstable angina over 12 months was 19.7 versus 13.8 per 100 patients (RR 1.42, 95% CI 0.82 to 2.47). In the latter trial, the frequency of unstable angina requiring admission did not differ between those who received echocardiography versus exercise ECG, 15.2 versus 12.3 per 100 patients (16/130), RR 1.23 (95% CI 0.67 to 2.27). In a third trial[180], in patients with suspected ACS, there was no difference in quality of life at 2 months as measured by the Nottingham Health Profile (Appendix Table O2).

Table 51. MACE frequency in trials comparing stress echocardiography vs. exercise ECG
MACE frequency in trials comparing stress echocardiography vs. exercise ECG

Author, year RCT	Time point	MACE components	Echocardiography	Exercise ECG	Risk Ratio (95% CI)
Suspected CAD, stable outpatient					
Sanfilippo 2005	Mean 28 ± 14.2 months	"Clinical events" (NOS)	7.7% (8/104)	7.4% (4/54)	1.04 (0.33 to 3.29)
		MI or unstable angina	2.5% (4/158)*		NA
Zacharias 2017, Gurunathan 2018	Mean 36 ± 8.4 months	Death, nonfatal MI, late revascularization (>6 months), or hospitalization for chest pain	10.5% (20/191)	13.4% (26/194)	0.78 (0.45 to 1.35)
Suspected or Known CAD, ED/hospital

9.1.3 Key Question 2: Clinical decision making

9.1.3.1 Suspected CAD (stable, non-emergent, outpatient)

Additional testing

One good-quality trial[91] (N=385) reported that stress echocardiography was associated with a reduction in referral for ICA compared with exercise ECG over a mean of 36 months: 6.3 versus 13.4 per 100 patients, RR 0.47 (95% CI 0.24 to 0.90), RD –7.1% (95% CI –13.0 to –1.2), Figure 35; most ICAs occurred within 4 months as a direct consequence of the initial test [4.7 vs. 9.8 per 100 patients, RR 0.48 (95% CI 0.22 to 1.04)]. The second, poor-quality trial in women only did not report ICA rates.[211]

In both trials, compared with exercise ECG, stress echocardiography was associated with a reduction in any downstream noninvasive testing (i.e., stress echocardiography, cardiac MRI, SPECT or exercise ECG) (2 RCTs, N=543, 5.8 vs. 42.7 per 100 patients; pooled RR 0.15, 95% CI 0.06 to 0.28, I^2=0%, Figure 36; pooled RD –31.6%, 95% CI –49.3% to –14.0%, I^2=84%); results were similar for any downstream noninvasive testing requiring stress or imaging (i.e., stress echocardiography, cardiac MRI, SPECT) (2

RCTs, N=543, 5.4 vs. 40.7 per 100 patients, pooled RR 0.15, 95% CI 0.06 to 0.28, I^2=0%; pooled RD –30.7%, 95% CI –46.3% to –15.1%, I^2=80%), Figure 37. Only the good-quality trial[91] reported downstream noninvasive testing requiring radiation with no difference between the echocardiography and the ECG group, respectively: 0 versus 1.1 per 100 patients, RR 0.20 (95% CI 0.01 to 4.20); both additional tests were SPECT.

Treatment

There was no difference between groups in the subsequent rate of any revascularization in one good-quality trial with a mean follow-up of 36 months (N=385, 5.8 vs. 6.2 per 100 patients; RR 0.93, 95% CI 0.42 to 2.06)[91], Figure 38. The second, poor-quality trial in women only did not report revascularization rates.[211] Neither trial reported change in medication therapy based on initial diagnostic strategy.

Hospitalization and ED visits

One good-quality trial reported no difference between groups in subsequent hospitalization for chest pain over a mean 36 months (N=385, 7.9 vs. 9.8 per 100 patients; RR 0.80, 95% CI 0.42 to 1.53), Figure 39, but fewer ED visits in the stress echocardiography arm [14 (8 overnight stays) vs. 30 (29 overnight stays), p<0.01]; it was unclear from the article if the latter represented patients or events.[91]

9.1.3.2 Suspected or known CAD and suspected ACS (acute chest pain, ED/similar setting)

Additional testing

There was no difference in the frequency of referral to ICA across three trials with follow-up periods ranging from 2 to 12 months (3 RCTs, N=716, 24.4 vs. 28.4 per 100 patients, pooled RR 0.85 95% CI 0.36 to 1.33, I^2=64%)[48,117,180], Figure 35. Individually, only one poor-quality trial[117] showed a reduction in ICA referral favoring echocardiography (14.2 vs. 23.4 per 100 patients; RR 0.61, 95% CI 0.37 to 0.99) over a mean follow-up of 8.5 months, however, the estimate was marginally statistically significant. In this same trial, of those referred to ICA, more patients in the echocardiography versus exercise ECG arm showed significant coronary artery disease though the difference was not statistically significant (72.6 vs. 55.6 per 100 patients; RR 1.37, 95% CI 0.94 to 2.0).

Only poor-quality one trial[180] (N=152), in patients with suspected ACS, reported the frequency of additional noninvasive testing which was similar following stress echocardiography versus exercise ECG over 2 months: 10.3 versus 9.3 per 100 patients; RR 1.11 (95% CI 0.42 to 2.92), Figure 36. Noninvasive tests included primarily exercise ECG followed by transthoracic echocardiography.

Treatment

There was no difference in the incidence of any revascularization between diagnostic strategies across the same three trials, both individually and when pooled (3 RCTs, N=701, 19.1 vs. 20.2 per 100 patients; pooled RR 0.95, 95% CI 0.64 to 1.29, I^2=0%), Figure 38. Results were similar when just the better- (fair) quality trial was considered.[48] Results were similar when PCI and CABG were considered separately in two of these trials[48,180], one fair and one poor quality (Figure 40 and Figure 41).

One poor-quality trial in patients with suspected ACS reported pharmacological treatments prescribed at discharge which included nitrates in 14.5% (22/152), beta blockers in 21.7% (33/152), calcium channel blockers in 19.7% (30/152) and antiplatelets in 31.6% (48/152) of the population with similar prescribing patterns between diagnostic testing arms.[180] It was unclear, however, if these constituted only new medications for patients not taking them at baseline or whether/the degree to which patients' medications were discontinued and/or changed.

Hospitalization and length of stay

There was no difference in hospitalization rates across two trials, both individually and when pooled, with follow-up periods of 2 and 12 months (2 RCTs, N=414, 10.5 vs. 10.2 per 100 patients, pooled RR 1.07, 95% CI 0.26 to 2.29, I^2=42%)[48,180], Figure 39. Similarly, length of hospital stay was similar between groups in both trials: mean 9 versus 10 days in one fair-quality trial (patients with uncomplicated MI)[48] and 40 versus 39 hours in the other poor-quality trial (patients with suspected ACS)[180], Appendix O, Table O2.

9.2 Stress Echocardiography versus Standard Care

One trial (N=201)[180] compared stress echocardiography with "standard care" in low-risk patients with suspected ACS presenting to the ED (See Appendix Q). Mean patient age was 54 years and 46% were female. Twenty percent of patients presented with atypical ACS. Baseline cardiac risk factors included prior MI (2%), prior unstable angina (2%), prior revascularization (4%), diabetes (11%), hypercholesterolemia (39%), hypertension (42%), and smoking (48%). Pharmacological treatment at admission included antiplatelets (23%), beta-blockers (15%) calcium channel blockers (13%), and nitrates (10%). Patients randomized to echocardiography received dobutamine-atropine stress echocardiography; those with a negative test were immediately discharged. Patients randomized to standard care were hospitalized until a diagnosis was reached according to local protocols; the final diagnosis was achieved using clinical judgment only (i.e., no additional diagnostic examinations) in 71% of patients, exercise treadmill ECG in 13%, stress echocardiography in 11% and ICA in 5%. The follow-up period was 2 months. The trial was conducted across five European countries and did not report any sources of funding.

This trial was considered poor quality due to the following methodological shortcomings: unclear randomization and allocation concealment methods, lack of blinding of outcome assessors, lack of a prespecified definition for a positive test, and high attrition. See Appendix D for details regarding study quality determination.

9.2.1 Summary of results

- Data from one small, poor-quality trial (N=201) in acute patients with suspected ACS are insufficient to draw conclusions regarding the risk of MI, all-cause or cardiac mortality, ICA, additional downstream NIT, any revascularization and rehospitalization for acute chest pain following stress echocardiography versus standard care.
- No MIs and no deaths were reported in either test arm. Stress echocardiography resulted in fewer referrals for ICA and additional NITs, and fewer rehospitalizations for acute chest pain, but no difference in revascularization rates (SOE Insufficient).

Detailed results

9.2.2 Key Question 1: Primary Outcomes (MI, all-cause mortality, cardiac death)

No MIs and no deaths were reported over the 2-month follow-up period, Table 52.

9.2.3 Key Question 2: Clinical decision making

Compared with standard care, stress echocardiography was associated with fewer referrals to ICA (0% vs. 11%; RR 0.06, 95% CI 0.0 to 0.96; RD –10.9%, 95% CI –19.2% to –2.7%) and fewer additional noninvasive tests (10 vs. 49 per 100 patients; RR 0.21, 95% CI 0.10 to 0.43, RD –38.7%, 95% CI –53.6% to –23.8%) with no statistical difference between groups in revascularization rates (6.5 vs. 3.6 per 100

patients) or pharmacological treatments prescribed at discharge (Table 52). Fewer patients randomized to stress echocardiography were re-hospitalized for ACP over the 2-month follow-up period (3 vs. 15 per 100 patients; RR 0.18, 95% 0.04 to 0.81, RD –12.0%, 95% CI –21.9% to –2.0%) and length of hospital stay was significantly reduced in the echocardiography arm (MD –55 hours, 95% –75 to –35). The latter may in part be due to the design of trial/triage at presentation.

Table 52. Stress echocardiography vs. standard care

Author, year RCT	Outcome	Echocardiography	Standard care	Risk Ratio (95% CI)

ACP = acute chest pain; ACS = acute coronary syndrome; CABG = coronary artery bypass graft; CI = confidence interval; ICA = invasive coronary angiography; MD = mean difference; MI = myocardial infarction; PCI = percutaneous coronary intervention; RCT = randomized controlled trial; SD = standard deviation.

9.3 Stress Echocardiography versus ICA

One good-quality trial (N=448)[220,241] compared stress echocardiography versus invasive coronary angiography (ICA) in patients with suspected or known (27% with prior MI) stable CAD referred for outpatient angiography (See Appendix Q). Referral to angiography was based on the results of an exercise ECG complete within 1 month of enrollment, the results of which were not available to the trial personnel. Patients in the echocardiography arm were randomized to undergo dobutamine-atropine stress echocardiography with contrast while those randomized to the control arm underwent ICA as originally planned. Mean patient age was 62 years, and 69% were male. Patients were considered high-risk (69%) or low-risk (31%) according to the Pryor risk assessment. Baseline cardiac risk factors included prior cerebrovascular accident (5%), peripheral vascular disease (8%), diabetes (12%), family history of CAD (27%), hypertension (55%), hyperlipidemia (77%), and smoking (45%). Patients were on a variety of cardiovascular related medications at baseline including antiplatelets, statins, and beta-blockers primarily as well as ACE inhibitors, calcium channel blockers, nicorandil, nitrates, diuretics, and

angiotensin-II receptor antagonists. The primary follow-up period was 18 months. The secondary publication by Thom et al. (focused on cost-effectiveness) provided mortality data out to 72 months and post-index revascularization rates out to 32 months. The trial was conducted at a single hospital in the United Kingdom and was funded by the National Institute for Health Research.

See Appendix D for details regarding study quality determination.

9.3.1 Summary of results

- There was insufficient evidence from one good-quality trial to draw conclusions regarding the risk of MI, all-cause mortality and cardiac mortality between groups. Over 18 months, the absolute risk was <3 per 100 patients across both test arms for all outcomes; at 72 months, the absolute risk of all-cause mortality was 4.9 vs. 3.2 per 100 patients. Given that these are rare events, the trial may not have been sufficiently powered to detect a difference (SOE Insufficient).
- There were no differences between stress echocardiography and ICA in the risk of additional downstream NIT (SOE Insufficient), any revascularization and hospitalization for chest pain across one trial (SOE Low for both).

9.3.2 Key Question 1: Primary Outcomes (MI, all-cause mortality, cardiac death)

Myocardial infarction, all-cause mortality, cardiac death

Six patients randomized to stress echocardiography compared with no patient randomized to ICA were admitted for acute MI over the 18-month follow-up (2.7 vs. 0 per 100 patients; p=0.01), Table 53. There were no differences in the incidence of all-cause (2.7 vs. 1.8 per 100 patients) or cardiac (0.4 vs. 1.4 per 100 patients) mortality between diagnostic strategies by 18 months[220] or for all-cause mortality through 72 months (4.9 vs. 3.2 per 100 patients; RR 1.54, 95% CI 0.61 to 3.91).[241]

Other clinical outcomes

There was no difference between diagnostic strategies for the composite outcomes of any nonfatal event and any fatal plus nonfatal event at 18 months, or in the proportion of patents achieving a clinically significant improvement in Canadian Cardiovascular Society angina class (Table 53). There were no differences between stress echocardiography and ICA on all subscales of the Seattle Angina Questionnaire or on the SF-36 health-related quality of life questionnaire at 6 and 18 months (Appendix O).

9.3.3 Key Question 2: Clinical decision making

Additional testing

Most patients (75%) in the stress echocardiography arm went on to get subsequent ICA during the 18-month follow-up. No patient in the ICA arm required repeat ICA. No patient in the stress

echocardiography arm received additional noninvasive testing compared with eight patients in the ICA arm (0 vs. 3.6 per 100 patients, p=0.01), including seven SPECT and one cardiac MRI (Table 53). The timing of additional noninvasive testing was unclear.

Treatment

Similar proportions of patients received revascularization following index testing with stress echocardiography versus ICA (35.4 vs. 34.2 per 100 patients, respectively; RR 1.03, 95% CI 0.80 to 1.33), to include rates of PCI and CABG. The cumulative rates of revascularization remained similar over 36 months (53.5 vs. 53.2 per 100 patients; RR 1.01, 95% CI 0.85 to 1.20), Table 53.

Hospitalization

More patients were admitted for chest pain over 18 months in the stress echocardiography arm versus the ICA arm, however the difference was not significant: 10.6 versus 6.3 per 100 patients, RR 1.68 (0.89 to 3.17), Table 53.

Table 53. Stress echocardiography vs. ICA: Summary of primary clinical and decision-making outcomes

Author, year RCT	Outcome	Timepoint	Echocardiography % (n/N)	ICA % (n/N)	Risk Ratio (95% CI)*

	Admission for chest pain	18 months	10.6% (24/226)	6.3% (14/222)	1.68 (0.89 to 3.17)
	Significant improvement in CCS angina class (≥2 decrease)	6 months	31% (67/226)	32% (66/222)	1.00 (0.75 to 1.33)
		18 months	34% (70/226)	32% (65/222)	1.06 (0.80 to 1.40)

ACP = acute chest pain; ACS = acute coronary syndrome; CABG = coronary artery bypass graft; CI = confidence interval; ICA = invasive coronary angiography; MD = mean difference; MI = myocardial infarction; PCI = percutaneous coronary intervention; RCT = randomized controlled trial; SD = standard deviation.
*Calculated by AAI
†Admission for chest pain or acute MI, unplanned PCI or CABG, and other (1 transient ischemic attack in echocardiography group; 1 cerebrovascular accident post-ICA, observed overnight in ICA group)

9.3.4 Key Question 3: Safety

Summary of results

- Data from one poor-quality trial is insufficient to draw conclusions regarding test-related complications.
- Across 11 case-series, the risk of major or life-threatening adverse events (e.g., death, MI, unstable angina, cerebrovascular accident, acute pulmonary edema) as a result of pharmacologic stress agents appears to be low: for dobutamine, ≤0.1% across all outcomes, and for dipyridamole and adenosine, no major adverse events were reported. Minor transient events (e.g., arrhythmias, chest pain, headache, dyspnea, nausea/vomiting) were not uncommon (SOE low for all); most reported symptoms are expected responses to the pharmacologic agents used.
- Definite or suspected contrast related adverse events and allergic reactions appear to be rare (≤2% across all studies/outcomes) (SOE Low)

Across all included trials and comparisons (stress echocardiography versus exercise ECG, "standard care" and ICA), only one trial comparing stress echocardiography with exercise ECG mentioned safety outcomes, the COSTAMI-II trials in patients with uncomplicated MIs presenting to the ED; the authors stated that no complications occurred during either test.[48]

Given the lack of safety data reported by the included RCTs, additional studies reporting test-specific adverse events related to stress echocardiography were evaluated for inclusion and are summarized below. Most identified studies were case series which are considered low quality (i.e., high risk of bias). See Appendix O (Tables O23-O25) for detailed results tables.

9.3.4.1 <u>Adverse events related to Dobutamine (with or without atropine)</u>

Eleven case series (N range, 86 to 2799), seven prospective and four retrospective, were identified that reported adverse events related to the use of dobutamine (with and without atropine) during stress echocardiography in patients with suspected or known CAD (10 studies)[20,45,87,122,155,164,181,191,193,229] and suspected ACS (one study).[77] The mean maximum dose of dobutamine ranged from 31.6 to 50.0 µg/kg/min. Six studies also used atropine (in 33% to 100% of the populations) to achieve target heart rate.

There were no deaths due to dobutamine as reported by six studies (total N=5512)[45,87,122,191,193,229] and the frequency of acute MI ranged from 0% to 0.1% across seven studies[45,87,122,155,191,193,229] (N range, 122

to 2799). One study reported a single case of unstable angina attributed to dobutamine (0.1%, N=802)[122] and another (N=1012) reported that no cerebrovascular accidents occurred.[45] The incidence of acute pulmonary edema was rare across two studies (0% [N=1012] and 0.1% [N=802]). Chest pain (not otherwise specified) was reported by three studies (N range, 86 to 1118) and ranged from 4.6% to 31.4%.

Arrythmia-related adverse events commonly reported across the studies included any arrhythmias or palpitations in six studies (range, 2.1% to 18.0%; N range, 122 to 1118), supraventricular or ventricular tachycardia in ten (range, 0% to 9.0%; N range, 86 to 2799), atrial or ventricular fibrillation in seven (range, 0% to 1.2%; N range 265 to 2799), and bradycardia in two large studies (≤0.2% in both). The occurrence of hypotension was reported in nine studies (range, 0.1% to 12.5%; N range, 86 to 2799) and hypertension in five studies (range, 0% to 7.5%; N range, 122 to 1118).

Other commonly reported side-effects included nausea and/or vomiting in six studies (range, 3.4% to 20.9%; N range, 86 to 1012), headache in four studies (0.8% to 13.6%; N range 122 to 1012), and dyspnea (range, 0% to 13.6%) and tremors (range, 0.4% to 2.4%) in three studies each (N range, 127 to 1012). Most studies reported that most events were minor and transient.

Most reported symptoms are expected responses to the pharmacologic agents used. All reported side effects can be found in Table O23 of the Appendix.

9.3.4.2 Adverse events related to Dipyridamole (with or without atropine) and Adenosine

Three case series (total N=946)[69,76,165], two prospective and one retrospective, were identified that reported adverse events related to the use of dipyridamole (with and without atropine) during stress echocardiography in patients with suspected or known CAD. In all studies the cumulative dose of dipyridamole was 0.84 mg/kg given over 4 min. No “major”, severe, or life-threatening adverse events, to include death, MI and acute coronary syndrome, were reported by two studies (total N=837). All three studies (N range, 109 to 500) reported the frequency of hypotension/bradycardia which ranged from 0.8% to 6.4%, vomiting and nausea which ranged from 0.2% to 5.5%, and headache which ranged from 2.1% to 43%. Two studies reported the occurrence of arrythmias during stress testing which ranged from 2.7% (N=337) to 10.4% (N=550). Studies reported that most events were minor and transient.

One prospective case series (N=1429)[166] was identified that reported adverse events related to the use of adenosine during stress echocardiography in patients with suspected or known CAD. The most commonly occurring side-effects were hyperpnea (16.7%), atypical chest pain (9.9%), flushing (9.4%) and headache (6.6%).

Most reported symptoms are expected responses to the pharmacologic agents used. All reported side effects can be found in Tables O24 and O25 of the Appendix.

9.3.4.3 Adverse events due to non-iodinated contrast agent

Two retrospective comparative cohort studies (N=6,750)[15,119] and one retrospective non-comparative database study (N=3,071)[4] were identified that reported adverse events related to the use of non-iodinated contrast during stress echocardiography. One of the cohort studies presented results stratified by stable patients with suspected or known CAD and acute patients with suspected ACS[15] while the indications for stress echocardiography in the second cohort study were primarily ischemia assessment (80%) and heart transplantation (12.5%).[119] The database study used medical records to identify patients undergoing their first stress echocardiogram during a specific time period and the indication for the test was unclear. The contrast agents used varied across the studies and included Luminity (54%) and SonoVue (46%) in one cohort[15], Definity (100%) in the second cohort[119], and Definity (86%) and Opstison (14%) in the database study.[4]

One cohort study reported acute MI which was rare in both the contrast and non-contrast groups: 0% vs. 0.1%, respectively.[15] Across both comparative cohorts, the risk of allergic reaction to contrast agent was low and occurred in <0.5% of patients who received stress echocardiography with contrast.[15,119] There was a similar, low risk of arrythmias, hypotension, or severe hypertension between groups in one cohort study[15] while the second cohort study reported an increased risk of chest pain (23% vs. 17%; RR 1.35, 95% CI 1.12 to 1.62) in those who received contrast but a lower risk of palpitations (6% vs. 10%; RR 0.62, 95% CI 0.47 to 0.82) compared with those who did not received contrast; there was no difference between groups in other complications in the latter study.

The noncomparative database study reported definite and suspected contrast-related adverse events in 1.3% (41/3071) and 2.2% (68/3071) of patients[4], respectively. Backache, headache or both were rare (<1% each). Other adverse events that may be indicative of an allergic reaction were very rare and occurred in one patient (0.03%) each: transient wheezing without urticaria, urticaria or hives (limb and thorax) and swelling in the mouth, and throat tingling. Adverse reactions thought to be caused by concomitant infusion of contrast agent and dobutamine included chest pain (0.78%), nausea and vomiting (0.10%), and shivering and tremors (0.16%).

9.3.5 Key Question 4: Differential Effectiveness or Safety

None of the included trials comparing stress echocardiography with exercise ECG, “standard care” or ICA reported differential effectiveness or safety.

10 Strength of Evidence (SOE)

Table 10.1. Key Question 1: Strength of evidence: CCTA versus functional testing, primary clinical outcomes across patient populations

Outcome	Follow-up	Studies	Risk of Bias	Serious Inconsistency	Serious Indirectness	Serious Imprecision	Conclusion Effect Estimate (95% CI)	Quality (SOE)
Myocardial infarction Cumulative	Up to 58 months following index test	17 RCTs (N =22,328) **Suspected ACS** ACRIN-PA 2012 Hoffman 2012 Chang 2008 Dedic 2016 Goldstein 2007 Goldstein 2011 Hamilton-Craig 2014 Linde 2015 Levsky 2017 Uretsky 2017 Pineiro-Portela 2021 **Stable patients** Douglas 2915 Min 2012 Karthikeyan 2017 Stillman 2020 McKavanagh 2014 SCOT-HEART 2015	Yes (-1)	No	No	No	**CCTA vs. functional testing** Risk: 1.2 vs. 1.8 per 100 persons Pooled estimates (14 RCTs, N= 21,651) RR 0.70, 95% CI 0.56 to 0.89, I^2=0% RD 0.4, 95% CI 0.1 to 0.8 per 100; I^2=19% 3 smaller RCTs (N=667) reported no MI in either testing arm. **Conclusions:** Pooled estimates following exclusion of one trial in stable outpatients (SCOT-HEART) in which 85% of patients in the CCTA group also received functional testing (ETT) bordered the null (13 RCTS RR, 0.75, 95% CI 0.57 to 0.99) suggesting no clear association for reduction of MI with CCTA. Across all 14 trials, CCTA was associated with lower MI risk compared with functional testing based on pooled estimates; the RD (0.4 per 100 patients) was, however, small. Absolute MI risk was < 2 per 100 patients in both testing arms. Patients' pre-test risk across studies was predominately low to intermediate.	⊕⊕⊕◯ MODERATE

Outcome	Follow-up	Studies	Risk of Bias	Serious Inconsistency	Serious Indirectness	Serious Imprecision	Conclusion Effect Estimate (95% CI)	Quality (SOE)
							Smaller trials may not have been sufficiently powered to detect a difference. **In patients with suspected ACS**, there was no difference in MI between tests at the time of index test, or at 1 to 6.5 months or ≥12 months after the index test. MI was most common around the time of index testing and occurred in 1.9 versus 2.8 per 100 patients. **In stable outpatients**, CCTA was associated with decreased risk of MI across 4 RCTS (pooled RR 0.64, 95% CI 0.44 to 0.87 I^2=0%) however following exclusion of the SCOT-HEART, results were no longer significant (3 RCTs pooled RR 0.69, 95% CI 0.27 to 1.14).	
All-cause Mortality Cumulative	Up to 58 months following index test	17 RCTs (N=21,680) **Suspected ACS** ACRIN-PA 2012 (Litt and Holland) Hoffman 2012 Chang 2008 Dedic 2016 Goldstein 2007 Goldstein 2011 Hamilton-Craig 2014 Linde 2015 Levsky 2015 Levsky 2018	Yes (-1)	No	No	No	**CCTA vs. functional testing** Risk: 1.2 vs. 1.3 per 100 persons Pooled estimate: 11 RCTs (N= 18,935) RR 0.99 95% CI 0.40 to 2.68, I^2=0% RD (not calculated, no association) 6 RCTs (N=2746) reported no mortality in either testing arm. **Conclusions:** CCTA was not associated with reduction in all-cause mortality compared with functional testing. The	⊕⊕⊕◯ MODERATE

Outcome	Follow-up	Studies	Risk of Bias	Serious Inconsistency	Serious Indirectness	Serious Imprecision	Conclusion Effect Estimate (95% CI)	Quality (SOE)
		Uretsky 2017 Pineiro-Portela 2021 **Stable patients** Douglas 2015 Min 2012 Karthikeyan 2017 McKavanagh 2014 SCOT-HEART 2015					absolute risk was 1.2 per 100 patients across testing arms. Patients' pre-test risk across studies was predominately low to intermediate. Smaller trials may not have been sufficiently powered to detect a difference.	
Cardiac Mortality	Up to 58 months following index test	13 RCTs (N=11,647) **Suspected ACS** ACRIN-PA 2012 (Litt and Holland) Hoffman 2012 Goldstein 2007 Goldstein 2011 Nabi 2016 Hamilton-Craig 2014 Linde 2015 Levsky 2018 Uretsky 2017 **Stable patients** Min 2012 Stillman 2020 McKavanagh 2014 SCOT-HEART 2015	Yes (-1)	No	No	Yes (-2)	10 RCTs (N=5559) reported no cardiac mortality in either testing arm. 3 RCTs reported cardiac death **Stable patients:** 1 RCT CCTA 0.28% (5/2073) vs. ETT 0.28% (12/2073), RR 0.42, 95% CI 0.15 to 1.18) **Suspected ACS**: 2 RCTs (N=1942), 2 total events: 1 in CCTA (1 RCT), 1 in functional testing (1 RCT); RR 0.72, 95% CI 0.04 to 13.3) **Conclusions:** Firm conclusions regarding the impact of CCTA or functional testing on cardiac death are not possible. Cardiac death was rare. Sample sizes in individual trials may have been insufficient to detect cardiac death. Populations across trials were generally reported as low to intermediate CAD risk.	⊕◯◯◯ INSUFFICIENT

Reasons for downgrading:

1. Serious risk of bias: The majority of studies are fair quality related to the outcome reported may be downgraded once; If the majority of studies are poor quality, this may be downgraded twice;
2. Inconsistency: differing estimates of effects across trials; If point estimates across trials are in the same direction, do not vary substantially or heterogeneity can be explained, results may not be downgraded for inconsistency. The consistency of single studies is unknown; evidence from single studies may be downgraded.
3. Imprecise effect estimate for an outcome: small sample size and/or confidence interval includes both negligible effect and appreciable benefit or harm with the intervention; If sample size is likely too small to detect rare outcomes, evidence may be downgraded twice. If the estimate is statistically significant, it is imprecise if the CI ranges from "mild" to "substantial". If the estimate is not statistically significant, it is imprecise if the CI crosses the threshold for "mild/small" effects and may be downgraded once. Wide (or unknown) confidence interval and/or small sample size may result in downgrade.
4. Indirect, intermediate or surrogate outcomes may be downgraded.

Table 10.2. Key Question 2: Strength of evidence: CCTA versus functional testing; decision-making, additional testing and management

Outcome	Follow-up	Studies	Risk of Bias	Serious Inconsistency	Serious Indirectness	Serious Imprecision	Conclusion Effect Estimate (95% CI)	Quality (SOE)
ICA referral Cumulative	Up to 58 months	19 RCTs (N=22,335) **Suspected ACS** ACRIN-PA 2012 Hoffman 2012 Chang 2008 Dedic 2016 Goldstein 2007 Goldstein 2011 Hamilton-Craig 2014 Linde 2015 Levsky 2015 Uretsky 2017 Pineiro-Portela 2021 Levsky 2018 Nabi 2016 Miller 2011	Yes (-1)	No	No	No	**CCTA vs. functional testing** **Risk:** 14.4 vs. 12.0 per 100 persons **Pooled estimates** RR 1.25, 95% CI 1.09 to 1.47, I^2=67% RD 2.7, 95% CI 1 to 4 per 100, I^2=59% **Conclusions:** CCTA was associated with more frequent referral to ICA compared with functional testing across patient populations. Sensitivity analyses excluding outliers and poor-quality studies did not alter conclusions. However, in the stable population, exclusion of SCOT-HEART increased the effect size and strengthen the association between CCTA and ICA referral compared with functional testing and substantially reduced the heterogeneity (4 RCTS	⊕⊕⊕◯ MODERATE

Evidence is insufficient to draw firm conclusions about the impact of testing on medication use. Medication use/change was documented differently across trials.	⊕◯◯◯ INSUFFICIENT

Reasons for downgrading:

1. Serious risk of bias: The majority of studies are fair quality related to the outcome reported may be downgraded once; If the majority of studies are poor quality, this may be downgraded twice;
2. Inconsistency: differing estimates of effects across trials; If point estimates across trials are in the same direction, do not vary substantially or heterogeneity can be explained, results may not be downgraded for inconsistency. The consistency of single studies is unknown; evidence from single studies may be downgraded.
3. Imprecise effect estimate for an outcome: small sample size and/or confidence interval includes both negligible effect and appreciable benefit or harm with the intervention; If sample size is likely too small to detect rare outcomes, evidence may be downgraded twice. If the estimate is statistically significant, it is imprecise if the CI ranges from "mild" to "substantial". If the estimate is not statistically significant, it is imprecise if the CI crosses the threshold for "mild/small" effects and may be downgraded once. Wide (or unknown) confidence interval and/or small sample size may result in downgrade.
4. Indirect, intermediate or surrogate outcomes may be downgraded.

Table 10.3. Key Question 3: Strength of evidence: CCTA versus functional testing; Safety, harms and consequences of testing

Outcome	Follow-up	Studies	Risk of Bias	Serious Inconsistency	Serious Indirectness	Serious Imprecision	Conclusion Effect Estimate (95% CI)	Quality (SOE)
Any major test-related AE	Index test up to 24 hours	**3 RCTs (N= 10,270)** Stable outpatients (N=9,470) PROMISE (Douglas 2015) Suspected ACS (N=800) PROSPECT (Levsky 2015) Levsky 2018	Yes (-1)	No	No	Yes (-1)	**CCTA vs. Functional testing** 0% vs. 0% **Conclusion**: No major complications were observed in either arm in 3RCTs. Major complications were defined as death, renal failure requiring dialysis, or anaphylaxis requiring emergency respiratory and/or circulatory support in the PROMISE trial; stroke and cardiac arrest as part of MACE were considered in the other two. The two trials in patients with suspected ACS (N= 400 each) in particular may have been underpowered to detect rare events.	⊕⊕◯◯ LOW

Hospital admission for test-related complication	Index test up to 24 hours	**1 RCT (N=9,470)** **Stable outpatients** PROMISE/Douglas 2015	No	Unknown	No	Yes (-1)	**CCTA vs. any functional test** 0% vs. 0.1% (nuclear stress test)	⊕⊕◯◯ LOW

Outcome(s)	Subgroups	Studies	Risk of Bias	Serious Inconsistency	Serious Indirectness	Serious Imprecision	Conclusion Risk, Effect Estimate (95% CI), p for interaction	Quality (SOE)
							Conclusion: Mean radiation dose at index varied by sex. Doses were higher for men receiving CCTA vs. functional testing.	
Radiation Exposure (mSv) (cumulative) To 28 days	Sex Diabetes Race	Suspected ACS ROMICAT-II trial (N=NR)	Yes (-2)	Unknown	No	Yes -1	**CCTA vs. functional testing (mSv mean (SD)** **Female** 11.0 (8.9) 6.0 (8.2) **Male** 14.7 (12.0) vs. 5.6 (10.7) p= 0.002 **Diabetes** 18.4 (14.7) 6.6 (10.4) **No diabetes** 13.4 (9.8) 5.1 (9.5) P=0.04 Median, IQR **White** 12.0 (7.9 to 17.2) vs 0.0 (0.0 to 12.4) **Black** 11.7 (8.6 to 16 vs. 0.0 (0.0 to 0.0) P=0.60 **Conclusion:** Mean cumulative radiation dose by 28 days varied by sex and diabetes status but not by race for CCTA vs. functional testing. Higher doses in the CCTA groups were seen for men and patients with diabetes. Race did not modify the relationship between testing and dose.	⊕◯◯◯ INSUFFICIENT

*Strength of evidence for evaluation of differential efficacy or safety considers of the overall study risk of bias (study quality) as well as whether subgroup variables and analyses were specified a priori, number of subgroups tested, the hypothesized impact and direction of a subgroup and sample size as evaluation of interaction requires greater sample size.

1. Serious risk of bias: The majority of studies are fair quality related to the outcome reported may be downgraded once; If the majority of studies are poor quality, this may be downgraded twice; For HTE evaluation this may be down-graded an additional level based on failure to specify subgroup analysis *a priori* or if the subgroup hypothesis was not one of a smaller number tested and/or not stated (i.e. large number of subgroups tested)
2. Inconsistency: differing estimates of effects across trials

3. Imprecise effect estimate for a continuous outcome: wide (or unknown) confidence interval and/or small sample size
4. Imprecise effect estimate for a dichotomous outcome: small sample size and/or confidence interval includes both negligible effect and appreciable benefit or harm with TT
5. Imprecise effect estimate for a dichotomous outcome: small sample size, rare outcome
6. Serious risk of bias in evaluation of HTE: the subgroup variables were specified at randomization, however the hypothesized direction was not stated; the subgroup hypothesis was not one of a smaller number tested

Table 10.5. Key Question 1, 2 and 3: Strength of evidence: CCTA vs. ICA

Outcome	Follow-up	Studies	Risk of Bias	Serious Inconsistency	Serious Indirectness	Serious Imprecision	Conclusion Effect Estimate (95% CI)	Quality (SOE)
Key Question 1: Primary clinical outcomes								
Myocardial infarction Cumulative **Mortality, all-cause** Cumulative **Mortality, cardiac** Cumulative	12 months, median 40 months	2 RCTs (N=1,832) **Chang 2019** Suspected CAD, stable outpatients **Dewey 2016** Suspected CAD, stable and acute, atypical chest pain	No	No	No	Yes (-2)	**MI** Risk: 0.3 vs. 0.2 per 100 patients Pooled estimates (2 RCTs, N=1,832): RR 1.26 (95% CI 0.24 to 6.67), I^2=0% RD (not calculated, no association) **All-cause mortality** Risk: 0.2 vs. 0.2 per 100 patients Pooled estimates (2 RCTs, N=1,832): RR 1.03 (95% CI 0.06 to 11.08), I^2=0% RD (not calculated, no association) **Cardiac mortality** Risk: 0 vs. 0.6 per 100 patients 1 RCT (N=329) **Conclusions:** There was no difference in the risk of MI or all-cause mortality for CCTA vs. ICA, despite difference in populations and follow-up duration across the trials. Firm conclusions	MI, all-cause mortality ⊕⊕◯◯ LOW Cardiac mortality ⊕◯◯◯ INSUFFICIENT

Outcome	Follow-up	Studies	Risk of Bias	Serious Inconsistency	Serious Indirectness	Serious Imprecision	Conclusion Effect Estimate (95% CI)	Quality (SOE)
							regarding the impact of CCTA or ICA on cardiac death are not possible. Cardiac death was rare. Sample sizes in individual trials may have been insufficient to detect cardiac death.	
Key Question 2: Clinical Decision-Making Outcomes								
ICA not showing obstructive CAD	12 months, median 40 months	2 RCTs (N=1,832) **Chang 2019** Suspected CAD, stable outpatients **Dewey 2016** Suspected CAD, stable and acute, atypical chest pain	No	No	No	Yes (-1)	Risk: 22 vs. 65 per 100 patients Pooled estimates (2 RCTs, N=1,019): RR 0.32 (95% CI 0.18 to 0.51), I^2=0% RD –48% (95% CI –67% to –29%), I^2=73% **Conclusions:** CCTA was associated with a decreased risk of ICA showing no obstructive CAD compared with direct referral to ICA.	⊕⊕⊕◯ MODERATE
Additional NIT (any)	12 months	1 RCT (N=1,503) **Chang 2019** Suspected CAD, stable outpatients	No	Unknown	No	Yes (-1)	Risk: 53 vs. 27 per 100 patients RR 1.96 (95% CI 1.71 to 2.25) RD 26.0% (95% CI 21.1% to 30.7%) **Conclusions:** CCTA was associated with an increased risk of additional downstream testing compared with direct referral to ICA.	⊕⊕⊕◯ MODERATE
Revascularization (any)	12 months, median 40 months	2 RCTs (N=1,832) **Chang 2019** Suspected CAD,	No	No	No	Yes (-1)	Risk: 13 vs. 18 per 100 patients Pooled estimates (2 RCTs, N=1,832): RR 0.71 (95% CI 0.55 to 0.96), I^2=0% RD –5.0% (95% CI –8.0% to –2.0%),	⊕⊕⊕◯ MODERATE

Outcome	Follow-up	Studies	Risk of Bias	Serious Inconsistency	Serious Indirectness	Serious Imprecision	Conclusion Effect Estimate (95% CI)	Quality (SOE)
		stable outpatients **Dewey 2016** Suspected CAD, stable and acute, atypical chest pain					I^2=0% **Conclusions:** CCTA was associated with a decreased risk of revascularization compared with direct referral to ICA.	
Hospitalization, cardiac causes	12 months	1 RCT (N=1,503) **Chang 2019** Suspected CAD, stable outpatients	No	Unknown	No	Yes (-1)	Risk: 4 vs. 4 per 100 patients RR 0.98 (95% CI 0.60 to 1.58) RD (not calculated, no association) **Conclusions:** There was no difference in the risk of cardiac hospitalization with CCTA compared with direct referral to ICA.	⊕⊕⊕◯ MODERATE
Key Question 3: Safety								
Major adverse events	≤48 hours, median 12 months	2 RCTs (N=1,832) **Chang 2019** Suspected CAD, stable outpatients **Dewey 2016** Suspected CAD, stable and acute, atypical chest pain	No	No	No	Yes (-2)	**Any complications prolonging hospital stay** Risk: no events in either test arm 1 RCT (N=327) **Major bleeding** Risk: 0 vs. 0.3 per 100 patients 1 RCT (N=1,503) **Conclusions:** There was no difference in the risk of major adverse events between CCTA and ICA. Given that the events are rare, trials may have been	⊕⊕◯◯ LOW

Outcome	Follow-up	Studies	Risk of Bias	Serious Inconsistency	Serious Indirectness	Serious Imprecision	Conclusion Effect Estimate (95% CI)	Quality (SOE)
							under powered to detect a difference.	
Minor adverse events	≤48 hours after last procedure	2 RCTs (N=327) **Dewey 2016** Suspected CAD, stable and acute, atypical chest pain	No	Unknown	No	Yes (-1)	**Any minor procedural complication** Risk: 4 vs. 11 per 100 patients RR 0.35 (0.14 to 0.86) RD –6.9% (–12.4% to –1.3%) **Hematoma at puncture site** Risk: 1 vs. 9 per 100 patients RR 0.07 (0.01 to 0.53) RD –8.0% (–12.5% to –3.6%) **Bradycardia** Risk: 1 vs. 0 per 100 patients **Other minor adverse events** Risk: <1 per 100 patients for each arm: Secondary bleeding at puncture site, angina without MI, allergic reaction to contrast agent, hypotension requiring treatment, stent migration **Conclusions:** CCTA was associated with a reduced risk of any minor procedural adverse event compared with ICA, driven by the frequency of hematoma at the puncture site. There was no difference in the risk of other specific minor events.	⊕⊕◯◯ LOW

Reasons for downgrading:

1. Serious risk of bias: The majority of studies are fair quality related to the outcome reported may be downgraded once; If the majority of studies are poor quality, this may be downgraded twice;

2. Inconsistency: differing estimates of effects across trials; If point estimates across trials are in the same direction, do not vary substantially or heterogeneity can be explained, results may not be downgraded for inconsistency. The consistency of single studies is unknown; evidence from single studies may be downgraded.
3. Imprecise effect estimate for an outcome: small sample size and/or confidence interval includes both negligible effect and appreciable benefit or harm with the intervention; If sample size is likely too small to detect rare outcomes, evidence may be downgraded twice. If the estimate is statistically significant, it is imprecise if the CI ranges from "mild" to "substantial". If the estimate is not statistically significant, it is imprecise if the CI crosses the threshold for "mild/small" effects and may be downgraded once. Wide (or unknown) confidence interval and/or small sample size may result in downgrade.
4. Indirect, intermediate or surrogate outcomes may be downgraded.

Table 10.6. Key Questions 1, 2 and 3: Strength of evidence: CCTA FFR versus any functional and versus ICA

Outcome	Follow-up	Studies	Risk of Bias	Serious Inconsistency	Serious Indirectness	Serious Imprecision	Conclusion Effect Estimate (95% CI)	Quality (SOE)
Key Question 1: Primary clinical outcomes								
Myocardial infarction cumulative	3, 12 months	1 prospective cohort (N=584) **Planned noninvasive test cohort (N=204)** CCTA FFR vs. any noninvasive test **Planned ICA cohort (N=380)** CCTA FFR vs. ICA	Yes (-1)	Unknown	No	Yes (-2)	**CCTA FFR vs. any noninvasive test** 3 months: No MIs in either arm 12 months: Risk: 0 vs. 1 per 100 patients **CCTA FFR vs. ICA** 3 months: Risk: 1 vs. 0 per 100 patients 12 months: Risk: 1 vs. 1 per 100 patients **Conclusion**: Firm conclusions regarding the impact of CCTA FFR vs. any noninvasive test or vs. ICA on MI are not possible. MI was rare (≤1 per 100 patients [3 MIs total] across both arms of both cohorts through 12 months). The sample size may have been insufficient to detect MI.	⊕◯◯◯ INSUFFICIENT
Mortality, all-cause cumulative	3, 12 months						**CCTA FFR vs. any noninvasive test** 3 and 12 months: No deaths in either arm **CCTA FFR vs. ICA** 3 months: No deaths in either arm 12 months: Risk: 0 vs. 1 per 100 patients	

Outcome	Follow-up	Studies	Risk of Bias	Serious Inconsistency	Serious Indirectness	Serious Imprecision	Conclusion Effect Estimate (95% CI)	Quality (SOE)
							Conclusion: Firm conclusions regarding the impact of CCTA FFR vs. any noninvasive test or vs. ICA on all-cause mortality are not possible. All-cause mortality was rare (1 death [planned ICA cohort] over 12 months across both cohorts). The sample size may have been insufficient to detect all-cause mortality.	
Key Question 2: Clinical Decision-Making Outcomes								
ICA	3, 12 months	1 prospective cohort (N=584) **Planned noninvasive test cohort (N=204)** CCTA FFR vs. any noninvasive test **Planned ICA cohort (N=380)** CCTA FFR vs. ICA	Yes (-1)	Unknown	No	Yes (-1)	**CCTA FFR vs. any noninvasive test** 3 months: Risk: 18 vs. 12 per 100 patients RR 1.52 (0.78 to 2.97) 12 months: Risk: 21 vs. 16 per 100 patients RR 1.32 (0.74 to 2.37) **CCTA FFR vs. ICA** 3 months: Risk: 39 vs. 100 per 100 patients RR 0.39 (0.33 to 0.47) 12 months: Risk: 51 vs. 100 per 100 patients • RR 0.51 (0.45 to 0.59)No events in the 61% of CCTA with FFR patients in whom ICA was cancelled **Conclusion**: Firm conclusions regarding the impact of CCTA FFR vs. any noninvasive test or vs. ICA on referral to ICA are not possible.	⊕◯◯◯ INSUFFICIENT
ICA without obstructive CAD (core lab quantitative analysis)	3 months						**CCTA FFR vs. any noninvasive test** 3 months: Risk: 13 vs. 6 per 100 patients RR 2.08 (0.82 to 5.27) **CCTA FFR vs. ICA**	⊕◯◯◯ INSUFFICIENT

Outcome	Follow-up	Studies	Risk of Bias	Serious Inconsistency	Serious Indirectness	Serious Imprecision	Conclusion Effect Estimate (95% CI)	Quality (SOE)
							3 months: Risk: 39 vs. 100 per 100 patients RR 0.39 (0.33 to 0.47) **Conclusion**: Firm conclusions regarding the impact of CCTA FFR vs. any noninvasive test or vs. ICA on the frequency of ICA without obstructive CAD are not possible.	
Revascularization (any)	3, 12 months						**CCTA FFR vs. any noninvasive test** 3 months: Risk: 10 vs. 5 per 100 patients RD (not calculated, no association) 12 months: Risk: 10 vs. 7 per 100 patients RR 1.37 (0.54 to 3.47) **CCTA FFR vs. ICA** 3 months: Risk: 29 vs. 32 per 100 patients RR 0.90 (0.66 to 1.23) 12 months: Risk: 34 vs. 36 per 100 patients RR 0.94 (0.71 to 1.24) **Conclusion**: Firm conclusions regarding the impact of CCTA FFR vs. any noninvasive test or vs. ICA on any revascularization are not possible.	⊕◯◯◯ INSUFFICIENT
Hospitalization (with urgent revascularization)	3, 12 months						**CCTA FFR vs. any noninvasive test** 3 and 12 months: No events in either arm **CCTA FFR vs. ICA** 3 and 12 months: Risk: 1 vs. 0 per 100 patients **Conclusion**: Firm conclusions regarding the	⊕◯◯◯ INSUFFICIENT

Outcome	Follow-up	Studies	Risk of Bias	Serious Inconsistency	Serious Indirectness	Serious Imprecision	Conclusion Effect Estimate (95% CI)	Quality (SOE)
							impact of CCTA FFR vs. any noninvasive test or vs. ICA on hospitalization with urgent revascularization are not possible. There was one hospitalization with urgent revascularization over 12 months across both cohorts which occurred in a patient who received CCTA with FFR rather than being referred directly to ICA (planned ICA cohort). Given that these likely are rare events (there was 1 event in a patient who received CCTA with FFR rather than direct ICA [planned ICA cohort]), the study may not have been sufficiently powered to detect them.	
Key Question 3: Safety								
Test-related AEs	12 months	1 prospective cohort (N=584) **Planned noninvasive test cohort (N=204)** CCTA FFR vs. any noninvasive test **Planned ICA cohort (N=380)** CCTA FFR vs. ICA	Low	Unknown	No	Yes (-2)	One mild contrast reaction from CCTA testing; no other information provided. **Conclusion**: Data are insufficient to draw conclusions.	⊕○○○ INSUFFICIENT
Cumulative radiation exposure (mSv)	12 months						**CCTA FFR vs. any noninvasive test** 3 months: 8.8 vs. 5.8 mSv MD 3.0 (0.6 to 5.4) 12 months: 9.6 vs. 6.4 mSv MD 3.1 (0.6 to 5.7) **CCTA FFR vs. ICA** 3 months: 9.9 vs. 9.4 mSv MD 0.50 (–0.93 to 1.93) 12 months: 10.7 vs. 10.4 mSv MD 0.36 (–1.32 to 2.04)	⊕⊕○○ LOW

Outcome	Follow-up	Studies	Risk of Bias	Serious Inconsistency	Serious Indirectness	Serious Imprecision	Conclusion Effect Estimate (95% CI)	Quality (SOE)
							Conclusion: Patients who received CCTA with FFR had significantly greater cumulative radiation exposure over 12 months compared to those who received any noninvasive test (planned noninvasive test cohort); there was no difference for CCTA with FFR versus direct referral to ICA (planned ICA cohort).	

Reasons for downgrading:

1. Serious risk of bias: The majority of studies are fair quality related to the outcome reported may be downgraded once; If the majority of studies are poor quality, this may be downgraded twice;
2. Inconsistency: differing estimates of effects across trials; If point estimates across trials are in the same direction, do not vary substantially or heterogeneity can be explained, results may not be downgraded for inconsistency. The consistency of single studies is unknown; evidence from single studies may be downgraded.
3. Imprecise effect estimate for an outcome: small sample size and/or confidence interval includes both negligible effect and appreciable benefit or harm with the intervention; If sample size is likely too small to detect rare outcomes, evidence may be downgraded twice. If the estimate is statistically significant, it is imprecise if the CI ranges from "mild" to "substantial". If the estimate is not statistically significant, it is imprecise if the CI crosses the threshold for "mild/small" effects and may be downgraded once. Wide (or unknown) confidence interval and/or small sample size may result in downgrade.
4. Indirect, intermediate or surrogate outcomes may be downgraded.

Outcome	Follow-up	Studies	Risk of Bias	Serious Inconsistency	Serious Indirectness	Serious Imprecision	Conclusion Effect Estimate (95% CI)	Quality (SOE)
Key Question 1: Primary clinical outcomes								
Myocardial infarction cumulative	30 days to mean 24 months	4 RCTs (N=1,908) **SPECT vs. Echo (Suspected or**	Yes (-1)	No	No	Yes (-2)	Risk: 0.3 vs. 1.3 per 100 patients Pooled estimates (2 RCTs, N=907): RR 0.32 (95% CI 0.05 to 1.96), I^2=0.0% RD (not calculated, no association)	⊕◯◯◯ INSUFFICIENT

Outcome	Follow-up	Studies	Risk of Bias	Serious Inconsistency	Serious Indirectness	Serious Imprecision	Conclusion Effect Estimate (95% CI)	Quality (SOE)
		known CAD) 2 RCTs (N=679) Sharples 2007 (stable, OP) Salame 2018 (acute, ED) **SPECT vs. ECG (Suspected CAD)** 2 RCT (N=1,229) Sabharwal 2007 Shaw 2011 (stable, OP)					1 RCT, SPECT vs. Echo (N=229): no events in either group 1 RCT, SPECT vs. ECG (N=772): 0.4 per 100 patients (not reported by test group) **Conclusions:** Firm conclusions regarding the impact of SPECT or functional testing (echocardiography or exercise ECG) on MI are not possible. MI was rare. Sample sizes in individual trials may have been insufficient to detect MI.	
Mortality, all-cause cumulative	30 days to 72 months	4 RCTs (N=1,908) **SPECT vs. Echo (Suspected or known CAD)** 2 RCTs (N=679) Sharples 2007 (stable, OP) Salame 2018 (acute, ED) **SPECT vs. ECG (Suspected CAD)** 2 RCT (N=1,229) Sabharwal 2007 Shaw 2011	Yes (-1)	No	No	Yes (-1)	Risk: 1.4 vs. 1.6 per 100 patients Pooled estimates (4 RCTs, N=1,908): RR 0.89 (95% CI 0.42 to 2.57), I^2=0.0% RD (not calculated, no association) **Conclusions**: There was no difference for SPECT versus stress echocardiography or exercise ECG in the risk of all-cause mortality, despite difference in populations and follow-up duration across the trials. Since this is a rare event, trials may not have been sufficiently powered to detect a difference.	⊕⊕◯◯ LOW

Outcome	Follow-up	Studies	Risk of Bias	Serious Inconsistency	Serious Indirectness	Serious Imprecision	Conclusion Effect Estimate (95% CI)	Quality (SOE)
		(stable, OP)						
Mortality, cardiac cumulative	18 to 24 months	3 RCTs (N=1,679) **SPECT vs. Echo (Suspected or known CAD)** 1 RCT (N=450) Sharples 2007 (stable, OP) **SPECT vs. ECG (Suspected CAD)** 2 RCT (N=1,229) Sabharwal 2007 Shaw 2011 (stable, OP)	Yes (-1)	Yes (-1)	No	Yes (-1)	1.1 vs. 0.5 per 100 patients Pooled estimates (2 RCTs, N=907): RR 2.21 (95% CI 0.05 to 35.30), I^2=0.0% RD (not calculated, no association) 1 RCT, SPECT vs. ECG (N=772): 0.1 per 100 patients (not reported by test group) **Conclusions:** Firm conclusions regarding the impact of SPECT or functional testing (echocardiography or exercise ECG) on cardiac mortality are not possible. Cardiac mortality was rare. Sample sizes in individual trials may have been insufficient to detect events.	⊕◯◯◯ INSUFFICIENT
Key Question 2: Clinical Decision-Making Outcomes								
ICA	30 days to 24 months	4 RCTs (N=1,908) **SPECT vs. Echo (Suspected or known CAD)** 2 RCTs (N=679) Sharples 2007 (stable, OP) Salame 2018 (acute, ED)	Yes (-1)	Yes (-1)	No	No	Risk: 24.5 vs. 31.9 per 100 patients Pooled estimates (4 RCTs, N=1,908) RR 0.64 (95% CI 0.31 to 1.22), I^2=86.5% RD (not calculated, no association) 1 RCT (N=457), SPECT vs. ECG 16.4 versus 47.3 per 100 patients RR 0.35 (95% CI 0.25 to 0.47) RD –30.9%, 95% CI –39.2% to –22.7%)	⊕⊕◯◯ LOW

Outcome	Follow-up	Studies	Risk of Bias	Serious Inconsistency	Serious Indirectness	Serious Imprecision	Conclusion Effect Estimate (95% CI)	Quality (SOE)
		SPECT vs. ECG (Suspected CAD) 2 RCT (N=1,229) Sabharwal 2007 Shaw 2011 (stable, OP)					**Conclusion:** There was no difference for SPECT versus stress echocardiography or exercise ECG in the risk of ICA across all 4 trials, however, there was substantial heterogeneity. Individually, only one fair-quality trial comparing SPECT with exercise ECG in stable patients at mixed pretest risk for CAD reported a statistically significant difference which favored SPECT (30% reduction in ICA). Differences in patient populations and/or pretest risk may have played a role in these findings.	
Additional NIT (any)	18 to 24 months	3 RCTs (N=1,679) **SPECT vs. Echo (Suspected or known CAD)** 1 RCT (N=450) Sharples 2007 (stable, OP) **SPECT vs. ECG (Suspected CAD)** 2 RCT (N=1,229) Sabharwal 2007 Shaw 2011	Yes (-1)	Yes (-1)	No	Yes (-1)	Risk: 4.3 vs. 14.6 per 100 patients Pooled estimates (3 RCTs, N=1,679) RR 0.24 (95% CI 0.01 to 8.67), I^2=70.0% RD (not calculated, no association) **SPECT vs. Echo** Risk: 0.4 vs. 0 per 100 patients 1 RCT (N=450) RR 3.03 (95% CI 0.12 to 73.90) RD (not calculated, no association) **SPECT vs. ECG** 5.7 vs. 20.2 per 100 patients Pooled estimate (2 RCTs, N=1,229) RR 0.11 (95% CI 0.00 to 8.87), I^2=93%	⊕◯◯◯ INSUFFICIENT

Outcome	Follow-up	Studies	Risk of Bias	Serious Inconsistency	Serious Indirectness	Serious Imprecision	Conclusion Effect Estimate (95% CI)	Quality (SOE)
							RD (not calculated, no association) 1 RCT (N=772): Risk: 9.4 vs. 18.6 per 100 patients RR 0.51 (95% CI 0.35 to 0.73) RD –8.2% (95% CI –14.0 to –4.3%) 1 RCT (N=457): Risk: 0 vs. 23.2 per 100 patients RR 0.01 (95% CI 0.00 to 0.14) RD –23.2% (95% CI –29.0 to –17.4%) **Conclusion:** It is difficult to draw firm conclusions across trials due to lack of precision and inconsistency. While both trials comparing SPECT with exercise ECG showed a reduction in risk of downstream NIT with SPECT, heterogeneity was substantial resulting in a pooled estimate that was not statistically significant. Differences in testing protocols, populations (1 trial was in women only), and pre-test risks may partly explain the heterogeneity.	
Revascularization (any)	30 days to 36 months	4 RCTs (N=1,908) **SPECT vs. Echo (Suspected or known CAD)** 2 RCTs (N=679)	Yes (-1)	Yes (-1)	No	No	Risk: 13.7 vs. 17.5 per 100 patients Pooled estimates (4 RCTs, N=1,908): RR 0.80 (95% CI 0.60 to 1.09), I^2=0.0% RD (not calculated, no association) **Conclusion:** There was no difference	⊕⊕⊕◯ MODERATE

Outcome	Follow-up	Studies	Risk of Bias	Serious Inconsistency	Serious Indirectness	Serious Imprecision	Conclusion Effect Estimate (95% CI)	Quality (SOE)
		Thom 2014 (stable, OP) Salame 2018 (acute, ED) **SPECT vs. ECG (Suspected CAD)** 2 RCT (N=1,229) Sabharwal 2007 Shaw 2011 (stable, OP)					for SPECT versus stress echocardiography or versus exercise ECG in the risk of revascularization, despite difference in populations and follow-up duration across the trials. Two trials in stable patients reported a lower risk of revascularization following SPECT, however, the differences were only marginally significant: 1 good-quality trial comparing SPECT with echocardiography (RR 0.82, 95% CI 0.67 to 0.99) and 1 fair-quality trial comparing SPECT with ECG (RR 0.60 (95% CI 0.38 to 0.96). There were no differences when PCI and CABG were considered separately.	
Hospitalization	30 days to 24 months	3 RCTs (N=1,451) **SPECT vs. Echo (Suspected or known CAD)** 2 RCTs (N=679) Sharples 2007 (stable, OP) Salame 2018 (acute, ED) **SPECT vs. ECG (Suspected CAD)** 1 RCT (N=772)	Yes (-1)	No	No	Yes (-1)	Risk: 5.4 vs. 5.9 per 100 patients Pooled estimates (3 RCTs, N=1,451): RR 0.89 (95% CI 0.54 to 2.14), I^2=0.0% RD (not calculated, no association) **<u>Conclusions</u>:** There was no difference for SPECT versus stress echocardiography or versus exercise ECG in the risk of hospitalization for cardiac causes, despite difference in populations and follow-up duration across the trials.	⊕⊕◯◯ LOW

ED revisit	30 days	1 RCT (N=229) **SPECT vs. Echo (Suspected or known CAD)** Salame 2018 (acute, ED)	Yes (-1)	Unknown	No	Yes (-1)	Risk: 2.6 vs. 2.7 per 100 patients RR 0.97 (95% CI 0.20 to 4.73) **Conclusions:** There was no difference for SPECT versus stress echocardiography in the risk of re-presentation to the ED within 30 days.	⊕⊕◯◯ LOW

Reasons for downgrading:

1. Serious risk of bias: The majority of studies are fair quality related to the outcome reported may be downgraded once; If the majority of studies are poor quality, this may be downgraded twice;
2. Inconsistency: differing estimates of effects across trials; If point estimates across trials are in the same direction, do not vary substantially or heterogeneity can be explained, results may not be downgraded for inconsistency. The consistency of single studies is unknown; evidence from single studies may be downgraded.
3. Imprecise effect estimate for an outcome: small sample size and/or confidence interval includes both negligible effect and appreciable benefit or harm with the intervention; If sample size is likely too small to detect rare outcomes, evidence may be downgraded twice. If the estimate is statistically significant, it is imprecise if the CI ranges from "mild" to "substantial". If the estimate is not statistically significant, it is imprecise if the CI crosses the threshold for "mild/small" effects and may be downgraded once. Wide (or unknown) confidence interval and/or small sample size may result in downgrade.
4. Indirect, intermediate or surrogate outcomes may be downgraded.

		NICE guideline-directed care Greenwood 2017 Suspected CAD (stable, OP)					directed care in the risk of any revascularization.	
Hospitalization	Index	1 RCT (N=1,508) **Clinical assessment alone** Lim 2013 Suspected ACS (acute, ED)	Yes (-1)	Unknown	No	No	Risk: 10.2 vs. 18.5 per 100 patients, RR 0.55 (95% CI 0.42 to 0.71), RD –8.3% (95% CI –12.2% to –4.4%) **Conclusions:** SPECT was associated with a decreased risk of hospitalization at the index visit compared with clinical assessment alone. Subsequent hospitalization following the index visit was not reported.	⊕⊕◯◯ LOW

*As described by the authors. Primary reasons cited for an unnecessary ICA included negative noninvasive test overruled by the attending physician (4.4 per 100 patients) and a false-positive test (2.5 per 100 patients) in the SPECT group, and direct referral to ICA (per algorithm) for patients with high pretest likelihood in the guideline-directed care group (24.6 per 100 patients).

Reasons for downgrading:

1. Serious risk of bias: The majority of studies are fair quality related to the outcome reported may be downgraded once; If the majority of studies are poor quality, this may be downgraded twice;
2. Inconsistency: differing estimates of effects across trials; If point estimates across trials are in the same direction, do not vary substantially or heterogeneity can be explained, results may not be downgraded for inconsistency. The consistency of single studies is unknown; evidence from single studies may be downgraded.
3. Imprecise effect estimate for an outcome: small sample size and/or confidence interval includes both negligible effect and appreciable benefit or harm with the intervention; If sample size is likely too small to detect rare outcomes, evidence may be downgraded twice. If the estimate is statistically significant, it is imprecise if the CI ranges from “mild” to “substantial”. If the estimate is not statistically significant, it is imprecise if the CI crosses the threshold for “mild/small” effects and may be downgraded once. Wide (or unknown) confidence interval and/or small sample size may result in downgrade.
4. Indirect, intermediate or surrogate outcomes may be downgraded.

All-cause mortality cumulative	72 months						**18 months** Risk: 2.7 vs. 1.8 per 100 patients, RR 1.47 (95% CI 0.42 to 5.15) RD (not calculated, no association) **72 months** Risk: 4.9 vs. 3.2 per 100 patients, RR 1.54 (95% CI 0.61 to 3.91) RD (not calculated, no association)	

Outcome	Follow-up	Studies	Risk of Bias	Serious Inconsistency	Serious Indirectness	Serious Imprecision	Conclusion Effect Estimate (95% CI)	Quality (SOE)
							Conclusion: The risk of all-cause mortality did not differ between stress echocardiography and ICA; however, the evidence is considered insufficient to draw firm conclusions.	
Cardiac mortality cumulative	18 months						Risk 0.4 vs. 1.4 per 100 patients, RR 0.33 (95% CI 0.03 to 3.12) RD (not calculated, no association) **Conclusion**: The risk of cardiac mortality was low and did not differ between stress echocardiography and ICA; however the evidence is considered insufficient to draw firm conclusions.	
Key Question 2: Clinical Decision-Making Outcomes								
Additional NIT (any)	Unclear	1 RCT (N=448) Sharples 2007 (Stable OP, suspected CAD)	No	Unknown	No	Yes (-2)	Risk: 0 vs. 3.6 per 100 patients, p=0.01 **Conclusion**: Firm conclusions regarding the impact of stress echocardiography or ICA on additional NITs are not possible.	⊕◯◯◯ INSUFFICIENT
Revascularization	36 months						**Index** Risk: 35.4 vs. 34.2 per 100 patients, RR 1.03 (95% CI 0.80 to 1.33) RD (not calculated, no association) **36 months** Risk: 53.5 vs. 53.2 per 100 patients, RR 1.01 (95% CI 0.85 to 1.20) RD (not calculated, no association)	⊕⊕◯◯ LOW

Outcome	Follow-up	Studies	Risk of Bias	Serious Inconsistency	Serious Indirectness	Serious Imprecision	Conclusion Effect Estimate (95% CI)	Quality (SOE)
							Conclusion: There was no difference between stress echocardiography and ICA in the risk of revascularization.	
Hospitalization for chest pain	18 months						Risk: 10.6 vs. 6.3 per 100 patients, RR 1.68 (95% CI 0.89 to 3.17) RD (not calculated, no association) **Conclusion**: There was no difference between stress echocardiography and ICA in the risk of hospitalization for chest pain.	⊕⊕◯◯ LOW

Reasons for downgrading:

1. Serious risk of bias: The majority of studies are fair quality related to the outcome reported may be downgraded once; If the majority of studies are poor quality, this may be downgraded twice;
2. Inconsistency: differing estimates of effects across trials; If point estimates across trials are in the same direction, do not vary substantially or heterogeneity can be explained, results may not be downgraded for inconsistency. The consistency of single studies is unknown; evidence from single studies may be downgraded.
3. Imprecise effect estimate for an outcome: small sample size and/or confidence interval includes both negligible effect and appreciable benefit or harm with the intervention; If sample size is likely too small to detect rare outcomes, evidence may be downgraded twice. If the estimate is statistically significant, it is imprecise if the CI ranges from "mild" to "substantial". If the estimate is not statistically significant, it is imprecise if the CI crosses the threshold for "mild/small" effects and may be downgraded once. Wide (or unknown) confidence interval and/or small sample size may result in downgrade.
4. Indirect, intermediate or surrogate outcomes may be downgraded.

Table 10.14. Key Question 3: Strength of evidence: Stress echocardiography

Outcome	Follow-up	Studies	Risk of Bias	Serious Inconsistency	Serious Indirectness	Serious Imprecision	Conclusion Effect Estimate (95% CI)	Quality (SOE)
Any complication	2 months	1 RCT (N=152)	Yes (-1)	Unknown	No	Yes (-1)	No test-related complications occurred in 1 RCT comparing stress	⊕◯◯◯ INSUFFICIENT

Outcome	Follow-up	Studies	Risk of Bias	Serious Inconsistency	Serious Indirectness	Serious Imprecision	Conclusion Effect Estimate (95% CI)	Quality (SOE)
		Nucifora 2009 Uncomplicated MI					echocardiography versus stress ECG. **Conclusions:** Insufficient evidence to draw conclusions.	
Dobutamine-related adverse events		11 case series (N range, 86–2799)* Baudhuin 1993 Dakik 1996 Geleijnse 2000 Gordon 1995 Karabinos 2004 Mertes 1993 Minardi 2007 Poldermans 1994 Picano 1994 O'Driscoll 2014 Sitges 2000 Stable, suspected or known CAD (10 studies) Suspected ACS (1 study)	Yes (-2)	Unknown	No	No	Potentially life threatening, major adverse events • **Mortality** (6 studies, N=5,512): No deaths • **MI** (7 studies, N range 122 to 2,799): range, 0% to 0.1% • **UA** (1 study, N=802): 0.1% • **CVA** (1 study, N=1,012): No CVAs • **Acute pulmonary edema** (2 studies, N=1,012, 802): 0% and 0.1% **Conclusion:** The risk of potentially life-threatening adverse event with dobutamine appears to be low, ≤0.1% across all outcomes.	⊕⊕◯◯ LOW
							Arrythmia-related AEs • **Any arrhythmias or palpitations** (6 studies, N range 122 to 1,118): range, 2.1% to 18.0% • **Supraventricular or ventricular tachycardia** (10 studies, N range 86 to 2,799): range, 0% to 9.0% • **Atrial or ventricular fibrillation** (7 studies, N range 265 to 2,799): range, 0% to 1.2% • **Bradycardia** (2 large studies,	⊕⊕◯◯ LOW

Outcome	Follow-up	Studies	Risk of Bias	Serious Inconsistency	Serious Indirectness	Serious Imprecision	Conclusion Effect Estimate (95% CI)	Quality (SOE)
							N=3,917): ≤0.2% in both. **Conclusion:** The frequency of any arrhythmia (not well defined) and tachycardias ranged from 0% to 18%. Atrial fibrillation and bradycardia appear to be infrequent events.	
							<u>Hypotension and Hypertension</u> • **Hypotension** (9 studies; N range 86 to 2799): range, 0.1% to 12.5% • **Hypertension** (5 studies; N range 122 to 1118): range, 0% to 7.5% **Conclusion:** Hypo- and hypertension were not uncommon with dobutamine for stress echocardiography. The severity of the events was not reported.	⊕⊕◯◯ LOW
							<u>Other, general adverse events</u> • **Chest pain (NOS)** (3 studies, N range 86 to 1,118): range, 4.6% to 31.4% • **Nausea and/or vomiting** (6 studies, N range 86 to 1012): range, 3.4% to 20.9% • **Headache** (4 studies, N range 122 to 1012): 0.8% to 13.6% • **Dyspnea** (3 studies, N range 127 to 1012): range, 0% to 13.6% • **Tremors** (3 studies, N range 127 to 1012): range, 0.4% to 2.4%	⊕⊕◯◯ LOW

Outcome	Follow-up	Studies	Risk of Bias	Serious Inconsistency	Serious Indirectness	Serious Imprecision	Conclusion Effect Estimate (95% CI)	Quality (SOE)
							Conclusions: The frequency of other adverse events, such as chest pain, nausea/vomiting, headache, dyspnea and tremors ranged from 0% to 31%; most authors reported that events were mild and transient.	
Dipyridamole and Adenosine		**Dipyridamole** 3 case series (N=946) Minardi 2002 Ferrara 1991 Gaibazzi 2009 **Adenosine** 1 case series (N=1429) Montisci 2017 Suspected or known CAD for all	Yes (-2)	Unknown	No	No	**Dipyridamole** 2 studies (total N=837): • No "major", severe, or life-threatening adverse events, to include death, MI and ACS 3 studies (N range, 109 to 500): • Hypotension/bradycardia: range, 0.8% to 6.4% • Vomiting and nausea: range, 0.2% to 5.5% • Headache: range, 2.1% to 43% **Adenosine** The most commonly occurring side-effects were hyperpnea (16.7%), atypical chest pain (9.9%), flushing (9.4%) and headache (6.6%). **Conclusions**: There were no major or life-threatening adverse events after dipyridamole administration. Minor adverse events with the use of these stressor agents for echocardiography	⊕⊕◯◯ LOW

Outcome	Follow-up	Studies	Risk of Bias	Serious Inconsistency	Serious Indirectness	Serious Imprecision	Conclusion Effect Estimate (95% CI)	Quality (SOE)
							are not uncommon and occurred with variable frequency and ranged from 0.2% to 43%.	
Noniodinated contrast		3 studies (N=9,821) 2 comparative cohorts (N=6,750) Anantharam 2009 Jin 2019 1 database study (N=3,071) Abdelmoneim 2009	Yes (-2)	Unknown	No	No	**Definite or suspected contrast-related adverse events** 1 database study: 1.3% (41/3071) and 2.2% (68/3071) **Allergic reaction to contrast** • 2 cohort studies: <0.5% of patients who received stress echocardiography with contrast • 1 database study: 0.03% each for transient wheezing without urticaria, urticaria or hives (limb and thorax) and swelling in the mouth, and throat tingling **Conclusions**: Definite or suspected contrast related adverse events and allergic reactions appear to be rare.	⊕⊕◯◯ LOW

CAD = coronary artery disease; CI = Confidence Interval; ECG = electrocardiography; ED = emergency department; OP = outpatient; RCT = randomized controlled trial; SOE = strength of evidence.

Reasons for downgrading:

1. Serious risk of bias: The majority of studies are fair quality related to the outcome reported may be downgraded once; If the majority of studies are poor quality, this may be downgraded twice;
2. Inconsistency: differing estimates of effects across trials; If point estimates across trials are in the same direction, do not vary substantially or heterogeneity can be explained, results may not be downgraded for inconsistency. The consistency of single studies is unknown; evidence from single studies may be downgraded.

3. Imprecise effect estimate for an outcome: small sample size and/or confidence interval includes both negligible effect and appreciable benefit or harm with the intervention; If sample size is likely too small to detect rare outcomes, evidence may be downgraded twice. If the estimate is statistically significant, it is imprecise if the CI ranges from "mild" to "substantial". If the estimate is not statistically significant, it is imprecise if the CI crosses the threshold for "mild/small" effects and may be downgraded once. Wide (or unknown) confidence interval and/or small sample size may result in downgrade.
4. Indirect, intermediate or surrogate outcomes may be downgraded.

Table 10.15. Key Questions 1 and 2: Strength of evidence: PET vs. SPECT

Outcome	Follow-up	Studies	Study Limitations	Serious Inconsistency	Serious Indirectness	Serious Imprecision	Conclusion Effect Estimate (95% CI)	Quality (SOE)
Key Question 1: Primary clinical outcomes								
Myocardial infarction Cumulative; **Mortality, all-cause** cumulative	12 months	1 RCT (N=322) Patel 2019 Known CAD, new or worsening symptoms	No	Unknown	No	Yes (-2)	**MI:** Risk: 0 vs. 1.2 per 100 patients **All-cause mortality:** Risk: 1 vs. 1.2 per 100 patients RR 0.50 (95% CI 0.04 to 5.46) RD (not calculated, no association) **Conclusion:** Firm conclusions regarding the impact of PET or SPECT on MI and all-cause mortality are not possible. Both outcomes were rare. The sample size may have been insufficient to detect events.	⊕◯◯◯ INSUFFICIENT

Outcome	Follow-up	Studies	Study Limitations	Serious Inconsistency	Serious Indirectness	Serious Imprecision	Conclusion Effect Estimate (95% CI)	Quality (SOE)
Mortality, cardiac cumulative	Mean 9 months	1 RCT (N=210) Mullani 2000 Stable, mixed suspected or known CAD	Yes (-1)	Unknown	No	Yes (-2)	Risk: 3 vs. 4 per 100 patients RR 0.75 (95% CI 0.17 to 3.27) RD (not calculated, no association) **Conclusion:** Data from one poor-quality trial were insufficient to draw conclusions.	⊕◯◯◯ INSUFFICIENT
Key Question 2: Clinical Decision-Making Outcomes								
ICA	3, 6, 12 months	1 RCT (N=322) Patel 2019 Known CAD, new or worsening symptoms	No	Unknown	No	Yes (-1)	**3 months** Risk: 20.5 vs. 15.5 per 100 patients RR 1.32 (95% CI 0.82 to 2.11) RD (not calculated, no association) **6 months** Risk: 22.4 vs. 18.6 per 100 patients RR 1.20 (95% CI 0.78 to 1.85) RD (not calculated, no association) **12 months** Risk: 28.6 vs. 28.0 per 100 patients RR 1.02 (95% CI 0.72 to 1.45) RD (not calculated, no association) **Conclusion:** No difference between PET and SPECT in the risk of ICA at any timepoint.	⊕⊕◯◯ LOW
Revascularization (any)							**3 months** Risk: 11.2 vs. 9.9 per 100 patients RR 1.13 (95% CI 0.60 to 2.13) RD (not calculated, no association) **6 months** Risk: 12.4 vs. 11.8 per 100 patients RR 1.05 (95% CI 0.58 to 1.90) RD (not calculated, no association) **12 months**	⊕⊕◯◯ LOW

Outcome	Follow-up	Studies	Study Limitations	Serious Inconsistency	Serious Indirectness	Serious Imprecision	Conclusion Effect Estimate (95% CI)	Quality (SOE)
							Risk: 15.5 vs. 14.9 per 100 patients RR 1.04 (95% CI 0.62 to 1.74) RD (not calculated, no association) **Conclusion:** No difference between PET and SPECT in the risk of any revascularization at any timepoint.	
Medication change*							Escalation in antianginal therapy* at **3 months** Risk: 26 vs. 23 per 100 patients RR 1.11 (95% CI 0.75, 1.63) RD (not calculated, no association)	

CI = Confidence Interval; NR = Not Reported; NS = Not significant;

*Footnote: Defined as addition of another anti-anginal medication class or increase in dose or frequency of one or more of existing anti-anginal medications within 3 months post baseline MPI

Reasons for downgrading:

1. Serious risk of bias: The majority of studies are fair quality related to the outcome reported may be downgraded once; If the majority of studies are poor quality, this may be downgraded twice;
2. Inconsistency: differing estimates of effects across trials; If point estimates across trials are in the same direction, do not vary substantially or heterogeneity can be explained, results may not be downgraded for inconsistency. The consistency of single studies is unknown; evidence from single studies may be downgraded.
3. Imprecise effect estimate for an outcome: small sample size and/or confidence interval includes both negligible effect and appreciable benefit or harm with the intervention; If sample size is likely too small to detect rare outcomes, evidence may be downgraded twice. If the estimate is statistically significant, it is imprecise if the CI ranges from “mild” to “substantial”. If the estimate is not statistically significant, it is imprecise if the CI crosses the threshold for “mild/small” effects and may be downgraded once. Wide (or unknown) confidence interval and/or small sample size may result in downgrade.
4. Indirect, intermediate or surrogate outcomes may be downgraded.

INTRODUCTION

Since the publication of the 2016 Position Statement on the Clinical Indications for Myocardial Perfusion PET [1], a growing body of evidence has reinforced the expanding role of positron emission tomography (PET) in the diagnosis and management of coronary artery disease (CAD). This momentum derives from an enhanced understanding of the unique capabilities of PET myocardial perfusion imaging (MPI) and the use of dynamic PET acquisitions to quantify myocardial blood flow (MBF). Extensive and convincing evidence on its excellent diagnostic accuracy and valuable risk stratification has been demonstrated in multiple clinical studies. As a result, major national and international multi-societal clinical guidelines now classify it as the preferred test, if available.

This updated Position Statement expands on the previous indications to now recommend, if available, the use of cardiac PET MPI as the preferred modality for CAD evaluation for all patients who meet criteria for MPI. It reflects a broader international consensus on the value of cardiac PET MPI in routine clinical care, informed by the expanding body of research and clinical experience worldwide. It aims to reaffirm and clarify the role of PET MPI as a powerful and excellent tool for assessment of CAD and related symptoms, supporting broader implementation in clinical practice. This document is not intended to be an extensive scientific review of the literature but to detail the position of the American Society of Nuclear Cardiology (ASNC) regarding the use of cardiac PET MPI and MBF for the assessment of CAD.

MULTI-SOCIETAL GUIDELINE RECOMMENDATIONS

Based on its many advantages and a robust scientific literature, PET MPI with MBF is now prominently and explicitly recommended in major U.S.

SPECT	Single-photon emission computed tomography

and European multi-societal clinical guidelines, including the 2021 Multi-societal Chest Pain Guidelines [2], the 2023 Multi-societal Chronic Coronary Disease Guidelines [3], and the 2024 European Society of Cardiology Guidelines for Chronic Coronary Syndromes [4]. These are mainstream cardiovascular clinical guidelines developed by broad coalitions of societies—not limited to nuclear cardiology organizations—underscoring the growing recognition of PET MPI's clinical value across disciplines.

Across these guidelines, PET MPI is consistently preferred over single-photon emission computed tomography (SPECT) MPI. In the U.S. guidelines [2], this preference is reflected as a class 2a recommendation, while the European guidelines elevate it to class 1—recognizing cardiac PET's superior diagnostic accuracy, risk stratification, image quality, and ability to quantify MBF [3,4]. In both U.S. and European guidelines, PET is favored for the evaluation of intermediate- to -high-risk patients with stable or acute chest pain (Class 1), enhanced risk stratification (Class 1), and microvascular assessment when MBF is included (Class 2A) (Figure 1).

ADVANTAGES OF PET MPI

PET offers numerous important advantages that make it the preferred modality, as extensively documented in the ASNC Model Coverage Policy [5], Table 1.

1. High diagnostic accuracy

PET MPI demonstrates high and, when compared to SPECT MPI, superior sensitivity and specificity for detecting and evaluating obstructive epicardial CAD [5]. Its diagnostic performance has been validated in numerous retrospective and prospective

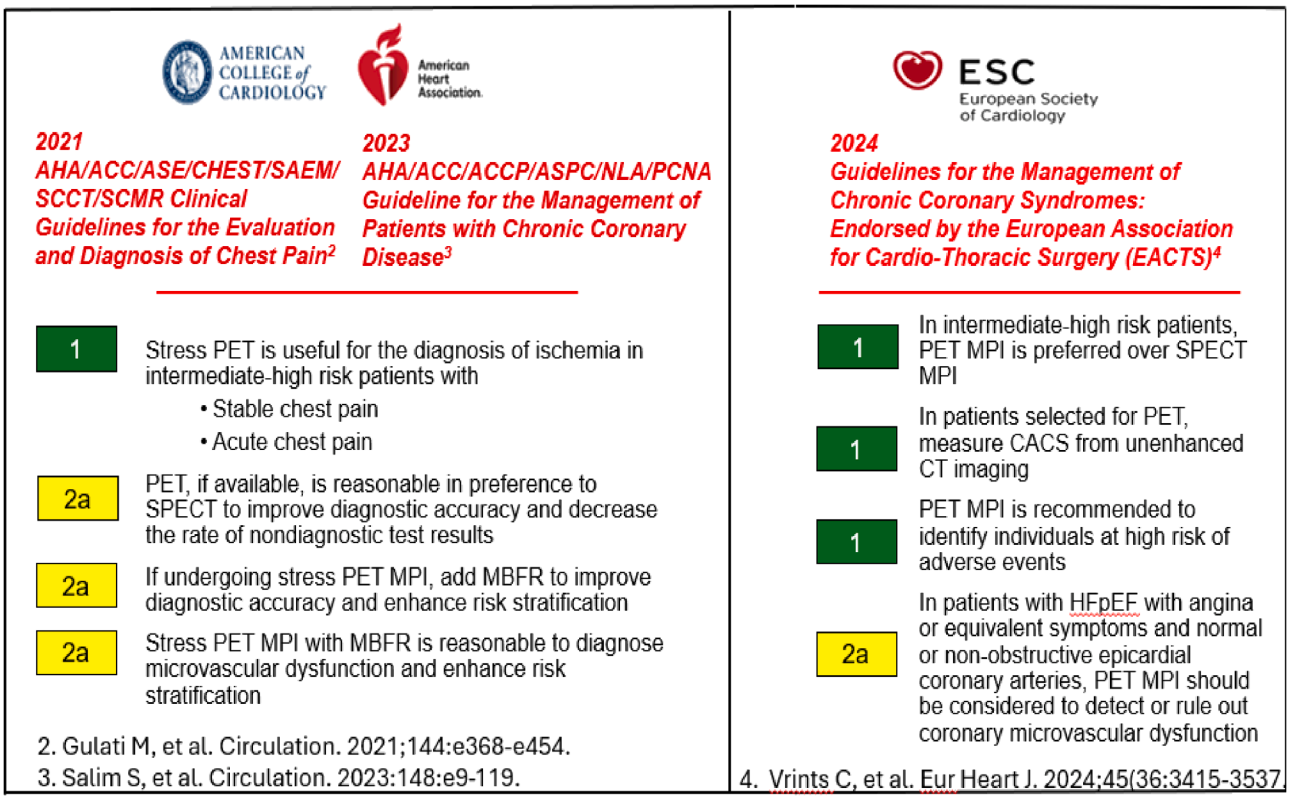

Figure 1. Recommendations for PET MPI in major US and European cardiology guidelines [2–4]. Green box = class 1 recommendation. Yellow box = class 2a recommendation. *MPI*, myocardial perfusion imaging; *PET*, positron emission tomography.

Table 1. Clinical advantages of cardiac PET MPI

Diagnostic accuracy
- ➢ Reduces unnecessary downstream testing.
- ➢ Identifies CAD in absence of perfusion defects.

Risk stratification
- ➢ Perfusion, myocardial-blood-flow, and cardiac function measurements provide independent information about risk.

Robust and reproducible quantification of MBF
- ➢ Requires no additional acquisition time or radiation exposure.
- ➢ Confirms adequacy of vasodilator effectiveness.
- ➢ Enhances diagnostic precision and prognostication.
- ➢ Identifies coronary microvascular dysfunction.

Equitable across diverse patient populations
- ➢ Body habitus, sex, and very high calcium score
- ➢ Arrhythmias, contrast allergies, and implanted devices
- ➢ Feasible in virtually all patients.

Rapid acquisitions
- ➢ Important for patient satisfaction.
- ➢ Minimizes patient motion with associated artifacts.

Low radiation exposure
- ➢ Key consideration for serial imaging.

High image quality
- ➢ Excellent spatial and contrast resolution.
- ➢ High myocardial count density.
- ➢ Superior tracer kinetics.
- ➢ Routine attenuation and scatter correction.

CAD, coronary artery disease; *MBF*, myocardial blood flow; *MPI*, myocardial perfusion imaging; *PET*, positron emission tomography.

studies and confirmed in large meta-analyses [6,7]. The combination of high-quality, high-spatial-resolution perfusion imaging with attenuation correction, rest-and-stress functional assessment (regional/global wall motion and ejection fraction), MBF, MBF reserve, and coronary artery calcium [CAC] when combined with computed tomography [CT] evaluation provides the following:

- Identification of very-low-risk patients, reducing unnecessary downstream testing.
- Identification of coronary-artery-disease in the absence of relative perfusion defects, including microvascular disease.
- More accurate identification of multi-vessel disease-related balanced flow reduction.

2. Improved risk stratification

- Perfusion, blood flow, and function measurements each provide independent information about risk, permitting more precise decisions about medical management and interventions for coronary-artery-disease.

3. Robust and reproducible quantification of MBF

PET is the gold standard, non-invasive modality for the assessment of MBF:

- Performed routinely without added acquisition time or radiation exposure
- Provides confirmation of vasodilator effectiveness
- Enhances diagnostic accuracy and prognostication
- Enables identification of coronary microvascular dysfunction, a key contributor to angina without obstructive CAD [8].
- Identifies the true extent of CAD, enhancing diagnosis of left main or multi-vessel disease and eliminates the concern of false negative perfusion results in the setting of "balanced ischemia" [9,10].

Quantitative assessment of MBF with PET offers substantial added value beyond relative perfusion imaging and gated MPI. By providing absolute measures of perfusion, MBF quantification improves diagnostic accuracy for epicardial CAD and enhances assessment of its extent and severity [9,10]. Myocardial blood flow provides incremental risk stratification information, refining prediction for future cardiovascular events [9,10]. Importantly, MBF quantification provides more informed decision-making to assess the need for coronary revascularization and/or intensified medical therapy [11,12]. In addition, it enables the identification of coronary microvascular dysfunction, in the presence of or in the absence of obstructive epicardial CAD [8]. Quantitative MBF also confirms the effectiveness of pharmacologic stress, adding a layer of confidence to study interpretation. Finally, it is valuable in patients with known CAD, prior PCI or CABG, and cardiac transplant, providing insights into disease progression, response to therapy, and detection of new or evolving disease [9–13].

4. Equitable across diverse patient populations

- Utility unaffected by sex or body habitus or amount of CAC making it equally effective in women, overweight patients, and those with very high CAC scores.
- Feasible in all patients including those capable of exercise, irrespective of cardiac rhythm, implanted devices, iodinated contrast allergy, and virtually all comorbidities.

- Offers robust performance even in those patients with multi-vessel disease or prior revascularization.

5. **Comparatively rapid acquisitions**

- PET acquisitions can be completed quickly, which is important to patient satisfaction, and minimize patient motion with associated artifacts that can erode accuracy.

6. **Low radiation exposure**

- PET MPI protocols typically result in low total-body effective dose, well below current societal recommendations [14]. This is a particularly important consideration for serial imaging in chronic CAD or transplant patients who are likely to undergo numerous radiation-exposing procedures in the course of their disease.

7. **High image quality**

PET MPI provides consistently high-quality images even in challenging patient populations due to:

- Excellent spatial and contrast resolution
- High myocardial count density
- Excellent tracer kinetics
- Routine attenuation and scatter correction

ADDED VALUE OF PET/CT

When available, adjunctive CT should be routinely used to provide additional important anatomic insights, particularly regarding the presence, extent, and severity of CAC. If ECG-gated CT is performed, a CAC score can be measured; in the absence of electrocardiographic gating, visual estimation of CAC remains informative [15]. Detection of CAC has important prognostic implications and can guide preventive and therapeutic medical management. In addition, the CT component may reveal relevant cardiac, vascular, and non-cardiovascular findings that can further inform patient care beyond MPI findings [15].

CONCLUSION

PET MPI with MBF quantification has several strengths that make it ideal for CAD evaluation—high diagnostic accuracy of both epicardial and microvascular disease, low radiation exposure, and powerful risk stratification. Therefore, the ASNC recommends that PET MPI, if available, be the preferred modality for all patients who meet criteria for MPI. There are no clinical scenarios or patient subgroups in which the use of PET MPI should be excluded, given its diagnostic accuracy, risk stratification, and unique quantitative capabilities.

DISCLOSURES

The authors declare the following financial interests/personal relationships, which may be considered as potential competing interests.
Dr. Bateman reports research grants from Bracco, GE HealthCare, and Spectrum Dynamics, is a consultant for GE HealthCare and Synektik, and has ownership in Cardiovascular Imaging Technologies. Dr. Al-Mallah reports research grants from Siemens and GE HealthCare and is a consultant for Jubilant Pharma, Pfizer, Phillips, Medtrace, Synektik, and GE HealthCare. Dr. Arumugam is a speaker for Blue Earth Diagnostics, Ltd. and IBA Radio Pharma Solutions. Dr. Chareonthaitawee is a consultant for GE HealthCare and Synektik is receiving royalty payments from UpToDate. Dr. Di Carli is consultant for Medtrace Pharma, Sanofi, Valo Health, Bitteroot Bio, and IBA Radio Pharma Solutions and reports an institutional research support from Sun Pharma and Gilead Sciences and an in-kind institutional grant from Amgen. Dr. Heller is on the Advisory Board of Molecular Imaging Services. Dr. Soman has received grant support from Pfizer and is receiving consulting fees from Alnylam, Eidos, Pfizer, Spectrum Dynamics, and Synektik is receiving royalty. Dr. Abuzaid is a consultant for BridgeBio. Dr. Osborne is a consultant for WCG Imaging. Dr. Patel reports research grants from the NIH and Jubilant Radiopharma. Dr. Phillips is a consultant for Novo Nordisk. Dr. Sanghani is a consultant and speaker for GE HealthCare.
The following contributors have nothing to disclose: Dr. Alnabelsi, Dr. Calnon, and Dr. Divakaran.

Section 6.0

2027 CPT code review

2027 CPT Code Review: Lymphovenous Surgery

Plain Language Summary:

Lymphedema is an unusual swelling of the arms or legs, sometimes caused by surgery. Lymphovenous surgery is a procedure done with a microscope to reconnect tiny lymph vessels, helping drain extra fluid out of the limb.

Although lymphovenous surgery looks promising, it hasn't been studied enough. Staff recommend not covering at this time.

This issue summary appeared in the March 19, 2026 meeting materials. No changes have been made to this document.

Staff Analysis Summary:

Significant proposed changes or discussion items:

1) Do not add coverage for lymphovenous surgery as a treatment for lymphedema

---

Codes:

*38X03, *38X04 "microvascular anastomosis services; addition of microvascular lymphovenous bypass surgery guidelines"

Similar codes: Previously coded with CPT *1019T Lymphovenous bypass (LVB), including robotic assistance, per extremity

Background:

Lymphedema is a condition in which fluid builds up in the body due to damage to the lymph system. This condition causes swelling and pain in the extremities and can lead to ulcers, infections, limited mobility and other complications. Lymphedema can either be idiopathic (no known cause) or can result from surgeries, typically cancer surgeries that

*CPT only copyright 2025 American Medical Association. All rights reserved.
** Current Dental Terminology © 2025 American Dental Association. All rights reserved

involve lymph node removal. Standard treatments include special physical therapy massage, compression garments, and manual drainage. Recently, there has been increasing interest in surgery to connect lymphatic vessels to improve drainage. Types of surgery include lymphovenous bypass that uses microsurgery to connect lymphatic vessels with vein grafts, and lymphaticovenular anastomosis that connects lymphatic vessels directly using microsurgical techniques. This surgery can be done prophylactically, at the time of surgery that removes lymph nodes, or afterwards.

Previous HSC/HERC reviews:

No previous reviews of these procedures have been conducted

Current Prioritized List/Coverage status:

ICD-10-CM I89.0 (Lymphedema, not elsewhere classified) and similar diagnoses are on line 420 LYMPHEDEMA. Line 420 contains procedure codes for PT/OT, and for drainage of lymph collections. Similar conditions and treatments are online 283 COMPLICATIONS OF A PROCEDURE ALWAYS REQUIRING TREATMENT

[Edits accepted at the January 2026 VBBS/HERC meetings shown in blue/red]

GUIDELINE NOTE 43, LYMPHEDEMA

Lines 283,419

ICD-10-CM I97.89 (Other postprocedural complications and disorders of the circulatory system, not elsewhere classified) is only included on Line 419 for post-operative lymphedema.

Lymphedema treatments (aside from DME) are included on this line when medically appropriate. These services are to be provided by a licensed practitioner who is

1) Certified by Lymphology Association of North America (LANA, http://www.clt-lana.org), OR
2) CLT-LANA eligible (graduates from a minimum 135-hour lymphedema program that meet the LANA eligibility requirements), only if a LANA-certified therapist is not available.

~~Services should be provided by a LANA certified therapist if available.~~

*CPT only copyright 2025 American Medical Association. All rights reserved.
** Current Dental Terminology © 2025 American Dental Association. All rights reserved

Treatments for lymphedema are not subject to the visit number restrictions found in Guideline Note 6 REHABILITATIVE AND HABILITATIVE THERAPIES.

~~ICD-10-CM I97.89 (Other postprocedural complications and disorders of the circulatory system, not elsewhere classified) is only included on Line 419 for post-operative lymphedema.~~

For DME: It is the intent of the HERC that compression dressings/garments and other medical equipment needed for the treatment of lymphedema be covered even in the absence of ulcers or other complications.

Evidence:

Treatment of existing lymphedema

1) **Brown 2026** Lymphovenous bypass for the treatment of secondary lymphedema: A meta-analysis of prospective outcomes
    a. N=8 studies (prospective cohort or database design)
        i. N=481 patients undergoing lymphaticovenous bypass (LVB)
    b. Significant limb volume reductions following LVB were observed in four studies. Other studies demonstrated volume reduction as well, although the outcomes did not reach statistical significance
    c. Patient-reported outcomes indicated significant improvements in quality of life (QoL) and symptom relief following LVB in six studies
    d. Four studies reported postoperative reductions in compression garment usage. Weighted pooled analysis across four studies showed that 46.3% (95% CI 24.9–69.1, p=0.002, I 2=79.5%) of patients reduced or discontinued compression therapy following LVB
    e. One study, by Boccardo et al., reported significant reduction (complete cessation of lymphangitis in 79 patients) in cellulitis episodes
    f. Authors conclusions: This meta-analysis consolidates fourteen years of research on LVB, confirming its efficacy in reducing limb volume, improving quality of life, and decreasing cellulitis frequency in patients experiencing lymphedema. The sustained benefits up to three years postoperatively

*CPT only copyright 2025 American Medical Association. All rights reserved.
** Current Dental Terminology © 2025 American Dental Association. All rights reserved

support LVB as a viable, long-term treatment option for secondary lymphedema

2) **Hahn 2025** Objectifying Clinical Outcomes After Lymphaticovenous Anastomosis and Vascularized Lymph Node Transfer in the Treatment of Extremity Lymphedema: A Systematic Review and Meta-Analysis
    a. N=52 articles (1920 patients)
        i. 25 retrospective, 23 prospective, two cross-sectional studies, and 2 RCTs (Jonis 2024 lymphovenous anastomosis, Dionyssiou 2016—lymph node transfer)
    b. Of the 1073 extremities that contributed to effect sizes in clinical improvement of upper extremity lymphedema, 528 underwent lymphaticovenous anastomosis (LVA), 496 underwent vascularized lymph node transfer (VLNT), and 49 received a combination of the two procedures. Likewise, of the 847 extremities that contributed to effect sizes in clinical improvement of LEL, 775 underwent LVA, and 72 underwent VLNT.
    c. The clinical improvement of lymphedema was determined based on the rate of postoperative circumference or volume reduction in the affected extremity
    d. A clinical improvement of 29.44% (95% CI: 15.58–43.29) was observed in upper extremities following LVA
    e. Authors conclusions: The clinical improvement in patients with UEL and LEL following microsurgery is estimated to be 36% and 34%, respectively
3) **Jonis 2024** The 6 month interim analysis of a randomized controlled trial assessing the quality of life in patients with breast cancer related lymphedema undergoing lymphaticovenous anastomosis vs. conservative therapy
    a. N=92 patients with 6 month follow up data (46 LVA group, 46 control)
    b. Health related quality of life measured by the lymphedema international classification of functioning (Lymph-ICF) questionnaire (0-100 scale)
        i. In the LVA group the mean difference in the total score of the Lymph ICF between baseline and follow up after three and six months was 8.93 ± 22.71 ($p>0.05$) and 8.57 ± 22.56 ($p>0.05$), respectively. For the domains physical function and mental function a decrease of more than 10 points was observed after 3 and 6 months, representing a statistically significant improvement. In the CDT group there was no

*CPT only copyright 2025 American Medical Association. All rights reserved.
** Current Dental Terminology © 2025 American Dental Association. All rights reserved

difference observed in the total score of the Lymph-ICF between baseline and follow up.

ii. The mean difference in the total score of the Lymph-ICF between LVA and control groups was -5.92 (-14.88, 3.04) at 6 months

1. HERC staff unable to find MCID for Lymph-ICF score

c. Volume reduction

i. The excess volume was measured by the difference in affected and non-affected arm. The absolute volume difference was 24.80 ± 179.93 mL (p=0.398) after 3 months and 20.04 ± 196.40 mL (p=0.497) after 6 months for the LVA group. For the CDT group, 13.88 ± 193.36 mL (p=0.640) and 33.98 ± 189.87 mL (p=0.236) after three months and six months, respectively

d. Limb circumference

i. The mean absolute difference in UEL index for the LVA group 3.65 ± 7.24 (p = 0.002) after 3 months and 1.84 ± 14.6, (p = 0.497) after 6 months, for the CDT group the mean absolute difference was respectively 3.3 0± 31.57 (p=0.521) and − 0.84 ± 14.6 (p=0.189) after three and six months

e. Discontinuation of compression garments

i. After 3 months 8 patients (17.0%) in the LVA group completely discontinued the use of compression garments. After 6 months the discontinuation rate increased to 10 patients (21.3%). Furthermore after 3 and 6 months, 10 patients (21.7%) partially discontinued use of compression garments. None of the patients in the CDT group discontinued the use of compression garments in the first 6 months.

f. Author conclusions: Lymphaticovenous anastomosis resulted in improvement of physical and mental function in patients with BCRL. Limb volume and limb circumference did not significantly improve after 6 months in both groups. However, in the LVA group around 40% could completely or partially stopped with the use of compression garments. The current results are promising, however longer follow up is required to assess the long term effect of LVA

4) **Chang 2021** Surgical Treatment of Lymphedema: A Systematic Review and Meta-Analysis of Controlled Trials. Results of a Consensus Conference

*CPT only copyright 2025 American Medical Association. All rights reserved.
** Current Dental Terminology © 2025 American Dental Association. All rights reserved

a. N=71 articles reporting on 66 studies
    i. 2 RCTs, 7 prospective cohort studies, 14 retrospective cohort studies, 43 case series
    ii. 8 studies reported on liposuction and compression therapy for treatment of lymphedema; 16 studies reported on lymphovenous bypass and compression therapy; and 17 studies reported on vascular lymph node transplantation and compression therapy. 3 case series reported on combination therapy.
b. Three studies (102 patients) compared lymphovenous bypass to pressure therapy in patients with upper extremity lymphedema or lower extremity lymphedema
    i. Koshima 2000 (retrospective cohort, N=12 LVA, N=12 pressure): arm circumference decreased by a mean 4.1 cm in the lymphovenous bypass group compared to 0.8 cm in the compression therapy group ($p < 0.05$)
    ii. Koshima 2003 (retrospective cohort, N=13 LVA, N=12 pressure): leg circumference decreased by a mean 4.7 cm in the lymphovenous bypass group compared to 0.6 cm in the compression therapy group ($p < 0.05$)
    iii. Engel 2018 (retrospective cohort, N=27 LVA, N=45 LNT, N=52 CDT): 17.3 percent reduction in arm circumference in the lymphovenous bypass group compared to a 9.8 percent reduction in the complex decongestive therapy group (mean difference, 7.50 percent; 95 percent CI, 4.89 to 10.11 percent; $p < 0.00001$
c. 10 studies (134 patients) reported on lymphovenous bypass for reducing limb circumference in patients with stage II to V (Campisi or International Society of Lymphology) upper extremity lymphedema or lower extremity lymphedema. Lymphovenous bypass combined with compression garments significantly reduced circumference by an average of 3.8 cm (95 percent CI, 2.93 to 4.67 cm; $p < 0.00001$; very low-quality evidence)
d. Three case series (14 lower extremity lymphedema and 23 upper extremity lymphedema patients) reported on the mean number of cellulitis infections per year before and after surgery. The incidence of cellulitis before surgery

*CPT only copyright 2025 American Medical Association. All rights reserved.
** Current Dental Terminology © 2025 American Dental Association. All rights reserved

was 67 percent (95 of 141) compared to 21 percent (29 of 141) after surgery (OR, 9.11; 95 percent CI, 2.31 to 35.97)

e. Three case series (141 upper or lower extremity lymphedema patients) reported on preoperative and postoperative cellulitis.32,33,51 Cellulitis was significantly reduced after lymphovenous bypass and compression therapy. The incidence of cellulitis before surgery was 67 percent (95 of 141) compared to 21 percent (29 of 141) after surgery (OR, 9.11; 95 percent CI, 2.31 to 35.97)
f. Consensus recommendations
    i. There is evidence to support that lymphaticovenous anastomosis can be effective in reducing severity of lymphedema (grade 1C)
    ii. There is a need for better designed studies that include more objective reporting of outcomes and longer follow-up

Prophylactic surgery

1) **Hinson 2025** Preventing Secondary Lymphedema: A Systematic Review and Meta-Analysis on the Efficacy of Immediate Lymphovenous Anastomosis
    a. N=39 studies (N=3597 patients total)
        i. N=1722 patients receiving immediate LVA
        ii. N=1975 controls
        iii. 1 RCT, 6 prospective cohort, 9 retrospective cohort or case-control, 23 case series
    b. Meta-analysis included 17 studies (917 LVA patients; 1975 controls)
        i. Immediate LVA was associated with a 69% lower risk of secondary lymphedema compared to the control group (RR: 0.31, 95% CI: 0.23–0.42, $p < 0.00001$). A total of 78 patients developed secondary lymphedema in the LVA group out of 917 patients (8.51%), compared to 692 patients in the control group out of a total of 1975 patients (35.04%).
    c. Authors conclusions: This systematic review and meta-analysis provide compelling evidence that immediate LVA significantly reduces secondary lymphedema risk across oncological indications, with the most pronounced benefit observed in breast cancer patients

Submitted literature:

None received to date

Expert guidelines:

1) **NICE 2024** Lymphovenous anastomosis during axillary or inguinal node dissection for preventing secondary lymphoedema
    a. Lymphovenous anastomosis during axillary dissection for preventing secondary lymphoedema in adults with breast cancer can be used in the NHS while more evidence is generated. It can only be used with special arrangements for clinical governance, consent, and audit or research
2) **International Society of Lymphology 2023** THE DIAGNOSIS AND TREATMENT OF PERIPHERAL LYMPHEDEMA: 2023 CONSENSUS DOCUMENT OF THE INTERNATIONAL SOCIETY OF LYMPHOLOGY
    a. Microsurgical procedures can be medically necessary to treat lymphedema in properly selected patients

Other payer policies:

1) Wellpoint 2025
    a. Microsurgical procedures for the *treatment* of lymphedema (including mastectomy related lymphedema) are considered **medically necessary** when **all** of the following criteria (A, B, C *and* D) are met:
        i. The individual has a diagnosis of lymphedema based on clinical findings and appropriate diagnostic testing; **and**
        ii. The individual has one or more of the following (1, 2 *or* 3):
            1. Physical function impairment (e.g., difficulty ambulating, performing activities of daily living); **or**
            2. History of chronic or recurrent skin conditions (e.g. cellulitis, ulcerations); **or**
            3. Significant pain or weakness in the affected extremity; **and**
        iii. Lymphedema persists or worsens despite at least 3 months of optimal conservative management; **and**
        iv. **One** of the following procedures are used:

*CPT only copyright 2025 American Medical Association. All rights reserved.
** Current Dental Terminology © 2025 American Dental Association. All rights reserved

1. Lymphovenous anastomoses; **or**
2. Lymphatic reconstruction techniques (for example, lymphatic-lymphatic bypass); **or**
3. Vascularized lymph node transfer.

v. Microsurgery for the *prevention* of lymphedema, or immediate lymphatic reconstruction, is considered **not medically necessary.**

2) United Healthcare 2026: Surgical procedures for the prevention or treatment of Lymphedema are unproven and not medically necessary due to insufficient evidence of safety and/or efficacy
3) Aetna 2025
   a. Considers the following experimental:
      i. Microsurgical treatments (microsurgical lymphatico-venous anastomosis, lymphatic-capsular-venous anastomosis, lymphovenous bypass) for the treatment of members with chronic obstructive lymphedema
4) Premara BCBS 2026
   a. The following surgical treatments to treat lymphedema (eg, upper or lower extremities or genitalia) are considered investigational:
      i. Lymphatic physiologic microsurgery
         1. Lymphatico-lymphatic bypass
         2. Lymphovenous bypass
         3. Lymphaticovenous anastomosis
         4. Autologous lymph node transplantation
         5. Vascularized lymph node transfer
      ii. Lymphatic physiologic microsurgery performed during nodal dissection or breast reconstruction to prevent lymphedema (including, but not limited to, the Lymphatic Microsurgical Preventing Healing Approach [LYMPHA]) in individuals who are being treated for breast cancer is considered investigational.
5) Cigna 2025
   a. EITHER of the following procedures is considered medically necessary for the treatment of lymphedema:

*CPT only copyright 2025 American Medical Association. All rights reserved.
** Current Dental Terminology © 2025 American Dental Association. All rights reserved

i. microsurgical treatment (e.g., microsurgical lymphatico-venous anastomosis, lymphaticcapsular-venous anastomosis [LCVA], lymphovenous bypass, lymph node-to-vein anastomosis [LVNA])
ii. vascularized lymph node transfer

b. When an individual meets ALL of the following criteria:
   i. ONE of the following signs and symptoms:
      1. physical function impairment (e.g., difficulty ambulating, performing activities of daily living)
      2. history of chronic or recurrent skin conditions (e.g. cellulitis, ulcerations)
      3. significant pain or weakness in the affected extremity
   ii. ONE of the following quantitative measurements:
      1. volumetry differential (circumferential measurements and/or perometry differential) >10% (if affected extremity dominant extremity) or >7% (affected extremity is non-dominant extremity)
      2. lymphoscintigraphy results show delayed transit time to first-level lymph nodes or a dermal back flow pattern
   iii. lack of response to at least three consecutive months of medical management (e.g., compression garments, manual lymphatic drainage)
   iv. postoperatively will continue to wear compression garments as instructed to maintain the benefits of treatment

c. The following surgical procedures for the prevention of lymphedema are considered experimental, investigational or unproven:
   i. immediate lymphatic reconstruction (e.g., lymphatic microsurgical preventing healing approach [LYMPHA]), microsurgical lymphatico-venous anastomosis, lymphatic- capsularvenous anastomosis, lymphovenous bypass)

Expert input:

None received to date

HERC staff summary:

Lymphovenous anastomosis (LVA) or lymphovenous bypass (LVB) microsurgery for existing lymphedema has been studied mostly in retrospective cohort studies and case series without control groups. A recent systematic review of 8 prospective cohort studies without control groups of patients undergoing lymphovenous bypass found significant limb volume reductions with surgeries in half of the studies, improved quality of life in 75% of studies, reduction in use of compression garments and in infections. Another recent systematic review of both retrospective and prospective studies included various lymph surgeries also found clinical improvement in upper limb size with LVA.

A more accurate evaluation of a surgical intervention requires comparison of the surgery to a standard of care control group. One RCT exists that compares LVA to standard compression garment therapy. This study of 92 patients found improvements in the quality of life scores, although it appears to be non-significant between groups at 6 months. Limb volume reduction and circumference change were not significantly different between groups. Approximately 20% of LVA patients were able to stop compression garments compared to no control patients. A recent systematic review identified three retrospective cohort studies that compared LVA to compression therapy. All three found reduced limb circumference in the surgery group compared to controls.

A recent systematic review was found that examined 39 studies of prophylactic LVA surgery, generally for breast cancer patients. This review found 1 RCT and the remainder were generally retrospective cohort studies or case series. Immediate LVA was found to have a lower risk of lymphedema (9% compared to 35% of patients).

Private insurers are mixed on coverage for lymphovenous anastomosis surgery for existing lymphedema. None cover prophylactic surgery. NICE also conducted a recent review and recommended against routine coverage of prophylactic lymphovenous surgery. The international lymphedema society supports lymphedema surgery in appropriate patients.

Based on the comparative studies, LVA/LVB appears to be promising as a treatment for existing lymphedema. However, the only RCT available did not show significant differences in most outcomes. Larger, better designed RCTs are needed in this area. The evidence is much more sparse for lymphovenous surgery as a prophylactic surgery. Based

*CPT only copyright 2025 American Medical Association. All rights reserved.
** Current Dental Terminology © 2025 American Dental Association. All rights reserved

on this review, HERC staff recommends against coverage of lymphevenous surgery for either existing lymphedema or as a prophylactic surgery at this time.

HERC staff recommendations:

1) Add an entry for lymphovascular surgery to Excluded Services Guideline E2 as shown below
    a. Replace the temporary CPT code in this entry with the 2027 CPT codes when they become available

EXCLUDED SERVICES GUIDELINE E2, INTERVENTIONS THAT ARE UNPROVEN, HAVE NO CLINICALLY IMPORTANT BENEFIT OR HAVE HARMS THAT OUTWEIGH BENEFITS FOR CERTAIN CONDITIONS

The following Interventions are unproven, have no clinically important benefit or have harms that outweigh benefits and should be excluded from coverage

Abstract

Background Despite the increasing popularity of microsurgical techniques for the treatment of lymphedema, there is a lack of high-level, prospective, long-term data and standardized outcome metrics. The purpose of this study was to analyze the long-term outcomes of Lymphovenous Bypass (LVB) surgery throughout the past two decades.

Methods We conducted a systematic review of PubMed, Embase, and Web of Science databases to identify prospective clinical trials investigating LVB for lymphedema treatment. Reported outcome data included limb volume measurements, number of cellulitis episodes, compression garment use, and the assessment of complications. For studies involving multiple procedures, only outcomes from the respective LVB cohorts were analyzed. Retrospective data analyses were excluded.

Results Eight prospective studies (2009–2023) were included in the meta-analysis, comprising a total of 431 patients undergoing LVB with a mean follow-up of 21.8 ± 7.7 months. An average of 3.4 ± 1.0 anastomoses were performed per patient. LVB was associated with a 14.26% mean reduction in limb volume (95% CI 6.63–21.88; $p < 0.0001$) at one-year, and 46.3% (95% CI 24.9%-69.1%; $p < 0.01$) reduction/discontinuation of compression therapy following surgery. Patients also reported subjective symptom relief and reduced cellulitis episodes.

Conclusions This systematic review provides the most comprehensive synthesis to date of long-term outcomes following LVB surgery for lymphedema. The findings support LVB as a safe and effective microsurgical intervention, with consistent reductions in limb volume, cellulitis episodes, and reliance on compression therapy.

Keywords Lymphedema · Breast cancer · Lymphovenous bypass

Introduction

Lymphedema is a chronic and progressive condition caused by impaired lymphatic drainage, resulting in the accumulation of lymphatic fluid in the interstitial tissues, most commonly affecting the extremities [1, 2]. It can lead to significant physical discomfort, limb swelling, functional limitations, and recurrent infections [3]. Cancer-related lymphedema is a lifelong and currently incurable condition with global prevalence estimates of 140 to 250 million people worldwide [4]. In developed countries, secondary lymphedema most commonly follows cancer treatment, particularly breast cancer, with incidence rates after axillary lymph node dissection reported between 15 and 40% [1, 4].

Lymphovenous bypass (LVB), a microsurgical technique designed to improve lymphatic drainage, has gained increasing attention over the past two decades. Originally described decades ago, LVB has benefited from significant technical

advances that allow for the anastomosis of smaller-caliber lymphatic vessels to adjacent veins [5]. The procedure involves creating functional lymphatic-venous anastomoses (LVAs) to divert lymphatic fluid into the venous circulation, reducing fluid accumulation in the affected limb [6]. These refinements in technique have led LVB to be an increasingly popular choice for lymphedema treatment [5, 7].

Prospective and randomized studies consistently demonstrate that LVB can lead to improvements in limb volume, quality of life, and reduction in cellulitis episodes in selected patients with lymphedema [8–10]. However, the magnitude and durability of these benefits vary. Some studies report significant limb volume reduction, while others find improvements primarily in quality of life and infection rates without consistent objective volume changes [8, 9, 11].

The literature highlights substantial heterogeneity in patient populations, surgical techniques, outcome measures, and follow-up periods, which complicates direct comparison and generalizability of results [5, 12]. There is no consensus on the ideal timing of LVB, the most appropriate candidates, or the long-term durability of benefit, as most studies have limited follow-up and are underpowered to detect late recurrences or complications [5]. Recent consensus recommendations from the American Association of Plastic Surgeons also emphasize these ongoing uncertainties and the need for further high-quality, long-term studies to refine patient selection and optimize outcomes [5].

To address these gaps, we conducted a systematic review and meta-analysis of prospective clinical trials published over the past two decades. We aimed to provide a comprehensive synthesis of long-term outcomes following LVB for the treatment of lymphedema, using standardized and clinically meaningful outcome measures.

Methods

Search strategy and inclusion criteria

A systematic review was conducted on PubMed/MEDLINE, Embase, and Web of Science to identify prospective clinical trials investigating LVB for secondary lymphedema treatment according to the Preferred Reporting Items for Systematic reviews and Meta-Analyses (PRISMA) guidelines. The systematic review included articles published on or before February 21st, 2025. The search strategies were initially developed on PubMed and adapted for other databases (Table 1).

Original studies in which LVB was performed as the sole surgical intervention, with or without adjunctive conservative treatment, specifically for secondary lymphedema, were included. Studies had to report at least one of the following outcomes following LVB: limb volume or circumference, patient-reported outcome measures (PROMs), compression garments usage, and frequency of cellulitis. Only prospective studies with post-operative follow-up of 12 months or longer were included.

Non-English publications, animal studies, review articles, expert opinions, case reports, and descriptive studies focusing solely on surgical techniques were excluded. Studies with duplicate data were also excluded. Additionally, we excluded studies where LVB was used to treat primary lymphedema or where LVB was performed in conjunction with other surgical procedures. For research groups with multiple publications potentially containing overlapping patient populations, only the most comprehensive and relevant study was included, as determined by at least two of the authors.

Data extraction

Each study identified through the database search were independently screened by two of the authors (YS, MN) using Covidence (Veritas Health Innovation, Melbourne, Australia). Risk of bias assessment was conducted using the Risk of Bias in Non-randomized Studies – of Interventions, Version 2 (ROBINS-I V2) [13]. Two independent reviewers (MN and YS) performed these assessments. In cases of disagreement, a third author (SB) resolved disagreements through verbal consensus. Data extraction was performed by two independent reviewers (YS, SB) and included: study design, sample size, patient demographics, follow-up duration, surgical details of LVB, percentage reduction in limb volume, PROs, and frequency of cellulitis episodes. Studies were categorized based on outcome metrics reported one year post-LVB.

Statistical analysis

Meta-analyses were conducted using random-effects models to account for heterogeneity across studies. Pooled estimates included the mean percentage reduction in limb volume compared to preoperative measurements, mean percentage reduction in excess volume relative to the contralateral (healthy) limb, QOL and compression use. All estimates were reported with 95% confidence intervals (CIs). Heterogeneity was quantified using the I^2 statistic, with values > 50% considered indicative of moderate to high heterogeneity. All statistical analyses were conducted using R (version 4.3.2; R Foundation for Statistical Computing, Vienna, Austria), and a p-value < 0.05 was considered statistically significant.

Results

Study selection and characteristics

After search and de-duplication, 1,733 studies entered the screening process (Fig. 1). The final analysis included eight studies published between 2009 and 2023, all of which employed a prospective database or cohort design with a single LVB intervention group [11, 14–21]. A total of 431 patients underwent LVB, with a mean follow-up duration of 21.8 ± 7.7 months. Sample sizes across studies ranged from 10 to 118 patients (Table 2).

Lymphedema and lymphovenous bypass surgery

The majority of patients had cancer-related lymphedema (419, 97.2%), with breast cancer being the most common underlying cause (209, 48.5%), followed by genitourinary/gynecologic cancers (150, 34.8%) and other or unspecified malignancies (60, 13.9%). Upper and lower extremity lymphedema were nearly equally represented, with 214 cases (49.7%) affecting the upper extremities and 217 cases (50.3%) affecting the lower extremities. On average, patients had experienced lymphedema for 5.46 years (range 1–35 years) before undergoing LVB. The International Society of Lymphology (ISL) staging system was the most commonly reported classification, used in five studies encompassing 294 patients. Among these, 261 patients (88.8%) were classified as stage I or II, while 33 patients (11.2%) had stage III disease.

All studies used dyes (Indocyanine Green (ICG), Blue Patent V, or Methylene Blue) and/or lymphoscintigraphy to visualize lymphatic vessels either pre-operatively or intra-operatively during LVB. Only one study reported two minor complications related to LVB surgery, both due to mild skin irritation from contrast injection [19]. Both end-to-end and end-to-side anastomoses were employed. In most studies, more than one anastomosis was performed per patient, with an average of 3.4 ± 1.0 (Table 3). Studies reported heterogeneous outcome measures, including changes in limb volume, excess volume reductions (EVR), PROMs, subjective symptom improvement, frequency of cellulitis episodes, and compression therapy usage.

Limb volume reduction

Significant limb volume reductions following LVB were observed in four studies [15, 17, 18, 21]. Chang et al. (2013) reported sustained volume reduction over a 3-year follow-up period with decreases of 33%, 36%, and 42% at 3, 6, and 12 months, respectively, and 35% and 38% at 2 and 3 years. Boccardo et al. (2022) demonstrated sustained volume reductions at 1 year (75–90% in early stage II, 60–75% in late stage II, $p < 0.001$), which persisted through 5 years across a cohort with both upper and lower extremity lymphedema [15]. Similarly, mean volume at 1, 3, and 5 years postoperatively remained significantly reduced compared to preoperative measurements ($p < 0.001$). For lower extremity lymphedema specifically, Kwon et al. (2023) observed significant limb volume reductions of 11.0% at 1 month, which were maintained at 6 months (10.4%) and 12 months (11.7%, $p < 0.001$) [18]. Phillips et al. (2019) also reported a significant reduction in unilateral lower extremity lymphedema, with excess volume decreasing by 44.42% ($p = 0.008$) [21]. Other studies demonstrated volume reduction as well, although the outcomes did not reach statistical significance. Damstra et al. (2009) noted a slight, non-significant excess volume reduction at one year (4.8%) [22]. Similarly, Cornelissen et al. (2017) also reported a moderate but non-significant

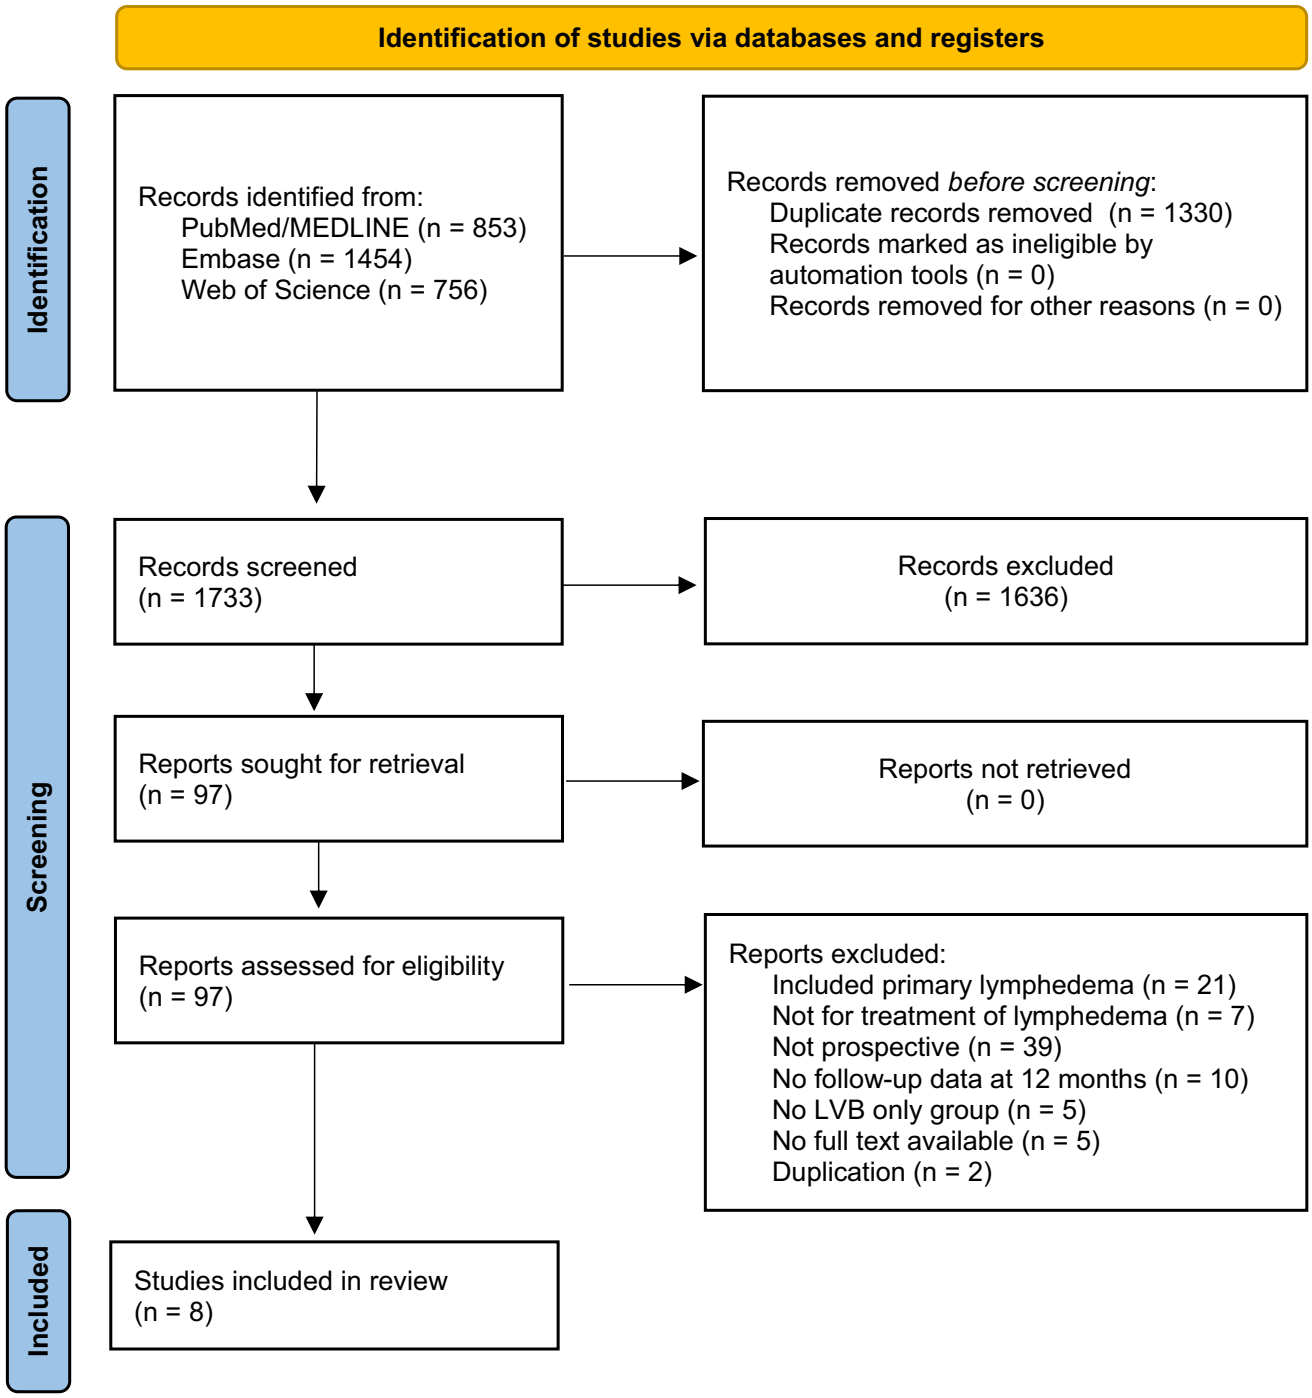

Fig. 1 Preferred reporting items for systematic reviews and meta-analyses (PRISMA) flow diagram of the study selection process

12.7% decrease in mean limb volume difference ($p = 0.58$) [19]. Khan et al. (2019) reported fluctuating excess volume reductions at different time points (− 14.0 ± 40.7% at 1 month; 2.9 ± 68.4% at 3 months; − 0.6 ± 49.6% at 6 months; 9.2 ± 71.8% at 12 months) [14]. Given that most studies reported either changes in limb volume or EVR, two random effects models were used, respectively, to estimate the pooled effects of LVB using these two measures. Pooled analysis showed that LVB significantly reduced the limb volume by 14.26% (95% CI 6.63–21.88, $p < 0.0001$, $I^2 = 98.6\%$) and the excess volume compared

Table 2 Summary of study characteristics

Author (year)	Country	N	Study design	Follow-up, mean	Outcome measures assessed	Timepoints assessed
Chang (2013)	United States	100	Prospective cohort	Upper (89): 30.4 months (3–84) Lower (11): 18.2 months (1–36)	Limb volume differential by perometer, Subjective symptom improvment	Pre-op 3/6/12 months postoperatively

to the contralateral healthy limb by 14.05% (95% CI -53.71–81.80, $p < 0.001$, $I^2 = 88.0\%$) one-year following LVB (Fig. 2, 3).

Patient-reported outcomes

Patient-reported outcomes indicated significant improvements in quality of life (QoL) and symptom relief following LVB in six studies [17–20, 22, 23]. At 6 months, 5 patients (50%) reported subjective symptom relief according to the SF-36 questionnaire (Damstra 2008) [22]. Two studies, Kwon et al. (2023) and Cornelissen et al. (2017), observed significant improvements in all domains and overall scores up to 12 months following LVB assessed by LYMQoL and Lymph-ICF, respectively. [18, 19] Another study by Phillips et al. (2019) also noted improved LYMQoL scores from 71.13 ± 21.43 preoperatively to 87.75 ± 17.52 at the last follow-up visit among the eight patients with > 12-month follow-up, though these did not reach statistical significance [23]. Other studies noted subjective symptom relief in the majority of patients undergoing LVB. In the study by Chang et al., symptoms improved in 96% of patients

with upper extremity lymphedema and 57% of patients with lower extremity lymphedema [17]. Klingelhoef et al. (2019) also observed subjective symptom improvement in 50% of patients [20]. Using infection as a proxy for disease burden, Boccardo et al. (2022) reported complete cessation of lymphangitis episodes over 5 years following LVB in all 79 (100%) patients previously experiencing frequent infections (1–3 episodes/year) [15]. Weighted pooled analysis of LYMQoL data from two studies demonstrated an average 46.7% (95% CI 28.3–65.0, $p = 0.593$, $I^2 = 0.0\%$) improvement in patient-reported quality of life after LVB Fig. 4).

Compression use

All patients were on compression therapy before LVB surgery. Four studies reported postoperative reductions in compression garment usage. Weighted pooled analysis across four studies showed that 46.3% (95% CI 24.9–69.1, $p = 0.002$, $I^2 = 79.5\%$) of patients reduced or discontinued compression therapy following LVB (Fig. 5) [14, 19–21]. Khan et al. (2019) observed a significant overall change in compression therapy usage of the entire cohort (27 patients) on contingency analysis ($p = 0.045$), with 10 (37.0%) patients reducing their compression garment therapy, and two discontinuing the use completely [14]. Similarly, Cornelissen et al. (2017) noted that 85% of patients discontinued compressive stockings during a mean follow-up of 7.8 months [19]. Klingelhoef et al. (2019) reported discontinuation of compression therapy and manual lymphatic drainage in 7.7% and 34.6% of patients, respectively. [20] Phillips et al. reported that 4 (13.8%) patients discontinued compression therapy, while 3 (10.3%) reported reduced usage(Table 4) [21].

Patency of lymphovenous anastomosis (LVA)

LVA patency was assessed in two studies using lymphoscintigraphy [15, 22]. Patency rates could not be pooled due to heterogeneity in assessment methods and incomplete reporting; while one study reported a numerical patency rate, others relied on indirect measures or did not quantify patency outcomes. Boccardo et al. (2022) reported a 97% patency rate at 18 months postoperatively [15]. The lymphatic transport index (LyTi) showed a significant decrease from preoperative levels to 18 months post-surgery. Three patients with late-stage II lymphedema demonstrated no patency, corresponding with less volume reduction compared to the rest of the cohort (45%-60% vs. > 60%). Damstra et al. found no significant differences in the Kleinhans transport index between preoperative and one-year post-surgical measurements[22].

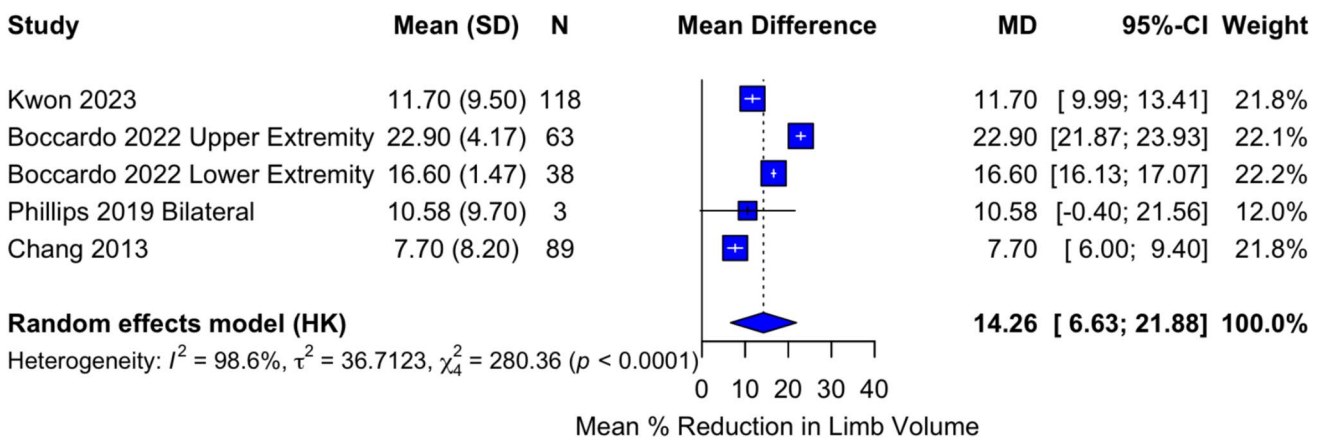

Fig. 2 Mean percentage reduction of limb volume one-year following LVB compared to preoperative limb volume measurement

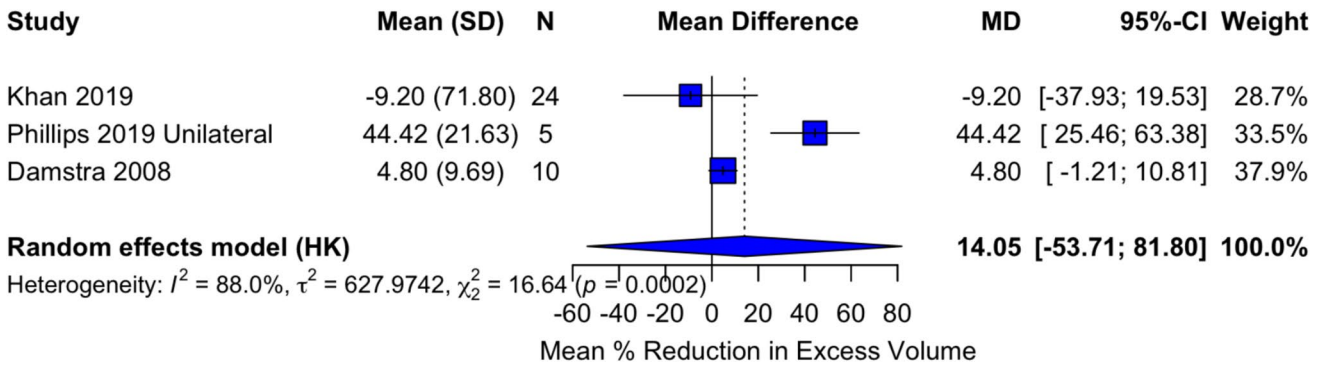

Fig. 3 Mean percentage change of excess volume (to contralateral healthy limb) reduction one-year following LVB compared to preoperative excess volume

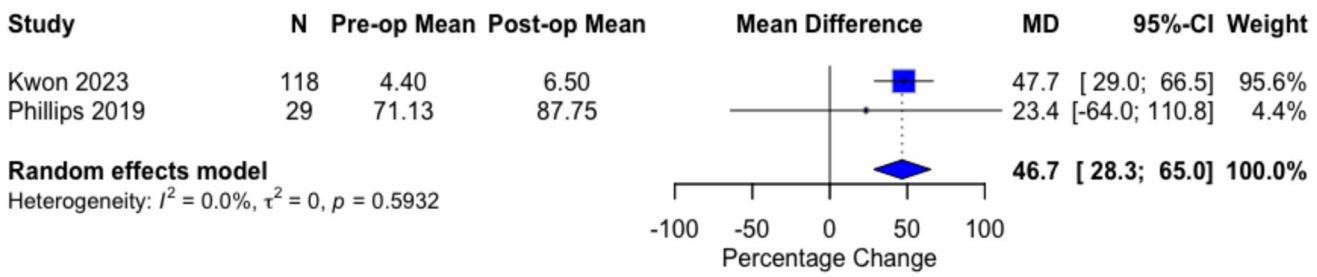

Fig. 4 Pooled percentage improvement in LYMQoL one-year after LVB

Risk of bias assessment

As illustrated in Figs. 6 and 7, the majority of studies demonstrated a low to moderate risk of bias across most domains, and no study was judged to have a critical risk of bias. Overall, the methodological quality of the included studies was deemed acceptable to support the validity of the meta-analysis findings.

Discussion

The most recent meta-analysis evaluating the efficacy of LVB in treating lymphedema was published by Chang et al. in 2021, synthesizing evidence from 10 studies published between 1996 and 2015. Their analysis reported that LVB significantly reduced limb circumference by an average of 3.8 cm. [5] However, most studies included

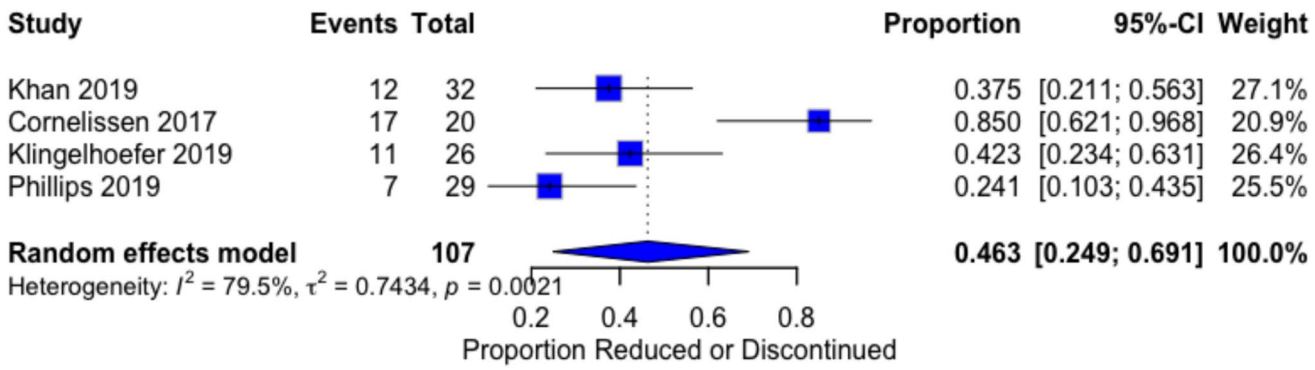

Fig. 5 Pooled proportion of patients who reduced or discontinued compression therapy after LVB

were retrospective, introducing inherent biases. Moreover, the absence of specific exclusion criteria regarding follow-up duration resulted in heterogeneity in the timing of outcome measurements. Since 2021, several prospective studies have been published, providing new data that warrant an updated analysis.

The present study represents the first systematic review and meta-analysis focused on prospective studies evaluating the long-term effect of LVB for secondary lymphedema. We included only studies reporting follow-up data of at least one year post-LVB, with a mean follow-up of 21.8 ± 7.7 months. Our analysis demonstrates that LVB yields sustained benefits beyond one year, including significant reductions in limb volume, improvements in patient-reported quality of life, and decreased compression use. Notably, some studies reported benefits persisting for up to three years, supporting LVB as a durable and effective long-term treatment option for patients with lymphedema [15, 17].

Volume reduction

In our analysis, LVB was associated with a significant mean reduction of 14.26% in absolute limb volume and 14.05% reduction in excess volume relative to the contralateral limb. While both outcomes point to the efficacy of LVB in reducing burden, it is important to interpret the EVR findings with caution. The notably wide confidence interval for EVR suggests a high degree of heterogeneity across studies, which may stem from differences in baseline disease severity, measurement protocols and surgical technique. This underscores the need for greater uniformity in reporting volumetric outcomes and for future studies to adopt standardized methods for EVR assessment.

Quality of life and symptom improvement

Patient-reported outcomes showed significant improvements in quality of life (QoL) and symptom relief following LVB. Our analysis demonstrated a 46.7% improvement in LYMQoL scores and a 46.3% reduction or discontinuation in compression therapy. These findings underscore the value of including psychosocial and functional metrics when evaluating lymphedema interventions. Patients reported enhanced physical mobility, emotional well-being, and social functioning, with many able to discontinue compression garments—highlighting LVB's potential to reduce dependence on lifelong conservative therapy. However, few studies systematically analyzed patients' reasons for discontinuation, which may include both symptomatic improvement and noncompliance or logistical factors. This underscores the need for future studies to capture these motivations more explicitly to better contextualize compression use patterns after surgery. Interestingly, QoL improvements were not closely linked to disease severity or limb volume reduction. For instance, Chang et al. found no significant difference in symptom improvement between early- and advanced-stage patients (16 vs 12, $p = 0.48$) [17], and Kwon et al. reported no correlation between QoL improvement and ISL stage, disease duration, or volume change [18]. Other prospective and randomized studies also showed substantial QoL gains despite minimal objective volume reductions [24]. These findings suggest that LVB may benefit a broader patient population than previously thought, including those with modest anatomical response or advanced-stage disease. The greater improvement in QoL relative to volume reduction indicates that volumetric change may not fully capture clinical benefit. Thus, reliance on volume metrics alone could underestimate LVB's value. [24] Incorporating validated patient-reported outcome measures into clinical trials and routine care is essential to reflect the full impact of surgery. Moreover, the ability to enhance QoL regardless of stage supports timely surgical referral and challenges previous assumptions that limit access based on chronicity or anatomical severity.

Table 4 Outcomes following LVB

Patency and infection rates

One study, by Boccardo et al., reported significant reduction (complete cessation of lymphangitis in 79 patients) in cellulitis episodes, which suggests that LVB not only addresses physical symptoms of lymphedema but also reduces the risk of infections that commonly affect lymphedema patients. This finding is in alignment with

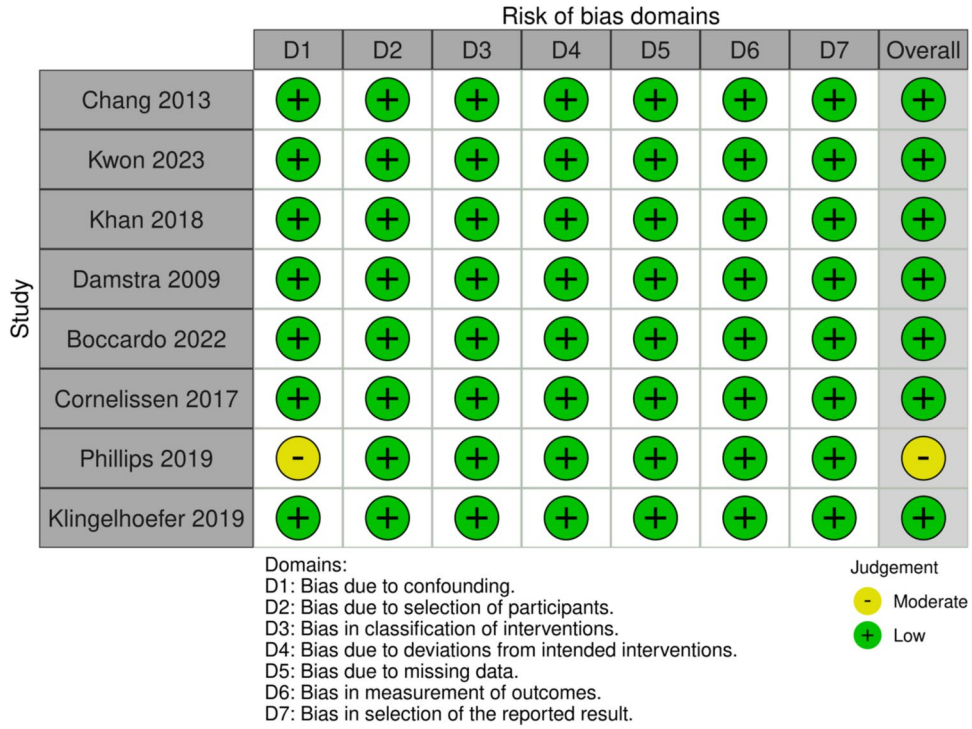

Fig. 6 Risk of bias analysis of included studies (traffic plot)

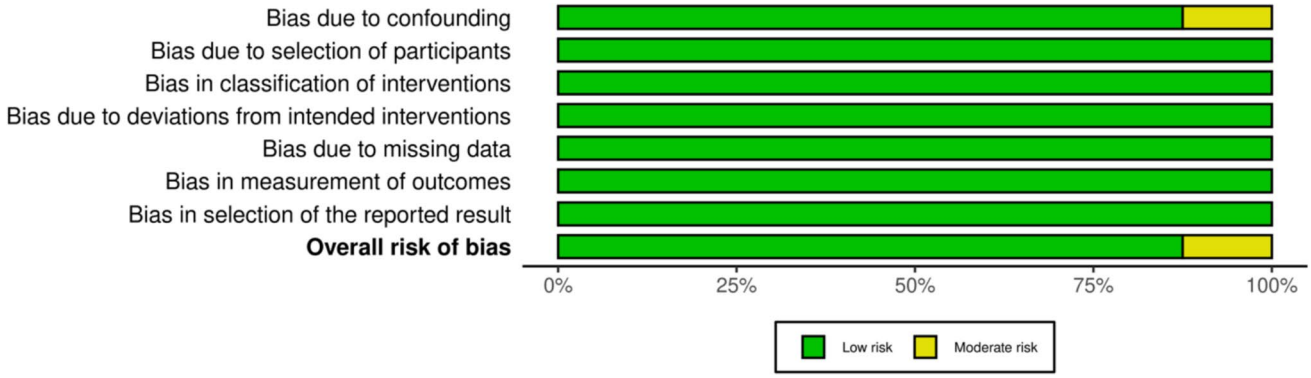

Fig. 7 Summary risk of bias analysis of included studies

previous studies, also showing that LVB leads to a marked decrease in the frequency of cellulitis episodes compared to conservative therapy alone, with reductions sustained over long-term follow-up [12, 25–27]. This reduction in infection risk translates into decreased healthcare utilization, including fewer hospital admissions, reduced need for intravenous and oral antibiotics, and less time off work due to illness. Cost-effectiveness analyses confirm that LVB significantly lowers direct healthcare costs related to cellulitis management, even when accounting for the upfront cost of surgery, and improves quality of life metrics [28].

Patient selection

Although pooled analysis showed significant limb volume reductions following LVB (Fig. 2, 3), individual outcomes varied considerably. Several studies identified early-stage intervention as a critical predictor of success. For example, Chang et al. reported that patients with early-stage lymphedema (MD Anderson stages 1–2) had more anastomoses and significantly greater volume reduction compared to those with advanced-stage disease [17]. Khan et al. found shorter lymphedema duration (< 2 years) was associated with greater excess volume reduction, and the number of anastomoses correlated with improved outcomes [14]. Boccardo et al. found earlier stages linked to

more anastomoses and better lymphatic transport indices [15]. However, Taliat et al. observed that patients with longstanding disease had lymphatic vessel characteristics comparable to those with shorter duration, suggesting duration alone may not predict outcomes [29]. Indeed, only one [30] study used duration as a selection criterion, while most relied on ICG lymphangiography or ISL staging [11, 14–21, 30–32]. This underscores that advanced clinical stage—not disease duration—typically guides surgical candidacy, though the two should not be conflated.

LVB and other surgical interventions

LVB functions as a physiologic bypass that diverts lymph into the venous system and is generally most effective in earlier-stage disease with functioning lymphatics, offering low morbidity and rapid recovery. In contrast, vascularized lymph node transfer (VLNT) may be better suited for more advanced or fibrotic disease through lymphangiogenic and pump mechanisms but involves donor-site morbidity and longer recovery. A recent retrospective cohort study comparing LVB and VLNT showed distinct patterns of reponse, with LVB showing greater but shorter-lasting response peaking within three months after surgery and VLNT showing a delayed but more durable response peaking at three and thirteen months [33]. Debulking techniques, such as liposuction, reduce fibroadipose hypertrophy and limb size but do not restore physiologic lymphatic drainage and often require ongoing compression [5, 10]. Taken together, these approaches may be complementary to LVB: LVB is typically considered first-line for ISL stage I–II disease, VLNT for more advanced or refractory cases (often in combination with LVB), and debulking as an adjunct in patients with significant adipose hypertrophy.

Limitations and future directions

Several limitations should be noted when interpreting these findings. No randomized controlled trials or matched control cohort studies were available for head-to-head comparisons between LVB and conservation therapy or other surgical interventions. Therefore, definitive comparative effectiveness cannot be established. However, the current evidence consistently demonstrates meaningful improvements following LVB in appropriately selected patients. Moreover, the current evidence base is shaped by variability in patient populations, disease severity, surgical techniques, and measurement methodologies. For example, the included studies used different approaches to quantify limb volume, such as percentage reduction, raw volume, raw excess volume, or percentage excess volume, which introduces heterogeneity and challenges to synthesize results across studies. Moderate to high statistical heterogeneity was observed across most pooled analyses, with I^2 values of 88–99% for limb and excess volume reductions (Figs. 2 and 3). Although the presence of heterogeneity warrants cautious interpretation of pooled meta-analysis, the direction and magnitude of effects were consistent across studies, supporting the overall validity of the findings. Future research should adopt standardized protocols for outcome measurement and include longer follow-up periods to conclusively establish the long-term efficacy of LVB.

The paucity of literature highlights the lack of prospective studies with long-term follow-up. Further large-scale, multicenter RCTs are needed to establish standardized guidelines for LVB. To our knowledge, a multicenter RCT, SurLym, was started in 2022 and is currently ongoing to compare the effect of conservative therapy alone to conservative therapy and reconstructive lymphatic surgery [34].

Conclusion

This meta-analysis consolidates fourteen years of research on LVB, confirming its efficacy in reducing limb volume, improving quality of life, and decreasing cellulitis frequency in patients experiencing lymphedema. The sustained benefits up to three years postoperatively support LVB as a viable, long-term treatment option for secondary lymphedema. Given its impact on reducing the physical and psychological burden of lymphedema, LVB holds promise as an important intervention in the management of this condition.

ABSTRACT

Background: Upper extremity lymphedema (UEL) and lower extremity lymphedema (LEL) can develop as a result of lymph node dissection in the treatment of various malignancies. While emerging microsurgical interventions using lymphaticovenous anastomosis (LVA) and vascularized lymph node transfer (VLNT) show promising outcomes for patients with lymphedema, the best approach to implementing the two procedures remains to be defined. This systematic review and meta-analysis provide a comprehensive overview of published literature on the clinical improvement of extremity lymphedema in patients who undergo either LVA, VLNT, or a combined microsurgical procedure.

Methods: From Embase, PubMed, and Web of Science databases, 52 studies were identified that met inclusion criteria. This review was conducted in accordance with the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines. The risk of bias was assessed using the Risk Of Bias In Nonrandomized Studies-of Interventions (ROBINS-I) tool and the Cochrane tool for randomized trials (RoB 2).

Results: Random-effects meta-analyses of means estimated a pooled clinical improvement of 36.46% (95% CI: 29.44–43.48) for UEL and 34.16% (95% CI: 23.93–44.40) for LEL. Subgroup analyses revealed differences in clinical improvement according to the microsurgical approach. Clinical improvement of UEL was 29.44% (95% CI: 15.58–43.29) for LVA, 41.66% (95% CI: 34.13–49.20) for VLNT, and 32.80% (95% CI: 21.96–43.64) for combined VLNT + LVA, while the improvement of LEL was 31.87% (95% CI: 18.60–45.14) for LVA and 39.53% (95% CI: 19.37–59.69) for VLNT.

Conclusion: The findings from this study elucidate the clinical improvement in extremity lymphedema from various microsurgical approaches. This knowledge could aid physicians in the shared decision-making process with UEL and LEL patients and better facilitate proper patient selection for microsurgical interventions.

1 | Introduction

Lymphedema is a condition characterized by the accumulation of interstitial fluid due to impaired lymphatic system function. While primary lymphedema is attributable to congenital abnormalities, secondary lymphedema is often iatrogenic in nature. Upper extremity lymphedema (UEL) typically develops following axillary lymph node irradiation and dissection in breast cancer patients, while lower extremity lymphedema (LEL) stems from inguinal lymph node dissection in the treatment of gynecologic, genitourinary, and dermatological malignancies. Lymphedema has been well documented to contribute to functional disability, pain, and discomfort (Warren et al. 2007; Grada and Phillips 2017). Limitations in the normal range of motion, as well as psychological distress and social isolation, can significantly impact patients' quality of life (Kim et al. 2015; Neuberger et al. 2022).

In contrast to the conservative approach to lymphedema management, emerging microsurgical interventions, such as lymphaticovenous anastomosis (LVA) and vascularized lymph node transfer (VLNT) show promising outcomes for patients with lymphedema (Carl et al. 2017; Ciudad et al. 2022). Microsurgical interventions do not involve the same long-term costs and time-consuming trajectory that physical therapy or compression therapy do, which often weakens patients' compliance (Kerchner et al. 2008; Liao et al. 2012; Masui et al. 2023). Furthermore, LVA and VLNT address the underlying cause of lymphedema by restoring damaged lymphatic draining. LVA facilitates the bypass of obstructed lymphatic vessels through anastomoses to nearby venules, effectively shunting excess lymphatic fluid from the obstructed extremity into the systemic circulation (Chang et al. 2013). VLNT has the potential to restore the physiological function of the affected extremity through the autologous transfer of vascularized lymphatic tissue (Patel et al. 2015).

While both LVA and VLNT have proven effective in alleviating symptoms in patients with lymphedema, the best approach to implementing the two procedures remains to be defined. LVA relies on the presence of patent lymphatic channels and is therefore typically limited to patients with earlier stages of lymphedema (Chang et al. 2020). Because VLNT does not necessitate that patients have complete lymphatic vessel function, the procedure is often reserved for patients with more advanced stages of lymphedema progression (Chang et al. 2020). Combining both procedures has been rationalized as a means to provide patients the immediate improvement in extremity circumference and volume reduction conferred by LVA while also offering the long-term benefits of physiologic function restored by VLNT (Chang 2021). Ultimately, the final decision regarding the type of microsurgical procedure is based on a combination of lymphatic vessel viability and patient preference.

A better understanding of the long-term impact of various microsurgical interventions in the upper and lower extremities could have significant implications for shared decision-making between lymphedema patients and their physicians. Proper selection of those who could benefit from LVA, VLNT, or a combination of the two performed during the same operation could also be improved if physicians were better guided by reported differences in clinical improvement of extremity lymphedema and associated patient characteristics. Furthermore, accurately documented surgical details, such as the number of lymphaticovenous anastomoses and the type of vascularized lymph node flap associated with favorable clinical outcomes could provide clinicians with clarity in determining the appropriate technical approach.

The substantial increase in research within this field in recent years has resulted in the availability of new literature to assess (Nacchiero et al. 2020; Chang et al. 2021; Meuli et al. 2023). Through a systematic review and meta-analysis, this study aims to provide a comprehensive overview of published literature on the clinical improvement in extremity lymphedema and to quantify the pooled effect of circumference and volume changes among patients who undergo either LVA, VLNT, or a combined microsurgical procedure.

2 | Methods

2.1 | Literature Search

A systematic literature review of electronically available publications was performed on June 19, 2024. This review was conducted in accordance with the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines (Page et al. 2021), and was registered in the international prospective register of systematic reviews (PROSPERO) under the registration number: CRD42024469481. No amendments were made to the registered protocol during the course of this research. Two reviewers (B.H. and D.K.) performed a search in three online databases (Embase, PubMed, and Web of Science) using a search string developed with the help of a librarian (Supporting Information S1). All studies identified through the search were independently reviewed and included if patients with various etiologies of unilateral secondary lymphedema in the upper or lower extremity received either LVA, VLNT, or a combination of the two performed during the same operation. Only studies that reported clinical improvement in lymphedema, calculated as the percentage change in the pre- and postoperative difference in circumference or volume between affected and healthy extremities, were included. Studies investigating outcomes other than changes in circumference or volume differences in extremities were excluded, as were those that only investigated outcomes in patients treated for primary lymphedema. Articles that investigated outcomes in patients with both primary and secondary lymphedema were included, however, if less than 10% of the study population comprised those with primary lymphedema. Duplicates, conference abstracts, systematic reviews, meta-analyses, case reports, nonclinical studies, and non-English studies were further excluded.

2.2 | Data Extraction

The following variables were extracted from included articles into a standardized spreadsheet: title, authors, year of publication, country of origin, study design, extremity investigated, sample size, age, body mass index (BMI), sex distribution, comorbidities, severity of lymphedema and staging used, type of microsurgical intervention, number of lymphaticovenous

anastomoses or lymph nodes transferred, type and recipient site of VLNT, postoperative care and complications, follow-up period, data collection and lymphedema measurement methods, and clinical improvement in lymphedema. Two reviewers (B.H. and D.K.) independently performed data extraction from articles, figures, and tables. The accuracy of entered data, as well as any uncertainties or disagreements were resolved by a third reviewer.

2.3 | Quality Assessment

The Risk Of Bias In Nonrandomized Studies-of Intervention (ROBINS-I) (Sterne et al. 2016) tool and the Cochrane tool for assessing risk of bias in randomized trials (RoB 2) (Sterne et al. 2019) were used to assess the quality of included studies. Each of the seven domains of bias encompassed in the ROBINS-I tool was addressed using a series of signaling questions that aimed to gather important information about the risk of bias due to confounding, selection of study participants, classification of interventions, deviations from intended interventions, missing data, measurement of outcomes, and selection of the reported result. Similarly, the RoB 2 tool assessed the risk of bias arising from the randomization process, deviations from the intended intervention, missing outcome data, measurement of the outcome, and selection of the reported result. All domains were taken into consideration before an overall risk of bias judgment for each article was made. Studies were classified as having either a low, moderate, serious, or critical risk of bias. Risk of bias was visualized using the Risk-of-bias VISualization (robvis) tool (McGuinness and Higgins 2021).

2.4 | Statistical Analysis

Random-effects meta-analyses of means were performed on all included studies to quantify the pooled effect of microsurgical interventions on clinical improvement of extremity lymphedema, the primary outcome of interest. Analyses were conducted separately for patients with UEL and LEL, ensuring each study contributed only one effect size even if patient populations in which either extremity was affected were investigated. The restricted maximum likelihood estimator (Viechtbauer et al. 2015) was used to calculate the heterogeneity of variance between studies before employing forest plots to visualize the distribution. Subgroup analyses were performed to investigate secondary outcomes—potential moderators of the overall observed effect size between studies. Studies were pooled into subgroups according to participants' age, BMI, preoperative lymphedema severity, number of lymphaticovenous anastomoses, type of VLNT, follow-up period, edema measurement methods, and study risk of bias. Studies that did not report data for certain variables of interest were excluded from corresponding subgroup analyses. A Q-test was used to determine if clinical improvement of extremity lymphedema differed significantly between various subgroups. All statistical analyses were performed using the meta package (Balduzzi et al. 2019) in R Statistical Software (v4.3.1; R Core Team 2023) (R Core Team 2024). A two-sided $p < 0.05$ was considered significant. The dataset and script used to perform analyses are available at: https://osf.io/nk3sp/?view_only=4478a9a7a16546a5937459cec96f4ee6.

3 | Results

3.1 | Study Characteristics

After removal of duplicates, a total of 2047 original articles were identified in PubMed, Embase, and Web of Science databases. Following initial title/abstract screening, 186 articles underwent full-text review, and 52 articles were included that met all inclusion and exclusion criteria (Agko et al. 2018; Aljaaly et al. 2019; Arrivé et al. 2017; Chung et al. 2022; Ciudad et al. 2017, 2019; Ciudad, Manrique, et al. 2020; Cornelissen et al. 2017; Demiri et al. 2024; Di Taranto et al. 2023; Dionyssiou et al. 2016, 2021; Drobot et al. 2021; Engel et al. 2018; Francis et al. 2022; Furukawa et al. 2011; Fuse et al. 2022; Gennaro et al. 2016; Gharb et al. 2011; Gustafsson et al. 2018; Ho et al. 2018; Jonis et al. 2024; Kim et al. 2021; Knoz et al. 2024; Koshima et al. 2000; Liang et al. 2023; Lin et al. 2009; Liu et al. 2018; Lo Torto et al. 2024; Manrique et al. 2020; Maruccia et al. 2019, 2023; Mousavi et al. 2020; Myung et al. 2023; Ngo et al. 2020; Phillips et al. 2019; Poumellec et al. 2017; Roh et al. 2023; Saaristo et al. 2012; Schaverien et al. 2022; Son et al. 2023; Thomas et al. 2023; Winters et al. 2017, 2019; Yang et al. 2020; Yang, Wu, et al. 2022; Yang, Wang, et al. 2022; Yasunaga et al. 2019, 2020, 2022, 2023). The search string and review methodology are described in the PRISMA flow diagram in Figure 1. Of the 52 articles included, 10 contributed multiple observed effect sizes; nine articles reported outcomes for patient populations who received microsurgery for either UEL or LEL (Agko et al. 2018; Ciudad et al. 2017, 2019; Drobot et al. 2021; Gennaro et al. 2016; Kim et al. 2021; Manrique et al. 2020; Maruccia et al. 2023; Thomas et al. 2023), and one article reported outcomes on two different types of microsurgical reconstructions (Engel et al. 2018).

All included articles were published between 2000 and 2024, and comprised 25 retrospective, 23 prospective, two cross-sectional studies, and two randomized controlled trials across 15 different countries. Clinical outcomes in a total of 1920 extremities were analyzed from 1920 patients who received microsurgical reconstruction (Table S1). Reported mean patient age and BMI ranged from 45 to 71 years old and 22.5 to 33.2 kg/m^2, respectively. Of the 1073 extremities that contributed to effect sizes in clinical improvement of UEL, 528 underwent LVA, 496 underwent VLNT, and 49 received a combination of the two procedures. Likewise, of the 847 extremities that contributed to effect sizes in clinical improvement of LEL, 775 underwent LVA, and 72 underwent VLNT. No studies were included in which patients with LEL underwent a combination of the two microsurgical procedures.

While most of the included studies reported staging of extremity lymphedema prior to surgical intervention, various classifications were used. Lymphedema severity was described according to the International Society of Lymphology (ISL) in 35 studies (Agko et al. 2018; Chung et al. 2022; Ciudad et al. 2017, 2019; Ciudad, Forte, et al. 2020; Cornelissen et al. 2017; Di Taranto et al. 2023; Dionyssiou et al. 2016, 2021; Drobot et al. 2021; Fuse et al. 2022; Gennaro et al. 2016; Gharb et al. 2011; Liu et al. 2018; Manrique et al. 2020; Maruccia et al. 2019, 2023; Myung et al. 2023; Ngo et al. 2020; Phillips et al. 2019; Roh et al. 2023; Thomas et al. 2023; Yang et al. 2020; Yang, Wu, et al. 2022; Yang, Wang, et al. 2022; Yang, Hayashi et al. 2022; Yasunaga

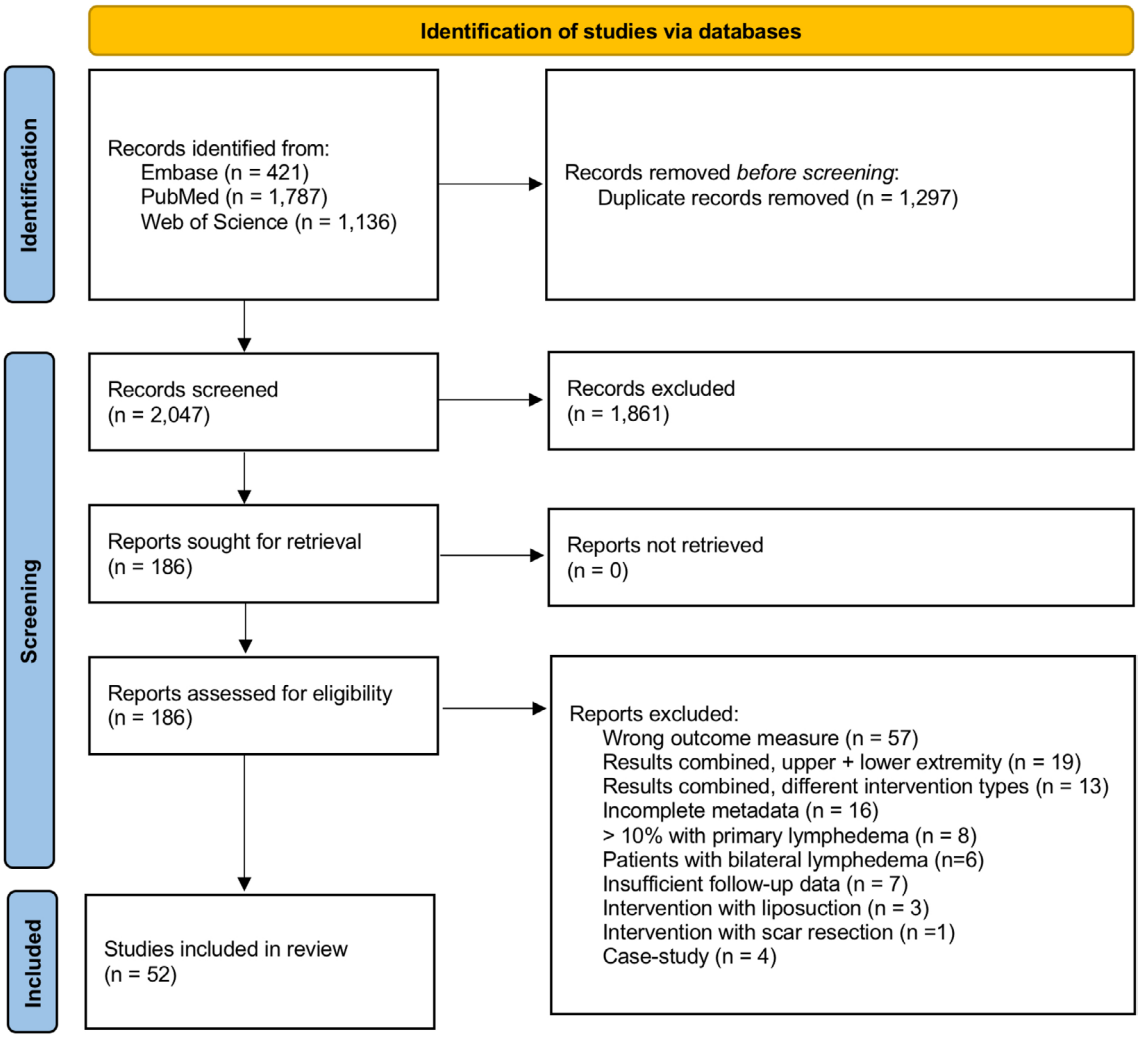

FIGURE 1 | Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) flow diagram of systematic database search.

et al. 2019, 2020, 2022, 2023), Cheng Lymphedema Grade in three studies (Aljaaly et al. 2019; Engel et al. 2018; Francis et al. 2022), Campisi in two studies (Poumellec et al. 2017; Winters et al. 2019), and the M.D. Anderson Cancer Center in one study (Schaverien et al. 2022). Eleven studies did not report preoperative lymphedema severity (Arrivé et al. 2017; Furukawa et al. 2011; Gustafsson et al. 2018; Ho et al. 2018; Kim et al. 2021; Koshima et al. 2000; Lin et al. 2009; Mousavi et al. 2020; Saaristo et al. 2012; Son et al. 2023; Winters et al. 2017). Studies that employed the ISL classification were pooled into groups according to the predominant preoperative lymphedema severity of participants. Effect sizes for patients with UEL were reported in 17 studies in which 50% or more of the population had preoperative ISL Stage II, in two studies with populations primarily in ISL Stages II–III, and in six studies with populations primarily in ISL Stage III. For patients with LEL, effect sizes were reported in eight studies where 50% or more of the population had preoperative ISL Stage II, in seven studies with populations primarily in ISL Stages II–III, and in three studies with populations primarily in ISL Stage III.

Among the studies in which the number of anastomoses performed during LVA was reported, a mean of 3.39 and 4.50 was calculated in patients who received treatment for UEL and LEL, respectively. Studies investigating the effects of VLNT for UEL included donor lymph nodes harvested from the groin ($n = 9$), gastroepiploic ($n = 8$), submental ($n = 1$), jejunal mesenteric ($n = 1$), and a mix of flap types ($n = 5$). Analogously, studies investigating the effects of VLNT for UEL included donor lymph nodes harvested from gastroepiploic ($n = 5$) and submental ($n = 1$) flap types.

The majority of studies outlined care protocols that patients were recommended to follow after surgery, which included either compression therapy ($n = 28$), manual drainage ($n = 8$), or both ($n = 1$). Four studies implemented a restrictive postoperative protocol, in which patients were explicitly instructed to refrain from any compression or physical therapy in the months after surgery. One study allowed patients to adhere to whichever care protocol they were following prior to surgery, and 10 studies did not report any specific postoperative care instructions. Most studies reported outcomes with a follow-up period ≥ 12 months ($n = 39$). Quality assessment of each nonrandomized intervention study using the ROBINS-I tool identified one study with serious risk of bias, nine with moderate risk, and 40 studies with low risk (Figure S1A). The two randomized controlled trials included were assessed as having a low risk of bias using the RoB 2 tool (Figure S1B).

3.2 | Clinical Improvement Extremity Lymphedema

The clinical improvement of lymphedema was determined based on the rate of postoperative circumference or volume reduction in the affected extremity. Circumference of affected and healthy extremities was recorded in 26 studies, while volume was recorded in 26 studies to compare preoperative and postoperative findings. Percentage clinical improvement of extremity lymphedema was defined as the difference between preoperative circumference or volume of the affected and healthy extremities minus the difference between the postoperative measurements of the affected and healthy extremities, divided by the preoperative difference and multiplied by 100. The pooled mean clinical improvement in UEL was 36.46% (95% CI: 29.44–43.48), with a high degree of heterogeneity between studies ($I^2 = 100\%$, $p < 0.001$) attributed in part to differences in outcomes observed by microsurgery type ($p = 0.17$) (Figure 2). A clinical improvement of 29.44% (95% CI: 15.58–43.29) was observed in upper extremities following LVA, 41.66% (95% CI: 34.13–49.20) following VLNT, and 32.80% (95% CI: 21.96–43.64) in the single study that investigated UEL outcomes following a combined VLNT + LVA surgical approach. Similarly, the pooled mean clinical improvement in LEL was 34.16% (95% CI: 23.93–44.40), with a high degree of heterogeneity between studies ($I^2 = 100\%$, $p < 0.001$) also attributed in part to differences in outcomes observed by microsurgery type ($p = 0.59$) (Figure 3). A clinical improvement of 31.87% (95% CI: 18.60–45.14) was observed in lower extremities following LVA, and 39.53% (95% CI: 19.37–59.69) following VLNT.

Subgroup analysis revealed no significant differences in clinical improvement of either UEL or LEL based on patient characteristics, such as mean age, BMI, or preoperative lymphedema severity (Table 1). Among patients with LEL who underwent VLNT, clinical improvement was significantly different according to the donor flap type used during surgery. Lower extremities that received donor flaps containing gastroepiploic lymph nodes had a pooled mean clinical improvement of 43.48% (20.43–66.52), while those that contained submental lymph nodes improved by 19.80% (95% CI: 16.75–22.85) ($p = 0.005$). The postoperative care protocols that patients undergoing treatment for LEL followed also had a significant impact on outcomes. Clinical improvement of LEL reported by studies that outlined a postoperative compression therapy protocol for patients to follow was 34.23% (95% CI: 21.13–47.33), while the study that implemented a restrictive protocol prohibiting patients from actively receiving therapy reported a 19.80% (95% CI: 16.75–22.85) reduction in lymphedema ($p < 0.0001$). The single study without any postoperative standard protocol, in which patients could adhere to the same care they were receiving preoperatively, reported LEL clinical improvement of 46.30% (95% CI: 43.21–49.39). No further statistically significant differences were found between subgroups pooled by the number of lymphaticovenous anastomoses, follow-up period, and edema measurement methods. Statistical significance seen between risk of bias subgroups in patients with UEL did not hold when the single study with serious risk of bias was eliminated from subgroup analysis.

4 | Discussion

This systematic review aimed to provide a comprehensive overview of published literature on the clinical improvement of extremity lymphedema in patients who undergo either LVA, VLNT, or a combined microsurgical procedure. Meta-analyses were designed to further elucidate factors associated with clinical improvement in order to better understand which patients stand to benefit the most from microsurgery. The pooled mean clinical improvement in UEL and LEL was 36.46% (95% CI: 29.44–43.48) and 34.16% (95% CI: 23.93–44.40), respectively. Heterogeneity between studies was attributed in part to differences in outcomes observed by microsurgery type. A clinical improvement of 29.44% (95% CI: 15.58–43.29) was observed in upper extremities following LVA, 41.66% (95% CI: 34.13–49.20) following VLNT, and 32.80% (95% CI: 21.96–43.64) in the single study that investigated UEL outcomes following a combined VLNT + LVA surgical approach. Similarly, clinical improvement of 31.87% (95% CI: 18.60–45.14) was observed in lower extremities following LVA and 39.53% (95% CI: 19.37–59.69) following VLNT. Subgroup analyses revealed no significant differences in clinical improvement of either UEL or LEL based on patient characteristics such as mean age, BMI, or preoperative lymphedema severity. Significant differences in the type of donor flap used in VLNT, as well as the postoperative care protocol followed by patients, were noted. While there was a high degree of heterogeneity between studies regardless of the affected extremity, no statistically significant differences were found in clinical improvement between subgroups pooled by the number of anastomoses performed during LVA, length of follow-up period, and type of edema measurement method used.

4.1 | Differences in Clinical Outcomes by Microsurgical Procedure

For both upper and lower extremities, clinical improvement of lymphedema was greater following VLNT compared to LVA. Although the detailed mechanism by which VLNT alleviates lymphedema remains incompletely understood, recent literature increasingly supports lymphangiogenesis mediated by vascular endothelial growth factor C (VEGF-C) (Alitalo 2011; Nguyen et al. 2017; Cook et al. 2018). When applied in therapeutic settings, VEGF-C has been shown to induce lymphatic capillary growth, which ultimately leads to the differentiation and maturation of functional lymphatic vessels (Alitalo 2011). Using northern blot analysis, Saaristo et al. (Saaristo et al. 2012). compared VEGF-C expression in lymph nodes with other tissue in nine patients who received VLNT for UEL. Results showed that the highest VEGF-C mRNA expression was detected in lymph nodes, further supporting the mechanism that VLNT and the resulting VEGF-C expression may thereby enhance regrowth of the lymphatic network in the transplanted region.

Subgroup analyses conducted on clinical improvement according to the type of donor flap used in VLNT further support this proposed mechanism. Gastroepiploic lymph nodes derived from omentum donor flaps contributed to a 44.27% clinical improvement in UEL and a 43.48% clinical improvement in LEL, the latter of which was statistically significant when compared

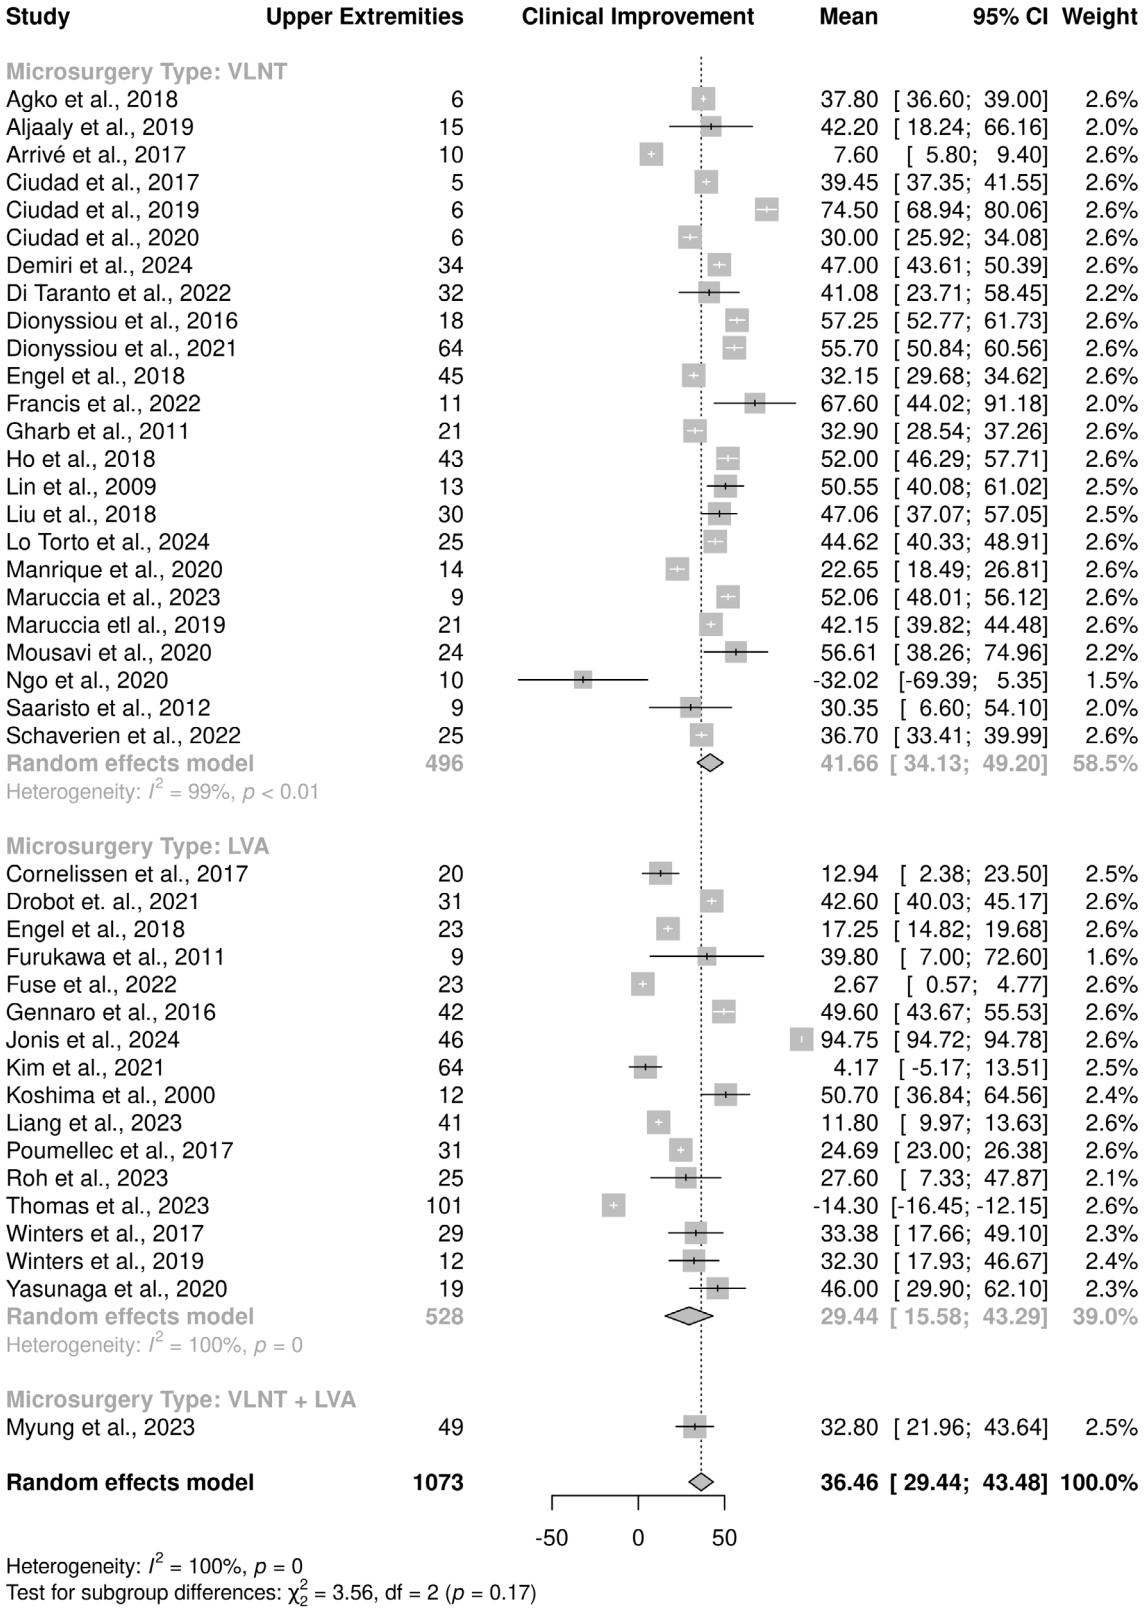

FIGURE 2 | Forest plot of clinical improvement of upper extremity lymphedema (UEL) according to microsurgery type.

with that of submental lymph nodes (19.80%). Not only does the omentum have the highest concentration of VEGF-C compared to that of other tissue, but it is also richly vascularized with an abundant network of lymph nodes (Nguyen et al. 2017; Cook et al. 2018).

Given the potential of VLNT to restore lymphatic vessel function even in cases in which existing vessels are sclerosed or fibrotic, the procedure has often been reserved for patients who present with more advanced stages of lymphedema (Chang et al. 2020). While not statistically significant, subgroup analyses revealed

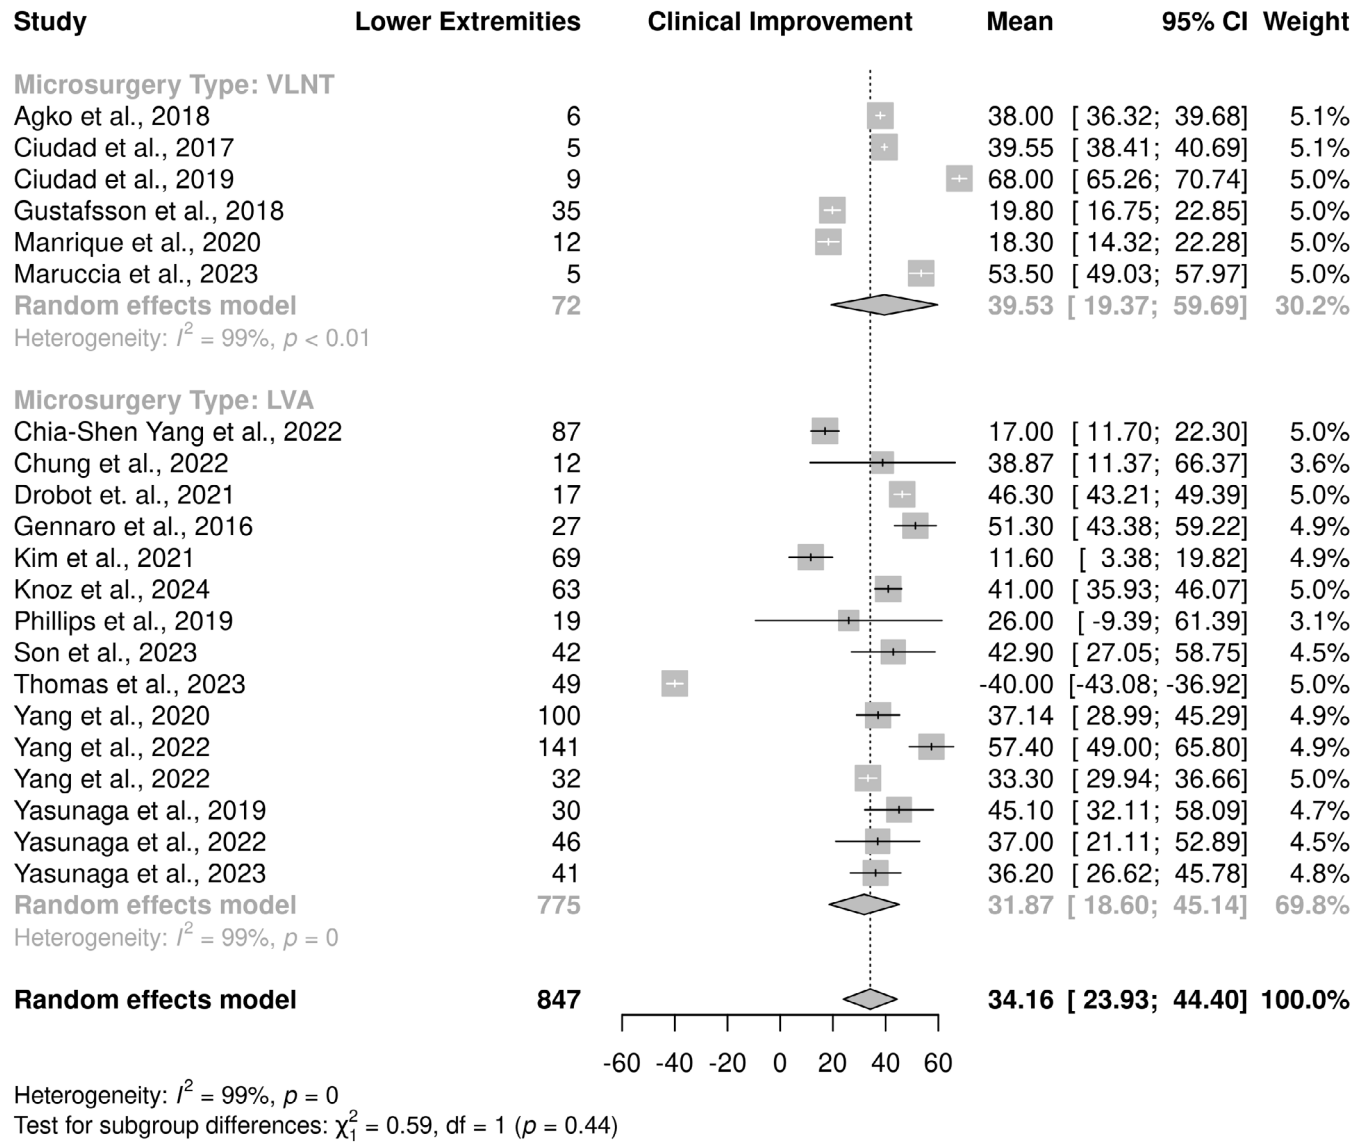

FIGURE 3 | Forest plot of clinical improvement of lower extremity lymphedema (LEL) according to microsurgery type.

that patients with more severe preoperative lymphedema, as determined by ISL stage, showed greater clinical improvement compared to those with lower severity. Not only was this observed in patients undergoing microsurgery for either UEL (32.51%, Stage II; 47.20%, Stage II–III; 45.26%, Stage III) or LEL (24.23%, Stage II; 40.71%, Stage II–III; 52.95%, Stage III), but it was also seen regardless of the type of microsurgery received. This meta-analysis reveals the potential clinical improvement in lymphedema for all patients undergoing LVA, regardless of preoperative severity.

4.2 | Describing Lymphedema Severity and Improvement

Lymphedema staging systems offer an objective paradigm through which the clinical presentation of symptoms can be assessed. The diverse range of classifications available to describe lymphedema severity, however, complicates their reliability in practice. While the majority of studies included in this literature review used the ISL staging system to characterize the severity of preoperative lymphedema, the Campisi staging system ($n = 2$), Cheng Lymphedema Grade ($n = 3$), and the M.D. Anderson Cancer Center staging system were also used ($n = 1$). Eleven studies did not report preoperative lymphedema severity in any of the extremities undergoing microsurgery. Each stage of the ISL system indicates the extent of swelling in the affected extremity, meant to reflect fibrotic soft tissue changes and lymphatic dysfunction (Executive Committee of the International Society of Lymphology 2020). Problematic with the ISL staging system, however, is its incongruence with functional staging that better incorporates the physiologic features of lymphedema. Imaging modalities, such as indocyanine green (ICG) lymphangiography or lymphoscintigraphy, have the ability to scan the layers of the collecting lymphatic channels and visualize lymphatic flow (Imai et al. 2022). Previous studies have demonstrated a weak correlation between ISL and functional imaging staging (Garza et al. 2019), further undermining the sole reliance on ISL for preoperative microsurgical decision-making. The possibility of patients with high ISL staging also having low ICG staging enhances the feasibility of performing LVA due to the potential availability of suitable target vessels.

Note: Studies pooled according to study design, age, BMI, preoperative lymphedema severity, number of anastomoses performed during LVA, donor flap type used during VLNT, postoperative compression protocol, follow-up period, method by which lymphedema was measured, and study risk of bias.
Abbreviations: BMI, body mass index; ISL, International Society of Lymphology; LVA, lymphaticovenous anastomosis; VLNT, vascularized lymph node transfer.
*$p < 0.05$.
[a]Preoperative ISL stage of ≥ 50% of study population.
[b]Mean number of lymphaticovenous anastomoses performed pooled and split into above average ("high") or below average ("low").

More importantly, perhaps, is the limited ability of lymphedema severity staging and imaging to determine and describe patient-reported outcomes following surgery. Studies in this review that reported extremities without any confirmed patent anastomoses or postoperative changes in clinical lymphedema, nevertheless reported improvement in quality of life measures and patients' responsiveness to conservative lymphedema management (Ngo et al. 2020; Thomas et al. 2023; Winters et al. 2017, 2019). Even in the absence of clinical improvement of lymphedema following microsurgery, patients reported either reduced use of compression garments or no longer felt the need to wear them after experiencing attenuation of their complaints. A better understanding of the psychological, physical, and social implications that compression garments have on quality of life is needed. Describing the improvement of lymphedema in relation to the lived experiences of patients burdened by it and its management is imperative to measuring the impact of microsurgical interventions.

4.3 | Strengths and Limitations

While the retrospective nature of the majority of studies included in this review enabled the analysis of large sample sizes across a wide timespan, it also proved to be a significant limitation. The quality and completeness of data recorded for each study participant was heterogeneous. Some studies did not report the BMI of participants, which could have further elucidated the impact of obesity on the clinical improvement of extremity lymphedema following microsurgery. Obesity has been associated with increased chronic inflammation, fibrosis, and adipose deposition that may impair lymphatic clearance. Furthermore, the increased propensity for inflammation in response to injury suggests that obese patients are at higher risk for lymphedema following lymph node dissection (Savetsky et al. 2014; Beesley et al. 2007). While most studies included in this review detailed postoperative care received by patients, such as compression therapy or manual lymphatic

drainage, preoperative interventions were not thoroughly documented. Although available literature on the efficacy of conservative interventions prior to microsurgery remains limited, recent consensus advocates for adequate prehabilitation that could optimize clinical outcomes (Doubblestein et al. 2023; Sacks et al. 2024). The inconsistencies in preoperative data, however, further widen the knowledge gap on which protocols have the potential to enhance response to surgery. Incomplete data on the number of anastomoses created during LVA, as well as the type of and lymph node count within VLNT donor flaps, make it difficult to draw any definitive conclusions on surgical technique. Studies with a moderate or serious risk of bias were evaluated as such with the ROBINS-I tool when complete metadata were not available for all participants who underwent microsurgery, which could have contributed to confounding in reported results. In order to produce the most accurate estimation of clinical improvement in extremity lymphedema, studies should strive to report comprehensive patient and surgical characteristics that could further elucidate any potential impact on outcomes.

This systematic review and meta-analysis provides new insights into the effectiveness of microsurgical options for treating extremity lymphedema. While older systematic reviews similar to this one reach congruent findings, they focus on qualitative outcomes and include fewer studies with quantitative effect sizes (Nacchiero et al. 2020; Chang et al. 2021; Meuli et al. 2023). Furthermore, this study has accounted for the variation in outcome measures rightfully pointed out by Meuli et al. (Meuli et al. 2023). By employing rigorous inclusion criteria and subsequently excluding studies that did not meet these standards. This systematic review and meta-analysis includes additional articles that have not yet been reported on elsewhere, further strengthening the novelty of findings in this study.

5 | Conclusion

The clinical improvement in patients with UEL and LEL following microsurgery is estimated to be 36% and 34%, respectively, with differences attributed in part to the type of microsurgical approach. While VLNT yielded greater improvement in lymphedema compared to LVA, further differences were observed between the type of donor flap used. More comprehensive metadata is needed to elucidate relationships between patient characteristics and outcomes following microsurgery. Furthermore, advances in quality of life may not always directly correspond with changes in extremity volume or circumference. Even in the absence of clinical improvement, patients' reduced reliance on compression therapy may be enough to justify the decision of undergoing microsurgery. Awareness among physicians of these impacts could serve as valuable discussion points to consider during the shared decision-making process with lymphedema patients.

Data Availability Statement

The data that support the findings of this study are openly available in Open Science Framework at https://osf.io/nk3sp/?view_only=4478a9a7a16546a5937459cec96f4ee6.

The 6 month interim analysis of a randomized controlled trial assessing the quality of life in patients with breast cancer related lymphedema undergoing lymphaticovenous anastomosis vs. conservative therapy

Y. M. J. Jonis[1], J. A. G. N. Wolfs[1], S. Hummelink[2], H. J. P. Tielemans[2], X. H. A. Keuter[1], S. van Kuijk[3], D. J. O. Ulrich[2], R. R. W. J. van der Hulst[1] & S. S. Qiu[1]✉

Breast cancer related lymphedema (BCRL) is a chronic condition with a detrimental impact on psychosocial and physical well-being. Lymphaticovenous anastomosis has shown promising results in alleviating physical symptoms and increasing quality of life in patients with BCRL. The aim of the study is to evaluate the effect on health related quality of life (HrQol) after LVA surgery versus conservative treatment in patients with BCRL. The study is a prospective, multicenter randomized controlled trial. Adult women with unilateral BCRL, with early stage lymphedema and viable lymphatic vessels were included. The primary outcome measure was HrQol measured by the lymphedema functioning disability and health (Lymph-ICF) questionnaire. The secondary outcomes were volume difference measured by the water displacement method; the Upper Extremity Lymphedema (UEL) index; and daily use of the compression garments after 3 and 6 months. For this interim analysis 46 patients per group were included. There was a significant improvement in the domains in physical and mental function in the Lymph-ICF questionnaire in the LVA group after 6 months, (− 16.46 ± 18.5, $p < 0.05$, − 10.12 ± 29.5, $p < 0.05$ respectively). However, there was no statistical difference in the total score of the Lymph-ICF after 6 months in both groups (LVA-group; − 8.57 ± 22.6, $p > 0.05$, CDT-group; − 2.65 ± 18.2, $p < 0.05$). Furthermore, there was no significant volume reduction in both groups (LVA-group: 20.04 ± 196.40, $p = 0.497$, CDT: 33.98 ± 189.87, $p = 0.236$). In the LVA group, 41% partially of completely stopped wearing the compression garments after six months whereas in the CDT group 0% discontinued to use of compression garments. LVA resulted in improvement of the domains physical and mental function of the Lymph-ICF. Limb volume did not significantly improve after 6 months. However, around 42% could completely or partially stopped with the use of compression garments in the LVA group. The current results are promising, however longer follow up is required to assess long term effect of LVA for secondary lymphedema.

Clinical Trial Registration: NCT02790021 registered on 03/06/2016

MLD	Manual lymphatic drainage
NIRF	Near infrared fluoroscopy
RCT	Randomized controlled trial
SAE	Severe adverse events
UEL-index	Upper extremity lymphedema index
VAS	Visual analogue score
WDM	Water displacement method

Breast cancer related lymphedema (BCRL) is a chronic condition, characterized by an aberrant accumulation of lymph fluid due to dysfunction of the lymphatic system[1–3]. It is a well-known consequence of breast cancer treatment and it represents an important survivorship topic in patients after breast cancer[4–7].

BCRL affects approximately 29.4% of breast cancer survivors within 2 years after surgery[1,7]. Axillary lymph node dissection, radiotherapy, mastectomy, number of positive lymph nodes and body mass are all independent risk factors for the development of BCRL[6,8,9].

Nowadays, Health related quality of life (HrQol) is one of the most relevant outcomes after cancer treatment[10,11]. BCRL is known to have a significant negative impact on physical, psychological, and social well-being[5]. Physical morbidities include skin infections, altered sensation, pain, decreased range of motion, strength, and function. In addition, a larger arm sizes requires women to alter daily activities, clothing, sleeping, employment, and sport. Symptoms of anxiety, depression, sexual dysfunction, disturbance of body image, and social avoidance are often associated with BCRL[12–14].

Currently, complex decongestive therapy (CDT) is the gold standard for the treatment of lymphedema, consisting of the use of compression garments and manual lymphatic drainage[5,15]. These treatment modalities however are not curative and require lifelong costly maintenance[16].

The first lymphaticovenous anastomosis (LVA) was described in the 1960 as a novel approach to divert lymphatic fluid through formation of an anastomosis from the lymphatic vessels to adjacent venules[17,18]. The concept was revolutionized by Koshima et al. in the 90 s who introduced the concept of supermicrosurgery in lymphatic surgery[19]. Since then the technique has been refined with the introduction of the microscope and designated supermicrosurgical instruments. LVA surgery has been widely implemented as a surgical treatment of lymphedema and it has shown promising results[20–22]. The aim of this 6-month interim analysis is to show the first results of the first randomized controlled trial (RCT) evaluating HrQol in patients with BCRL undergoing LVA surgery in comparison to conservative treatment.

Methods

From 2018 to 2022, 100 women with BCRL, with stage 1 or 2a, according to the international society of lymphology (ISL) with viable lymphatic vessels and ICG stage II–III according to Narushima measured by near infrared fluoroscopy (NIRF) were included[23,24]. The patients were allocated into two groups, an LVA group and CDT group. The full protocol for the trial has been previously published[25]. The protocol and related documents were approved by the Dutch Medical ethical assessment committee (NL67059.068.18/ METC18-024) registered on 19/12/2018. Clinical Trial Registration: NCT02790021 registered on 03/06/2016. This study followed the Consolidated Standards of Reporting Trials (CONSORT) reporting guidelines.

Design

The trial was an multi-center randomized controlled trial (RCT). Patients were included in the Maastricht University Medical Center + , Radboud University Medical Center, Zuyderland Medical Centre and the Canisius-Wilhelmina Hospital in the Netherlands. All eligible patients were invited to participate in the RCT. Written informed consent was obtained from all participants.

Randomization

Surgeon investigators (S.S.Q, H.T, D.U) determined whether the patients were eligible for surgery. The collection of outcomes was performed at the outpatient clinic (J.W, S.H and Y.J). After inclusion and informed consent, participants were randomly assigned to either the LVA or conservative (CDT) group with a 1:1 allocation as per a computer-generated randomization schedule stratified by site using block randomization. This computer-generated randomization was done within the electronic Case Report Form in CASTOR EDC.

Interventions

CDT

All patients in both groups underwent at least 3 months of CDT prior to inclusion. The patients allocated in the CDT group continued to be treated according to standard protocol known as the 'Verdonkmethod' which is implemented in all patients receiving CDT in the Netherlands[25]. The CDT consisted of two stages, the first phase entailed skincare, MLD, exercises aimed at improvement of mobility/range of motion, and compression therapy. The second phase was focused on maintenance of the achieved limb volume reduction through compression therapy with therapeutic elastic compression garment for the arm. Skincare, mobility exercises and MLD is continued in this phase if needed.

Using this standardized protocol we were able to compare the outcomes within the CDT group. The conservative treatment and the frequency is controlled by the skin therapist. During follow up all changes in conservative therapy were noted by each patient in the patient diary.

LVA

The eligibility for participation in the study was determined with near infrared fluorescence imaging (NIRF) during the outpatient clinic. 0.01 to 0.04 ml of indocyanine green (ICG) (5 mg/ml) was injected into the second and fourth finger webspace intradermally of the lymphedematous limb. Using NIRF the viable lymph vessels were identified, marked, and photographed[23].

The procedure was performed under general or local anesthesia. This was left at the surgeon's discretion. During surgery viable lymphatic collecting vessel and similarly sized adjacent recipient venules were identified in the subdermal plane. Subsequently an anastomosis was performed in an end-to-end fashion with 11–0 suture between the lymphatic collecting vessel and the venule, with the use of a surgical microscope. After the anastomosis was made, the patency was confirmed under the microscope. Between 1 and 5 anastomosis were performed in a lymphedematous arm. The superficial wound was closed using 4–0 Ethilon covered by adhesive plasters.

Two weeks after the surgery the patients were able to continue in the maintenance phase of the CDT protocol.

Outcomes variables

All data was collected according to a standardized protocol. The primary outcome was HrQoL, which was measured by the lymphedema international classification of functioning (Lymph-ICF) questionnaire (Dutch version)[26]. The Lymph-ICF is a validated quality of life questionnaire for patients with upper extremity lymphedema. The questionnaire is divided into five domains: physical function, mental function, household, mobility, life and social activities. A low score on the questionnaire indicates a better quality of life and a higher score indicates of a bad quality of life. A decrease in the sum of scores of more than 10 points, and an increase of more than 9, was considered statistically significant ($p < 0.05$). A decrease in the sum of scores of more than 15 points was considered clinically significant[27].

The secondary outcomes were volume reduction, measured by the water displacement method, circumference reduction measured by the upper extremity lymphedema (UEL) index, the complete or partial discontinuation rate of the use of compression garments, reported through a patient diary. Lastly adverse-, and serious adverse events were reported during follow up[28,29]. The data was collected after 3, 6, 12, 18 and 24 month follow up. The data used for the current article are based on the first six months follow up.

Statistical analysis

We made the following assumptions for the calculation of the sample size to show a statistically significant and clinically relevant difference in quality of life between treatment groups follow-up as measured with the Lymph-ICF questionnaire:

Comparing LVA group to CDT group, the minimal difference in HRQoL that is considered as clinically relevant is 15 points on the Lymph-ICF questionnaire.

To be able to achieve a power of 80%, a total of 45 patients are needed per treatment group, when the SD is 25%, using an alpha of 0.05. If a drop-out rate (loss-to-follow-up and patients with missing data) of 25% is taken into account, a sample size of 60 patients per study group is required and a total of 120 patients will be randomized. Due to the COVID pandemic outpatient clinic at hospitals in the Netherlands were cancelled and there was a lower inclusion rate. In concordance with the ethical committee an amendment was approved to reduce the sample size to 100 patients considering the low dropout rate ($n = 1$).

Continuous variables were reported as mean with standard deviation. Categorical data were reported as frequencies. To examine the effect of LVA, the paired-samples t-test was used to evaluate the changes between baseline, 3 and 6 months within the groups for the Lymph ICF questionnaire, the relative volume difference measured by water displacement and the UEL index. To measure the effect of the LVA between groups the independent-samples t-test was performed for the above-mentioned variables.

Furthermore, a linear regression was used to determine the relationship between the number of LVAs, follow-up months, lymphedema onset, BMI and ICG stage and for the HrQoL and volume reduction (measured by volume displacement). Results were expressed as regression coefficient with a 95% confidence interval (CI). The use of compression garments, adverse and serious adverse events were reported as frequency. All analysis were performed with IBM SPSS version 25 (IBM Corp., Armonk, N.Y).

Ethical approval

The study was carried out in accordance to the declaration of Helsinki. The study was approved by the Ethics Committee of Maastricht University Medical Center on 19 December 2018 (NL67059.068.18/ METC18-024). Written consent has been obtained from all participants.

Results

One hundred consecutive patients with unilateral BCRL were eligible for inclusion. Ninety-two patients finished at least 6 months follow up and were included in the interim analysis. The other eight patients had not finished the 6 month follow up. The patient characteristics are listed in Table 1. Ninety patients had stage 2a lymphedema according to the ISL classification. Eighty-five patients had an ICG stage III lymphedema. After 6 months one patient in the CDT group had discontinued follow up.

Primary outcome

HrQoL

In the LVA group the mean difference in the total score of the Lymph ICF between baseline and follow up after three and six months was 8.93 ± 22.71 ($p > 0.05$) and 8.57 ± 22.56 ($p > 0.05$), respectively. For the domains physical function and mental function a decrease of more than 10 points was observed after 3 and 6 months, representing

	Difference in Lymph-ICF score[a]		
Independent variable	B	95% CI	P
Constant	30.57	[− 148.9, 210.0]	0.732
Anastomosis (count)	− 13.12	[− 27.96, 1.69]	0.081
ICG stage	− 11.75	[− 57.45, 33.96]	0.606
Onset lymphedema	− 0.107	[− 0.317, 0.103]	0.309
BMI	2.39	[− 1.73, 6.53]	0.248

Table 4. Linear regression analysis: using the difference in the Lymph-ICF score as dependent variable. Unstandardized beta (B): Calculated using linear regression analysis. A negative value means a decrease in Lymph-ICF, representing an increase in Quality of Life. [a]Lymph-ICF score difference is calculated by subtracting the post-OR lymph-ICF score from the pre-OR lymph-ICF score.

Secondary outcomes

Volume reduction

The excess volume was measured by the difference in affected and non-affected arm. The absolute volume difference was 24.80 ± 179.93 mL (p = 0.398) after 3 months and 20.04 ± 196.40 mL (p = 0.497) after 6 months for the LVA group. For the CDT group, 13.88 ± 193.36 mL (p = 0.640) and 33.98 ± 189.87 mL (p = 0.236) after three months and six months, respectively. All data respecting volume measurements is presented in Table 5. There was no significant difference observed between the two groups, − 2.82 (p = 0.737) after 6 months.

Furthermore, there was no correlation between volume difference and preoperative ICG stage, the amount of anastomosis, lymphedema onset, and BMI (see Table 6).

Limb circumference

The mean absolute difference in UEL index for the LVA group 3.65 ± 7.24 (p = 0.002) after 3 months and 1.84 ± 14.6, (p = 0.497) after 6 months, for the CDT group the mean absolute difference was respectively 3.30 ± 31.57 (p = 0.521) and − 0.84 ± 14.6 (p = 0.189) after three and six months. The data is presented in Table 7. Furthermore, there is no significant difference in UEL index between the LVA and CDT group, 2.43 (p = 0.458).

Discontinuation of compression garments

After 3 months 8 patients (17.0%) in the LVA group completely discontinued the use of compression garments. After 6 months the discontinuation rate increased to 10 patients (21.3%). Furthermore after 3 and 6 months, 10 patients (21.7%) partially discontinued use of compression garments. None of the patients in the CDT group discontinued the use of compression garments in the first 6 months.

Adverse events (AE)

Within the first 3 months 7 AE's were observed.

In the CDT group one subject had a mild episode erysipelas, treated with oral antibiotics and in one patient moderate erysipelas occurred, where treatment with intravenous antibiotics were required. One patient had COVID, one patient was diagnosed with muscular rheumatism.

Table 6. Linear regression analysis: using the difference in volume as dependent variable. Unstandardized beta (B): Calculated using linear regression analysis. [a]The difference in volume measured by WDM and is calculated by subtracting the post-OR volume from the pre-OR volume.

	0–3 months			0–6 months		
	UEL-index					
	Mean absolute difference ± SD	95% CI	P-value	Mean absolute difference ± SD	95% CI	P-value
LVA	3.65 ± 7.24	[1.42, 5.88]	0.002	1.84 ± 9.14	[− 0.94, 4.62]	0.189
CDT	3.30 ± 32.7	[− 6.93, 13.47]	0.521	− 0.84 ± 14.6	[− 5.17,3.49]	0.189

Table 7. The relative difference in circumference after 0–3 and 0–6 months. The relative difference in circumference after 0–3 and 0–6 months is calculated using the Paired Samples *T*-test.

In the LVA group one patient had moderate erysipelas, treated with intravenous antibiotics, one patient had a skin infection and 1 patient had pneumonia.

After 6 months, 5 AEs occurred in the CDT group and 3 AE in the LVA group occurred. In the CDT group 4 patients had erysipelas, in the LVA group 3 patients. All patients received oral antibiotics for the treatment of erysipelas. One patient in the LVA group had an allergic reaction of unknown origin.

Severe adverse events (SAE)

After 3 months no SAE were reported. After six months one patient in the LVA group reported recurrence of her breast cancer but she remained in the study.

Discussion

Previous published studies on the efficacy of the LVA surgery have shown promising results[30–33]. A decrease on subjective complaints and a volume reduction between 0 and 61% have been reported[34–36]. However, most of the studies included a small heterogeneous population and have a retrospective design[28,37–40]. The reported studies did not compare LVA surgery with other conservative treatment modalities and use different assessment tools resulting in disparate results[35,41,42].

To our knowledge, this the first large scale prospective randomized multicenter study assessing the effectiveness of LVA surgery compared with conservative treatment in patients with BCRL with HrQoL as primary outcome. Currently, there is a wide variety of quality of life questionnaires in lymphedema. The Lymph-ICF for the upper extremity has been well rated in regards to content validity, reliability, and construct validity based on good-quality evidence[43].

Intra group analyses demonstrated that physical function and mental function were significantly improved in the LVA group after 3 and 6 months. Moreover, the physical function was significantly improved in the LVA group compared to the CDT group. Indicating that the patients in the LVA group experience a significant improvement in physical symptoms such as heaviness, swelling, weakness, tingling and tightness of the arm as early as 3 months after LVA surgery. Previous studies reported an overall improvement of the subjective symptoms after LVA surgery[21,37,44,45]. However so far, the total score of the Lymph-ICF in the LVA and CDT group showed no statistically significant improvement.

Notwithstanding, the total score of the Lymph-ICF in the LVA group are promising in comparison to the CDT group where smaller differences in total score of the Lymph-ICF were seen. Furthermore, there was a high variability in the overall cohort. Moreover, patients with lymphedema present a wide array of complaints and symptoms. While some patients experience a detrimental effect in the arm volume, other patients experience more loss of mobility, pain and heaviness[5].

After 3 and 6 months no significant changes in arm volume were observed for both groups. Interestingly, after 3 months UEL index significantly improved in the LVA group, however this trend did not persist after 6 months. The volume reductive effect of the LVA treatment could not be evidenced during the first 6 months in the current study. This is concordant with previous studies[21,25,45].

However, the absence of volume reduction does not equate treatment failure. Even though the population had early stage lymphedema a discrepancy was seen between the ISL stage and ICG stage. Most of the cohort had ISL-stage 2a lymphedema, however using NIRF we mostly saw patients with ICG stage 3. Moreover, the patients in our cohort have had lymphedema for an average of ~ 7 years. Altogether this could indicate that even in early stage (ISL stage 2a) lymphedema determined by the ISL classification, the lymph vessels in the subdermal plane could already be nonfunctioning. Furthermore, in ISL stage 2a lymphedema changes in the tissue have been established using Dual Energy X-Ray Absorptiometry, such as lymph vessel dysfunction, fat deposition and, fibrosis. However, little is known about the exact physiological progression of lymphedema over time, which makes it difficult to establish which patients will benefit from LVA surgery[46–49].

Other systematic reviews have demonstrated that limb circumference significantly decreased, however these studies have a smaller patient population, reported heterogeneous assessment modalities and a had longer follow up[39,50]. There are many factors that might influence the outcome of the LVA, however there is a lack of consensus on what these factors are[42,51–53]. A positive correlation between Lymph-ICF and the amount of anastomosis has been reported[21]. As of yet, in our study no correlation was found between Lymph-ICF the amount of anastomosis, ICG stage, BMI and onset of lymphedema. However, in the study by Qiu et al. patients received multiple LVA surgeries and a longer follow up period then our current cohort[21].

In our study there was no correlation shown between volume reduction and the number of anastomosis performed. This concurs with the study conducted by Winters et al. where there was no correlation between the amount of anastomosis and volume reductive effect of the LVA[28]. In the current cohort there was no relationship between the volume, the duration and severity of lymphedema. Concurrently, a meta-analysis conducted by Nacchiero et al. reported that the stage and duration of lymphedema were not dependent on the success of the operation[39,54].

Lastly approximately 42% of the patient population in the LVA group completely of partially discontinued the use of compression garments. The discontinuation rate in our population is line with previously published articles[21,44,45]. Unfortunately, we did not include the reason for discontinuation in our questionnaire, which might be interesting to investigate in the future.

This study is a 6-month interim analysis where 92% of the population completed six-month follow up. At the time of analysis, one patient had dropped out. Because the design of the current study eliminates any form of selection bias, this study more closely resembles results of the general population in comparison to other smaller and retrospective studies. In our study, patients were only able to receive one LVA surgery whereas in other previously published studies patients were able to receive more sessions, and ultimately more LVA's[21,55].

Although the results of the first 6 months may be encouraging, a longer follow up period is required the assess the true effect of the LVA in comparison to CDT for secondary lymphedema.

Conclusion

Lymphaticovenous anastomosis resulted in improvement of physical and mental function in patients with BCRL. Limb volume and limb circumference did not significantly improve after 6 months in both groups. However, in the LVA group around 40% could completely or partially stopped with the use of compression garments. The current results are promising, however longer follow up is required to assess the long term effect of LVA.

Data availability

Background: The goal of this consensus conference, sponsored by the American Association of Plastic Surgeons, was to perform a systematic review and meta-analysis of controlled trials to examine both the benefits and risks of surgical treatment and surgical prevention of upper and lower extremity lymphedema.
Methods: The panel met in Boston for a 3-day, face-to-face meeting in July of 2017. After an exhaustive review of the existing literature, the authors created consensus recommendations using the Grading of Recommendations, Assessment, Development and Evaluation criteria. Important directions for future research were also identified.
Results: There is evidence to support that lymphovenous anastomosis can be effective in reducing severity of lymphedema (grade 1C). There is evidence to support that vascular lymph node transplantation can be effective in reducing severity of lymphedema (grade 1B). Currently, there is no consensus on which procedure (lymphovenous bypass versus vascular lymph node transplantation) is more effective (grade 2C). A few studies show that prophylactic lymphovenous bypass in patients undergoing extremity lymphadenectomy may reduce the incidence of lymphedema (grade 1B). More studies with longer follow-up are required to confirm this benefit. Debulking procedures such as liposuction are effective in addressing a nonfluid component such as fat involving lymphedema (grade 1C). There is a role for liposuction combined with physiologic procedures although the timing of each procedure is currently unresolved (grade 1C).
Conclusions: Many studies seem to support some efficacy of lymphovenous bypass and vascular lymph node transplantation. Many studies show the important role of lymphedema therapy and other procedures such as liposuction and debulking. The management of lymphedema is a challenging field with many promising advances. However, many questions remain unanswered. (*Plast. Reconstr. Surg.* 147: 975, 2021.)

There is no cure for lymphedema and the optimal treatment is unknown. The purpose of this consensus conference was to develop evidence-based consensus statements and recommendations for surgical treatment and prevention of secondary lymphedema by performing a meta-analysis of randomized and nonrandomized clinical trials. The objectives included the following:

1. To assess the effectiveness and safety of surgical treatment of lymphedema. Surgical treatments included lymphovenous bypass, vascular lymph node transplantation, and liposuction. Comparators included surgery (i.e., lymphovenous bypass, vascular lymph node transplantation, or liposuction) and compression therapy.

2. To assess the effectiveness and safety of surgical treatment to prevent secondary lymphedema. Surgical treatments included lymphovenous bypass. The comparator was no surgery.
3. To develop consensus statements and recommendations for surgical treatment of lymphedema.

PATIENTS AND METHODS

Consensus panel members were selected based on content and methodologic expertise. After considering the evidence, the consensus panel made recommendations regarding surgical treatment for patients with lymphedema and for surgical prevention of lymphedema in high-risk patients. The Grading of Recommendations, Assessment, Development and Evaluation framework was used to assess the overall quality of evidence and the strength of recommendations.[1–3] Randomized trials start as high-quality evidence and nonrandomized studies start as low-quality evidence. Studies may be downgraded because of risk of bias, indirectness, heterogeneity, imprecision, and publication bias. The overall quality of evidence was determined after considering each of these elements and categorized as high, moderate, low, or very low quality. The Grading of Recommendations, Assessment, Development and Evaluation criteria were used to classify recommendations as strong (grade 1) or weak (grade 2).[1] Recommendations were further classified as A, B, or C based on the quality of evidence informing the recommendation. Recommendations to use or not use an intervention are made on the basis of tradeoffs between benefits, risks, and burdens. If the benefits clearly outweigh risks and burdens, a strong recommendation is made. If the benefits, risks, and burdens are finely balanced, or uncertainty exists regarding the extent of benefits or risks, a weak recommendation is made.

Search Methods for Identification of Studies

The MEDLINE, Embase, and Cochrane Library databases were searched from inception to September 20, 2019. (**See Appendix, Supplemental Digital Content 1**, which shows the MEDLINE, Embase, and Cochrane Library search strategy, *http://links.lww.com/PRS/E392*.)

Inclusion Criteria

Randomized controlled trials and observational studies including prospective and retrospective cohort and case-control studies were considered for inclusion. Case series that reported on preoperative and postoperative outcomes of interest were also included.

Adult patients with secondary lymphedema (stages 1, 2, 3, or 4) were considered for inclusion. Surgical interventions for treatment of lymphedema included lymphovenous bypass (lymphaticovenular anastomosis), vascular lymph node transplantation, and liposuction. Studies that used combined procedures (e.g., vascular lymph node transplantation plus liposuction) were also considered for inclusion. The comparison group for surgical treatment studies included surgery and/or compression therapy. Eligible surgical comparators included lymphovenous bypass, vascular lymph node transplantation, and liposuction. Compression therapy could include graduated compression stockings, sequential compression devices, complex decongestive therapy, and physiotherapy.

We were also interested in the effectiveness and safety of surgical treatment to prevent lymphedema. Thus, studies that assessed surgical treatment for prevention of secondary lymphedema in high-risk patients were also considered for inclusion. Surgical interventions for the prevention of lymphedema included lymphaticovenular anastomosis (Lymphatic Microsurgical Preventive Healing Approach technique). The comparison group for surgical prevention studies included a no-surgery control group.

Exclusions

Studies published in abstract form only were excluded. Pediatric patients were excluded. Other types of surgery (e.g., excisional) and microsurgery (e.g., lymph vessel transplant) used for the treatment of lymphedema were excluded.

The primary outcomes for surgical treatment of lymphedema were reduction in limb volume (as a percentage or in milliliters) as measured by a validated system for limb volume measurement (e.g., truncated cone and water displacement) and reduction in limb circumference (as a percentage or in centimeters). The primary outcome for surgical prevention was the proportion of patients who developed lymphedema within 1 year of surgery. Secondary outcomes included surgical complications, ability to discontinue lymphedema interventions (e.g., pressure therapy), and patient-reported outcomes using validated questionnaires (e.g., quality of life).

The Cochrane risk-of-bias tool was used to assess the methodologic quality of randomized controlled trials.[4] The methodologic quality of cohort and case control studies was assessed using the Newcastle-Ottawa Scale.[5]

Data Extraction and Analysis

Meta-analysis was conducted if the interventions, patient groups, and outcomes were sufficiently similar. We calculated the odds ratio and 95 percent confidence interval for dichotomous outcomes obtained from case-control and cohort studies. For dichotomous outcomes from randomized controlled trials, we calculated the risk ratio and 95 percent confidence interval. For continuous outcomes, we calculated the mean difference and 95 percent confidence interval. Heterogeneity was assessed using the chi-square test. A value of $p = 0.10$ was considered statistically significant. The I^2 statistic was used to quantify heterogeneity.[6] If statistically significant heterogeneity was detected, we visually inspected the forest plots for outliers and conducted sensitivity analyses to explore potential explanations for the heterogeneity. Meta-analysis was carried out using a random-effects model. We planned subgroup analysis by location of lymphedema (i.e., upper extremity lymphedema versus lower extremity lymphedema). We used the software Review Manager (computer program) Version 5.3 (Nordic Cochrane Centre, Cochrane Collaboration, Copenhagen, Denmark).

RESULTS

Two hundred fifty-eight studies were excluded. Common reasons for exclusion included lack of usable data, no reporting of prespecified outcomes, ineligible surgical comparators or surgery, and abstract publications. Seventy-one articles reporting the results of 66 studies met the predefined inclusion criteria.[7–77] (**See Figure, Supplemental Digital Content 2**, which shows the study flow chart, *http://links.lww.com/PRS/E393*.) Two studies were randomized controlled trials[13,28]; seven included studies were prospective cohort studies[8,16,17,24,47,52,65]; 14 retrospective cohort studies were included[21,25,29,31,34,40,42,44,60–64,66]; 43 included studies were case series; eight studies reported on liposuction and compression therapy for treatment of lymphedema[7,15,20,26,36,43,57,74]; 16 studies reported on lymphovenous bypass and compression therapy[9–11,14,22,32,33,37–39,46,48,51,58,71,77]; and 17 studies reported on vascular lymph node transplantation and compression therapy.[23,24,27,35,45,49,50,53,56,59,67,69,70,72,73,75,76] Three case series reported on combination therapy.[12,55,68] The characteristics of included studies are described in Table 1 and results are described in Table 2.[7–78]

The risk of bias assessment is summarized. (**See Figure, Supplemental Digital Content 3**, which shows the risk of bias assessment, *http://links.lww.com/PRS/E394*.) The quality assessment of the cohort and case-control studies (Newcastle-Ottawa scale) is reported in Table 3.

Liposuction

A pooled analysis of two studies ($n = 48$ patients) showed that the combination of liposuction and controlled compression therapy was significantly superior to controlled compression therapy for reducing edema volume in patients with stage II (International Society of Lymphology) upper extremity lymphedema.[16,17] On average, patients who had liposuction and controlled compression therapy had a 63.95 percent greater reduction in volume compared to patients who had controlled compression therapy only (95 percent CI, 49.57 to 78.33; very low-quality evidence). [**See Figure, Supplemental Digital Content 4**, which shows the liposuction versus controlled compression therapy; outcome = reduction in limb volume (percent), *http://links.lww.com/PRS/E395*.] Similarly, a pooled analysis of two studies ($n = 69$ patients) showed that the combination of liposuction and controlled compression therapy was significantly superior to controlled compression therapy for reducing the volume of edema (in milliliters) in patients with stage II (International Society of Lymphology) upper extremity lymphedema. On average, patients who had liposuction and controlled compression therapy reduced their lymphedema volume by 895 ml more than controlled compression therapy patients (95 percent CI, −1140.63 to 650.98; very low-quality evidence). [**See Figure, Supplemental Digital Content 5**, which shows the liposuction versus controlled compression therapy; outcome = percentage reduction in limb volume (in milliliters), *http://links.lww.com/PRS/E396*.]

Two case series (163 patients) reported on liposuction for reducing percentage excess limb volume in patients with stage II to III (International Society of Lymphology) lymphedema.[15,20] Liposuction combined with compression therapy significantly reduced excess limb volume by an average 26.59 percent (95 percent CI, 18.64 to 34.54; very low-quality evidence). [**See Figure, Supplemental Digital Content 6**, which shows the liposuction; reduction in excess limb volume (percentage), *http://links.lww.com/PRS/E397*.] This benefit was significant for patients with upper extremity lymphedema (mean difference, 28.68; 95 percent CI, 6.06 to 51.29) and lower extremity lymphedema (mean difference, 29.23; 95 percent CI, 5.56 to 52.90). A high degree of heterogeneity was detected ($I^2 = 91$ percent), which likely

reflects differences in surgical technique, patients, and lymphedema. Six case series (294 patients) reported on liposuction for reducing excess limb volume (in milliliters) in patients with stage I to III (International Society of Lymphology) upper extremity lymphedema or lower extremity lymphedema.[7,17,26,36,68,74] Liposuction combined with compression therapy significantly reduced excess limb volume by an average 1702.44 ml (95 percent CI, 1558.64 to 1846.23 ml). [**See Figure, Supplemental Digital Content 7**, which shows the liposuction; reduction in volume (in milliliters), *http://links.lww.com/PRS/E398*.] This benefit was significant for patients with upper extremity lymphedema (mean difference, 1666.04 ml; 95 percent CI, 1543.97 to 1788.10 ml) and lower extremity lymphedema (mean difference, 2181.22 ml; 95 percent CI, 1328.00 to 3034.44 ml). A moderate degree of heterogeneity was detected (I^2 = 51 percent). One case series of 10 patients with upper extremity lymphedema and lower extremity lymphedema reported on preoperative and postoperative cellulitis.[34] Cellulitis was significantly reduced after treatment with liposuction and compression therapy. The incidence of severe cellulitis before surgery was 70 percent (seven of 10) compared to 10 percent (one of 10) after surgery (OR, 21.00; 95 percent CI, 1.78 to 248.10).

Lymphovenous Bypass

Three studies (102 patients) compared lymphovenous bypass to pressure therapy in patients with upper extremity lymphedema or lower extremity lymphedema.[40,42,62] Two studies reported significantly higher circumference reduction in lymphovenous bypass patients compared to patients who received compression alone. Koshima et al. reported that leg circumference decreased by a mean 4.7 cm in the lymphovenous bypass group compared to 0.6 cm in the compression therapy group ($p < 0.05$). This corresponded to a 55.6 percent reduction in leg circumference in the lymphovenous bypass group compared to an 8 percent reduction in the compression therapy group.[42] Koshima et al. reported that arm circumference decreased by a mean 4.1 cm in the lymphovenous bypass group compared to 0.8 cm in the compression therapy group ($p < 0.05$). This corresponded to a 47.3 percent reduction in arm circumference in the lymphovenous bypass group compared to a 11.7 percent reduction in the compression therapy group.[40] Engel et al. reported a 17.3 percent reduction in arm circumference in the lymphovenous bypass group compared to a 9.8 percent reduction in the complex decongestive

therapy group (mean difference, 7.50 percent; 95 percent CI, 4.89 to 10.11 percent; $p < 0.00001$).[62]

Ten studies (134 patients) reported on lymphovenous bypass for reducing limb circumference in patients with stage II to V (Campisi or International Society of Lymphology) upper extremity lymphedema or lower extremity lymphedema.[9–11,37,39,40,42,46,48,58] Lymphovenous bypass combined with compression garments significantly reduced circumference by an average of 3.8 cm (95 percent CI, 2.93 to 4.67 cm; $p < 0.00001$; very low-quality evidence) (Fig. 1) after surgery. Two studies[39,71] also reported a significantly reduced circumference difference after lymphovenous bypass combined with compression garments in 29 patients (mean difference, 3.26 cm; 95 percent CI, 0.44 to 6.08 cm; $p = 0.02$). This benefit was significant for patients with upper extremity lymphedema (six patients) (mean difference, 5.30 cm; 95 percent CI, 3.12 to 7.48 cm; $p < 0.00001$) and lower extremity lymphedema (23 patients) (mean difference, 1.82 cm; 95 percent CI, 0.92 to 2.71 cm; $p < 0.0001$). Similarly, Ito et al.[38] found no significant difference in postoperative excess circumference reduction in five patients with lower extremity lymphedema who received lymphovenous bypass with compression garments (mean difference, 3.50 percent; 95 percent CI, −6.89 to 13.89 percent; $p = 0.51$). Ayestaray and Bekara[11] reported a significant reduction in limb volume of 504 ml (95 percent CI, 32.06 to 975.94 ml; $p < 0.05$) after lymphovenous bypass combined with compression garment use in 20 patients with upper and lower

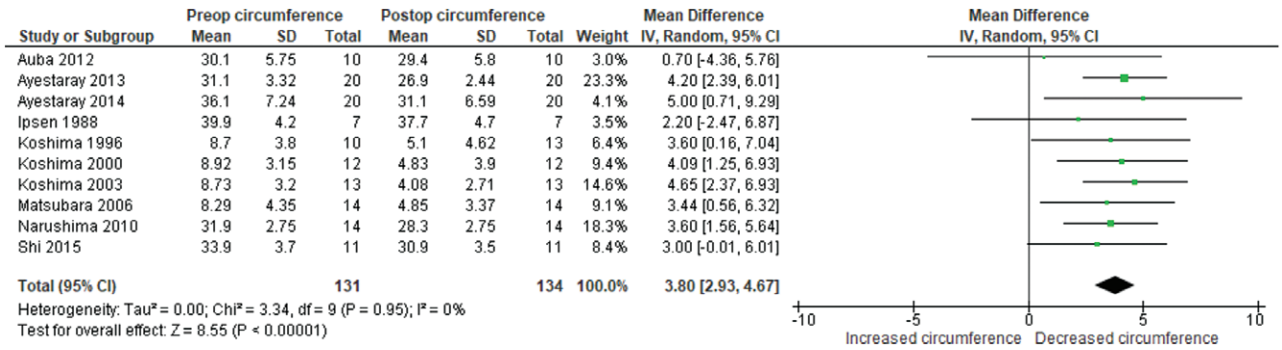

Fig. 1. Lymphovenous bypass; reduction in circumference (in centimeters).

extremity lymphedema. Similarly, Boccardo et al.[14] reported a large and significant excess volume reduction of 1858.6 ml (95 percent CI, 1721.48 to 1995.72 ml; $p < 0.00001$) after lymphovenous bypass combined with compression garment use in seven patients with lower extremity lymphedema. Winters et al.[77] reported a significant volume reduction of 234 ml (95 percent CI, 43.74 to 424.26 ml; $p = 0.02$) after lymphovenous bypass and compression garments in 29 patients with upper extremity lymphedema. Five studies (81 patients) reported on the proportion of patients who were able to discontinue compression garment use postoperatively.[10,11,14,38,77] Although 81 of 81 of patients (100 percent) used compression garments before lymphovenous bypass, 39 of 81 (48 percent) were able to stop using compression garments after surgery (OR, 0.03; 95 percent CI, 0.01 to 0.11; $p < 0.00001$).

Three case series (14 lower extremity lymphedema and 23 upper extremity lymphedema patients) reported on the mean number of cellulitis infections per year before and after surgery.[38,46,62] Mean cellulitis infections were significantly reduced after treatment with lymphovenous bypass and compression therapy (mean difference, 2.57; 95 percent CI, 1.75 to 3.38). Three case series (141 upper or lower extremity lymphedema patients) reported on preoperative and postoperative cellulitis.[32,33,51] Cellulitis was significantly reduced after lymphovenous bypass and compression therapy. The incidence of cellulitis before surgery was 67 percent (95 of 141) compared to 21 percent (29 of 141) after surgery (OR, 9.11; 95 percent CI, 2.31 to 35.97). A high degree of heterogeneity was detected (I^2 = 75 percent), which could reflect differences in surgical technique, patients, and lymphedema stage.

Vascularized Lymph Node Transfer

Four studies (300 patients) reported usable data for the comparison of vascularized lymph node transfer versus physiotherapy.[24,28,62,65] Dionyssiou et al.[28] reported significantly reduced percentage excess arm volume in patients who had vascularized lymph node transfer and physiotherapy compared to physiotherapy alone (mean difference, −15.00 ml; 95 percent CI, −22.0 to −7.97 ml; $p < 0.001$). Similarly, a pooled analysis of two studies showed a significant improvement in both circumferential differentiation (mean difference, 3.99 cm; 95 percent CI, 2.62 to 5.32 cm; 200 patients),[24,65] and circumferential reduction (mean difference, 24.29 percent; 95 percent CI, 21.81 to 26.76 percent; 84 patients),[24,62] in patients who underwent vascularized lymph node transfer and physiotherapy compared to physiotherapy alone. A pooled analysis of two studies (56 patients) shows a nonsignificant reduction in the number of infections per year in patients who underwent vascularized lymph node transfer and physiotherapy compared to physiotherapy alone (mean difference, −0.48; 95 percent CI, −1.25 to 0.29; $p = 0.22$). Patients who underwent vascularized lymph node transfer and physiotherapy had significantly reduced pain (36 patients) (mean difference, −4.00; 95 percent CI, −5.09 to −2.91; $p < 0.00001$) and heaviness (36 patients) (mean difference, −4.17; 95 percent CI, −5.62 to −2.72; $p < 0.00001$) and significantly improved overall function (36 patients) (mean difference, −3.39; 95 percent CI, −5.08 to −1.70; $p < 0.00001$) compared to physiotherapy patients.

Five studies (72 patients) reported on vascularized lymph node transfer for reducing limb circumference in stage II (International Society of Lymphology) upper extremity lymphedema.[31,45,50,56,59] Vascularized lymph node transfer combined with compression garments and complex decongestive therapy significantly reduced circumference by an average of 1.64 cm (95 percent CI, 0.87 to 2.42 cm; $p < 0.0001$; very low-quality evidence) (Fig. 2). Two studies (28 patients with upper extremity lymphedema) reported on circumference difference.[56,59] Circumference

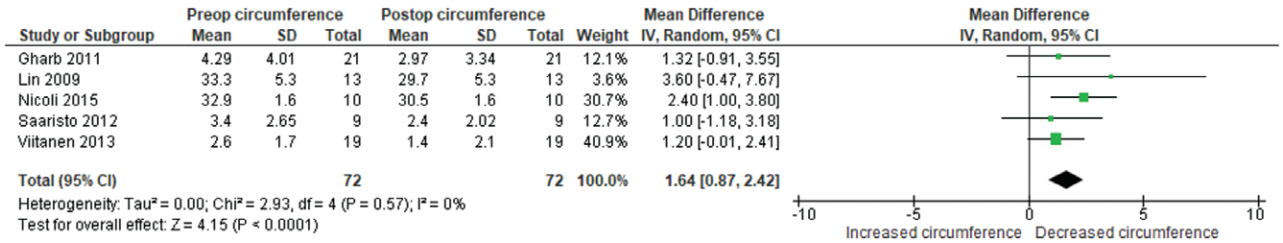

Fig. 2. Lymph node transplantation; reduction in circumference (in centimeters).

difference was significantly lower after vascularized lymph node transfer combined with compression garments and complex decongestive therapy (mean difference, 1.15 cm; 95 percent CI, 0.09 to 2.21 cm; $p = 0.03$). Two studies[53,73] reported on percentage excess volume reduction after vascularized lymph node transfer in 101 patients. Vascularized lymph node transfer significantly reduced excess limb volume by an average 9.60 percent (95 percent CI, 5.98 to 13.22 percent; $p < 0.00001$). This benefit was significant for patients with upper extremity lymphedema (45 patients) (mean difference, 7.83 percent; 95 percent CI, 5.09 to 10.57 percent; $p < 0.00001$) and lower extremity lymphedema (56 patients) (mean difference, 12.98 percent; 95 percent CI, 11.87 to 14.08 percent; $p < 0.00001$). Batista et al.[12] reported on preoperative and postoperative volume (in milliliters) in 15 lower extremity lymphedema patients. Vascularized lymph node transfer combined with physiotherapy and compression stockings reduced leg volume by an average of 900.0 ml (95 percent CI, −104.50 to 1904.50 ml; $p = 0.08$). Some of these patients also received liposuction. Leppapuska et al.[64] reported on preoperative and postoperative excess volume (in milliliters) in 27 upper extremity lymphedema patients. Vascularized lymph node transfer combined with compression stockings reduced arm volume by an average of 112.6 ml (95 percent CI, −81.61 to 306.81 ml; $p = 0.26$). Three studies (175 upper extremity lymphedema patients) reported on the proportion of patients who required physiotherapy and complex decongestive therapy postoperatively.[27,35,65] Although 104 of 175 patients (59 percent) required physiotherapy and complex decongestive therapy before vascularized lymph node transfer, 57 of 175 (33 percent) required physiotherapy and complex decongestive therapy after surgery (OR, 45.37; 95 percent CI, 8.73 to 235.78; $p < 0.00001$).

Eight case series (248 patients) reported on the mean number of cellulitis infections per year before and after surgery.[23,53,60,65–67,72,73] Cellulitis infections were significantly reduced after vascularized lymph node transfer (mean difference, 2.34; 95 percent CI, 1.82 to 2.85; $p < 0.00001$). This benefit was significant for upper extremity lymphedema (181 patients) (mean difference, 2.68; 95 percent CI, 1.94 to 3.41; $p < 0.00001$) and for lower extremity lymphedema (67 patients) (mean difference, 2.01; 95 percent CI, 1.12 to 2.91; $p < 0.001$). Six case series (233 patients with upper extremity lymphedema or lower extremity lymphedema) reported on the proportion of patients with preoperative and postoperative cellulitis.[35,49,61,64,69,75] Cellulitis was significantly reduced after vascularized lymph node transfer. The incidence of cellulitis before surgery was 53 percent (124 of 233) compared to 18 percent (42 of 233) after surgery (OR, 9.37 percent; 95 percent CI, 5.39 to 16.27 percent; $p < 0.0001$). Patel et al.[53] reported on quality of life using the Lymphoedema Quality-of-Life tool. Quality of life improved significantly after vascularized lymph node transfer (25 patients) (mean difference, −3.95; 95 percent CI, −4.33 to −3.57; $p < 0.00001$). This benefit was significant for upper extremity lymphedema (15 patients) (mean difference, −3.70; 95 percent CI, −4.14 to −3.26; $p < 0.00001$) and lower extremity lymphedema (10 patients) (mean difference, −4.10; 95 percent CI, −4.30 to −3.90; $p < 0.00001$).

Vascularized Lymph Node Transfer and Donor Site

Ciudad et al.[25] compared the morbidity of different donor sites for vascularized lymph node transfer in 110 patients with stage II to III (International Society of Lymphology) lymphedema. Donor sites included groin ($n = 20$), supraclavicular ($n = 54$), and right gastroepiploic, where an open ($n = 19$) or laparoscopic approach ($n = 17$) was used. No significant differences in complications were found across donor sites. Ciudad et al.[61] compared the circumference reduction rates across different donor sites for vascularized lymph node transfer in 45 patients with stage II (International Society of Lymphology) lymphedema. Donor sites included groin ($n = 10$), supraclavicular ($n = 10$), and gastroepiploic ($n = 25$).

No significant differences in circumference reduction rates were found across donor sites.

Lymphovenous Bypass versus Vascularized Lymph Node Transfer

Three studies (161 patients) compared the efficacy and safety of lymphovenous bypass to vascularized lymph node transfer in stage I to III upper extremity lymphedema or lower extremity lymphedema patients.[8,34,44,62] A pooled analysis of two studies[8,44] showed no significant difference in lymphatic function at 12- to 18-month follow-up. Seventeen of 26 patients (65 percent) who underwent vascularized lymph node transfer had improved lymphatic function at 12- to 18-month follow-up compared to 26 of 62 patients (42 percent) who underwent lymphovenous bypass (OR, 1.73; 95 percent CI, 0.29 to 10.15). Similarly, a pooled analysis of two studies,[34,44] showed no significant difference in clinical improvement (lymphatic function) at 24-month follow-up. Fourteen of 21 patients (67 percent) who underwent vascularized lymph node transfer had improved lymphatic function at 24-month follow-up compared to 15 of 27 patients (56 percent) who underwent lymphovenous bypass (OR, 1.57; 95 percent CI, 0.48 to 5.17). Lee et al. also reported 48-month follow-up data.[44] Although the difference was not significant, more patients in the vascularized lymph node transfer group continued to experience improved lymphatic function at 48-month follow-up. Six of 13 patients (46 percent) who underwent vascularized lymph node transfer still had improved lymphatic function at 48 months compared to three of 19 lymphovenous bypass patients (16 percent) (OR, 4.57; 95 percent CI, 0.88 to 23.71; $p = 0.07$). Engel et al.[62] compared circumferential reduction rates, and patients who underwent vascularized lymph node transfer had a 16.7 percent (95 percent CI, 13.32 to 20.08 percent) greater reduction in circumference than patients who underwent lymphovenous bypass.

Two studies reported on postoperative complications.[8,34] Postoperative complications were reported in two of 41 lymphovenous bypass patients (5 percent), compared to six of 21 vascularized lymph node transfer patients (29 percent) (OR, 4.86; 95 percent CI, 0.99 to 23.86 percent; $p = 0.05$). Engel et al. compared cellulitis rates and, on average, patients who underwent vascularized lymph node transfer had 1.2 more episodes of cellulitis per year than patients who underwent lymphovenous bypass (95 percent CI, 0.42 to 1.98; $p = 0.02$). Granzow et al.[34] reported on compression garment use at 24-month follow-up. Six of eight vascularized lymph node transfer patients (75 percent) reported no compression garment use at 24 months compared to three of eight lymphaticovenous anastomosis patients (38 percent) (OR, 5.00; 95 percent CI, 0.58 to 42.80; $p = 0.14$). Akita et al. reported a significantly shorter hospital stay among lymphovenous bypass patients compared to vascularized lymph node transfer patients.[8] The mean hospital stay in the vascularized lymph node transfer group was 15.2 ± 1.6 days compared to 8.9 ± 2.9 days in the lymphovenous bypass group (mean difference, 6.30 days; 95 percent CI, 5.07 to 7.53 days).

Lymphatic Microsurgical Preventive Healing Approach

Three studies (154 patients) reported on the development of lymphedema at greater than 15-month follow-up in cancer patients who underwent lymphovenous bypass for prevention of lymphedema compared to a no-surgery control.[13,47,52,63] Significantly fewer lymphedemas developed in patients who underwent preventive lymphovenous bypass. Nine of 62 patients (14 percent) who underwent lymphovenous bypass developed lymphedema at 15 to 29 months' follow-up compared to 52 of 92 control patients (56 percent) (OR, 0.15; 95 percent CI, 0.06 to 0.35; $p < 0.0001$; very low-quality evidence). (**See Figure, Supplemental Digital Content 8**, which shows the lymphaticovenous anastomosis versus no preventive surgery; outcome = lymphedema at >18-month follow-up, *http://links.lww.com/PRS/E399*.) Two studies (140 patients) reported on complications.[47,52] Patients who had lymphovenous bypass and lymph node dissection were not at increased risk of developing complications compared to patients who only had lymph node dissection.

DISCUSSION

Limitations of Meta-Analysis

This meta-analysis has several limitations. Only two randomized controlled trials were included. The majority of included studies were observational studies, which are at high risk of bias, and the conclusions that can be drawn from these studies are limited. It was difficult to report a meta-analysis on these studies because of the variation in outcome measurements and lack of reported standard deviations. Although there was a lack of standardization in outcomes measurements, the magnitude of limb volume reduction was large for some procedures, particularly for liposuction.

Physiologic Surgery (Lymphovenous Bypass and Vascularized Lymph Node Transfer)

A lymphedema therapist is recommended for patients undergoing lymphatic surgery. However, the failure of conservative management is not a prerequisite for physiologic surgery. This is based on a plurality of studies demonstrating that patients with earlier stage disease have better outcomes.

There is level I evidence demonstrating vascularized lymph node transfer and 6 months of compression and physiotherapy was more effective in reducing limb volume (grade 1B) and incidence of cellulitis than compression and physiotherapy alone.[28] Further studies that provide a nonsurgical control group are needed in this field. Mapping of the lymphatics is encouraged when harvesting lymph nodes adjacent to the limbs such as reverse lymphatic mapping to avoid lymphatics draining the limb and to minimize the risk of donor-site lymphedema.

A few studies compared lymphovenous bypass to vascularized lymph node transfer, but because of heterogeneous patient populations, there is currently no consensus regarding which procedure is more effective. We understand that patients with more advanced disease who may be offered vascularized lymph node transfer may not be candidates for lymphovenous bypass, and there may be inherent selection bias in these studies.

A few studies show that prophylactic lymphovenous bypass in patients undergoing lymphadenectomy may reduce the incidence of lymphedema. Prophylactic lymphovenous bypass should be avoided in cases of extremity malignancy. Lymphovenous bypass after mastectomy or inguinal dissection may reduce the incidence of lymphedema (grade 1B). The potential for hematogenous spread of extremity malignancies is unknown.

Liposuction

Liposuction is indicated for moderate to advanced lymphedema with a significant component of fat hypertrophy (grade 1C). Evidence of fat hypertrophy of the limb can be provided either by physical examination or by imaging. There is sufficient evidence that liposuction is safe with a large benefit in terms of limb volume reduction (grade 1C). There is a role for liposuction combined with physiologic procedures, although the timing of each procedure is currently unresolved.

Unresolved Questions

Is there a body mass index cutoff for offering physiologic procedures given the correlation with elevated body mass index and impaired lymphatic function? What is the role of scar release? Do physiologic procedures respond better in patients with preserved lymphatic architecture/early stage? Do physiologic procedures work better in upper extremity lymphedema or lower extremity lymphedema? We agree that the International Society of Lymphology staging system is a limited staging system that does not incorporate physiologic measures but is useful in communicating in general terms with the patient population.

CONSENSUS AND RECOMMENDATIONS

- There is evidence to support that lymphaticovenous anastomosis can be effective in reducing severity of lymphedema (grade 1C). A plurality of studies demonstrates that patients with earlier stage disease have better outcomes. There is no evidence that lymphovenous bypass can cure lymphedema.
- There is evidence to support that vascularized lymph node transfer can be effective in reducing the severity of lymphedema (grade 1B). There is no evidence that vascularized lymph node transfer can cure lymphedema.
- Currently, there is no consensus on which procedure (lymphovenous bypass versus vascularized lymph node transfer) is more effective (grade 2C).
- A few studies show that prophylactic lymphovenous bypass in patients undergoing extremity lymphadenectomy may reduce the incidence of lymphedema (grade 1B). More studies with longer follow-up are required to confirm this benefit.
- Debulking procedures such as liposuction are effective in addressing nonfluid component such as fat involving lymphedema (grade 1C).
- There is a role for liposuction combined with physiologic procedures, although the timing of each procedure is currently unresolved (grade 1C).
- Lymphatic procedures are highly complex, and anyone contemplating performing lymphatic surgery is encouraged to visit a high-volume center. To decrease the incidence of complications, microsurgical training is encouraged.
- A consensus on staging of lymphedema and preoperative and postoperative evaluation would be helpful.

Copyright © 2021 American Society of Plastic Surgeons. Unauthorized reproduction of this article is prohibited.

- There is a need for more quantitative methods for measuring fat, fluid, and physiologic measures and immunologic function.
- There is a need for better designed studies that include more objective reporting of outcomes and longer follow-up.

CONCLUSIONS

The role of surgery in the treatment of lymphedema has evolved from debulking procedures to those that aim to counteract the pathophysiology of lymphedema using microsurgical techniques. Many studies seem to support some efficacy of lymphovenous bypass and vascularized lymph node transfer. Many studies show the important role of lymphedema therapy and other procedures such as liposuction and debulking. The management of lymphedema is a challenging field with many promising advances. However, many questions remain unanswered.

Keywords: immediate lymphovenous anastomosis | lymph node surgery | lymphatic bypass | lymphedema | microsurgery | oncologic reconstruction | supermicrosurgery

ABSTRACT

Background: Secondary lymphedema is a debilitating condition following oncologic lymphadenectomy. Despite advancements in rehabilitation and microsurgical interventions, there is no cure for lymphedema. Performing a lymphovenous anastomosis (LVA) at the time of a regional node dissection has been purported to reduce the risks of secondary lymphedema; however, there are conflicting studies and no clear consensus about the routine use of LVA for preventing lymphedema after lymphadenectomy. The present study aims to perform a comprehensive review and meta-analysis on immediate LVA for the prevention of secondary lymphedema.

Methods: A systematic review and literature search were performed using PubMed, Embase, Web of Science, and Cochrane databases. Studies evaluating primary or immediate LVA in oncologic surgery were included. Studies with a control group were included in the meta-analysis.

Results: Overall, 39 studies, including 3697 patients (1,722 LVA; 1975 control), met inclusion criteria. Seventeen of the studies were included in the meta-analysis. Pooled analysis across all studies revealed a secondary lymphedema incidence of 7.1% in the LVA cohort versus 35.0% in controls. Meta-analysis demonstrated a significant reduction in lymphedema risk with immediate LVA (RR: 0.31). Subgroup analysis confirmed strong protective effects in breast cancer patients (RR: 0.28) and a significant but lesser benefit in dermatologic malignancies (RR: 0.35).

Conclusion: Based on the current literature, immediate LVA at time of lymphadenectomy significantly reduces the risk of secondary lymphedema in patients undergoing oncologic treatment. Given these findings, patients undergoing multimodal oncologic treatment including radiation and surgical lymphadenectomy should be considered candidates for immediate LVA.

1 | Introduction

Oncologic reconstruction is an essential component of comprehensive cancer care, restoring both form and function following surgical resection. Patients undergoing treatment for breast, dermatological, and gynecologic malignancies often require complex reconstructive procedures to optimize esthetic and functional outcomes. However, these surgeries frequently involve lymph node dissection and radiation therapy, both of which significantly disrupt the lymphatic system and place patients at risk for secondary lymphedema [1–4]. Secondary lymphedema is a progressive and often debilitating condition characterized by

impaired lymphatic drainage, leading to chronic limb swelling, fibrosis, inflammation, recurrent infections, and reduced quality of life [5, 6]. The incidence of secondary lymphedema varies by cancer type and surgical intervention, with rates reported as high as 40% following axillary lymph node dissection for breast cancer and around 20% following inguinal lymphadenectomy for melanoma and gynecologic malignancies [7–9]. Despite advances in microsurgery and rehabilitation strategies, there is no cure for lymphedema which underscores need for preventative strategies.

The lymphovenous anastomosis (LVA) is a supermicrosurgical procedure that aims to restore lymphatic drainage by creating bypasses between lymphatic vessels and nearby venules, allowing lymphatic fluid to drain directly into the venous circulation [10]. LVA is a well-documented surgical treatment for lymphedema proven to have a significant benefit in volume reduction, decreased incidence of infection, reduced dependency on compression garments, and improvements in quality of life [11, 12]. More recently, interest has grown in the application of immediate LVA at the time of lymphadenectomy, where lymphatic vessels that are ligated during a nodal dissection are repaired to an adjacent vein to preserve the lymphatic drainage [13, 14]. While a number of modalities exist, all techniques utilize a dye that permits identification of the lymphatic vessels to be repaired [15]. Preliminary studies have suggested promising outcomes, with some reports indicating a significant reduction in lymphedema rates following immediate LVA [16–18].

Despite these promising early outcomes, immediate LVA or immediate lymphatic reconstruction is not yet considered the standard of care in oncological reconstruction when the lymph system is dissected. While many studies have demonstrated a significant reduction in the risk of lymphedema, others have reported contradictory results. Similarly, previous meta-analysis have been limited by inconsistency or short follow-up periods. Many meta-analyses are also outdated given the recent increase in new publications examining the efficacy of immediate LVA. This study aims to provide a comprehensive review of the current literature and perform an in-depth analysis to establish the true value of immediate LVA in mitigating the risks of secondary lymphedema following lymphadenectomy in oncological reconstruction.

2 | Materials and Methods

2.1 | Strategy

This study was performed according to the Preferred Reporting Items for Systematic Reviews and Meta-analyses guidelines. Our protocol for this review was registered on PROPSERO and is accessible at https://www.crd.york.ac.uk (Record: CRD42025642808).

2.2 | Search and Data Sources

A literature review was performed using PubMed, Embase, Web of Science, and Cochrane. No time constraints were placed on the search. The predetermined search terms utilized included "primary" OR "prophylactic" OR "immediate" AND "lymphaticovenous anastomosis" OR "lymphovenous bypass" OR "lymphatic-venous anastomosis" OR "lymphovenous anastomosis" OR "lymphedema prevention" OR "lymphatic reconstruction" AND "lymphedema" OR "lymphoedema" OR "secondary lymphedema" OR "postoperative lymphedema." Appendix 1 contains the full search terms for each database.

2.3 | Selection Criteria

The Covidence platform (Veritas Health Innovation, Melbourne, Australia) was used for screening. The screening was performed independently by two investigators (C.H. and M.S.); first by title and abstract and then by full-text review. A third investigator (A.O.) resolved conflicts. Studies were eligible if they included patients undergoing immediate LVA at time of lymphadenectomy and reported on secondary lymphedema. Studies that did not focus on immediate LVA or did not report secondary lymphedema were excluded.

2.4 | Data Extraction

The variables extracted from the studies included publication year, lead author, study design, patient sample size, age, body mass index (BMI), area of lymph node dissection, number of lymph nodes removed, number of LVAs performed, frequency of radiotherapy treatment, frequency of secondary lymphedema, and follow-up period. Weighted means and frequencies along with pooling of secondary lymphedema data were performed using Microsoft Excel (Redmond, WA; College Station, TX).

2.5 | Definition of Treatment and Comparison Groups

The treatment group consisted of patients who underwent immediate LVA at the time of lymphadenectomy, which could be at or before oncological resection such as mastectomy or dermatological excision. Additionally, all LVAs, both regionally at site of lymphadenectomy or distally, were included; however, all patients included in the study had LVAs regionally to the lymphadenectomy. The control group included patients who underwent the same types of oncological surgery without immediate LVA. Studies that included patients who had therapeutic LVA for established lymphedema were excluded. There was no strict age cutoff for patient inclusion; however, pediatric patients were not included in the reviewed studies given the rarity of cancer-related lymph node dissection in this population. Studies that were case reports, case series with less than five patients, systematic reviews, and meta-analysis were excluded. Case series with five patients or greater were included only for pooling rates of secondary lymphedema after LVA use; however, they were not included in the meta-analysis.

2.6 | Definition of Outcomes

The immediate outcome assessed was the incidence of secondary lymphedema following lymphadenectomy and oncologic surgery, comparing patients who underwent immediate LVA to those who did not. While each study utilized different

techniques to assess lymphedema, it was defined for this study as an increase in extremity circumference with patient reported symptoms including extremity swelling, feeling of heaviness or tightness in an extremity, skin changes such as thickening or redness, or extremity discomfort or aching. A subgroup analyses was performed based on the type of malignancy. Specifically, secondary lymphedema incidence was stratified by breast and dermatological malignancies that required lymphadenectomy. This analysis aimed to determine whether immediate LVA had differential efficacy based on malignancy type.

2.7 | Statistical Analysis

Meta-analysis was performed using Cochrane Review Manager RevMan 5.4 (London, United Kingdom). Weighted means and frequency were calculated for patient characteristics of both cohorts (LVA cohort and control). Total incidence for lymphedema was calculated along with risk ratios (RR) with 95% confidence intervals (CI). Statistical differences were noted as a $p < 0.05$.

2.8 | Risk of Bias

Two investigators (C.H. and M.S.) independently conducted a quality and bias assessment using a data extraction form, following the Downs and Black (D&B) checklist. The quality of each study was evaluated based on the established criteria for the D&B score, categorized as excellent (≥ 26), good (20–25), fair (15–19), or poor (≤ 14). Additionally, a level of evidence score was assigned to each study according to the American Society of Plastic Surgeons (ASPS) Level of Evidence (LOE) Rating Scale for Therapeutic Studies.

3 | Results

3.1 | Search Results

Our initial search identified 1024 citations (Figure 1). Following the removal of duplicates, 726 citations were screened based on their titles and abstracts. Subsequently, 78 articles were selected for full-text review, resulting in the inclusion of 39 studies (Table S1) [18–55]. Studies were excluded for several reasons: incorrect indications (patients did not receive immediate LVA), inappropriate study design, or incorrect outcome assessment (did not report secondary lymphedema). The inclusion criteria for the meta-analysis component included studies that compared rates of secondary lymphedema between patients who had and had not received LVA, with 17 studies meeting this requirement to be included for meta-analysis.

3.2 | Pooled Baseline Characteristics: Lymphovenous Anastomosis and Control Cohorts

A total of 3697 patients were included in this study with 1722 patients receiving immediate LVAs while the remaining 1975 served as controls. The weighted mean age (standard deviation [SD]) of the LVA cohort was 55.4 (5.76) while for the control cohort it was 56.62 (6.12). Notably, two studies did not provide patient ages. The weighted mean BMI (SD) was 27.10 (1.95) for the LVA cohort and 27.55 (1.66) for the control cohort, with 12 studies not reporting BMI.

Females were the predominant gender in both cohorts, comprising 93.87% of the LVA group (with four studies not reporting gender). The most common oncological pathology treated was breast cancer in both groups, occurring in 79.66% of LVA patients and 81.35% of controls. Melanoma was the second most common pathology, seen in 13.93% of LVA patients and 16.21% of controls, followed by squamous cell carcinoma (2.91%) in the LVA cohort and sarcoma (1.33%) in the control group.

The mean (SD) number of lymph nodes removed during oncological resection was similar between groups: 15.78 (3.52) for the LVA cohort and 15.75 (3.62) for the control cohort. However, 13 studies did not report lymph node counts for the LVA group. The majority of dissections and anastomoses were performed in the axilla (88.92%) for the LVA group, whereas the control cohort predominantly had dissections in the axilla as well (85.94%).

Regarding surgical characteristics, the mean (SD) number of anastomoses created in the LVA group was 2.11 (0.82), though 19 studies did not report the number of anastomoses created. Among anastomotic techniques, end-to-end was the most common (63.48%), followed by intussusception (18.17%) and sleeve (14.13%). Nine studies did not specify the type of anastomosis utilized.

For adjuvant oncologic treatment, 78.92% of LVA patients and 65.94% of control patients received radiotherapy, though 11 studies did not report radiotherapy status. The mean follow-up time (SD) across all studies was 21.34 months (19.72).

Pooling across all studies, the rate of secondary lymphedema was significantly lower in the LVA cohort at 7.14% compared to 35.04% in the control cohort. Table 1 presents the demographics, surgical characteristics, and rates of lymphedema for both groups.

3.3 | Meta-Analysis

The meta-analysis utilized 17 studies and included studies that had both an LVA and control cohort, which directly assesses the impact of LVA on secondary lymphedema across different oncological indications. Immediate LVA was associated with a 69% lower risk of secondary lymphedema compared to the control group (RR: 0.31, 95% CI: 0.23–0.42, $p < 0.00001$) (Figure 2). A total of 78 patients developed secondary lymphedema in the LVA group out of 917 patients (8.51%), compared to 692 patients in the control group out of a total of 1975 patients (35.04%). Heterogeneity was low ($I^2 = 22\%$, $p = 0.20$), suggesting consistent results across studies.

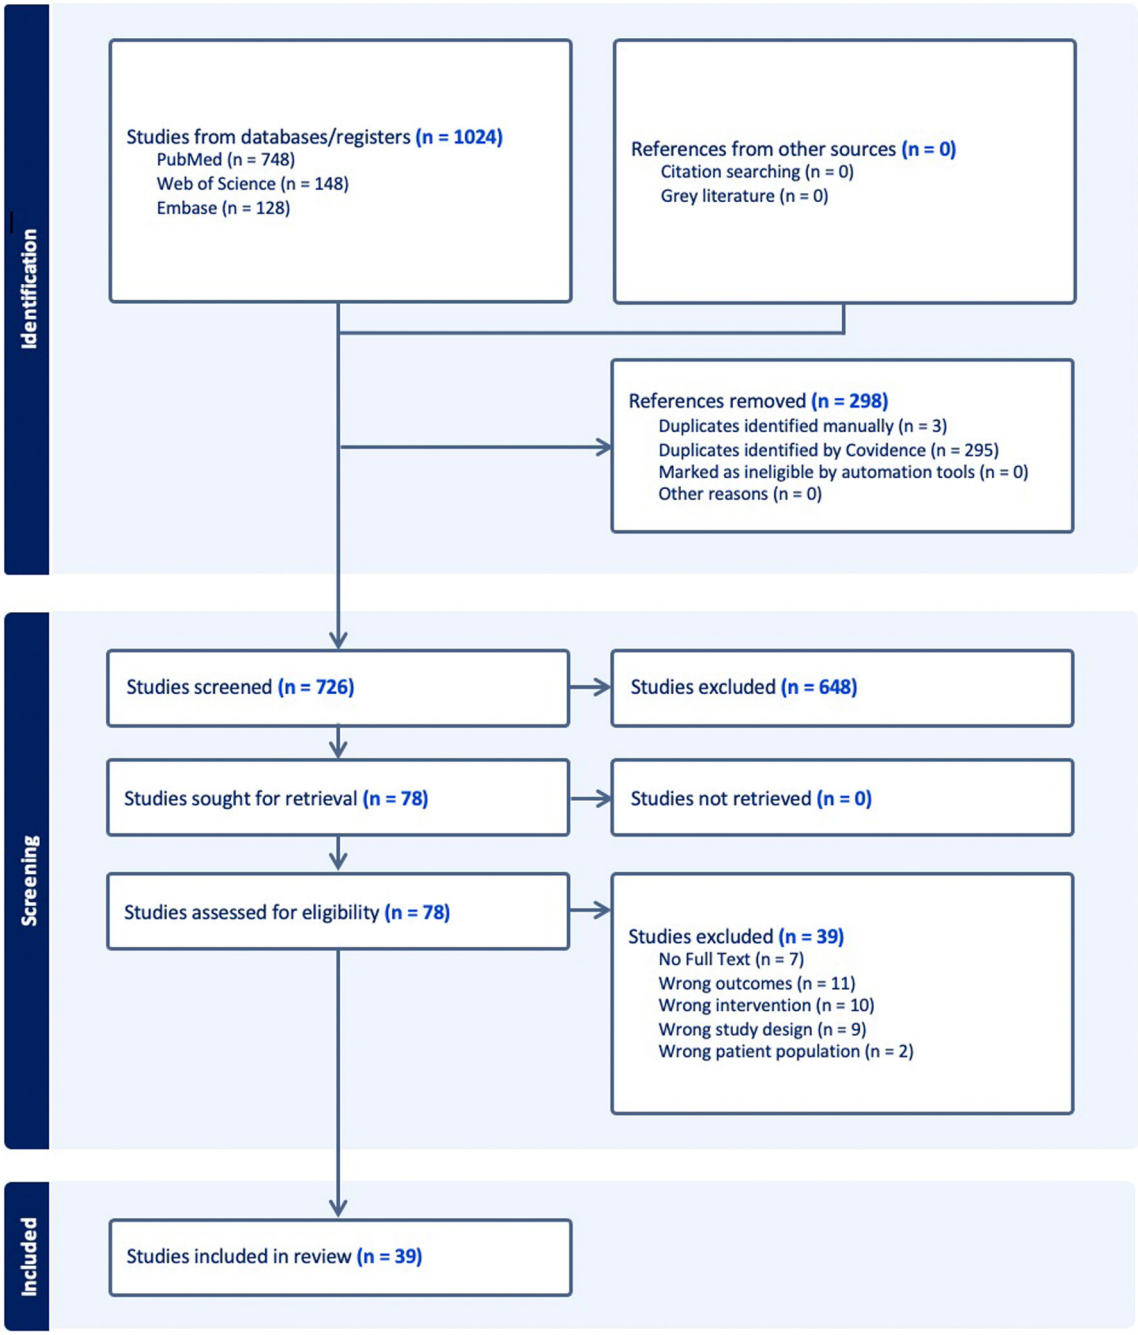

FIGURE 1 | Figure 1 illustrates the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) flow diagram for the study selection process. The initial search identified 1024 records from three databases: PubMed ($n = 748$), Web of Science ($n = 148$), and Embase ($n = 128$). No additional references were obtained through other sources such as citation searching or gray literature. After removing 298 duplicates, 726 studies remained for screening. Of these, 648 studies were excluded based on title and abstract screening, leaving 78 studies for full-text assessment. No studies were unavailable for retrieval. Following eligibility assessment, 39 studies were excluded due to reasons such as lack of full text ($n = 7$), reporting of irrelevant outcomes ($n = 11$), use of the wrong intervention ($n = 10$), incorrect study design ($n = 9$), or an inapplicable patient population ($n = 2$). Ultimately, 39 studies were included in the final systematic review.

3.4 | Subgroup Analysis: Malignancy Type

In subgroup analysis of breast surgery, LVA was associated with a 72% reduction in risk of secondary lymphedema compared to the control group (RR: 0.28, 95% CI: 0.20–0.39, $p < 0.00001$) (Figure 3), A total of 62 patients developed secondary lymphedema out of 778 patients who were in the LVA group (7.97%), compared to 571 patients out of 1596 patients in the control group (35.78%). Heterogeneity was similarly low ($I^2 = 22\%$, $p = 0.23$), indicating a consistent effect across the studies within this subgroup.

For the subgroup analysis of dermatologic malignancies, which includes both melanoma and squamous cell carcinomas, the effect of LVA was slightly less pronounced with a 65% reduction in risk of secondary lymphedema compared to the control group (RR: 0.35,

TABLE 1 | This table presents patient demographics, surgical characteristics, and lymphedema incidence between the prophylactic lymphovenous anastomosis (LVA) cohort and the control cohort. Variables include sample size, mean age, body mass index (BMI), frequency of female patients, number of lymph nodes removed, percentage of upper extremity lymphadenectomy, mean number of anastomoses performed, frequency of radiotherapy, and incidence of secondary lymphedema. Values are reported as mean (standard deviation [SD]) or frequency (%) with corresponding sample sizes provided in brackets.

	LVA cohort	Control cohort
Sample	1722	1975
Age: Mean (SD) [Sample Size]	55.41 (5.76) [1630]	56.62 (6.12) [1975]
BMI: Mean (SD) [Sample Size]	27.20 (1.95) [1271]	27.56 (1.66) [1239]
Female Frequency [Sample Size]	93.87% [1565]	92.90% [1832]
Lymph Nodes Removed: Mean (SD) [Sample Size]	15.78 (3.52) [1195]	15.75 (3.63) [631]
LVA Site: Upper Extremity Frequency [Sample Size]	88.92% [1742]	85.94% [1921]
Anastomosis: Mean (SD) [Sample Size]	2.11 (0.82) [634]	N/A
Radiotherapy: Frequency [Sample Size]	78.92% [1309]	65.94% [869]
Lymphedema: Frequency [Sample Size]	7.14% [1722]	35.04% [1975]

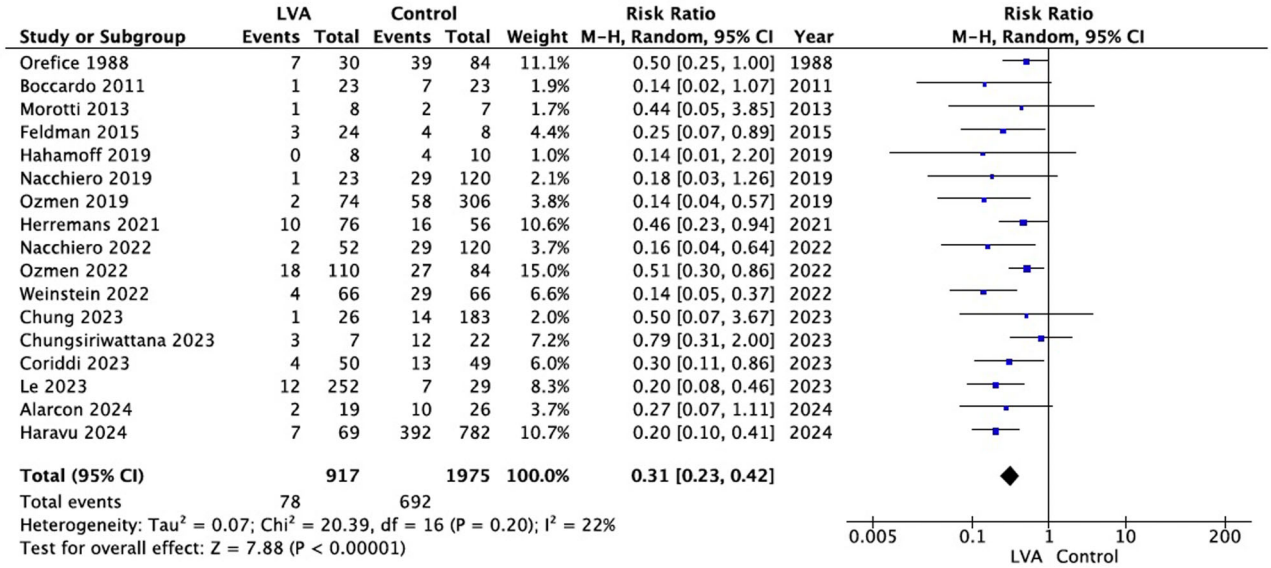

FIGURE 2 | This forest plot illustrates the pooled risk ratio (RR) with 95% confidence intervals (CI) for the incidence of secondary lymphedema in patients undergoing immediate LVA compared to controls. Each included study is represented as a data point, with the horizontal lines indicating the confidence interval and the size of the square reflecting the study weight. The diamond at the bottom represents the overall effect estimate. The meta-analysis demonstrates a significant reduction in secondary lymphedema risk in the LVA cohort (RR: 0.31, 95% CI: 0.23–0.42, $p < 0.00001$), indicating that immediate LVA is associated with a 69% lower risk of developing lymphedema compared to standard oncologic surgery alone. Heterogeneity analysis ($I^2 = 22\%$, $p = 0.20$) suggests low variability among included studies.

95% CI: 0.13–0.98, $p = 0.05$) (Figure 3). There were 7 patients who developed secondary lymphedema out of 90 LVA patients (7.78%), compared to 72 patients in 269 control group patients (26.77%). Heterogeneity was moderate ($I^2 = 46\%$, $p = 0.14$), suggesting some variability among included studies (Figure 4).

3.5 | Risk of Bias and Quality Score

The risk of bias and quality assessment for the included studies were conducted using the D&B checklist. Of the 39 studies evaluated, the mean (SD) D&B score was 19.72 (2.87) (Table S1). This means the average score was "Good" as there was a mix of case series, retrospective, and prospective cohort. The mean ASPS LOE (SD) was 3.31 (0.89). All studies received between 2 and 4 for LOE.

4 | Discussion

Although immediate LVA has garnered recent popularity, the overall effectiveness of this procedure being routinely used in preventing secondary lymphedema remains uncertain. In our meta-analysis, we find that immediate LVA at time of lymphadenectomy was associated with a reduction in the risk of secondary lymphedema across every oncological patient

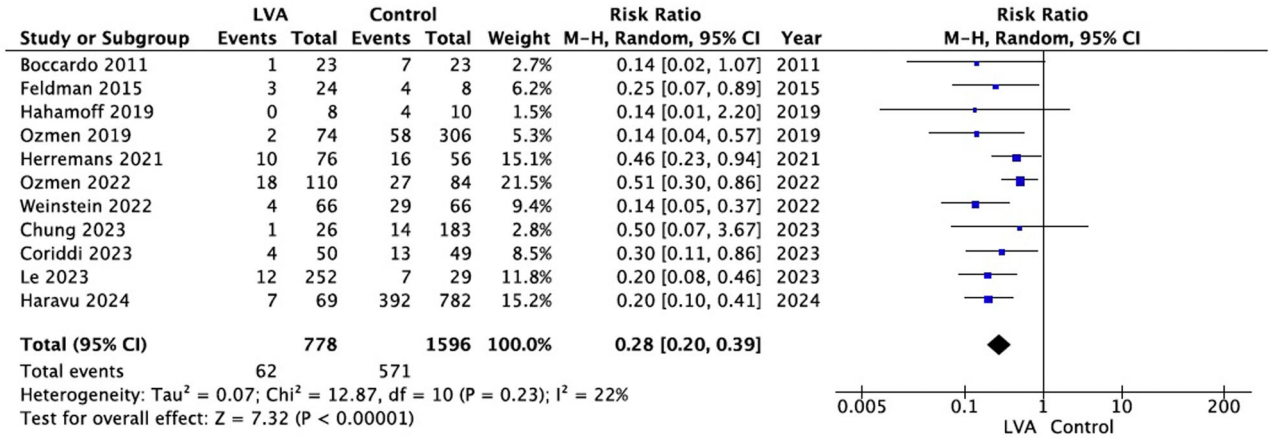

FIGURE 3 | This forest plot presents the pooled risk ratio (RR) with 95% confidence intervals (CI) for the development of secondary lymphedema after mastectomies with immediate lymphovenous anastomosis (LVA) compared to those who did not receive LVA. Each study is represented as a square, with the horizontal lines denoting the confidence interval, while the size of the square reflects the study's weight in the analysis. The diamond at the bottom represents the overall effect estimate. The meta-analysis indicates a significant reduction in lymphedema risk for the LVA cohort (RR: 0.28, 95% CI: 0.20–0.39, $p < 0.00001$), demonstrating a 72% lower risk of developing secondary lymphedema compared to controls. Heterogeneity analysis ($I^2 = 22\%$, $p = 0.23$) suggests a low degree of variability across included studies.

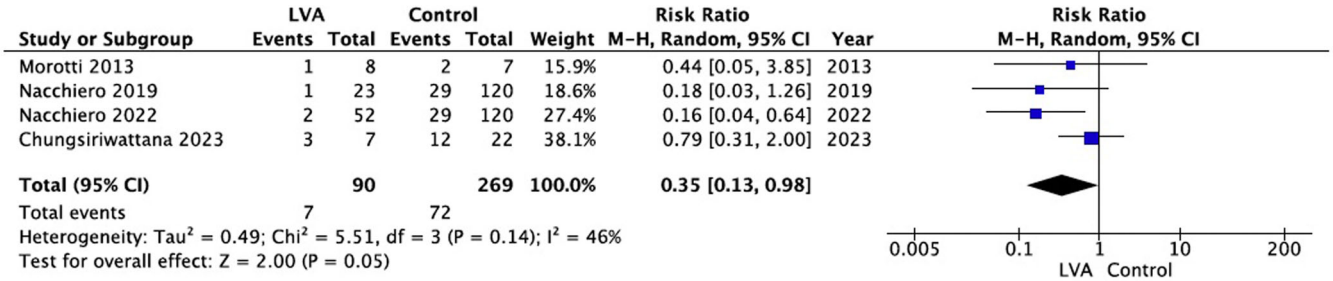

FIGURE 4 | This forest plot displays the pooled risk ratio (RR) with 95% confidence intervals (CI) for the incidence of secondary lymphedema in patients undergoing immediate lymphovenous anastomosis (LVA) following lymphadenectomy for dermatologic malignancies, including melanoma and squamous cell carcinoma. Each included study is represented by a square, with horizontal lines indicating the confidence interval, while the size of the square reflects the study's weight in the analysis. The diamond at the bottom represents the overall effect estimate. The meta-analysis demonstrates a significant reduction in lymphedema risk for the LVA cohort (RR: 0.35, 95% CI: 0.13–0.98, $p = 0.05$), indicating a 65% lower risk of developing secondary lymphedema compared to controls. Heterogeneity analysis ($I^2 = 46\%$, $p = 0.14$) suggests moderate variability among included studies.

population studied. These findings suggest that immediate LVA is beneficial in reducing the risk of secondary lymphedema after surgical treatment of a malignancy.

4.1 | Biologic Rationale for Immediate Lymphovenous Anastomosis

The pathophysiology of secondary lymphedema is driven by the disruption of lymphatic drainage pathways following oncologic lymphadenectomy, leading to chronic fluid stasis, inflammation, and fibrosis [56]. Once fibrosis sets in, lymphatic function is irreversibly compromised, limiting the effectiveness of delayed interventions [57]. Our findings indicate that immediate LVA mitigates this process by establishing direct lymphatic-to-venous bypasses, ensuring uninterrupted lymphatic flow postoperatively. Biologically, LVA prevents lymphatic endothelial apoptosis and vessel regression, mechanisms that contribute to progressive lymphatic failure [58]. Studies have demonstrated that early restoration of lymph flow sustains vessel integrity and reduces inflammatory signaling, ultimately promoting long-term lymphatic remodeling and function preservation [59–61]. Our subgroup analysis confirms that immediate LVA is effective in minimizing risk of secondary lymphedema in both breast and dermatologic malignancies, supporting the hypothesis that earlier intervention leads to superior outcomes.

Additionally, LVA may counteract radiotherapy-induced lymphatic damage, as 78.92% of patients in the LVA cohort had received adjuvant radiotherapy; yet, this cohort still exhibited significantly lower lymphedema rates compared to controls whom also had a high frequency of adjuvant radiotherapy use. This suggests that LVA provides a protective effect even in patients with additional risk factors, reinforcing its role as a key adjunct to oncologic surgery.

4.2 | Impact of Lymphovenous Anastomosis on Quality of Life and Patient-Reported Outcomes

Secondary lymphedema significantly reduces health-related quality of life, leading to chronic limb swelling, physical

discomfort, restricted mobility, and psychological distress [62–64]. While none of the studies included in the meta-analysis directly reported on quality of life measures, it has been shown in the literature how microsurgical treatments improve quality of life for those with breast cancer-related lymphedema [65–67]. Our study adds to the growing body of evidence demonstrating that patients who undergo immediate LVA report 26.53% risk reduction in symptoms associated with lymphedema due to its prevention.

Additionally, our analysis contributes to the research around the economic burden of secondary lymphedema, as lifelong management strategies—such as manual lymphatic drainage, compression therapy, and physical therapy—incur significant costs and impose long-term limitations on patients [68–70]. By substantially lowering the incidence of lymphedema, immediate LVA reduces dependency on conservative management, translating to lower long-term healthcare costs and improved patient autonomy.

4.3 | Lymphovenous Anastomosis in Sentinel Lymph Node Biopsy and Axillary Dissection

Within breast cancer treatment, sentinel lymph node biopsy (SLNB) and axillary lymph node dissection (ALND) cause direct trauma to the lymphatic system, with ALND carrying a particularly high risk of lymphedema due to extensive nodal clearance [71, 72]. Despite its less invasive nature, some studies have highlighted that SLNB can still result in subclinical lymphatic dysfunction, which may progress to symptomatic lymphedema over time [73]. Amongst the included studies in this review, all LVAs were conducted after ALND or other forms of lymphadenectomy, not after SLNB alone or with mastectomy. Additionally, all ALNDs and lymphadenectomies in this study were done during the same procedure. While we are unable to highlight its benefits amongst those patients that received SLNB, our study highlights the importance of integrating LVA in procedures that dissect lymph nodes. LVA can be helpful particularly in treating patients with additional risk factors which are known to increase risk of lymphedema such as high nodal burden cancer, obesity, or adjuvant radiation therapy [74–77]. Immediate LVA at the time of ALND offers a practical solution by rerouting lymphatic fluid into the venous circulation, preventing stagnation and inflammatory changes that lead to chronic lymphedema. Given our findings of a 27.81% risk reduction in breast cancer patients, LVA should be strongly considered as a standard adjunct for all patients undergoing ALND within their breast cancer treatment.

4.4 | Immediate Lymphovenous Anastomosis in Different Malignancies

The risk reduction associated with immediate LVA in preventing secondary lymphedema appears to vary by oncological malignancy, highlighting potential differences in pathophysiology, surgical burden, and lymphatic compromise across malignancies. The differences in risk reduction may be attributable to distinct tumor biology, variations in lymphatic disruption, and surgical techniques used for different malignancies. For example, breast cancer surgeries often involve axillary lymphadenectomy, where LVA may provide more consistent lymphatic drainage restoration, whereas dermatologic malignancies can require inguinal or cervical lymphadenectomy, which may introduce greater variability in lymphatic reconstruction efficacy. These findings reinforce the importance of considering malignancy-specific factors when evaluating LVA's role in lymphedema prevention.

4.5 | Study Quality, Limitations, and Future Directions

Despite the strength of our meta-analysis, several limitations must be acknowledged. Most included studies were retrospective cohort studies, thereby introducing selection bias and limiting the ability to establish causal relationships. Additionally, only a small number of randomized controlled trials have assessed prophylactic LVA, emphasizing the need for prospective, multi-institutional trials to further validate these findings. Heterogeneity in surgical technique, patient selection, and follow-up duration also presents a challenge. Future studies should focus on standardizing anastomotic techniques, vein caliber selection, and postoperative monitoring to optimize LVA outcomes. Furthermore, multiple year long-term follow-up data is limited, highlighting the need for extended studies assessing late-onset lymphedema development. Additionally, quality of life assessments should be utilized to assess decrease in morbidity associated with immediate LVA. Despite these limitations, this study differs from previous systematic reviews and meta-analyses in several keyways. First, it includes the largest sample size to date, incorporating a broader and more comprehensive data set that enhances statistical power and generalizability. Additionally, this study integrates more recent studies, reflecting advancements in surgical techniques, patient selection, and postoperative management. Secondly, we stratify the results based on malignancy type, specifically analyzing outcomes by both breast and dermatologic malignancies. Prior reviews have primarily focused on breast, limiting their ability to assess potential differences in efficacy across various other oncologic populations.

5 | Conclusion

This systematic review and meta-analysis provide compelling evidence that immediate LVA significantly reduces secondary lymphedema risk across oncological indications, with the most pronounced benefit observed in breast cancer patients. While some view LVA as only an experimental technique, this study highlights the potential of LVA to be the standard of care when lymphadenectomy occurs in oncological reconstruction. This study shows LVA as an effective intervention that significantly reduces lymphedema risk. Despite inherent study limitations, the findings strongly support the clinical utility of LVA as a preventative strategy. Future research should prioritize randomized trials and standardized surgical techniques to refine patient selection and optimize long-term outcomes.

Ethics Statement

Study is nonhuman subjects research and didn't require IRB approval.

Conflicts of Interest

The authors declare no conflicts of interest.

Data Availability Statement

The study was registered on PROPSERO and data is accessible at https://www.crd.york.ac.uk/PROSPERO/ (Record: CRD42025642808). Any additional details regarding the data analysis is available upon request from the authors.

NICE guidance

Lymphovenous anastomosis during axillary or inguinal node dissection for preventing secondary lymphoedema

Interventional procedures guidance
Published: 16 April 2024

www.nice.org.uk/guidance/ipg785

Your responsibility

This guidance represents the view of NICE, arrived at after careful consideration of the evidence available. When exercising their judgement, healthcare professionals are expected to take this guidance fully into account, and specifically any special arrangements relating to the introduction of new interventional procedures. The guidance does not override the individual responsibility of healthcare professionals to make decisions appropriate to the circumstances of the individual patient, in consultation with the patient and/or guardian or carer.

All problems (adverse events) related to a medicine or medical device used for treatment or in a procedure should be reported to the Medicines and Healthcare products Regulatory Agency using the Yellow Card Scheme.

© NICE 2024. All rights reserved. Subject to Notice of rights (https://www.nice.org.uk/terms-and-conditions#notice-of-rights).

Commissioners and/or providers have a responsibility to implement the guidance, in their local context, in light of their duties to have due regard to the need to eliminate unlawful discrimination, advance equality of opportunity, and foster good relations. Nothing in this guidance should be interpreted in a way that would be inconsistent with compliance with those duties. Providers should ensure that governance structures are in place to review, authorise and monitor the introduction of new devices and procedures.

Commissioners and providers have a responsibility to promote an environmentally sustainable health and care system and should assess and reduce the environmental impact of implementing NICE recommendations wherever possible.

1 Recommendations

Breast cancer

1.1 Lymphovenous anastomosis during axillary dissection for preventing secondary lymphoedema in adults with breast cancer can be used in the NHS while more evidence is generated. It can only be used with special arrangements for clinical governance, consent, and audit or research.

1.2 Clinicians wanting to do lymphovenous anastomosis during axillary node dissection for preventing secondary lymphoedema in people with breast cancer should:

- Inform the clinical governance leads in their healthcare organisation.
- Ensure that people (and their families and carers as appropriate) understand the procedure's safety and efficacy, and any uncertainties about these.
- Take account of NICE's advice on shared decision making, including NICE's information for the public.
- Audit and review clinical outcomes of everyone having the procedure. The main efficacy and safety outcomes identified in this guidance can be entered into NICE's interventional procedure outcomes audit tool (for use at local discretion).
- Discuss the outcomes of the procedure during their annual appraisal to

© NICE 2024. All rights reserved. Subject to Notice of rights (https://www.nice.org.uk/terms-and-conditions#notice-of-rights).

reflect, learn and improve.

1.3 Healthcare organisations should:

- Ensure systems are in place that support clinicians to collect and report data on outcomes and safety for everyone having this procedure.
- Regularly review data on outcomes and safety for this procedure.

1.4 Patient selection should be done by a multidisciplinary team experienced in managing the condition.

1.5 This procedure should only be done by a multidisciplinary team experienced in it, including a surgeon with specific training in microvascular surgery.

Other cancers

1.6 More research is needed on lymphovenous anastomosis during axillary or inguinal node dissection for preventing secondary lymphoedema for other cancers in adults.

1.7 This procedure should only be done as part of a formal research study, and a research ethics committee needs to have approved its use.

More research

1.8 More research is needed on:

- patient selection
- quality of life
- longer-term outcomes for lymphoedema incidence in different conditions
- limb volume
- safety outcomes (including survival and metastatic cancer).

Why the committee made these recommendations

© NICE 2024. All rights reserved. Subject to Notice of rights (https://www.nice.org.uk/terms-and-conditions#notice-of-rights).

Evidence from clinical trials and observational studies suggests that the procedure reduces the risk of lymphoedema after axillary node dissection in people with breast cancer. It also suggests that there are no major safety concerns. While there are some limitations in the evidence, including a lack of quality-of-life data and long-term follow up, overall it is considered adequate. So, it can be used with special arrangements for breast cancer.

The evidence for the procedure's efficacy in other cancers (that is, lower limb cancers and malignant melanoma) is more limited. Also, there are some safety concerns about the risk of the cancer spreading after lymphatic vessels around the dissected lymph nodes have been rediverted to nearby veins. So, it should be used only in research for other cancers.

2 The condition, current treatments and procedure

The condition

2.1 Lymphoedema is the build-up of lymph fluid in a limb, causing swelling of that limb. It is a common complication after treatments for various cancers, and can be chronic and debilitating. The condition can severely damage the skin, and cause aching in or difficulty moving the affected limb. There can also be recurrent skin infections, needing frequent antibiotic use and sometimes hospitalisation.

Current treatments

2.2 There are no curative treatments but there are various treatments to help control the symptoms of lymphoedema. They aim to reduce swelling and infection while improving lymphatic flow in the body, and include:

- decongestive lymphatic therapy, which comprises compression garments, manual lymphatic draining, skin care, exercise and massage done with specialist help or alone by the person with lymphoedema
- the 2 surgical techniques, liposuction and lymphovenous anastomosis.

© NICE 2024. All rights reserved. Subject to Notice of rights (https://www.nice.org.uk/terms-and-conditions#notice-of-rights).

The procedure

2.3 This version of lymphovenous anastomosis is done during axillary or inguinal node dissection to reduce the risk of lymphoedema developing after surgery. This procedure, also known as LYMPHA (lymphatic microsurgical preventive healing approach), involves creating a bypass from the transected lymphatics to nearby veins. Before the node dissection, a dye is injected to map the lymphatic circulation from the arm or thigh. During the node dissection, the surgical team inserts the cut lymphatic vessels into a small branch of the axillary or saphenous veins with the aim of restoring normal lymph flow.

2.4 The standard LYMPHA technique is done by surgeons with microvascular experience, using an operating microscope and, typically, 9-0 to 12-0 sutures.

2.5 There is also a simplified technique known as S-LYMPHA, which can be done by surgeons without microsurgical training, without an operating microscope and using 7-0 sutures.

3 Committee considerations

The evidence

3.1 NICE did a rapid review of the published literature on the efficacy and safety of this procedure. This comprised a comprehensive literature search and detailed review of the evidence from 12 sources, which was discussed by the committee. The evidence included 4 systematic reviews, 1 randomised controlled trial, 1 prospective study and 6 retrospective cohort studies. It is presented in the summary of key evidence section in the interventional procedures overview. Other relevant literature is in the appendix of the overview.

3.2 The professional expert and the committee considered the key efficacy outcomes to be: a reduction in secondary lymphoedema and technical success of lymphovenous anastomosis.

3.3 The professional expert and the committee considered the key safety outcomes

© NICE 2024. All rights reserved. Subject to Notice of rights (https://www.nice.org.uk/terms-and-conditions#notice-of-rights).

to be: pain, bleeding, infection, overall survival and disease-free survival.

3.4 Patient commentary was sought but none was received.

Committee comments

3.5 Current treatments for lymphoedema, such as manual lymphatic drainage and compression garments, are often uncomfortable, time-consuming and need to be lifelong. This procedure has the potential to improve a person's quality of life and could have other benefits such as reduced hospitalisation.

3.6 There has been limited uptake of the lymphatic microsurgical preventive healing approach (LYMPHA) in the UK. The clinical expert explained that this is mainly because it needs to be done with specialist equipment by microsurgery-trained surgeons. There is a simplified version of the procedure (S-LYMPHA) that can be done by the operating breast surgeon (without microsurgical training) and does not need specialist equipment. But most of the evidence is for LYMPHA and not S-LYMPHA.

3.7 The clinical expert explained that lymphatic reconstruction may potentially increase the risk of metastatic disease if the procedure is done for lower limb (non-central) cancers such as malignant melanomas, and that more safety evidence is needed.

3.8 The clinical expert advised that studies with 5-year follow up are needed to better establish the safety and efficacy of the procedure.

3.9 Patient consent should include that additional operating time is needed for this procedure, and that it is still possible that lymphoedema may develop.

Section 7.0

Previously Discussed Items

Septoplasty for Breathing Issues Alone May 2026

Plain Language Summary:

A surgery to straighten the divider inside the nose (nasal septum) may help with breathing problems.

Medical studies show that the surgery helps only for more severe disease based on patient symptom scales. HERC staff propose two options for discussion: one would add coverage for nasal surgery for severe disease and the other would not.

Changes after public comment period:

One public comment was received on this topic from an OHP provider. The commentor supported coverage and provided CPT codes and guideline wording regarding rhinoplasty that should be covered if septoplasty alone is not sufficient. These CPT codes and substantially similar guideline wording would be covered/included if the option that would including adding coverage for septoplasty for breathing issues is approved. Therefore, no changes were made to the staff recommendation based on this comment.

Staff Analysis Summary:

Significant proposed changes or discussion items:

Staff propose discussing two options.

1) Do not add coverage for septoplasty for breathing issues alone.
2) Add coverage for severe cases when other treatments have not been effective.

Coverage Question:

Should recent coverage decisions regarding septoplasty be reconsidered particularly for patients with significant nasal breathing issues?

Question source:

Mendy Maccabee, MD ENT in Hood River and Anthem medical director

*CPT only copyright 2025 American Medical Association. All rights reserved.
** Current Dental Terminology © 2025 American Dental Association. All rights reserved

Background:

Reconstructive septoplasty is the surgical correction of defects and deformities of the nasal septum (partition between the nostrils) by altering, splinting or removing obstructive tissue while maintaining or improving the physiological function of the nose. Cosmetic rhinoplasty and/or septoplasty are performed solely to enhance appearance. However, Dr. Maccabee says that rhinoplasty or rhinoseptoplasty is sometimes needed in order to perform septoplasty.

Septoplasty can also be performed for a variety of medical indications. Septoplasty is currently not covered on the Prioritized List for breathing issues alone. Septoplasty is covered for patients with chronic sinusitis so that surgeons can access the sinuses in order to treat the sinusitis. Dr. Maccabee is requesting reconsideration of lack of coverage of septoplasty or rhinoseptoplasty for inability to breathe through the nose.

Rhinoplasty and septoplasty were discussed as part of the BUP ENT review, with final decisions made at the June 2025 VBBS/HERC meeting. Septoplasty was again discussed at the March 2026 VBBS/HERC meetings. In March, members requested that the two septoplasty issues, breathing alone and CPAP tolerance, be separated and the discussion from the EBGS/HERC discussion of septoplasty from the BUP review be summarized.

The Sino-Nasal Outcome Test (SNOT-22) and Nasal Obstruction and Septoplasty Effectiveness scale (NOSE) are standard symptom measurement instruments for breathing issues.

Previous HSC/HERC reviews:

HERC staff recommendations for the June 2025 EBGS/HERC meeting was to include coverage of septoplasty for inability to breathe through the nose. Committee members disagreed and requested that the section of the guideline referring to this indication (currently on an uncovered line) be deleted. From the June 2025 EBGS minutes:

> Septoplasty and rhinoplasty: members were concerned with adding coverage for nasal obstruction as this condition is more of an irritation rather than a medical problem, and removed the section about nasal obstruction from the

*CPT only copyright 2025 American Medical Association. All rights reserved.
** Current Dental Terminology © 2025 American Dental Association. All rights reserved

> guideline…A procedure code for nasal valve repair was recommended for the Not Medically Necessary file

The June EBGS discussion did not include any evidence review of septoplasty for breathing issues.

At the March 2026 VBBS and HERC meetings, RCT data on breathing outcomes after septoplasty compared to optimal medical management was reviewed. Expert guidelines were also reviewed.

Current Prioritized List/Coverage status:

ICD-10-CM J34.2 (Deviated nasal septum) is on line 562 DEVIATED NASAL SEPTUM, ACQUIRED DEFORMITY OF NOSE, OTHER DISEASES OF UPPER RESPIRATORY TRACT

CPT *30520 (Septoplasty or submucous resection, with or without cartilage scoring, contouring or replacement with graft) is on lines

> 42 CLEFT PALATE WITH AIRWAY OBSTRUCTION
> 119 CHOANAL ATRESIA
> 244 LIFE-THREATENING EPISTAXIS
> 285 CANCER OF ORAL CAVITY, PHARYNX, NOSE AND LARYNX
> 309 GENDER AFFIRMING TREATMENT
> 464 CHRONIC SINUSITIS
> 495 NASAL POLYPS, OTHER DISORDERS OF NASAL CAVITY AND SINUSES
> 512 BENIGN NEOPLASM OF NASAL CAVITIES, MIDDLE EAR AND ACCESSORY SINUSES
> 562 DEVIATED NASAL SEPTUM, ACQUIRED DEFORMITY OF NOSE, OTHER DISEASES OF UPPER RESPIRATORY TRACT
> 599 ANOMALIES OF RELATIONSHIP OF JAW TO CRANIAL BASE, MAJOR ANOMALIES OF JAW SIZE, OTHER SPECIFIED AND UNSPECIFIED DENTOFACIAL ANOMALIES
> 625 TMJ DISORDERS

CPT *30620 (Septal or other intranasal dermatoplasty (does not include obtaining graft)) is on lines 42, 244, 464, 495, and 562

*CPT only copyright 2025 American Medical Association. All rights reserved.
** Current Dental Terminology © 2025 American Dental Association. All rights reserved

CPT *30420 (Rhinoplasty, primary; including major septal repair) is on lines 309, 464, 495, and 562

Beginning 1/1/2027 with the BUP Prioritized List, CPT *30420 will be in the code group RHINOPLASTY AND SEPTOPLASTY AND CHRONIC SINUSITIS SURGERY. ICD-10-CM J34.2 will also be in code group RHINOPLASTY AND SEPTOPLASTY AND CHRONIC SINUSITIS SURGERY. CPT *30520 and 30620 will be placed only on currently covered lines with BUP.

Current Prioritized List guideline:

GUIDELINE NOTE 118, SEPTOPLASTY

Lines 42,119,201,244,285,309,464,495,512,562

Septoplasty is included on Line 309 for gender affirming treatment.

Septoplasty is included on Lines 42, 119, 201, 244, 285, 464, 495, 512 and 562 when

A) The septoplasty is done to address symptomatic septal deviation or deformity which
   1) Fails to respond to a minimum 6-week trial of conservative management (e.g. nasal corticosteroids, decongestants, antibiotics); AND
   2) Results in persistent or recurrent epistaxis, OR documented recurrent sinusitis felt to be due to a deviated septum and the patient meets criteria for sinus surgery in Guideline Note 35, SINUS SURGERY; OR
B) Septoplasty is performed in association with cleft lip or cleft palate repair or repair of other congenital craniofacial anomalies; OR
C) Septoplasty is performed as part of a surgery for a neoplasm or facial trauma involving the nose.

Septoplasty for other nasal obstruction not meeting the criteria above is included only on Line 562.

Septoplasty is not included on these lines for treatment of obstructive sleep apnea and is not included on Line 201 SLEEP APNEA, NARCOLEPSY, INSOMNIA, HYPERSOMNIA, AND REM BEHAVIORAL DISORDER.

BUP guideline

COVERAGE GUIDELINE ~~NOTE~~ 118, SEPTOPLASTY

Code Groups ~~Lines~~ 42,119,201,244,285,309~~,463,499,518,570~~, 499 10XXX RHINOPLASTY AND SEPTOPLASTY AND CHRONIC SINUSITIS SURGERY

Septoplasty is medically necessary ~~included on Line 309~~ for gender affirming treatment.

Septoplasty is medically necessary ~~included on Lines 42, 119, 201, 244, 285, 463, 499, 518 and 570~~ when

A) The septoplasty is done to address symptomatic septal deviation or deformity which
   1) Fails to respond to a minimum 6-week trial of conservative management (e.g. nasal corticosteroids, decongestants, antibiotics); AND
   2) Results in one or more of the following:
      a) Persistent or recurrent epistaxis, OR
      b) Documented recurrent sinusitis felt to be due to a deviated septum and the patient meets criteria for sinus surgery in Coverage Guideline ~~Note~~ 35, SINUS SURGERY~~; OR~~
      c) ~~Nasal obstruction with documented absence of other causes of obstruction likely to be responsible for the symptoms (for example, nasal polyps, tumor, etc.) [note: this indication is included only on Line 570; OR~~
B) Septoplasty is performed in association with cleft lip or cleft palate repair or repair of other congenital craniofacial anomalies; OR
C) Septoplasty is performed as part of a surgery for a neoplasm or facial trauma involving the nose.

Septoplasty is not ~~covered~~ medically necessary for treatment of obstructive sleep apnea and is not included in code grouping ~~on Line~~ 201 SLEEP APNEA, NARCOLEPSY, INSOMNIA AND REM BEHAVIORAL DISORDER.

Date of last review: June 2025

GUIDELINE NOTE 216, RHINOPLASTY

Lines 42,119,201,244,285,309,464,495,512

Rhinoplasty is included on Line 309 for gender affirming treatment.

Rhinoplasty is included on Lines 42 and 119 when

*CPT only copyright 2025 American Medical Association. All rights reserved.
** Current Dental Terminology © 2025 American Dental Association. All rights reserved

A) It is performed to correct a nasal deformity secondary to congenital cleft lip and/or palate or other severe congenital craniofacial anomaly.

B) Rhinoplasty is included on Lines 227, 285, 495, 512 and 562 when it is performed as part of reconstruction after accidental or surgical trauma or disease (for example, Wegener's granulomatosis, nasal malignancy, abscess, septal infection with saddle deformity) AND

1) There is prolonged, persistent obstructed nasal breathing unresponsive to a six-week trial of conservative management (e.g. nasal corticosteroids, decongestants, antibiotics); AND
2) Airway obstruction will not respond to septoplasty and turbinectomy alone; AND
3) Photographs demonstrate an external nasal deformity; AND
4) There is significant obstruction of one or both nares, documented by nasal endoscopy, computed tomography (CT) scan or other appropriate imaging modality.

C) Rhinoplasty is included on Line 464 when there is nasal airway obstruction causing chronic rhinosinusitis when all of the following are met:

1) The criteria for sinus surgery are met in Guideline Note 35, SINUS SURGERY; AND
2) Airway obstruction will not respond to septoplasty and turbinectomy alone; AND
3) Photographs demonstrate an external nasal deformity; AND
4) There is significant obstruction of one or both nares, documented by nasal endoscopy, computed tomography (CT) scan or other appropriate imaging modality

Care for acute nasal fractures (up to 14 days from the injury) is included on Line 227. Sequalae of nasal fractures, including nasal deformities, are included on Line 562.

Evidence:

Effectiveness of septoplasty for breathing issues alone

*CPT only copyright 2025 American Medical Association. All rights reserved.
** Current Dental Terminology © 2025 American Dental Association. All rights reserved

1) **Carrie 2023**: Clinical effectiveness of septoplasty versus medical management for nasal airways obstruction: multicentre, open label, randomised controlled trial
    a. NAIROS trial, funded by the National Institute for Health and Care Research (NIHR) Health Technology Assessment programme in the UK
    b. N=307 adults with symptoms of nasal obstruction associated with septal deviation and at least moderate symptoms of nasal obstruction (score >30 out of 100 on the Nasal Obstruction and Symptom Evaluation (NOSE) scale). The NOSE scale is an patient survey that can help measure how a patient's breathing symptoms are affecting your quality of life.
        i. N=152 in surgical group at 6 months post-op (4 did not receive surgery). Some of these patients also received inferior nasal turbinate reduction, which is covered on the Prioritized List for the same conditions as septoplasty.
        ii. N=155 in the medical management group (5 received septoplasty)
            1. Participants randomized to receive medical management were supplied with six months' supply of isotonic nasal saline spray (Sterimar; Sofibel, Paris, France) to be used twice daily, and mometasone furoate nasal steroid spray to be used twice daily after the saline spray and then 100 µg twice daily for six weeks, then reduced to 100 µg once daily or 50 µg twice daily for the remainder of the six months.
            2. Participants could cross-over to septoplasty at 6 months
    c. **Six month outcomes:** Patient reported symptoms improved in both groups. In those participants randomized to receive septoplasty in the ITT population (n=152), mean SNOT-22 scores were 44.5 (95% confidence interval 41.1 to 47.8) at baseline and 19.9 (17.0 to 22.7) at six months. The corresponding scores for those participants randomized to receive medical management in the ITT population (n=155) were 44.1 (40.8 to 47.4) and 39.5 (36.1 to 42.9). Participants randomized to the septoplasty group (n=188) reported on average a greater improvement of 20.0 units over those randomized to the medical management group (n=190) (95% confidence interval improvement 16.4 to 23.7). Patients with moderate NOSE scores (less than 50) did not have a clinically-significant improvement in SNOT scores, but those with higher NOSE scores (severe, or extreme) did.

*CPT only copyright 2025 American Medical Association. All rights reserved.
** Current Dental Terminology © 2025 American Dental Association. All rights reserved

i. Minimally clinically important change in SNOT score=9 points
ii. Note: SNOT is a subjective test of self reported physical and emotional symptoms and sleep, which is different from the NOSE scale used for patient inclusion criteria.

d. **12-month outcomes (crossover was allowed; 5 of 155 crossed over and received septoplasty):** The mean SNOT-22 score in the septoplasty group was 21.2 (95% confidence interval 17.7 to 24.6) at 12 months, whereas the corresponding values in the medical management group were 30.4 (26.6 to 34.3). Participants randomized to the septoplasty group (n=119) reported on average 10.1 units greater improvement in symptoms at 12 months compared with those randomized to the medical management group (n=125), as measured by SNOT-22 (95% confidence interval improvement 5.6 to 14.5, P<0.001). The study did not report whether effect size was different for patients with more severe symptoms at 12 months.
    i. MCID SNOT-22 score is 9 points
        1. Quality of life and symptom measures are both components of SNOT-22

e. Serious adverse events
    i. N=14 (out of 188) in the septoplasty group
    ii. N=9 (out of 190) in the medical management group
    iii. seven readmissions with bleeding (4% of 174 participants who underwent septoplasty), 20 infections requiring antibiotics (12%), 19 reported events of altered sense of smell (11%), 18 events of upper teeth numbness (11%), 17 reported changes in the appearance of the nose (10%), 7 clinician observed adhesions (4%), and 6 clinician observed septal perforations (3%). No participants required repeat surgery

f. Authors conclusions: Septoplasty is a superior treatment for nasal obstruction associated with septal deviation compared with a defined regimen of nasal steroid and saline sprays. Baseline NOSE scores can estimate the likely improvement in symptoms and guide decision making for patients and clinicians. The authors recommend that adults presenting with nasal obstruction associated with a deviated nasal septum should be offered septoplasty

*CPT only copyright 2025 American Medical Association. All rights reserved.
** Current Dental Terminology © 2025 American Dental Association. All rights reserved

g. HERC staff note: clinically meaningful improvement in subjective SNOT-22 score only found for patients with initial NOSE scores in the severe range or higher (>50)

2) **Srinivasan 2021**: Comparison of the Efficacy of Septoplasty with Nonsurgical Management in Improving Nasal Obstruction in Patients with Deviated Nasal Septum – A Randomized Clinical Trial
   a. No reported funding source
   b. N=140 patients randomized, 117 with 6 month follow up data
      i. N=60 septoplasty group with 6 month follow up
         1. Baseline SNOT-22 score 19.5 (12-24.5), indicating mild to moderate disase
      ii. N=57 medical management (fluticasone, nasal decongestant, other medications) with 6 month follow up
         1. Baseline SNOT-22 score 15 (10-22), indicating mild to moderate disease
   c. At 6 month follow up
      i. VAS score surgical group 2.9 (1) vs non-surgical group 5.26 (2.3), P=0.001
      ii. SNOT-22 score surgical group 10 (8-16) vs non-surgical group 12 (8-20), P=0.002
         1. MCID SNOT-22 score is 8.9 points
   d. Authors' conclusions: Surgical correction of DNS by septoplasty improves nasal obstruction better than nonsurgical management at 6 months postsurgery. Note: the difference was not clinically significant in this cohort of patients, who had mild to moderate SNOT scores before surgery.

3) **Van Egmond 2019** Septoplasty with or without concurrent turbinate surgery versus non-surgical management for nasal obstruction in adults with a deviated septum: a pragmatic, randomized controlled trial
   a. Funded by the Netherlands Organisation for Health Research and Development
   b. N=197 adults with symptoms of nasal obstruction associated with septal deviation
      i. N=97 in surgical group

*CPT only copyright 2025 American Medical Association. All rights reserved.
** Current Dental Terminology © 2025 American Dental Association. All rights reserved

1. Mean SNOT-22 score 64.1 (SD 15.0) (These scores were inverted on a 100-point scale and represent moderate disease, equivalent scoring to the studies above would be 35.9 (SD 15.0) or moderate disease for the mean group, with the standard deviation including mild disease))

ii. N=100 in the control group (watchful waiting or medical management)

1. Non-surgical management did not involve a prespecified treatment regime. Medications could be used
2. 30 patients actually had septoplasty
3. Mean SNOT-22 score 62.1 (SD 16.4) (These scores were inverted on a 100-point scale and represent moderate disease, equivalent scoring to the studies above would be 37.9 (SD 16.4) or moderate disease in the mean group with the standard deviation including mild to severe disease)

c. At our primary timepoint of 12 months, the mean Glasgow Health Status Inventory (GHSI) score of patients assigned to septoplasty was 72.2 (SD 12.2) and to non-surgical management was 63.9 (SD 14.5; mean difference 8.3 [95% CI 4.5–12.1]). The Glasgow Health Status Inventory is a broader measure of quality of life than the NOSE or SNOT score. It is patient reported and includes measures of general health, social health and physical health related to conditions treated by ENTs. Higher scores indicate better perceived health status and the score ranges from 0 to 100. This study inverted the GHSI score, making 100 no symptoms and 0 severe symptoms.

i. MCID for the GHSI is 35-44 points, making these changes not clinically significant

d. At 12 months, the NOSE scale for the septoplasty group was 67.5 (SD 24.5) and the non-surgical group was 49.6 (SD 23.6). The surgical group score was reduced 36.2, which is clinically significant. The non-surgical group score was reduced by 15.2 points, which is not clinically significant. . (

i. Note: scales are inverted from standard reporting

e. At 12 months, the SNOT-22 score for the septoplasty group was 76.8 (SD 17.1) and the non-surgical group was 67.0 (SD 19.5). The surgical group

*CPT only copyright 2025 American Medical Association. All rights reserved.
** Current Dental Terminology © 2025 American Dental Association. All rights reserved

score was reduced 12.7, which is clinically significant. The non-surgical group score was increased by 4.9 points

i. Note: scales are inverted from standard reporting

f. Postoperative complications occurred in 23 (18%) patients who were assigned to septoplasty or had crossed-over to surgery. The most frequent complications were hemorrhage and infection (table 3); these complications occurred directly after surgery and were mild, meaning that patients either did not require treatment or could be treated at the outpatient clinic with nasal packing or local or oral antibiotics. Septal perforation occurred in two patients and septal abscess in one patient, who was hospitalized to receive intravenous antibiotics; consequently, the septal abscess was classified as a serious adverse event. No other serious adverse events related to the treatments under study occurred during the trial. No adverse events related to nasal medication were reported. Revision surgery because of persisting complaints was required in one patient

g. Authors conclusions: Septoplasty is more effective than non-surgical management for nasal obstruction in adults with a deviated septum and severe patient-reported breathing quality of life. This effect was sustained up to 24 months of follow-up

Submitted literature:

1) Alkholaiwi 2023: small retrospective cohort study (N=42) of qualify of life impacts of septoplasty
2) Hismi 2020: prospective cohort study of quality of life impacts of septoplasty
3) Han 2015: included in expert guidelines section below
4) Shedden 2005: phone survey of impact of nasal congestion on quality of life in patients with allergic rhinitis
5) Premara BCBS 2025 coverage policy for septoplasty: included in other payer policies section below

Expert guidelines:

1) **Han 2015** Clinical Consensus Statement: Septoplasty with or without Inferior Turbinate Reduction

*CPT only copyright 2025 American Medical Association. All rights reserved.
** Current Dental Terminology © 2025 American Dental Association. All rights reserved

a. Limited to adults (age 18 and older)
b. Septoplasty can be used in the primary management of obstructive sleep apnea for patients with deviated septum
c. Septoplasty can be effective in reducing primary snoring in patients with a deviated septum
d. Septoplasty can reduce facial pain caused by intranasal contact points
e. Septoplasty may benefit anosmia or hyposmia, but the effect is unpredictable
f. A trial of medical therapy .4 weeks' duration is unnecessary to assess surgical candidacy for septoplasty
g. Septoplasty can improve continuous positive air pressure tolerance for patients with sleep apnea and a deviated septum
h. Septoplasty may be useful in managing epistaxis
i. Septoplasty can improve quality of life for patients with septal deviation.
j. Septoplasty can improve outcomes of sinus surgery when the septum is contacting the middle turbinate and obstructing the drainage of the ostiomeatal complex

2) American Academy of Otolaryngology-Head and Neck Surgery 2012 Clinical Indicators: Septoplasty
   a. Available at https://www.entnet.org/resource/clinical-indicators-septoplasty/
      i. Accessed January 15, 2026
   b. History (one or more required)
      i. Nasal airway obstruction (unilateral or bilateral) causing any of the following: mouth breathing, snoring, nasal congestion, sleep apnea, unresponsive to medical management.
      ii. Frequent nosebleeds, unresponsive to medical management, and for which deviation is a causative factor.
      iii. Atypical facial pain of nasal origin. (Positive response to topical anesthetic, where deformed septum contacts a turbinate or lateral wall, supports, but may not prove, septal causation or contribution.)
      iv. Asymptomatic deformity that prevents surgical access to other intranasal or paranasal areas, e.g., sinuses, turbinates.

** Current Dental Terminology © 2025 American Dental Association. All rights reserved

Other payer policies:

1) Premara BCBS 2025
    a. Rhinoplasty may be considered medically necessary for nasal obstruction when the following criteria are met:
        i. Clinical findings of collapsed internal nasal valve at rest or collapsed external nasal valve (lateral walls) with inspiration (nasal vestibular stenosis) OR
        ii. To correct a nasal deformity secondary to trauma that is causing a significant functional impairment (e.g., nasal bone fracture causing nasal airway obstruction) AND
        iii. Individual has symptoms of nasal obstruction (difficulty breathing or chronic rhinosinusitis [inflammation/swelling of the nasal passages and/or sinus cavities]) affecting quality of life AND
        iv. Infection, allergy, rhinitis, and polyps have been ruled out as the primary cause of nasal obstruction as evidenced by:
            1. Obstructive symptoms persist despite conservative management for 8 weeks or greater with one of the following:
                a. Decongestants or antihistamines
                b. Nasal lavage
                c. Oral or intranasal steroids
                d. A course of antibiotics for rhinosinusitis
                e. Allergy assessment and treatment
2) Aetna 2025
    a. Aetna considers septoplasty medically necessary when *any* of the following clinical criteria is met:
        i. Asymptomatic septal deformity that prevents access to other intranasal areas when such access is required to perform medical necessary surgical procedures (e.g., ethmoidectomy); *or*
        ii. Documented recurrent sinusitis felt to be due to a deviated septum not relieved by appropriate medical and antibiotic therapy; *or*
        iii. Recurrent epistaxis (nose-bleeds) related to a septal deformity; *or*

*CPT only copyright 2025 American Medical Association. All rights reserved.
** Current Dental Terminology © 2025 American Dental Association. All rights reserved

iv. Septal deviation causing continuous nasal airway obstruction resulting in nasal breathing difficulty not responding to 4 or more weeks of appropriate medical therapy; *or*
v. When done in association with cleft palate repair.

3) NHS 2026
   a. Coverage criteria based on the NAIROS trial (Carrie 2024)
   b. Septoplasty covered for patients with
      i. severe symptoms on the NOSE (score 55 or higher) or SNOT-22 (score greater than 50) AND
      ii. Failure of trial of appropriate medical and conservative measures (intranasal corticosteroids and nasal irrigation for 3 months, avoidance of exacerbating factors, no use of nasal decongestants that cause rhinitis medicamentosa, and treatment of allergic or drug induced rhinitis if appropriate) AND
      iii. The severe nasal symptoms are associated with septal or nasal wall deformities or a clinical diagnosis of chronic sinusitis

Expert input:

Dr. Peggy Kelley, pediatric ENT

Indications for septoplasty for breathing are covered by commercial insurances. If a person has no response to medical therapy and is still unable to breathe through their nose secondary to a physical blockage of a deviated septum, a septoplasty is indicated. In fact, sometimes a septoplasty is needed to be able to get medical therapy to the turbinates. Nasal breathing is preferred over mouth breathing for more than cosmesis. The nose is set up to be a filter for our airway as well as to humidify and warm the air before reaching the lungs. These functions are only partially met with mouth breathing. Constant mouth breathing will decrease dental health as the teeth need to be bathed in saliva to breaks down the peridontal bacteria.

Dr. Sara Yang, OHSU adult ENT

A septoplasty is not a cosmetic procedure. It does not alter the outward appearance of the nose. Its function is to address an anatomical obstruction that physically obstructs nasal air flow.

Topical medical therapy or nasal saline rinses impact the mucosal layer. It is wonderful for addressing nasal congestion but not nasal obstruction. There is no evidence or published papers that topical therapy would improve a deviated septum (anatomical issue).

Therefore, when a physical exam reveals an anatomical obstruction that is impacting nasal breathing (resulting in detriments to sleep, exercise, or daily functions) or obstructs the placement of topical medication for chronic nasal or sinus conditions, I believe that a septoplasty should be covered by insurance. One corrective surgery may overall reduce the healthcare utilization burden by addressing the root cause of the issue.

HERC staff summary:

The majority of the literature on the impact of septoplasty on quality of life in patients with breathing difficulties consists of retrospective and prospective cohort studies. Three RCTs were identified by HERC staff that compared septoplasty to medical management/watchful waiting and reported on quality of life measures. An RCT of 307 adults found clinically meaningful improvement in the SNOT and SNOT-22 scores, which are subjective quality of life rating scales, in patients undergoing septoplasty, but not in patients with medical management at 6 months and 1 year. Of note, this clinically meaningful impact was only found in patients with severe disease at baseline. Similarly, an RCT of 117 adults did not find a clinically meaningful difference between surgical and medical groups in the SNOT-22 scores at 6 months in patients with mild to moderate disease. The third RCT of 197 adults with mild to moderate disease did not find a clinically significant improvement in quality of life with the Glasgow Health Status Inventory at 12 months between surgical and medical management but did find clinically significant improvement in the NOSE and SNOT-22 scores with surgery; of note, there was considerable cross-over of the medical group to surgery in this study which would tend to make the differences between groups smaller than expected. All three studies reported

*CPT only copyright 2025 American Medical Association. All rights reserved.
** Current Dental Terminology © 2025 American Dental Association. All rights reserved

significant adverse surgical events, including bleeding, abscess, need for repeat surgery, or readmission.

HERC staff conclude from this literature review that for patients with mild to moderate disease, there is mixed evidence that septoplasty is superior to medical management. However, in patients with more severe disease, septoplasty resulted in a clinically significant improvement in breathing symptoms compared to medical management. Serious complications from the surgery have been reported. The improvements seen with surgery are in patient reported outcomes.

Expert groups and Oregon experts recommend septoplasty for breathing issues. Private and public payers are covering septoplasty for this indication. The NHS is covering septoplasty for severe disease after a trial of medical management.

HERC staff propose two options for discussion. One is to make no change as the clinically significant impact of septoplasty is measured by a subjective score. The second is to adopt coverage for severe disease based on the Carrie 2023 study with wording added to the guideline based on NHS coverage policy.

HERC staff recommendation:

Consider the following options:

Option 1

Make no change in non-coverage of septoplasty for breathing issues alone

Option 2

A) Add ICD-10-CM J34.2 (Deviated nasal septum) to line 464 CHRONIC SINUSITIS and keep on line 562 DEVIATED NASAL SEPTUM, ACQUIRED DEFORMITY OF NOSE, OTHER DISEASES OF UPPER RESPIRATORY TRACT
B) Modify Guideline Note 118 as shown below [Note: additional changes to GN118 proposed in a separate issue summary]
C) Modify Guideline Note 216 as shown below

GUIDELINE NOTE 118, SEPTOPLASTY

*CPT only copyright 2025 American Medical Association. All rights reserved.
** Current Dental Terminology © 2025 American Dental Association. All rights reserved

Lines 42,119,201,244,285,309,464,495,512,562

Septoplasty is included on Line 309 for gender affirming treatment.

Septoplasty is included on Lines 42, 119, 201, 244, 285, 464, 495, 512 and 562 when

D) The septoplasty is done to address symptomatic septal deviation or deformity which
   1) Fails to respond to a minimum 6-week trial of conservative management (e.g. nasal corticosteroids, decongestants, antibiotics); AND
   2) Results in persistent or recurrent epistaxis, OR documented recurrent sinusitis felt to be due to a deviated septum and the patient meets criteria for sinus surgery in Guideline Note 35, SINUS SURGERY; OR
   4) Nasal obstruction with documented absence of other causes of obstruction likely to be responsible for the symptoms (for example, nasal polyps, tumor, etc.) for patients with
      a. Severe symptoms on the NOSE (score 55 or higher) or SNOT-22 (score greater than 50) AND
      b. Failure of trial of appropriate medical and conservative measures (intranasal corticosteroids and nasal irrigation for 3 months, avoidance of exacerbating factors, no use of nasal decongestants that cause rhinitis medicamentosa, and treatment of allergic or drug induced rhinitis if appropriate) AND
      c. The severe nasal symptoms are associated with septal or nasal wall deformities or a clinical diagnosis of chronic sinusitis; OR

E) Septoplasty is performed in association with cleft lip or cleft palate repair or repair of other congenital craniofacial anomalies; OR

F) Septoplasty is performed as part of a surgery for a neoplasm or facial trauma involving the nose.

Septoplasty for other nasal obstruction not meeting the criteria above is included only on Line 562.

Septoplasty is not included on these lines for treatment of obstructive sleep apnea and is not included on Line 201 SLEEP APNEA, NARCOLEPSY, INSOMNIA, HYPERSOMNIA, AND REM BEHAVIORAL DISORDER.

GUIDELINE NOTE 216, RHINOPLASTY

*CPT only copyright 2025 American Medical Association. All rights reserved.
** Current Dental Terminology © 2025 American Dental Association. All rights reserved

Lines 42,119,201,244,285,309,464,495,512

Rhinoplasty is included on Line 309 for gender affirming treatment.

Rhinoplasty is included on Lines 42 and 119 when

A) It is performed to correct a nasal deformity secondary to congenital cleft lip and/or palate or other severe congenital craniofacial anomaly.

B) Rhinoplasty is included on Lines 227, 285, 495, 512 and 562 when it is performed as part of reconstruction after accidental or surgical trauma or disease (for example, Wegener's granulomatosis, nasal malignancy, abscess, septal infection with saddle deformity) AND

1) There is prolonged, persistent obstructed nasal breathing unresponsive to a six-week trial of conservative management (e.g. nasal corticosteroids, decongestants, antibiotics); AND
2) Airway obstruction will not respond to septoplasty and turbinectomy alone; AND
3) Photographs demonstrate an external nasal deformity; AND
4) There is significant obstruction of one or both nares, documented by nasal endoscopy, computed tomography (CT) scan or other appropriate imaging modality.

C) Rhinoplasty is included on Line 464 when there is nasal airway obstruction causing chronic rhinosinusitis or nasal obstruction meeting Guideline Note 118 criteria when all of the following are met:

1) The criteria for sinus surgery are met in Guideline Note 35, SINUS SURGERY OR the criteria for septoplasty are met in Guideline Note 118 SEPTOPLASTY; AND
2) Airway obstruction will not respond to septoplasty and turbinectomy alone; AND
3) Photographs demonstrate an external nasal deformity; AND
4) There is significant obstruction of one or both nares, documented by nasal endoscopy, computed tomography (CT) scan or other appropriate imaging modality

Care for acute nasal fractures (up to 14 days from the injury) is included on Line 227.

Sequalae of nasal fractures, including nasal deformities, are included on Line 562.

A	I, first wanted to take a moment to recognize OHP's commitment to patients and access and the first step of bringing nasal obstruction treatment to patients at OHP with the authorization of septoplasty. It may seem trivial but the impact of being able to breath through ones	Thank you for your comments. The staff coverage option (new since the March meeting) which would add coverage for septoplasty also includes adding coverage for

ID/#	Comment	Disposition
	nose when you have not been able to for years is really impactful for your members. I see patient after patient post operatively who say, "I can not believe you did not suggest surgery for me YEARS ago…." They are a grateful set of patients; thank you. I do want to take this opportunity to focus on the original ask and the standard approach for all the commercial payors; the problem being addressed is nasal airway obstruction. Septoplasty is an approach and is only appropriate for septal deviation in the mid portion of the septum (please see Dr. Brennan's submitted slide deck for anatomical reference and have it available for us to revisit at the upcoming meeting). For patients who have blockage along the bridge of the nose and/or columella (part of the nose you pinch between your thumb and forefinger right in the front of the nose) we can not access the deviation via septoplasty alone. More importantly, we can not put the nose structurally back together with long term integrity via the septoplasty approach in these cases. For deviations in this location we must use the rhinoplasty approach (cpt code 30420) or nasal valve reconstruction code (cpt code 30465) sometimes with cadaver, rib or ear cartilage donor tissue cpt codes. I realize that there is a social concept that "rhinoplasty" is a cosmetic procedure. It is. AND, it is as or more often a functional approach. The code and its utilization should not be unfairly deemed exclusively a cosmetic procedure. It simply is not. OHP is going to set its fee schedule for these codes and I assure you that the risk will be that most providers will not accept OHP patients for these functional and life impacting procedures because they are technically challenging cases and time consuming. Historically	rhinoplasty when septoplasty is not sufficient. For that option, CPT 30420 and 30465 would pair with deviated nasal septum if the guideline criteria are met. The wording you propose "rhinoplasty is allowable when septoplasty alone is inadequate to address the obstruction" are substantially similar to guideline wording already in place. The HERC does not set fee schedules for OHP.

ID/#	Comment	Disposition
	speaking OHP fee schedules have not covered practice costs. I do not think it is good practice to 'not' write a fair and accurate policy because of a bias against a code based on inaccurate cultural perception or because patients wont have access anyway due to low reimbursement. For bariatric surgery OHSU and most programs limit OHP patients and the wait list is long for your patients to access the procedure but when they do the impact is immense. I think that allowing access for nasal airway obstruction via septoplasty or rhinoplasty thru documented need is the right thing to do. Even if patient have long waits they will eventually still have access to impactful care and the policy will be fairly and accurately written to modern standards of care. The typical wording in nasal airway obstruction policies is that rhinoplasty is allowable when septoplasty alone is inadequate to address the obstruction. I have included Drs. Brennan, Schindler and Yang here who I am guessing will all agree that the policy should be one that allows access to these two approaches for adequate for access to the level of obstruction and rebuilding of the nasal structure. Respectfully, Mendy S. Maccabee MD FACS FAAOA ENT, Sinus & Allergy Care

ABSTRACT

OBJECTIVE
To assess the clinical effectiveness of septoplasty.

DESIGN
Multicentre, randomised controlled trial.

SETTING
17 otolaryngology clinics in the UK's National Health Service.

PARTICIPANTS
378 adults (≥18 years, 67% men) newly referred with symptoms of nasal obstruction associated with septal deviation and at least moderate symptoms of nasal obstruction (score >30 on the Nasal Obstruction and Symptom Evaluation (NOSE) scale).

INTERVENTIONS
Participants were randomised 1:1 to receive either septoplasty (n=188) or defined medical management (n=190, nasal steroid and saline spray for six months), stratified by baseline symptom severity and sex.

MAIN OUTCOME MEASURES
The primary outcome measure was patient reported score on the Sino-Nasal Outcome Test-22 (SNOT-22) at six months, with 9 points defined as the minimal clinically important difference. Secondary outcomes included quality of life and objective nasal airflow measures.

RESULTS
Mean SNOT-22 scores at six months were 19.9 (95% confidence interval 17.0 to 22.7) in the septoplasty arm (n=152, intention-to-treat population) and 39.5 (36.1 to 42.9) in the medical management arm (n=155); an estimated 20.0 points lower (better) for participants randomised to receive septoplasty (95% confidence interval 16.4 to 23.6, P<0.001, adjusted for baseline continuous SNOT-22 score and the stratification variables sex and baseline NOSE severity categories). Greater improvement in SNOT-22 scores was predicted by higher baseline symptom severity scores. Quality of life outcomes and nasal airflow measures (including peak nasal inspiratory flow and absolute inhalational nasal partitioning ratio) improved more in participants in the septoplasty group. Readmission to hospital with bleeding after septoplasty occurred in seven participants (4% of 174 who had septoplasty), and a further 20 participants (12%) required antibiotics for infections.

CONCLUSIONS
Septoplasty is a more effective intervention than a defined medical management regimen with a nasal steroid and saline spray in adults with nasal obstruction associated with a deviated nasal septum.

TRIAL REGISTRATION
ISRCTN Registry ISRCTN16168569.

WHAT IS ALREADY KNOWN ON THIS TOPIC

In 2014, the UK National Institute for Health and Care Research commissioned a randomised controlled trial to address the lack of high quality evidence to support nasal septoplasty

A study in 2019 reported higher levels of general quality of life at 12 months in participants after septoplasty compared with those who received variable non-surgical management

In that study, score on the Sino-Nasal Outcome Test (SNOT-22) was a secondary outcome, with greater improvement observed in participants after septoplasty

WHAT THIS STUDY ADDS

Septoplasty is a clinically effective treatment for nasal obstruction associated with septal deviation compared with a defined regimen of nasal steroid and saline sprays

Participants who underwent septoplasty had greater improvement in nasal obstruction and quality of life, as measured using the SNOT-22 questionnaire

However, people with a deviated nasal septum and at least moderate nasal obstruction do tend to improve over time with medical treatment

Introduction

Septoplasty is a common operation to alleviate nasal obstruction associated with deviation of the nasal septum. It may be accompanied by reduction of the inferior turbinate to increase airflow through the nasal cavities. Surgery is typically predicated on clinical history and a visual assessment of the nasal septum. To date, no objective nasal airflow measures have proven definitively beneficial in the selection of patients. Despite the lack of an evidence base, in 2019/20 about 16 700 septoplasty procedures were performed in England[1] at an estimated cost of £15.9m ($19.9m; €18.5m) for the operations alone. More than 250 000 septoplasties are performed in the United States annually.[2]

Many UK clinical commissioning guidelines propose a trial of medical treatment before surgical referral.[3] Medical treatment usually entails intranasal steroid spray, although recommendations on dose and length

BMJ: first published as 10.1136/bmj-2023-075445 on 18 October 2023. Downloaded from https://www.bmj.com/ on 14 January 2026 by guest. Protected by copyright, including for uses related to text and data mining, AI training, and similar technologies.

of treatment are inconsistent. Some National Health Service commissioning bodies in England have placed septoplasty on a list of restricted treatments. Other healthcare providers will only routinely fund septoplasty for nasal obstruction that is causing documented medical problems, such as sleep or breathing disruption, and only after all non-surgical treatments have been tried.[4]

The Nasal Airways Obstruction Study (NAIROS) was designed to provide definitive evidence and recommendations for the clinical effectiveness of septoplasty, to inform guidance on which patients may benefit from this treatment, and to standardise treatment across the UK.

Methods

The Nasal Airways Obstruction Study was a multicentre, non-adaptive, open label randomised controlled trial conducted in 17 hospitals in the UK's NHS. The regional ethics committee approved the trial protocol.[5] Independent data monitoring and trials steering committees oversaw the trial.

Participants

Participants were adults (≥18 years) newly referred to otolaryngology clinics with symptoms of nasal obstruction associated with septal deviation and confirmed by endoscopic assessment. Participants were offered entry into the trial if their presenting Nasal Obstruction and Symptom Evaluation (NOSE)[6] score was ≥30 (out of a potential score of 100), with 30 defined as the cut-off to differentiate patients with nasal obstruction from those without.[7] We excluded participants with relevant systemic inflammatory diseases or previous septal surgery (see supplementary material for inclusion and exclusion criteria). All participants provided written informed consent.

Randomisation

The Newcastle Clinical Trials Unit Randomisation Service, an in-house bespoke internet based system, performed randomisation centrally using permuted random blocks of variable length. All allocations were generated by an automated process within the system. Participants were randomised 1:1 to receive either surgical intervention or medical management, stratified by sex and baseline severity of symptoms according to scores on the NOSE scale: 30-50 (moderate), 55-75 (severe), 80-100 (extreme).[7] Open label randomisation was administered centrally through the Newcastle University Clinical Trials Unit, using a secure web based system.

Interventions

Septoplasty—Participants randomised to septoplasty received surgery up to 12 weeks post-randomisation. The surgery was encouraged to take place within eight weeks of randomisation, with a further four weeks permissible for extenuating circumstances. Experienced surgeons not in training performed the surgery. Because septoplasty is a commonly performed procedure, data on individual surgeons was not collected, with the surgical team represented by the recruitment site within the analysis. As a pragmatic study, we permitted surgery for unilateral inferior turbinate reduction on the wider side at the discretion of the surgeon, reflecting the considerable variation in current UK surgical practice. Deviation of the septum often causes bilateral nasal obstruction as a result of the deviation blocking one side and the inferior turbinate becoming enlarged in the opposite nasal cavity. Surgical methods employed were the same as those used in standard surgical care at recruitment sites—the only stipulations being that the surgery had to be through a closed approach (that is, no external incisions), and no grafts were to be used. Surgeons were, however, allowed to adopt a variety of techniques to manipulate the nasal septum cartilage into place, and so overall results reflect the generality of current surgical practice. The only stipulation for the method used to perform the inferior turbinate reduction was that mucosal preserving techniques should be undertaken.

Medical management—Participants randomised to receive medical management were supplied with six months' supply of isotonic nasal saline spray (Sterimar; Sofibel, Paris, France) to be used twice daily, and mometasone furoate nasal steroid spray to be used twice daily after the saline spray and then 100 µg twice daily for six weeks, then reduced to 100 µg once daily or 50 µg twice daily for the remainder of the six months. Participants randomised to receive medical management were assured they would have the opportunity to discuss the option of septoplasty after the six month primary outcome time point.

Outcome measures

Primary outcome measure

The primary outcome measure was the score on the Sino-Nasal Outcome Test (SNOT-22) at six months (defined protocol time window −2 to 4 weeks for completion). SNOT-22 is a patient reported outcome measure that has been validated to assess symptoms related to chronic rhinosinusitis[8] but has been used to assess outcomes after septal surgery.[9] SNOT-22 comprises 22 items, each scored from zero to 5. The total score ranges from zero to 110, with higher scores indicating worse symptoms.

Secondary outcome measures

Four secondary patient reported outcome measures were assessed:

- SNOT-22 score at 12 months.
- SNOT-22 subscale (nose, sleep, ear/facial pain, psychological) score at baseline, six months, and 12 months.[8]
- Score on the NOSE scale at baseline, six months, and 12 months.[6] This scale comprises five items, each scored from zero to 4. The total score is multiplied by 5 to give an overall range from zero to 100, with higher scores indicating worse symptoms.

BMJ: first published as 10.1136/bmj-2023-075445 on 18 October 2023. Downloaded from https://www.bmj.com/ on 14 January 2026 by guest. Protected by copyright, including for uses related to text and data mining, AI training, and similar technologies.

- General quality of life, measured at baseline, six months, and 12 months using the physical component scores and mental component scores of the 36 item Short Form survey (SF-36), which assesses recall over the preceding week, with higher scores indicating better quality of life.[10] The scores are transformed into a range from zero to 100, with zero representing the worst possible health and 100 representing the best possible health.

Secondary clinical measures at baseline, six months, and 12 months were:

- The double ordinal airway subjective scale, which is a subjective comparator of right and left nasal patency,[11] with each nostril rated from 1 to 10, with higher scores indicating better airflow. The results are presented as the modulus of the absolute subjective double ordinal airway subjective scale=(left score−right score)/left score+right score)—that is, ignoring positive or negative results. Scores range from 0 to 1; scores closer to 0 indicating symmetrical nasal airways.
- Objective assessments of nasal patency after decongestant use, including peak nasal inspiratory flow, measured using a peak nasal inspiratory flow meter (GM Instruments, Kilwinning, UK).[12] Nasal partitioning ratio (using mean volumes from three maximal inhalation measurements, scored 0 to ±1, with 0 indicating symmetrical nasal airways and ±1 indicating complete left side (+1) and right side (−1) unilateral airflow), tidal volume, and maximal inhalation flow rate measured using a rhinospirometer (NV1 rhinospirometer; GM Instruments, Kilwinning, UK).
- An imbedded economic evaluation is to be reported separately in a future publication.

Statistical analysis

Analyses were performed according to a predetermined analysis plan.[13] Summary statistics of overall scores, including means with associated 95% confidence intervals, are presented. The primary intention-to-treat (ITT) analysis, whereby participants are retained in the arms to which they are randomised, was based on multivariable linear regression adjusted for baseline continuous SNOT-22 score and the stratification variables sex and baseline severity categories based on the NOSE scale (model 1). Goodness of fit for model 1 was assessed by a series of plots of residuals. We considered a two sided P<0.05 to be statistically significant.

The planned population defining analyses included an ITT analysis, a per protocol analysis, and a per treatment analysis.

ITT analysis—this analysis was limited to those participants who completed the primary outcome SNOT-22 within the specified window of six months (−2 to 4 weeks). This analysis was termed the compliant ITT analysis.

Per protocol analysis—this analysis was performed as per the ITT analysis, restricted to those participants randomised to, and undergoing, septoplasty within the specified 12 weeks after randomisation and who completed the primary outcome within the specified window, compared with those randomised to receive medical management who remained within that group and did not cross over to surgery.

Per treatment analysis—this analysis was performed as per the ITT analysis, comparing participants who underwent septoplasty, regardless of initial randomisation group, at any time during follow-up (but >10 weeks before the primary outcome measure at six months, to ensure postoperative inflammation had settled), and all those treated with medical management, both regardless of initial randomisation group, with participants who completed the primary outcome within the specified window.

We explored the impact of the recruitment site on the primary outcome analysis by inserting the centre as a random effect with the mixed effect model.

Table 1 | Baseline characteristics of recruited participants. Values are number (percentage) unless stated otherwise

Characteristics	Septoplasty (n=188)	Medical management (n=190)	Total (n=378)
Sex			
Male	126 (67)	127 (67)	253 (67)
Female	62 (33)	63 (33)	125 (33)
Age (years)			
Median (IQR)	38 (27.5, 51)	37 (28, 50)	38 (28, 50)
Mean (SD)	40.3 (14. 9)	39.4 (13.9)	39.8 (14.4)
Range	18-79	18-80	18-80
Ethnicity

Severe	89 (47)	89 (47)	178 (47)
Extreme	69 (37)	69 (36)	138 (37)

IQR=interquartile range; NOSE Nasal Obstruction and Symptom Evaluation scale; SD=standard deviation.

BMJ: first published as 10.1136/bmj-2023-075445 on 18 October 2023. Downloaded from https://www.bmj.com/ on 14 January 2026 by guest. Protected by copyright, including for uses related to text and data mining, AI training, and similar technologies.

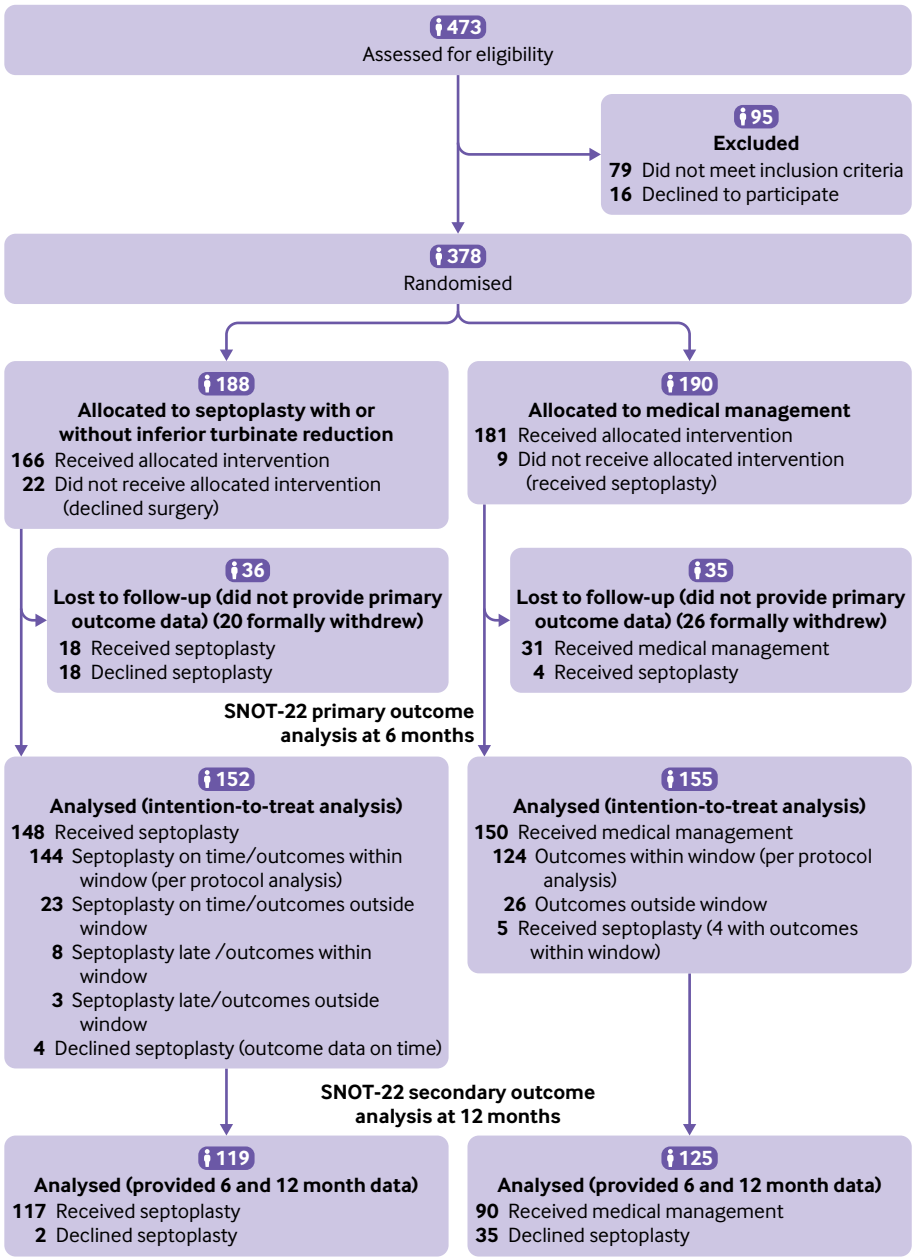

Fig 1 | Flow of participants through study

Analyses of the secondary outcome measures followed the same primary multiple linear regression modelling. Although inferior turbinate reduction was not a randomised intervention, its effect on the primary outcome was explored as a planned covariate in the linear regression model.

Further planned multivariable linear regression sensitivity of the ITT analyses considered adjustment for other important baseline factors in the regression model. To utilise the full information from the continuous measure, model 2 adjusted for continuous baseline score on the NOSE scale rather than the three categories used at baseline. Model 3 included age, ethnicity, recruitment site (as a random effect), smoking history, double ordinal airway subjective scale, endoscopy findings (location of deviation, severity of airway blockage, and enlargement of the inferior turbinate), and four nasal patency variables. These variables were initially regressed univariately against the primary outcome measure to screen for independent relatedness. Any variable with P>0.1 was included for consideration in further modelling based on forward selection. Non-linear continuous covariates were considered for fractional polynomial transformations, if appropriate.

The importance of baseline severity within the ITT population, as a continuous distribution of score on the NOSE scale at randomisation, was further explored graphically using a subpopulation treatment effect pattern plot (STEPP) analysis.[14] This analysis enabled the predicted point estimates of any treatment effect (with 95% confidence intervals)

BMJ: first published as 10.1136/bmj-2023-075445 on 18 October 2023. Downloaded from https://www.bmj.com/ on 14 January 2026 by guest. Protected by copyright, including for uses related to text and data mining, AI training, and similar technologies.

Table 2 | Patient reported SNOT-22 score at six months (primary outcome) adjusted for baseline SNOT-22 score and stratification variables sex and NOSE categories in 307 participants in intention-to-treat population

	Coefficients (95% CI)	P value
Septoplasty arm (reference category medical management)	−20.01 (−23.63 to −16.40)	<0.001
Baseline SNOT-22 score	0.50 (0.39 to 0.60)	<0.001
Male sex (reference category female sex)	−0.55 (−4.38 to 3.27)	0.78
NOSE severity (reference category moderate):		
Severe	1.98 (−3.85 to 7.81)	0.50
Extreme	5.81 (−1.00 to 12.62)	0.094
Constant	14.95 (8.48 to 21.43)	<0.001

NOSE=Nasal Obstruction and Symptom Evaluation scale; SNOT-22=Sino-Nasal Outcome Test-22.
Adjusted R^2=0.472. Probability $F_{5,301}$=55.69, P<0.001.

between the randomised groups to be displayed over the range of NOSE scale values (30-100), with the aim of further informing patient selection guidance and recommendations.

All data were analysed using STATA, version 16.

Missing data

SNOT-22 questionnaires with up to 20% of items missing were imputed with the average of the completed questions used for missing items. A sensitivity analysis using multiple imputation was also carried out that included all participants who provided consent and were randomised, including those with missing SNOT-22 scores at the primary endpoint. Baseline variables found to be predictive of missing data status were included in multiple imputation equations. To make the missing at random assumption as plausible as possible, the multiple imputation equation included baseline data on sex, NOSE scale categories, baseline SNOT-22 score, and predictors of missing data. Overall, 1000 multiple imputation datasets were created in STATA16 using chained equations. A conservative approach was adopted, and treatment group was included in the imputation model.

Sample size calculation

The sample of 378 participants was based on 90% power to detect a minimal clinically important difference of 9 points on SNOT-22,[8] assuming a conservative standard deviation of 24 points[15] and a type 1 error rate of 5%, and to allow for 20% drop-out.

Patient and public involvement

Patient and public involvement was integrated throughout the design and conduct of the trial. More than 20 patients were consulted about the primary outcome measure, with most favouring the items covered by SNOT-22 over NOSE scale questionnaire. Patients' views were integrated into the design to encourage any crossover to septoplasty to occur after six months. All patient facing documents were reviewed for acceptability.

Results

Between 26 January 2018 and 5 December 2019, 378 eligible participants (67% men) were randomised. Baseline personal characteristics were balanced across treatment groups (table 1).

The onset of the covid-19 pandemic resulted in the suspension of all face-to-face clinics from 30 March 2020, therefore remaining trial participants were invited to complete the primary outcome six month SNOT-22 measure (n=8, 2%) and the secondary outcome 12 month SNOT-22 measure (n=25, 7%) remotely. By then recruitment had been achieved and all trial interventions had been completed. Information on adverse events was collected remotely by telephone at the six month and 12 month follow-ups. Only 66 participants in the septoplasty group and 72 in the medical management group completed the 12 month objective flow measures.

Four SNOT-22 questionnaires had missing items at baseline—two in each treatment group (1%), five

Box represents middle 50% of data (lower quartile to upper quartile), horizontal line in box shows median (50th centile), whiskers show data that fall within 1.5× interquartile range, and points show data that fall outside these limits. SNOT-22=Sino-Nasal Outcome Test-22

at the primary six month endpoint (2%) and four at the final 12 month data collection point (1%). All of these were imputed as each had <20% missing. One participant had one item missing from the NOSE scale questionnaire (20%) at the six month follow-up. This was also imputed, using the mean of the other four responses.

Treatment received

Of the 378 participants randomised, 188 were assigned to receive septoplasty and 190 were assigned to receive medical management (fig 1). Overall, 307 participants (81%) were included in the ITT analysis of the primary outcome. In the ITT septoplasty group, four (3%) participants did not receive the surgical intervention; in the ITT medical management group, five (3%) participants received septoplasty. Consultant surgeons carried out 128 of 166 (77%) of the septoplasties for participants randomised to the septoplasty arm, who received the intervention. Associate specialists carried out 17 (10%) of the septoplasties, and other grades carried out 16 (10%). The records of five (3%) failed to record the grade of the most senior operative surgeon. In total, 112 out of 148 participants (76%) randomised to septoplasty and who received the intervention in the ITT analysis, underwent surgery within eight weeks after randomisation (see supplementary analysis figure S1). Twenty five (17%) underwent surgery within eight and 12 weeks after randomisation. One hundred and twenty two (64%) of the 190 participants randomised to medical management completed the drug adherence feedback, of whom 87 (71%) used nasal steroid spray >90% of the time, 101 (83%) used it >75%, and 17 (14%) had rarely used the drug.

Primary outcome analysis

Patient reported symptoms improved in both groups. In those participants randomised to receive septoplasty in the ITT population (n=152), mean SNOT-22 scores were 44.5 (95% confidence interval 41.1 to 47.8) at baseline and 19.9 (17.0 to 22.7) at six months. The corresponding scores for those participants randomised to receive medical management in the ITT population (n=155) were 44.1 (40.8 to 47.4) and 39.5 (36.1 to 42.9). Baseline SNOT-22 scores were approximately symmetrically distributed about the mean and were not transformed for the analysis (see supplementary material figures S2 and S3). In the primary ITT analysis, participants randomised to the septoplasty group reported on average 20.0 units greater improvement in symptoms compared with those randomised to the medical management group, as measured by SNOT-22 (95% confidence interval improvement 16.4 to 23.6, P<0.001; table 2). The lower limit of the 95% confidence interval is greater than the minimal clinically important difference of 9 points. With the presence of baseline SNOT-22 in the model (table 2), the stratification variables did not appear to have a major influence on the primary outcome. The primary outcome results were unchanged when further baseline variables were considered in the analysis, including the recruitment site when entered into model 2 as a random effect (see supplementary material tables S1 and S2 and figure S4).

The planned population defining analyses all showed similar results and supported the primary ITT analysis (fig 2). After multiple imputation to account for missing data (n=378), participants randomised to the septoplasty group (n=188) reported on average a greater improvement of 20.0 units over those randomised to the medical management group (n=190) (95% confidence interval improvement 16.4 to 23.7, P<0.001) supporting the primary ITT analysis

Secondary outcomes

The improvement in SNOT-22 scores in the septoplasty group remained at 12 months but was less noticeable compared with those in the medical management group (fig 3). The mean SNOT-22 score in the septoplasty group was 21.2 (95% confidence interval 17.7 to 24.6) at 12 months, whereas the corresponding values in the medical management group were 30.4 (26.6 to 34.3). Participants randomised to the septoplasty group (n=119) reported on average 10.1 units greater improvement in symptoms at 12 months compared with those randomised to the medical management group (n=125), as measured by SNOT-22 (95% confidence interval improvement 5.6 to 14.5, P<0.001).

BMJ: first published as 10.1136/bmj-2023-075445 on 18 October 2023. Downloaded from https://www.bmj.com/ on 14 January 2026 by guest. Protected by copyright, including for uses related to text and data mining, AI training, and similar technologies.

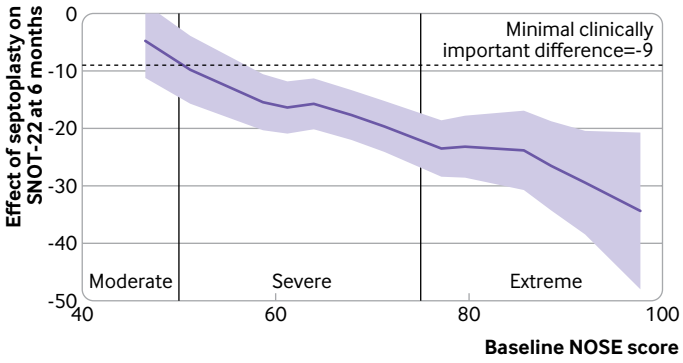

Fig 4 | Outcome data using subpopulation treatment effect pattern plot to assess individual changes in SNOT-22 scores from baseline to six months. Purple line shows average effect of being randomised to septoplasty for those with specific NOSE scores at baseline and shading represents 95% confidence intervals. Minimal clinically important difference is 9 points on SNOT-22. NOSE=Nasal Obstruction and Symptom Evaluation; SNOT-22=Sino-Nasal Outcome Test-22

Supplementary table S3 shows that the secondary outcomes measured at six months improved more in the septoplasty group than in the medical management group, including the objective flow measures. A noticeable improvement in SNOT-22 scores was observed between six and 12 months for 29 of the 37 participants randomised to receive medical management and who chose to undergo septoplasty after six months, restricted to those who provided 12 months' data. The SNOT-22 scores for these 37 participants had not improved between baseline and six months (see supplementary figure S5). The analysis between the groups in the 12 month objective assessments was affected by lack of face-to-face assessments during the covid-19 pandemic.

For the ITT population (n=307) mean scores on the SF-36 physical component summary and mental component summary at six months were 2.74 (95% confidence interval 1.23 to 4.25) and 4.39 (2.43 to 6.36) units higher, respectively (better health), in the septoplasty group than in the medical management group (adjusted for baseline severity and stratification variables, P<0.001; see supplementary tables S5-S8 for full details).

The STEPP analysis shows that for the 18 participants with moderate NOSE scores at baseline the average improvement in SNOT-22 score was around 5 units compared with medical management (fig 4). The 77 participants with scores around 60 had an average improvement of around 15 units compared with medical management, whereas the 57 participants with extreme scores at baseline improved by as much as 30 units compared with medical management. No major differences were noted in the STEPP analysis graphs between male and female participants. When included in the primary outcome multiple regression model, baseline NOSE scores scored on a continuous scale were positively related to the six month SNOT-22 scores (P=0.041, see supplementary table S1).

For the 148 participants who underwent septoplasty and had SNOT-22 scores at both baseline and six months, there was no difference in primary outcome scores between those chosen to receive inferior turbinate reduction and those chosen not to receive inferior turbinate reduction: 2.8 points difference (95% confidence interval −2.78 to 8.35 points difference; P=0.33).

No other clinically relevant factors showed a statistically significant association with the primary outcome of patient reported SNOT-22 score at six months (see supplementary tables S1 and S2). The primary outcome SNOT-22 scores were not altered appreciably by the reported adherence rates in participants treated with medical management (see supplementary figure S6).

Safety

Table 3 summarises the reported serious adverse events and adverse events. Specific complications related to septoplasty (including participants from both randomised groups who underwent septoplasty and including both serious adverse events and adverse events in table 3) were seven readmissions with bleeding (4% of 174 participants who underwent septoplasty), 20 infections requiring antibiotics (12%), 19 reported events of altered sense of smell (11%), 18 events of upper teeth numbness (11%), 17 reported changes in the appearance of the nose (10%), 7 clinician observed adhesions (4%), and 6 clinician observed septal perforations (3%). No participants required repeat surgery.

Discussion

Septoplasty results in significantly greater improvement in patient reported SNOT-22 scores at six months compared with a regimen of nasal steroid and saline sprays, and this improvement is sustained

Table 3 | Reported serious adverse events and adverse events among all participants

Adverse events	Septoplasty group (n=188)	Medical management group (n=190)	Total
Total reported serious adverse events	14	9	23
Anaesthetic complication	3	2	5
Infection	2	2	4
Postoperative bleeding	5	1	6
Vasovagal episode	2	0	2
Multi-pill overdose	0	3	3
Trauma unrelated to the trial	0	1	1
Overnight hospital admission after surgery	2	0	2
Total No of reported adverse events*	132	95	227
Deaths	0	0	0

BMJ: first published as 10.1136/bmj-2023-075445 on 18 October 2023. Downloaded from https://www.bmj.com/ on 14 January 2026 by guest. Protected by copyright, including for uses related to text and data mining, AI training, and similar technologies.

to 12 months. We therefore recommend that adults presenting with nasal obstruction associated with a deviated nasal septum, in the absence of coexistent nasal or sinus disease and with a baseline NOSE score >30, can reliably be offered surgery. The per protocol and per treatment analyses corroborated the ITT results, confirming the greater improvement in patient reported outcomes of those participants who received surgery compared with those treated medically.

The STEPP analysis provided evidence of the increasing improvement in SNOT-22 scores as baseline NOSE score severity increased. This effect was observed in both male and female participants. This analysis can enable clinicians to quantify expected improvements in outcomes of patients considering septoplasty, predicated on baseline NOSE score. The STEPP analysis, in parallel with an understanding of the potential risks associated with both medical treatment and surgery, substantially improved the quality of information available to the clinician and patient in the decision making process around septoplasty.

In 2014 when the National Institute for Health and Care Research commissioned this trial, no high level evidence existed for surgery compared with medical management for nasal obstruction associated with septal deviation. No specific guidance was available as to who should be referred for consideration of surgery, or the likely outcomes. The intervention was practice based, not evidence based. To our knowledge, in 2019 van Egmond et al reported the first randomised clinical trial assessing septoplasty.[16] Guidance on referrals has not been updated since its publication.[4] The study by van Egmond et al reached similar conclusions to that of the current study in a trial of 203 participants in the Netherlands randomised to receive either septoplasty or non-surgical management. Some important distinctions need to be mentioned between these two trials conducted in different healthcare systems: in the study by van Egmond et al, non-surgical management was not defined, whereas in the current study we specified a standardised medical management arm, which we considered offered the optimal medical treatment for any intranasal mucosal inflammation. The primary endpoint in the study by van Egmond et al was 12 months, and by that stage 30% of the non-surgical arm had crossed over to the surgical arm. The shorter time point of six months for our primary outcome aimed to minimise crossovers from the medical management arm while allowing sufficient healing time after surgery to give a true representation of any clinical difference between arms in an ITT analysis. In addition, we used a disease specific patient reported outcome measure rather than a general quality of life measure for the primary outcome.

We estimated a superiority for septoplasty of 20 points on SNOT-22 at six months compared with 9.7 points at 12 months in the study by van Egmond et al. Their data transformation and variable non-surgical arm treatments make direct comparison with the current study difficult. The two clinical trials report concordant results in showing that septoplasty is clinically effective. The current study substantially enhances understanding of the role of quantitative patient reported data in the selection of patients for surgery by showing that the degree of improvement in symptoms (as measured by SNOT-22) is closely related to baseline severity stratification (as measured by NOSE score). This improvement in SNOT-22 score remained across each of the four SNOT-22 subdomains— nose, sleep, ear/facial pain, psychological. The impact of septal surgery in improving SNOT-22 scores is also found in studies of snoring[17] and eustachian tube dysfunction.[18]

In the current study, although a greater and sustained improvement was observed in the surgical arm, we did note a potentially clinically important improvement in SNOT-22 scores in the medical management arm of 9.1 points between six and 12 months. In the ITT analysis, some of the improvement at 12 months in the medical management group may have been affected by 37 participants who were randomised to receive medical management undergoing septoplasty after six months. The primary outcome, SNOT-22 score at six months, did not improve from baseline in these 37 participants, suggesting that these participants undergoing septoplasty had an important impact on the medical management group.

The benefits of septoplasty were also seen in the secondary outcome measures, including clinical airflow assessment, patient reported outcome measures, and objective measurements of peak nasal inspiratory flow and rhinospirometry. Absolute subjective double ordinal airway subjective scale, the subjective comparator of the worse versus the better nostril airflow, revealed a substantial treatment related shift from predominantly unilateral nasal airflow to equal airflow through both nostrils, more noticeable in magnitude in the surgical arm than in the medical management arm at both six and 12 months. It may be a useful tool to audit surgical outcomes, or future trials of nasal airway surgery.

The results of the current study infer that turbinate surgery added no additional improvement to septoplasty alone. The decision to perform turbinate surgery was, however, pragmatic and left to the discretion of the operating surgeon. The results for inferior turbinate reduction may not be generalisable to other techniques or to bilateral reduction practices. The study by van Egmond et al similarly reported no additional benefit of turbinate surgery.[16] As in the current study, turbinate reduction was a surgeon led decision and not a randomised intervention. Neither clinical trial can draw firm conclusions on the impact of inferior turbinate reduction in combination with septoplasty. A recent single centre trial randomised participants undergoing septoplasty to inferior turbinate reduction or no inferior turbinate reduction.[19] This study reported a statistically significant and sustained additional benefit of inferior turbinate reduction, as measured using the NOSE score, implying that further multicentre clinical trials should be considered to define the

BMJ: first published as 10.1136/bmj-2023-075445 on 18 October 2023. Downloaded from https://www.bmj.com/ on 14 January 2026 by guest. Protected by copyright, including for uses related to text and data mining, AI training, and similar technologies.

impact of inferior turbinate reduction in combination with septoplasty.

Limitations of this study

The study has several limitations. At baseline, more than 80% of patients had NOSE scores in the severe or extreme category. This may reflect the population currently referred to secondary care. However, the conclusions for these two subgroups were strong. The benefits for those participants with moderate baseline symptoms was less clear, whereas those with moderate NOSE scores at baseline did not report an improvement that reached the minimal clinically important difference of 9 points on SNOT-22—only 18 participants were included in this subgroup of the STEPP analysis.

Nasal obstruction is a non-specific symptom with many underlying possible causes (chronic rhinosinusitis, allergic rhinitis, non-allergic rhinitis, nasal valve dysfunction). As a pragmatic trial, the current study did not seek to diagnose or treat these conditions before randomisation. Also, surgical interventions were performed by experienced surgeons. In NHS practice, septoplasty is often performed by junior trainee surgeons, albeit many are supervised by more senior colleagues. The evidence is limited for septoplasty outcomes and surgeon experience. However, previous studies have found no association between grade of surgeon and septoplasty outcomes when assessing the need for revision surgery[20] or the postoperative appearance of the septum.[21] Covid-19 had a considerable impact on the current trial. All forms of airway clinical assessment and objective measurements of nasal patency were suspended from March 2020 onwards. As a result of the smaller numbers of participants, this may have had an impact on the precision of the statistical results. All other patient reported outcome measures were collected remotely during the pandemic, ensuring that we could report the trial results reliably.

The current trial did not assess, and therefore cannot define, what should constitute an appropriate trial of medical management for patients and clinicians to consider before septal surgery is discussed. Participants in the medical management group reported an improvement in symptoms with mometasone nasal steroid and saline sprays. Participants with an element of underlying rhinitis contributing to the nasal obstruction in addition to the septal deviation may have responded to this treatment. Consensus opinion from the US recommends a course of medical management for four weeks before septoplasty is considered.[22]

Conclusions

Septoplasty is a superior treatment for nasal obstruction associated with septal deviation compared with a defined regimen of nasal steroid and saline sprays. Baseline NOSE scores can estimate the likely improvement in symptoms and guide decision making for patients and clinicians. The authors recommend that adults presenting with nasal obstruction associated with a deviated nasal septum should be offered septoplasty.

participant recruitment. YO contributed to the trial methodology design. JM acted as a co-applicant and primary care lead. QG, NK, SK, SL, SM, and PN were clinical co-applicants and contributed to participant recruitment. SC and JOH, as guarantors, accept full responsibility for the work and/or the conduct of the study, had access to the data, and controlled the decision to publish. The corresponding authors attests that all listed authors meet authorship criteria and that no others meeting the criteria have been omitted.

Funding: The study was funded by the National Institute for Health and Care Research (NIHR) Health Technology Assessment programme (reference 14/226/07). The NIHR commissioned the research trial with some stipulation on the trial design. Thereafter, the funders were independent of the running of the trial, analysis and interpretation, and the decision to publish the results.

Competing interests: All authors have completed the ICMJE uniform disclosure form at www.icmje.org/disclosure-of-interest/ and declare: support from the National Institute for Health and Care Research and salaries part funded through host institutions (SC, JOH, TF, TH, NR, LR, AB, DDS, LT, KR, AJS, JD, MD, KL, CWilson, SK, JWilson, and MDT); no financial relationships with any organisations that might have an interest in the submitted work in the previous three years; no other relationships or activities that could appear to have influenced the submitted work.

Ethical approval: The North East – Newcastle and North Tyneside 2 UK Health Research Authority Regional Ethics Committee (August 2017, study reference No 17/NE/0239).

Data sharing: The chief investigator and collaborators will act as custodians of the trial data and manage data sharing requests through ReShare, a UK online data repository recommended by the funder. Parties interested in data sharing will directly contact the chief investigator and collaborators and complete a project proforma and provide the rationale and the information required and comply with the regulation of responsibilities of users. If agreed to be appropriate, requested anonymised data will be made available. An access advisor who is independent of the trial team will periodically review access decisions.

The lead authors (SC and JOH) affirm that the manuscript is an honest, accurate, and transparent account of the study being reported; that no important aspects of the study have been omitted; and that any discrepancies from the study as planned have been explained.

Dissemination to participants and related patient and public communities: A lay summary of results will be available on the NAIROS website. Access to the Health Technology Assessment report will also be available through the trial website. Members of the patient and public involvement focus groups will review results and they will be involved in writing lay summaries of results for dissemination to relevant patient groups.

Provenance and peer review: Not commissioned; externally peer reviewed.

Abstract

Introduction In the current era, the major indication for septoplasty is nasal obstruction due to deviated nasal septum (DNS). Even though septoplasty is a commonly performed surgery, its effectiveness in relieving nasal obstruction in DNS has not been proven.

Objective The present study involved the measurement of both objective (nasal patency) and subjective (quality of life measures) outcome measures for the evaluation of the efficacy of septoplasty as compared with medical management.

Methods Patients with DNS presenting with nasal obstruction were included and randomized into a septoplasty group or into a nonsurgical management group, with 70 patients in each group. The improvement in nasal obstruction was assessed subjectively by the visual analogue scale (VAS), and the sino-nasal outcome test-22 (SNOT-22) and the nasal obstruction symptom evaluation (NOSE) questionnaires and was measured objectively by assessment of nasal patency by peak nasal inspiratory flow (PNIF) at 0, 1, 3, and 6 months of treatment in both groups.

Results The average VAS, SNOT-22 and NOSE scores for the septoplasty versus the nonsurgical group before treatment were 6.28 versus 6.0, 19.5 versus 15, and 14 versus 12, respectively, and at 6 months post-treatment, the scores were 2.9 versus 5.26, 10 versus 12, and 8 versus 10 ($p = 0.001$), respectively. The average PNIF scores at 0 and 6 months were 60/50 l/min and 70/60 l/min, respectively, in the septoplasty group ($p = 0.001$); the scores at 0 and 6 months in the nonsurgical management group were 60/60 l/min and 70/70 l/min, respectively ($p = 0.001$).

Conclusion Surgical correction of DNS by septoplasty improves nasal obstruction better than nonsurgical management at 6 months postsurgery.

Introduction

Deviated nasal septum (DNS) is a widespread clinical condition that affects up to 80% of the population, as shown in various studies.[1] It is characterized by displacement of the nasal septum, which normally divides the nasal cavity into right and left nasal passages. Although it is asymptomatic in the majority of patients, the most common and troublesome symptom of DNS is nasal obstruction.

Surgical correction of DNS by septoplasty is one of the most common otorhinolaryngology surgeries in adults.[2] In the current era, the major indication for septoplasty is nasal obstruction and other associated symptoms of DNS. Although septoplasty is a commonly performed surgery, its effectiveness in relieving nasal obstruction in adults with DNS has not been proven and remains indecisive. Scientific evidence from the literature on the benefits of septoplasty are not well-described.[3]

Many studies have revealed that septoplasty improves health-related quality of life significantly in the postoperative period.[4] The risk of bias is high, since all available evidence in the literature are based on studies that are only observational in nature, and randomized clinical trials are lacking. The beneficial effects could also be explained by additional factors like the course of the disease or additional interventions such as turbinate reduction or conchoplasty performed in these patients. The biases mentioned above make the advocated benefits of septoplasty questionable and possibly exaggerated.

The present study involves the measurement of both objective (nasal patency) and subjective (quality of life measures) outcome measures for the evaluation of the efficacy of septoplasty, and it is compared with medical management for ameliorating nasal obstruction in patients with DNS. The lack of evidence of the effectiveness of septoplasty explains the need for the present randomized clinical trial.

The aim of the present study was to assess and compare the efficacy of septoplasty with nonsurgical management in improving nasal obstruction in patients with DNS by both subjective and objective measures. The subjective assessment was done by the visual analogue scale (VAS), the nasal obstruction symptom evaluation (NOSE) scale and the sinonasal outcome test-22 (SNOT-22) scores, and the objective assessment was done by peak nasal inspiratory flow (PNIF).[5]

Materials and Methods

Study Design

The present study was a randomized clinical trial conducted during the period from February 2017 to December 2018. Informed consent was taken from all the patients who participated in the study. Approval from the Institute Research Council and Ethics Committee (JIP/IEC/2016/1061) was obtained. All provisions of the Declaration of Helsinki were followed. Patients > 18 years old with nasal obstruction due to DNS were included. Patients with prior septal surgeries, septoplasty done for indications other than DNS, and those with a strong preference to surgery were excluded from the study. With a 5% level of significance and 90% power, the sample size was calculated to be 70 in each group for an expected dropout rate of 20%.

Once the diagnosis of DNS was made based on the history of nasal obstruction, clinically by anterior rhinoscopy, and confirmed by diagnostic nasal endoscopy, the patients were randomized into either the septoplasty or the nonsurgical management group by the opaque envelope method.

Nasal patency was assessed at the time of enrollment into the study and at intervals of 1, 3, and 6 months after treatment, subjectively by VAS, SNOT-22, and NOSE score, and objectively by PNIF measurement in both groups.

The VAS scale ranges from 0 to 10; with 0 signifying the least severe and 10 the most severe nasal obstruction. In SNOT-22, problems are rated over the past 2 weeks, and each symptom is rated based on its severity. In the NOSE scale, 5 symptoms are considered, and severity is graded from 0 to 4, with 0 being 'not a problem' and 4 being 'severe problem'. The answers were added and multiplied by 5 to base the scale out of a possible score of 100 points for analysis.

Peak nasal inspiratory flow measures inspiratory flow through the nasal passage. The patients were asked to exhale fully, hold the flow meter horizontally, were ensured that the facemask formed an airtight seal around the nose and inhaled forcibly through the nose. The procedure was done in one nostril at a time by blocking the other. The peak nasal inspiratory maneuver should be a short, sharp, inspiratory action of a duration of ~ 1 second (►**Fig. 1**). The peak nasal inspiratory test was repeated three times, and the highest result was taken into account. The mask was disinfected between patients to avoid cross-infection.

The patients of the septoplasty group were put under sedation, and the procedure was performed under local anesthesia using aseptic precautions. A hemi-transfixion incision was made on the caudal end of the septum and extending from the floor of the vestibule to the dorsum of the columella. Following the incision, mucoperichondrial flaps were elevated from the quadrilateral cartilage until the bony

cartilaginous junction using a Freer elevator, and an anterior and inferior tunnel were created connecting them. The cartilaginous incision was made anteriorly, and flap elevation and exposure was performed on the contralateral side. The inferior strip of cartilage was removed along the maxillary crest, and at least 1 cm of the caudal end of the septum was preserved to maintain support of the nasal tip.

Deviated portions of septum were removed, preserving nondeviated parts and a dorsal and a caudal strut to maintain support of the dorsum. Bilateral nasal cavities were packed with merocel or with an antibiotic-antiseptic coated pack to achieve hemostasis. The patients were kept reclined on a couch with 30° of head end elevation to reduce venous congestion in the septum and reduce bleeding. The pack was removed within 48 hours, and the patients were discharged on a weeklong course of antibiotics and analgesics.

The nonsurgical management group underwent subjective as well as objective assessments of nasal patency as soon as the diagnosis was established and were started on nonsurgical measures like topical nasal decongestants (1% ephedrine drops) for 1 week during each follow-up visit and topical nasal corticosteroid sprays (50 mcg of fluticasone nasal spray – 1 spray in each nostril administered twice daily up to a total dose of 200 mcg/day for 6 months). Patients in both groups were followed up at 1, 3, and 6 months from initiation of the the treatment with the same assessment repeated each time.

Results

The baseline characteristics, including the symptom scores and PNIF values, were comparable between the septoplasty and the nonsurgical management groups in our study. On studying the various parameters from baseline to 6 months in the septoplasty group, there was a significant improvement in symptom scores as well as in PNIF values ($p < 0.001$) (►**Table 1**). The improvement in symptom scores and in PNIF values was also significant in the nonsurgical management group over 6 months (►**Table 2**).

On comparing the septoplasty and the nonsurgical management groups for improvement in subjective and objective measures from baseline to 1 month, there was a statistically significant difference in NOSE scores ($p = 0.01$) and in PNIF left side scores ($p = 0.018$). There was no significant difference in VAS scores ($p = 0.679$), SNOT-22 scores ($p = 0.389$), and PNIF right side values ($p = 0.059$) (►**Table 3**). On comparing the improvement in symptom scores from baseline to 3 months in both groups, there was a significantly higher improvement in the septoplasty group when compared with the nonsurgical management group. The *p-value* for VAS, SNOT-22 and NOSE scores were 0.001, 0.021, and 0.035, respectively. There was also a significantly higher improvement in the septoplasty group in the objective assessment as measured by PNIF values from both the right ($p = 0.003$) and left side ($p = 0.001$) (►**Table 4**). At 6 months, there was a statistically significant difference in improvement in all the symptom scores and in PNIF values between the groups (►**Table 5**).

Discussion

A total of 140 patients were recruited in the present study. The patients were randomized into a septoplasty group ($n = 70$) and a nonsurgical management group ($n = 70$). The efficacy of each arm with respect to treatment was assessed at different timepoints, namely, baseline (0 month) and at the 1-, 3-, and 6-month post-treatment follow-up.

Out of the 140 patients with nasal obstruction due to DNS, 73 (52%) were males and 67 (48%) were females. In our study, the ratio between males and females affected by DNS was 1.1:1, which is similar to the findings seen in the study by Sriprakash.[6] In the studies by Moorthy et al. and by Sam et al., the ratio between males and females affected by DNS was 2:1.[7,8] Sam et al. mentioned the increased occurrence of

trauma among males as one of the reasons for the male preponderance in DNS with trauma being a common etiology for DNS.[8]

The ratio of DNS on the right side to DNS on the left side in our study was 1:1. In the study by Moorthy et al., DNS was more common on the left side (1.47:1).[7] A preponderance of left-sided DNS was also observed in a large Korean series by Min et al. In their study, 56% of the patients had DNS on the left side and 39% had DNS on the right. The remaining 5% had S-shaped deformity.[9]

The laterality of DNS could be affected by fetal positions *in utero*. A right-sided DNS occurs in the left occipitoanterior position, and vice-versa. In the study by Mogarnad et al., right-sided deviations were more common, with a right side to left side ratio of 1.3:1.[10] Serifoglu et al. also found a predominance of right-sided nasal septal deviations in their study, with 107 patients presenting with DNS to the right side and 96 patients presenting with DNS to the left.[11] This shows that there is no definite pattern in the laterality of DNS, since its cause is multifactorial.

The age range of patients with DNS in our study was between 18 and 55 years old. The average age of all the patients included in our study was 31 years old. In the study by Sam et al., the average age of the patients with DNS was 34.7 years old, and in the study by Ozkul et al., the average age was 32.31 years old, which were in line with our

*Mann-Whitney test.

study.[8,12] Possibly, the reason for this can be that patients with DNS usually present in their 3rd decade of life with symptoms of nasal obstruction.

At the end of 6 months, 10 patients were lost to follow-up in the septoplasty group, and 13 were lost to follow-up in the nonsurgical management group. The sample size of 70 patients in each group in our study was calculated with an anticipated dropout rate of 20%. The number of patients who completed the 6 months of follow-up required for the present study was sufficient for analysis.

In the study by Stewart et al., the follow-up rate after septoplasty was of 81% after 3 months and of 65% after 6 months.[13] The follow-up rates were better in our study. Patients who underwent surgical intervention were more inclined to comply with the follow-up for the treatment than the patients in the nonsurgical management group.

The baseline characteristics such as age, gender as well as the questionnaire scores and PNIF values were comparable between the two groups in our study.

Although there was a difference in the baseline SNOT-22 scores between the septoplasty and nonsurgical management groups (19.5 versus 15), this difference was not statistically significant ($p = 0.095$). The mean baseline SNOT-22 score in a study by Hytönen et al. was 21.52.[14] The mean SNOT-22 score in our study on 140 patients was 18.5. The mean scores before the treatment was initiated were similar in both studies.

The normal PNIF value in healthy individuals without DNS is between 130 and 140 L/min.[12,15,16] In our study, the median preoperative PNIF was 60/50 L/min, and the median postoperative score at 6 months was 70/60 L/min. This could possibly be due to blocking of one nostril and measuring PNIF on the other side leading to decreased inspiratory effort.

In the septoplasty group, in the comparison of parameters from baseline to 6 months, there was a significant improvement in the VAS, SNOT-22, NOSE and PNIF scores over a period of 6 months ($p = 0.001$).

The nonsurgical management group also showed a significant improvement in parameters from baseline over a period of 6 months ($p = 0.001$).

Comparing the scores of both groups from baseline to 1 month, there was no significant difference in their efficacy ($p > 0.05$). This can be explained by the fact that most patients in the septoplasty group had postoperative edema and crusting in the nasal mucosa as a result of the surgical intervention.[17] This can be managed by daily regular saline nasal irrigation at home and diagnostic nasal endoscopy with suction clearance in their postoperative visit at the hospital. Nasal decongestants can be added to reduce postoperative edema. Nasal decongestants improve sinus ventilation and drainage due to their vasoconstrictor property, causing shrinkage of the turbinates and, therefore, relieving the obstruction of the osteomeatal complex.[18]

However, comparing the improvement in scores between both groups from baseline to 3 as well as 6 months, there was a significant difference in symptom scores as well as in PNIF values, with septoplasty showing better efficacy in alleviating nasal obstruction than nonsurgical management as measured by their p-value ($p < 0.05$).

In the study by Stewart et al., the mean NOSE scores improved from 67.5 to 26.6 from baseline to 6 months among patients who underwent surgery for DNS.[13] The median NOSE scores in the septoplasty group in our study were 70 at baseline and 40 at 6 months.

Our results are similar to those of a study by Ozkul et al., in which the mean preoperative and postoperative PNIF values were 102 L/min and 139 L/min, respectively, which showed an objective significant improvement in nasal obstruction by the septoplasty technique.[12]

A meta-analysis involving only 3 prospective controlled trials was performed by Singh et al., in which the authors demonstrated a reduction in the resistance of nasal airway following septoplasty ($p = 0.018$).[19]

Moore et al., in a systematic review, concluded that septoplasty improved nasal patency as reflected by objective measurements and, thus, has beneficial effects on the patients undergoing septal surgery.[20]

Hsu et al., in their retrospective cohort study, followed-up patients for 1 year before and after septoplasty with VAS, NOSE score and active anterior rhinomanometry. The patients showed a significant symptom improvement over the period of 1 year.[21]

Teixeira et al. evaluated the usefulness of PNIF in patients with nasal obstruction for objective assessment and found a positive correlation of PNIF with VAS scores.[22] Our study is the only prospective study to assess the improvement with treatment in DNS patients by all three subjective assessment scores (VAS, SNOT-22 and NOSE). An added strength to our study is the usage of an objective measurement tool in the form of PNIF values.

Our study was a well-planned prospective randomized clinical trial performed with a good sample size of 70 patients in each group. All patients in the surgical treatment group in our study underwent only septoplasty as the surgical technique. Most studies that evaluated subjective and objective parameters on DNS patients with nasal obstruction were observational or retrospective in nature or involved different types of surgical procedures and were performed with much smaller sample sizes.[23–25]

In septoplasty, DNS is straightened, causing a widening of the nasal passages. This results in improved ventilation and inspiratory effort in patients with nasal obstruction. It also improves mucociliary clearance and, therefore, improves nasal breathing.[26,27] It also alleviates other associated symptoms of DNS such as headache, epistaxis, snoring, and sleep disturbances, therefore improving quality of life.[14] This was evident from the improvement in subjective assessment scores in our study.

Limitations of the Study

The severity of nasal obstruction based on degrees of septal deviation was not measured. The evaluation of long-term complications in both treatment groups was not studied in detail. The cost-efficacy of the treatment groups was not studied in the present study. Septoplasty surgeries were not performed by the same surgeon in our study. The types of septal deviation and their specific treatment outcomes were not studied.

Conclusion

Septoplasty is more efficacious than medical management in the long run in alleviating nasal blockade in DNS patients. Nonsurgical management is effective in a short-term basis (when used for a period of 1 month) and fails to show significant improvement thereafter. Hence, it can be considered in patients while awaiting surgery. Patients with mild to moderate DNS can be considered for a trial of nonsurgical management and, if it fails to show improvement beyond 1 month, they should be submitted to septoplasty.

Summary

Background Septoplasty (surgical correction of the deviated nasal septum) is the most frequently performed ear, nose, and throat operation in adults, but no randomised controlled trials or non-randomised comparative studies on the effectiveness of septoplasty have been published. Consequently, health-care providers, health insurance companies, and policy makers are concerned about the effectiveness of the procedure. We aimed to assess the effectiveness of septoplasty for nasal obstruction in adults with a deviated septum.

Methods We did this open, multicentre, pragmatic, randomised controlled trial in 16 secondary and two tertiary referral hospitals in the Netherlands. Adults (aged ≥18 years) with nasal obstruction, a deviated septum, and an indication to have septoplasty done were randomly allocated (1:1) to receive either septoplasty with or without concurrent turbinate surgery or non-surgical management. Patients were stratified by sex, age (<35 years or ≥35 years), and deviation severity (mild, moderate, or severe). The primary outcome was health-related quality of life, measured with the validated Glasgow Health Status Inventory at 12 months. Analyses were done on an intention-to-treat basis. The trial is registered with the Netherlands Trial Register, number NTR3868.

Findings Between Sept 2, 2013, and Dec 12, 2016, we randomly assigned 203 participants to receive either septoplasty with or without concurrent turbinate surgery (n=102) or non-surgical management (n=101). 189 participants were analysed at 12 months. At 12 months, mean score on the Glasgow Health Status Inventory of patients assigned to septoplasty was 72·2 (SD 12·2) and for those assigned to non-surgical management was 63·9 (SD 14·5, mean difference 8·3 [95% CI 4·5–12·1], favouring septoplasty). Septal abscess occurred in one surgical patient and septal perforation in two surgical patients. No side-effects of nasal medication were reported.

Interpretation Septoplasty is more effective than non-surgical management for nasal obstruction in adults with a deviated septum. This effect was sustained up to 24 months of follow-up.

Introduction

Septoplasty (surgical correction of the deviated nasal septum) is the most frequently performed ear, nose, and throat (ENT) operation in adults, but its effectiveness is uncertain.[1] In 2010, the professional membership body representing British ENT surgeons (ENT UK) noted that some hospital administrations were suggesting to abolish or severely restrict septoplasty because of doubts about its benefits.[2] The Dutch ear, nose, and throat society and the British National Institute for Health Research prioritised research on this topic, considering it an important knowledge gap in otorhinolaryngology.[3] Still, the American Academy of Otorhinolaryngology had to rely on consensus to substantiate its 2015 paper on septal surgery, as evidence was found poor.[4]

To date, no randomised controlled trials (RCTs) or non-randomised comparative studies on the effectiveness of septoplasty have been published.[5] Existing literature is methodologically flawed and inconclusive, which has led to a vigorous debate as to whether patients benefit from straightening the deviated septum, and if so, which patients benefit most.[6,7] Evidence-based guidelines are absent and annual performance rates differ remarkably between countries: the number of septoplasties per 10 000 inhabitants varies from 3·9 in England, 6·6 in the Netherlands, 8·7 in the USA, to 12·2 in Germany (Dutch Hospital Data, personal communication).[8–10]

The current era of value-based health care is characterised by an increasing demand for evidence that interventions provide outcomes valued by patients and society. The lack of evidence for septoplasty's effectiveness prompted several National Health Service (NHS) Clinical Commissioning Groups in England to add septal surgery to their list of restricted treatments and procedures. To overcome the evidence gap, this pragmatic RCT aimed to

Research in context

Evidence before this study

We systematically searched PubMed, the Cochrane Library (both from inception), and Ovid Embase (from Jan 1, 1974) up to Oct 10, 2017, for randomised controlled trials or non-randomised studies comparing septal surgery with non-surgical management for nasal obstruction in adults with a deviated septum. Keywords (MeSH and Emtree) and free text terms were included in the search query, which combined synonyms for nasal obstruction, nasal septal deviation, septoplasty, and various subjective as well as objective outcome measures, such as the Glasgow Health Status Inventory, Glasgow Benefit Inventory, SinoNasal Outcome Test, Nasal Obstruction Symptom Evaluation, EuroQol 5 Dimensions, Short Form 36, RhinoSinusitis Outcome Measure, and Rhinomanometry. No language or date restrictions were applied. Nonetheless, the systematic literature search yielded no results. The evidence base for septal surgery consists solely of observational studies, comparing preoperative and postoperative measurements of quality of life or nasal patency. These studies have a high risk of bias, as the reported effects could also be explained by other factors (such as natural course), leaving whether patients benefit from septoplasty uncertain.

Added value of this study

Because of the methodologically flawed and inconclusive literature, there are no evidence-based guidelines on septal surgery and annual performance rates differ remarkably between countries. Doubts about septoplasty's benefits have prompted several professional associations of ear, nose, and throat surgeons and the British National Institute for Health Research to call for further research. In response to their call, this is the first randomised controlled trial on the effectiveness of septal surgery.

Implications of all the available evidence

Given the evidence gap and the uncertainty surrounding the surgery's benefits, septoplasty was added to the restricted treatments and procedures list of several National Health Service Clinical Commissioning Groups in England, an example that might be followed by policy makers and insurance carriers across the globe. The results of this trial, showing that septoplasty is more effective than non-surgical management (medication or watchful waiting), are pivotal in reaching better informed decisions and developing evidence-based guidelines on the treatment of nasal obstruction in adults with a deviated septum.

assess the effectiveness of septoplasty compared with non-surgical management for nasal obstruction in adults with a deviated septum, in terms of subjective (health-related quality of life) and objective (nasal patency) outcome measures.

Methods

Study design and participants

We did an open, multicentre, pragmatic, randomised controlled trial in 16 secondary referral hospitals and two tertiary referral hospitals in the Netherlands. The trial protocol has been published previously and was approved by the accredited medical ethics committee of Radboud University Medical Center.[6] Adults (aged 18 years or older) with nasal obstruction, a deviated septum, and an indication to have septoplasty done, were eligible for trial participation.

Nasal septal deviation is commonly accompanied by (compensatory) turbinate hypertrophy, which can involve the mucosa as well as the conchal bone and might not regress spontaneously after septoplasty.[11] Accordingly, septal surgery often includes the lateralisation of turbinates or partial submucosal turbinectomy to prevent postoperative complaints of nasal obstruction due to this compensatory turbinate enlargement.[12,13] As the trial was pragmatic, concurrent turbinate surgery was allowed. The indication for septoplasty (with or without concurrent turbinate surgery) had to be based on an internal examination of the nose, consisting of anterior rhinoscopy and nasal endoscopy, which showed that the septal deviation was obstructing the nasal airway, leading to impaired nasal breathing. This assessment reflected regular practice and was also in line with the pragmatic nature of the trial.

Nasal obstruction had to be the main indication for septoplasty. Patients were excluded if the indication was primarily based on concurrent complaints, such as impairment of normal sinus drainage, sleep disorders, or headaches. We also excluded patients with enlarged turbinates but without a deviated septum, patients with a history of nasal septal surgery, patients with untreated allergic rhinitis or allergic rhinitis unresponsive to medical treatment, patients selected for septoplasty because of septal perforation, patients in whom septoplasty was to be done as part of a cosmetic rhinoplasty procedure, and patients with a cleft lip or palate.

Eligible patients visiting the outpatient clinic were approached for trial participation by their ENT surgeon. When patients gave informed consent to share their personal information, the ENT surgeon forwarded the clinical history, results of physical examination, and contact details to our research team. We contacted patients by telephone, informed them about the trial, and checked inclusion and exclusion criteria. Eligible patients who were willing to participate were invited for a baseline visit, during which written informed consent for trial participation was obtained. At baseline, demographic and disease-specific data were collected, and subjective and objective outcome measures were administered. Afterwards, patients were randomly assigned to a treatment group.

Randomisation and masking

An independent data manager generated a randomisation sequence (using block sizes of 6), with stratification according to sex, age (<35 years or ≥35 years), and severity of the deviation (mild, moderate, or severe). The deviation was classified by the ENT surgeon as mild if it obstructed less than half of the nasal passage; moderate if it obstructed half or more than half of the nasal passage; and severe if the deviation was in contact with the lateral nasal wall. The study physician accessed the trial randomisation website to obtain the treatment assignment. The assignment was concealed and could not be predicted in advance of or during enrolment. Assignments were balanced in a 1:1 ratio for the two treatment groups, septoplasty and non-surgical management. No masking was applied.

Procedures

Patients assigned to septoplasty had surgery within 6–8 weeks after the baseline visit. Septoplasty was done with or without concurrent turbinate surgery (unilateral or bilateral), as considered appropriate by the ENT surgeon. A detailed and standardised operation report was kept for each trial participant. Given the pragmatic nature of the trial, ENT surgeons were encouraged to operate according to their regular practice, and patients could use any kind of medication in addition to their surgical treatment.

Patients assigned to non-surgical management underwent watchful waiting or medical treatment. As the trial was pragmatic, we aimed to assess the effectiveness of septoplasty and non-surgical management in daily practice, instead of assessing their effectiveness under specific conditions dictated by the study. Consequently, non-surgical management did not involve a prespecified treatment regime; the decision between watchful waiting and medical treatment (usually local corticosteroids) was made on an individual patient basis. Also, similar to surgical patients, those assigned to non-surgical management could use additional medication if needed (such as normal saline nasal spray or drops, xylometazoline nasal spray or drops, paracetamol, or ibuprofen). If persistent complaints prompted patients assigned to non-surgical management to undergo septoplasty within the 24 months of trial follow-up, they were classified as cross-over and monitored as planned. At 3, 6, 12, and 24 months, follow-up visits were scheduled, during which subjective and objective outcomes were measured.

See Online for appendix

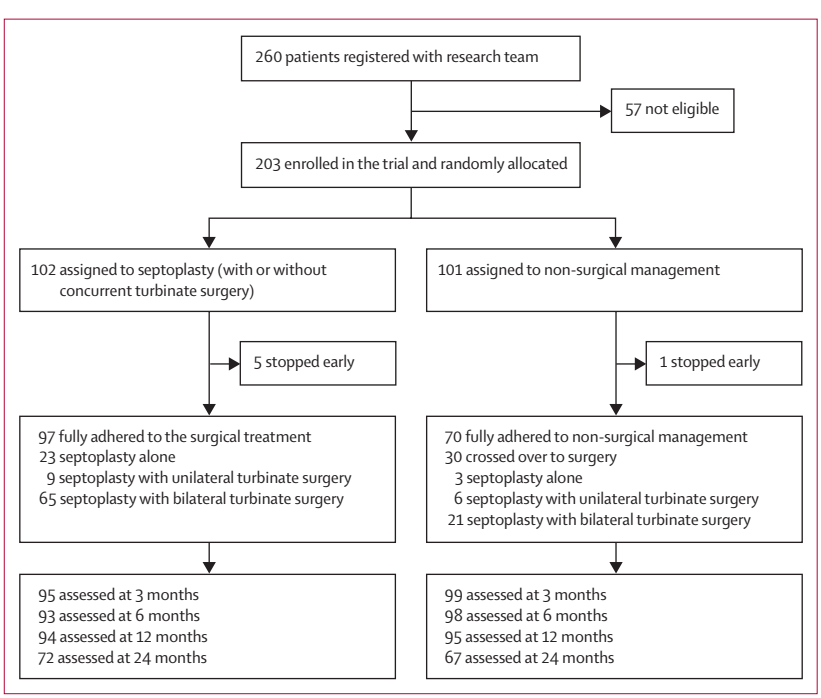

Figure 1: **Trial profile**

Outcomes

For all outcome measures, our timepoint of primary interest was 12 months. The primary outcome was health-related quality of life, measured using the patient-reported Glasgow Health Status Inventory (GHSI).[14,15] Secondary outcomes were objective assessments of nasal patency with peak nasal inspiratory flow (PNIF) and 4-phase rhinomanometry (4PR); health-related quality of life measured using the Nasal Obstruction Symptom Evaluation (NOSE) scale, sino-nasal outcome test-22 (SNOT-22), the three-level EuroQol, five dimensions (EQ-5D-3L), and Glasgow Benefit Inventory (GBI); and complications and serious adverse events. The study physician visited each of the participating centres to assess all outcomes. An overview of our subjective and objective measurement instruments is provided in the appendix (p 3). The instruments used for PNIF were produced by Clement Clarke International (Essex, UK) and for 4PR by RhinoLab GmbH (Freiburg im Breisgau, Germany). Objective measurements were done before and after application of 0·1% xylometazoline spray to examine the effect of mucosal decongestion on nasal patency.

The GHSI, PNIF, 4PR, NOSE scale, and GBI have all been validated for use in adults with nasal obstruction and a deviated septum.[16–18] The SNOT-22 has been validated for patients with chronic rhinosinusitis but is also used in patients with nasal obstruction because of its broad coverage of nasal complaints.[19]

Statistical analysis

The main comparison in our trial was septoplasty with or without concurrent turbinate surgery versus non-surgical management. The sample size calculation was based on a clinically relevant improvement on the GHSI of 10 (SD 15). Assuming a health-related quality of life of 70 in the non-surgical group and assuming an α of 0·05 and a power of 0·90, each treatment group had to include at least 48 patients. To allow for objective assessments of nasal patency and subgroup analyses, we decided to include 100 adults in each treatment group.

Effects of septoplasty on health-related quality of life and nasal patency were calculated as mean differences with 95% CIs. All analyses were done on an intention-to-treat basis (additional per-protocol analyses given in the appendix p 7). Analyses were stratified by sex, age (<35 years or ≥35 years), deviation severity (mild, moderate, or severe), deviation cause (congenital or traumatic), and type of surgery (septoplasty alone or septoplasty with concurrent turbinate surgery). If stratified analyses indicated potential modification of the effect of septoplasty, subgroups were analysed further using multiple regression. Considering the type of variables for which data were missing and the nature of the trial, missing data were assumed to be missing at random and were multiply imputed using chained equations. Baseline variables and study outcomes were used as predictors in the imputation model (appendix p 5). Analyses were done with SPSS (version 22) and R (version 3.5.1). Data collection was overseen by independent data managers and an independent monitor. The trial is registered with the Netherlands Trial Register, number NTR3868.

Role of the funding source

The funder of the trial had no role in study design, data collection, data analysis, data interpretation, or writing of the report. All authors had full access to all the data in the trial. MR and NvH had final responsibility for the decision to submit the report for publication.

Results

Between Sept 2, 2013, and Dec 12, 2016, clinical and contact information from 260 potential participants were shared with our research team by the participants' ENT surgeons. We enrolled 203 eligible patients; 57 patients either did not fulfil the eligibility criteria or were not willing to participate, mostly because of the time investment or strong treatment preferences. All 203 patients were randomly allocated: 102 were assigned to septoplasty and 101 to non-surgical management. 23 patients assigned to surgery received septoplasty alone; nine received septoplasty with unilateral turbinate surgery; and 65 received septoplasty with bilateral turbinate surgery (figure 1). The most frequently done type of turbinate surgery was lateralisation (116/230 [50%]), followed by partial turbinectomy (52 [23%]), turbinate coblation (22 [10%]), and turbinate cautery (16 [7%]); the remaining 24 (10%) were classified as other. Analyses at our primary timepoint of 12 months were done in 94 patients (92%) assigned to septoplasty and 95 patients (94%) assigned to non-surgical management.

Baseline characteristics of the trial participants are shown in table 1. There were slightly more men than there were women. The mean age was 38 years (SD 15) and the median duration of nasal obstruction before trial entry was 7 years (IQR 3–15). Most patients (n=125 [62%]) had

SNOT-22=sino-nasal outcome test-22. EQ-5D-3L=three-level EuroQol, five dimensions. VAS=visual analogue scale. GBI=Glasgow Benefit Inventory. NA=not applicable.

Table 2: **Subjective and objective outcomes at 12 months**

bilateral complaints. The septal deviation was bilateral in 48 (24%) patients. Turbinate hypertrophy was present in 93 (46%) patients, mostly unilaterally (n=53 [26%]).

At our primary timepoint of 12 months, the mean GHSI score of patients assigned to septoplasty was 72·2 (SD 12·2) and to non-surgical management was 63·9 (SD 14·5; mean difference 8·3 [95% CI 4·5–12·1]). At 3, 6, and 24 months, patients in the septoplasty group had higher GHSI scores than did patients in the non-surgical management group (appendix p 4). The largest difference between the two groups was found at 6 months, with scores of 72·8 (SD 12·8) in the septoplasty arm and 61·7 (SD 13·5) in the non-surgical management arm (mean difference 11·1, 95% CI 7·4–14·9 [figure 2; appendix p 4]).

At 12 months, nasal airflow before mucosal decongestion was 124·3 L/min (SD 45·7) in patients in the septoplasty group and 95·0 L/min (SD 37·6) in patients in the non-surgical management group (table 2). After mucosal decongestion, nasal airflow was 133·0 L/min (SD 50·08) in surgical patients and 109·7 L/min (SD 48·2) in non-surgical patients (table 2). The mean difference between the two groups in nasal resistance varied between –0·07 Pa/cm³/s (95% CI –0·25 to 0·11) and –0·20 Pa/cm³/s (–0·40 to –0·01) , indicating surgical benefit; although overall 4PR differences were rather small and less consistent than were the results from PNIF (table 2; appendix p 4; figure 3).

The disease-specific NOSE scale and SNOT-22 showed consistently large effects in favour of septoplasty (table 2). The EQ-5D-3L did not show significant differences between the two groups in generic health-related quality of life. However, the GBI score (available only in surgical patients because of the nature of the questionnaire) showed positive scores on each timepoint of outcome assessment, indicating that surgical patients felt that they benefited from their treatment (table 2; appendix p 4).

Subjective and objective benefits of septoplasty persisted over the full 24 months of follow-up. An overview of all trial outcomes at all timepoints is provided in the appendix (p 4).

Postoperative complications occurred in 23 (18%) patients who were assigned to septoplasty or had crossed-over to surgery (table 3). The most frequent complications were haemorrhage and infection (table 3); these complications occurred directly after surgery and were mild, meaning that patients either did not require treatment or could be treated at the outpatient clinic with nasal packing or local or oral antibiotics. Septal perforation occurred in two patients and septal abscess in one patient, who was hospitalised to receive intravenous antibiotics; consequently, the septal abscess was classified as a serious adverse event. No other serious adverse events related to the treatments under study occurred during the trial. No adverse events related to nasal medication were reported. Revision surgery because of persisting complaints was required in one patient (table 3).

Analyses of imputed data did not alter our findings (appendix p 5). Stratified analyses by sex, age, deviation severity, deviation cause, and type of surgery did not show potential modification of the effect of septoplasty

(appendix p 6). Additional per-protocol analyses did not alter our findings (appendix p 7).

Discussion

In this pragmatic RCT, we found that septoplasty is more effective than non-surgical management in adults with nasal obstruction and a deviated septum. Patients assigned to septoplasty scored significantly higher than did patients assigned to non-surgical management on disease-specific quality of life, measured with the GHSI, NOSE scale, and SNOT-22; and on nasal airflow, measured with PNIF. The difference between the two groups was largest at 6 months, but beneficial effects of surgery persisted over the full 24 months of follow-up.

So far, evidence for the effectiveness of septoplasty was based on observational studies, comparing preoperative and postoperative measurements of quality of life or nasal patency.[20–24] These studies had a high risk of bias, as the reported effects could also be explained by other factors (such as natural course).

The main strength of our trial is that this is the first RCT to answer the call for further research, which has been voiced from clinical practice. Some of our findings deserve further discussion. Masking of participants was impossible, as medical ethics committees in the Netherlands consider it unethical to do sham surgery in the control group. However, the effect of septoplasty was assessed using not only subjective, but also objective outcomes, which showed similar results.

Also, about 30% of patients assigned to the non-surgical management group crossed over to septoplasty over the full 24 months of follow-up. This crossover is part of the pragmatic nature of the trial, directed at assessing the effect of septoplasty in daily practice. Even with a crossover rate of 30%, analyses on an intention-to-treat basis showed that septal surgery was better than non-surgical management.

Generic health-related quality of life measured with EQ-5D-3L and nasal patency measured with 4PR did not show effects as clear as the other outcomes. This finding is probably due to the measurement properties of the instruments rather than the intervention, given the overall consistency of our findings. The EQ-5D-3L is valuable to assess utility, but has insufficient sensitivity and ceiling effects.[25] Also, 4PR has poor responsiveness, as shown by a clinimetrics study done after the trial had begun but before the trial's data collection was finished.[16] Despite the instruments' unfavourable clinimetric properties, EQ-5D-3L and 4PR results were pre-registered outcomes; accordingly, we reported the results. We selected multiple instruments for subjective and objective outcome assessments in our trial on the basis of the specific characteristics of each instrument. The GHSI was chosen as a primary outcome because it includes generic and disease-specific quality of life items, as opposed to the NOSE scale. Including generic quality-of-life questions facilitates a transdisciplinary view and enables the comparison of septoplasty with other interventions.

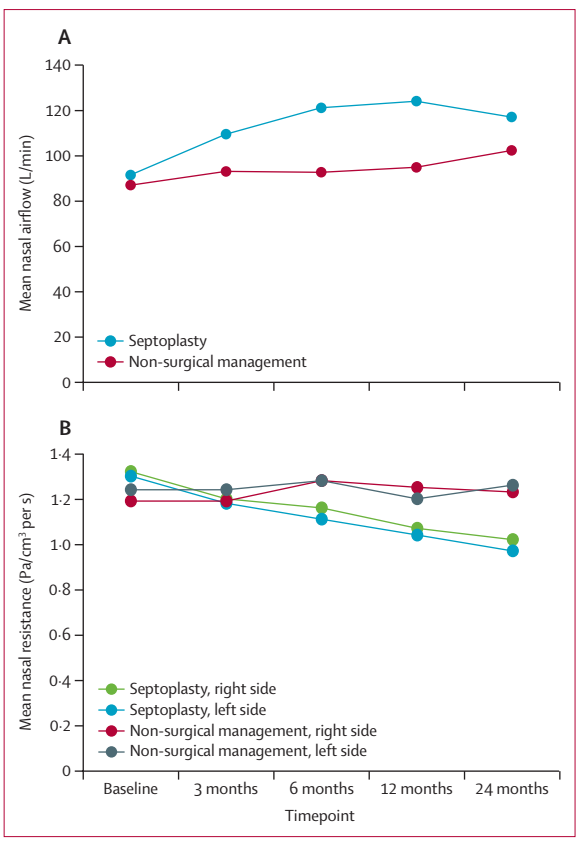

Figure 3: **Nasal airflow and nasal resistance**
(A) Mean nasal airflow in L/min as measured by peak nasal inspiratory flow (before decongestion) and (B) mean nasal resistance in Pa/cm³/s as measured by 4-phase rhinomanometry (before decongestion).

	Septoplasty with or without concurrent turbinate surgery (n=97)	Non-surgical management (n=100)*	All patients (n=197)†
Postoperative complications			
Haemorrhage	6/97 (6%)	2/30 (7%)	8/127 (6%)
Infection	7/97 (7%)	2/30 (7%)	9/127 (7%)
Septal abscess	1/97 (1%)	0	1/127 (1%)
Septal perforation	2/97 (2%)	0	2/127 (2%)
Other‡	2/97 (2%)	1/30 (3%)	3/127 (2%)
Revision septoplasty	1/97 (1%)	0	1/127 (1%)
Medication-related adverse events	0	0	0
Non-trial-related adverse events	35/97 (36%)	38/100 (38%)	73/197 (37%)
Trial-related serious adverse events§	1/97 (1%)	0	1/197 (1%)
Non-trial-related serious adverse events§	1/97 (1%)	4/100 (4%)	5/197 (3%)

Data are n/N (%). *30 patients crossed over. †127 patients had surgery. ‡Other complications were severe postoperative pain and severe postoperative swelling, not classified as septal haematoma. §Serious adverse events were untoward medical occurrences that made hospital admission necessary. No fatal or life-threatening serious adverse events occurred. All serious adverse events were reported to the accredited medical ethics committee and the funder.

Table 3: **Complications and adverse and serious adverse events**

The rate of mild postoperative complications in our trial was somewhat high.[26] This finding might be induced by the long-term follow-up and intensified monitoring of trial patients compared with regular care, in which underreporting could occur.

Most patients receiving surgical treatment had septoplasty with concurrent turbinate surgery, even though turbinate hypertrophy was detected in less than half of the patients at baseline. The most frequent type of turbinate surgery was lateralisation, which ENT surgeons might consider a pragmatic and minor procedure complementary to septal surgery that is often required to prevent postoperative complaints of nasal obstruction due to the turbinate enlargement that accompanies the septal deviation. As with the other subgroups, stratified analyses comparing septoplasty alone with septoplasty with concurrent turbinate surgery did not show clinically relevant differences (appendix p 6).

Furthermore, recruiting a sample that is representative of the whole target population can be a challenge with RCTs.[27] However, we believe that the results of this multicentre, pragmatic trial are applicable to all patients with nasal obstruction and a deviated septum, as seen in daily practice. We compared baseline characteristics of trial participants with 52 patients indicated for septoplasty in three hospitals that did not participate in our multicentre trial and found no relevant differences, especially not in previous treatment or severity of the deviation (appendix p 8). In both samples, about three-quarters of patients had already received medical treatment with local corticosteroids before trial entry, and in about a third of patients the septal deviation was classified as severe.

The clinical implications of this RCT are far-reaching. Despite the globally acknowledged evidence gap, septoplasty is one of the most common procedures within the field of otorhinolaryngology, affecting numerous patients each year. Over the past decades, uncertainty surrounding its effectiveness has put an increasing strain on septal surgery, as shown by the addition of septoplasty to the restricted treatments and procedures list of several NHS Clinical Commissioning Groups in England. Our trial, however, shows that many patients, despite medical treatment, continue to live with nasal obstruction for years before being referred to the ENT surgeon. In these patients, septoplasty offered considerable subjective and objective benefits compared with non-surgical management, which were sustained up to 24 months of follow-up. This information provides a basis for the development of evidence-based guidelines on the treatment of nasal obstruction in adults with a deviated septum.

Contributors

MMR and NvH conceived the trial and initiated the design. MMHTvE, CTMH, MMR, and NvH did the trial. MMHTvE, GH, MMR, and NvH analysed the data. All authors had full access to all the data in the trial. All authors drafted this manuscript and approved the final version. MMR and NvH had final responsibility for the decision to submit the report for publication.

Declaration of interests

MMHTvE, MMR, CTMH, and NvH report a grant from ZonMw (the Netherlands Organisation for Health Research and Development) to do the study. GH declares no competing interests.

Data sharing

Deidentified participant data will be made available to researchers whose proposed use of the data has been approved by the principal investigators (MMR and NvH), with a signed data access agreement and only for purposes specified in the approved research proposal. Requests for data must be sent to niels.vanheerbeek@radboudumc.nl. The trial protocol is available online.

Acknowledgments

We thank the patients who participated in the trial; the ear, nose, and throat (ENT) surgeons who contributed to the enrolment of trial participants (a full list of contributing surgeons is available in the appendix p 10); the independent data managers for creating the trial randomisation website and overseeing data collection; Tim Govers for data monitoring; medical students Charlotte Michels, Sanne Leuwerink, and Beau de Korte for administrative and practical support; Anne Schilder for advice regarding the design of the trial and feedback on the draft manuscript; and the Dutch ENT society for supporting the trial's initiation and conduct. The trial was funded by the Netherlands Organisation for Health Research and Development (ZonMw), project number 837002001.

Septoplasty for CPAP Tolerance May 2026

Plain Language Summary:

A surgery to straighten the divider inside the nose (nasal septum) may help people who use a breathing machine to help with sleep apnea, called a Continuous Positive Airway Pressure (CPAP) device.

Staff did not find strong evidence the surgery helps using CPAP and do not recommend adding coverage for this reason alone.

This issue summary has been changed from the March 19, 2026 meeting materials

Staff Analysis Summary:

Significant proposed changes or discussion items:

1) HERC staff recommend not adding coverage for septoplasty to allow CPAP use for sleep apnea

Changes after public comment period:

One public comment was received on the general topic of septoplasty. This comment was addressed in the companion issue on septoplasty for breathing issues.

Coverage Question:

Should the septoplasty be covered when nasal obstruction makes CPAP use ineffective for treatment of OSA?

Question source:

1) OHA Hearings Division

*CPT only copyright 2025 American Medical Association. All rights reserved.
** Current Dental Terminology © 2025 American Dental Association. All rights reserved

Background:

OHA Hearings Division is requesting clarity regarding whether septoplasty is meant to be considered when a patient has obstructive sleep apnea and cannot tolerate their CPAP. Currently, the septoplasty guideline states that surgery is not covered for OSA, but it is unclear if this is only as a primary surgery for OSA treatment or as treatment for any OSA related indication.

Previous HSC/HERC reviews:

This issue was discussed at the March 2026 VBBS/HERC meetings. Members commented that expert guidelines on CPAP did not mention nasal surgery. HERC staff were directed to look at expert guidelines and break this portion of the septoplasty discussion into a separate issue summary. Members agreed with the staff analysis that nasal surgery was not indicated as a primary treatment of sleep apnea.

Current Prioritized List/Coverage status:

ICD-10-CM J34.2 (Deviated nasal septum) is on line 562 DEVIATED NASAL SEPTUM, ACQUIRED DEFORMITY OF NOSE, OTHER DISEASES OF UPPER RESPIRATORY TRACT

CPT *30520 (Septoplasty or submucous resection, with or without cartilage scoring, contouring or replacement with graft) is on lines

42 CLEFT PALATE WITH AIRWAY OBSTRUCTION
119 CHOANAL ATRESIA
244 LIFE-THREATENING EPISTAXIS
285 CANCER OF ORAL CAVITY, PHARYNX, NOSE AND LARYNX
309 GENDER AFFIRMING TREATMENT
464 CHRONIC SINUSITIS
495 NASAL POLYPS, OTHER DISORDERS OF NASAL CAVITY AND SINUSES
512 BENIGN NEOPLASM OF NASAL CAVITIES, MIDDLE EAR AND ACCESSORY SINUSES
562 DEVIATED NASAL SEPTUM, ACQUIRED DEFORMITY OF NOSE, OTHER DISEASES OF UPPER RESPIRATORY TRACT

Septoplasty for CPAP tolerance

599 ANOMALIES OF RELATIONSHIP OF JAW TO CRANIAL BASE, MAJOR ANOMALIES OF JAW SIZE, OTHER SPECIFIED AND UNSPECIFIED DENTOFACIAL ANOMALIES
625 TMJ DISORDERS

CPT *30620 (Septal or other intranasal dermatoplasty (does not include obtaining graft)) is on lines 42, 244, 464, 495, and 562

CPT *30420 (Rhinoplasty, primary; including major septal repair) is on lines 309, 464, 495, and 562

Beginning 1/1/2027 with the BUP Prioritized List, CPT *30420 will be in the code group RHINOPLASTY AND SEPTOPLASTY AND CHRONIC SINUSITIS SURGERY. ICD-10-CM J34.2 will also be in code group RHINOPLASTY AND SEPTOPLASTY AND CHRONIC SINUSITIS SURGERY. CPT *30520 and 30620 will be placed only on currently covered lines with BUP.

Current Prioritized List guidelines:

GUIDELINE NOTE 118, SEPTOPLASTY

Lines 42,119,201,244,285,309,464,495,512,562

Septoplasty is included on Line 309 for gender affirming treatment.

Septoplasty is included on Lines 42, 119, 201, 244, 285, 464, 495, 512 and 562 when

A) The septoplasty is done to address symptomatic septal deviation or deformity which
   1) Fails to respond to a minimum 6-week trial of conservative management (e.g. nasal corticosteroids, decongestants, antibiotics); AND
   2) Results in persistent or recurrent epistaxis, OR documented recurrent sinusitis felt to be due to a deviated septum and the patient meets criteria for sinus surgery in Guideline Note 35, SINUS SURGERY; OR
B) Septoplasty is performed in association with cleft lip or cleft palate repair or repair of other congenital craniofacial anomalies; OR
C) Septoplasty is performed as part of a surgery for a neoplasm or facial trauma involving the nose.

*CPT only copyright 2025 American Medical Association. All rights reserved.
** Current Dental Terminology © 2025 American Dental Association. All rights reserved

Septoplasty for CPAP tolerance

Septoplasty for other nasal obstruction not meeting the criteria above is included only on Line 562.

Septoplasty is not included on these lines for treatment of obstructive sleep apnea and is not included on Line 201 SLEEP APNEA, NARCOLEPSY, INSOMNIA, HYPERSOMNIA, AND REM BEHAVIORAL DISORDER.

GUIDELINE NOTE 27, TREATMENT OF SLEEP APNEA

Line 201

For adults over the age of 18 years:

A) CPAP is covered initially when all of the following conditions are met:
   1) 12 week 'trial' period to determine benefit. This period is covered if apnea-hypopnea index (AHI) calculated using the CMS definition of hypopnic episode of at least 4% oxygen desaturation or respiratory disturbance index (RDI) is greater than or equal to 15 events per hour; or if between 5 and 14 events with additional symptoms including one or more of the following:
      a) excessive daytime sleepiness defined as either an Epworth Sleepiness Scale score >10 or daytime sleepiness interfering with ADLs that is not attributable to another modifiable sedating condition (e.g. narcotic dependence), or
      b) documented hypertension, or
      c) ischemic heart disease, or
      d) history of stroke
   2) Additionally:
      a) Providers must provide education to patients and caregivers prior to use of CPAP machine to ensure proper use; and
      b) Positive diagnosis through polysomnogram (PSG) or Home Sleep Test (HST).

B) CPAP coverage subsequent to the initial 12 weeks is based on documented patient tolerance, compliance, and clinical benefit. Compliance (adherence to therapy) is

*CPT only copyright 2025 American Medical Association. All rights reserved.
** Current Dental Terminology © 2025 American Dental Association. All rights reserved

defined as use of CPAP for at least four hours per night on 70% of the nights during a consecutive 30-day period.

C) Mandibular advancement devices (oral appliances) are covered for those for whom CPAP fails or is contraindicated.

D) Surgery for sleep apnea in adults is not included on this line (due to lack of evidence of efficacy). Surgical codes are included on this line only for children who meet criteria below

E) Hypoglossal nerve stimulation for treatment of obstructive sleep apnea is not included on this line due to insufficient evidence of effectiveness and evidence of harm.

For children age of 18 years or younger:

A) Adenotonsillectomy is an appropriate first line treatment for children with OSA. Adenoidectomy without tonsillectomy is only covered when a child with OSA has previously had a tonsillectomy, when tonsillectomy is contraindicated, or when tonsillar hypertrophy is not present. More complex surgical treatments are only included on this line for children with craniofacial anomalies.

B) Intranasal corticosteroids are an option for children with mild OSA in whom adenotonsillectomy is contraindicated or for mild postoperative OSA.

C) CPAP is covered for a 3-month trial for children through age 18 who have

1) undergone surgery or are not candidates for surgery, AND

2) have documented residual sleep apnea symptoms (sleep disruption and/or significant desaturations) with residual daytime symptoms (daytime sleepiness or behavior problems)

D) CPAP will be covered for children through age 18 on an ongoing basis if:

1) There is documentation of improvement in sleep disruption and daytime sleepiness and behavior problems with CPAP use, AND

*CPT only copyright 2025 American Medical Association. All rights reserved.
** Current Dental Terminology © 2025 American Dental Association. All rights reserved

2) Annual re-evaluation for CPAP demonstrates ongoing clinical benefit and compliance with use, defined as use of CPAP
for at least four hours per night on 70% of the nights in a consecutive 30-day period

The development of this guideline note was informed by a HERC coverage guidance. See https://www.oregon.gov/oha/HPA/DSI-HERC/Pages/Evidence-based-Reports.aspx

Septoplasty is not ~~covered~~ medically necessary for treatment of obstructive sleep apnea and is not included in code grouping ~~on Line~~ 201 SLEEP APNEA, NARCOLEPSY, INSOMNIA AND REM BEHAVIORAL DISORDER.

Date of last review: June 2025

Evidence:

Effectiveness of septoplasty for CPAP utilization

1) **Camacho 2015** The Effect of Nasal Surgery on Continuous Positive Airway Pressure Device Use and Therapeutic Treatment Pressures: A Systematic Review and Meta-Analysis
    a. N=18 articles (279 patients)
        i. N=17 retrospective or prospective case series
        ii. N=1 RCT (22 patients)
    b. N=11 studies (153 patients) that evaluated CPAP acceptance, compliance, tolerance, adherence, or use before and after nasal surgery
        i. N=3 studies (N=40 patients) used objective data from the CPAP device
        ii. N=3 studies (N=49 patients) used subjective reports of use from patients
        iii. N=6 studies (N=81 patients) did not report data source
    c. The percentage of patients regularly using CPAP prior to nasal surgery was 38.7% (36 of 93 patients) and the percentage of patients who were adherent (synonymous with compliant), accepting, or tolerating CPAP after nasal surgery was 90.2% (92 of 102 patients). A subgroup analysis demonstrated that 89.1% (57 of 64 patients) who were not using CPAP prior to nasal surgery subsequently accepted, adhered to, or tolerated CPAP after nasal surgery
    d. Authors conclusions: Isolated nasal surgery in patients with OSA with nasal obstruction reduces therapeutic CPAP device pressures, and the currently

*CPT only copyright 2025 American Medical Association. All rights reserved.
** Current Dental Terminology © 2025 American Dental Association. All rights reserved

published literature's objective and subjective data consistently suggest that it also increases CPAP use in select patients

e. HERC staff notes: authors acknowledge possibility of publication bias; lack of reporting of actual surgeries in several studies meaning that additional surgeries could have been done (nasal polyp removal, functional rhinoplasty, etc.) that would affect CPAP tolerance; the authors discuss that patients who were motivated enough to seek surgery were likely more motivated to re-attempt CPAP therapy.

Submitted literature:

None received to date

Expert guidelines:

1) **American Academy of Sleep Medicine 2019** Treatment of Adult Obstructive Sleep Apnea with Positive Airway Pressure: An American Academy of Sleep Medicine Clinical Practice Guideline
    a. Recommendation 8: We suggest that behavioral and/ or troubleshooting interventions be given during the initial period of PAP therapy in adults with OSA. (CONDITIONAL)
        i. Troubleshooting interventions: Interventions focused on close patient communication to identify PAP-related problems and to initiate potential solutions during the initial period of PAP therapy
    b. Appropriate mask selection will benefit patients by reducing side effects such as air leak and discomfort, which may then potentially improve adherence and subsequently patient outcomes
    c. The use of humidification could also potentially reduce side effects from PAP therapy
    d. Nasal surgery is not mentioned in this guideline
2) American Academy of Otolaryngology-Head and Neck surgery 2017 Position Statement: Nasal Surgery and OSAS
    a. Available at https://www.entnet.org/resource/position-statement-nasal-surgery-and-osas/

** Current Dental Terminology © 2025 American Dental Association. All rights reserved

b. Nasal surgery can facilitate the treatment of OSA by improving compliance with CPAP (Continuous Positive Airway Pressure). There is significant correlation between nasal resistance or obstruction and CPAP non-acceptance where for each 0.1 Pa/cm3/s increase in resistance the odds ratio of non-acceptance increases 1.48-fold (Sugiura 2007). Nasal surgery lowers nasal resistance. Nakata & coworkers (Nakata et al 2008) showed that using septoplasty and inferior turbinate reduction for CPAP non-adherent patients demonstrated that there was a reduction in nasal resistance from 0.57 to 0.16 Pa/cm3/s, and postoperatively all patients became CPAP adherent. Nasal surgery may lower CPAP pressures by 2-3cm H2O (Friedman 2000; Zonato 2006). Nasal surgery (septoplasty and turbinoplasty) led to increased CPAP use and decreased CPAP pressure (Poirrier et al, 2014).

Other payer policies:

1) Anthem BCBS 2025
    a. Does not cover septoplasty for OSA/CAP tolerance
        i. Septoplasty has also been proposed for septal deviation when there is intolerance to continuous positive airway pressure (CPAP) for obstructive sleep apnea. Current literature is limited to small group sizes with short-term follow-up for CPAP compliance
        ii. Note: does cover septoplasty for “distressing symptoms of nasal obstruction when other treatable causes of obstruction are either not documented, documented as absent or documented as unlikely to be responsible for symptoms”
2) Aetna 2025
    a. Does not list CPAP compliance or OSA among covered indications for septoplasty.
3) EmblemHealth 2026
    a. Obstructive sleep apnea. (to aid in ability to utilize CPAP and help upper airway obstruction) (Note: for those members with allergic rhinitis who also have OSA, documentation of conservative management failure in the presence of allergic rhinitis [i.e., allergic precautions, antihistamines,

*CPT only copyright 2025 American Medical Association. All rights reserved.
** Current Dental Terminology © 2025 American Dental Association. All rights reserved

topical nasal steroids and plus/minus desensitization injections] should be submitted)

4) United Healthcare 2026
    a. Does not list CPAP compliance or OSA among covered indications for nasal procedures

Expert input:

Dr. Peggy Kelley, pediatric ENT and Dr. Sara Yang, OHSU adult ENT.

Drs. Kelley and Yang recommended coverage of deviated nasal septum when causing or contributing to obstructive sleep apnea (OSA).

HERC staff summary:

Limited evidence has been published regarding the impact of septoplasty on CPAP utilization. The majority of the literature consists of case series or small cohorts as well as one very small RCT. The study authors point out a number of issues with the literature and conclude that the data is suggestive but that more definitive studies should be done. The AASM does not mention nasal surgery in their guideline for OSA treatment; instead, they discuss education and mask fitting to improve CPAP tolerance. The AAO-HNS do recommend nasal surgery for both primary treatment of OSA and for CPAP tolerance. The majority of private payers do not cover septoplasty for the indication of CPAP tolerance; however, these payers generally cover septoplasty for breathing issues which may result in some coverage for CPAP tolerance through that pathway. HERC staff received feedback from CCO medical directors that they felt that the evidence supporting nasal surgery for CPAP tolerance was very weak and that the current guideline should continue to indicate that nasal surgery is not covered for OSA-related indication. Based on re-review of the systematic review on this topic as well as specific coverage policy reviews, HERC staff no longer recommend coverage of septoplasty for CPAP tolerance/compliance.

HERC staff recommend making clarifying changes to Guideline Note 118 as shown below

HERC staff recommendation:

A) Modify GN 118 as shown below

*CPT only copyright 2025 American Medical Association. All rights reserved.
** Current Dental Terminology © 2025 American Dental Association. All rights reserved

Septoplasty for CPAP tolerance

1) Specifically state that septoplasty is not medically necessary to improve CPAP adherence. This is consistent with CCO medical director feedback on the limitations of the literature in this area

GUIDELINE NOTE 118, SEPTOPLASTY

Lines 42,119,201,244,285,309,464,495,512,562

Septoplasty is included on Line 309 for gender affirming treatment.

Septoplasty is included on Lines 42, 119, 201, 244, 285, 464, 495, 512 and 562 when

A) The septoplasty is done to address symptomatic septal deviation or deformity which

1) Fails to respond to a minimum 6-week trial of conservative management (e.g. nasal corticosteroids, decongestants, antibiotics); AND

2) Results in persistent or recurrent epistaxis, OR documented recurrent sinusitis felt to be due to a deviated septum and the patient meets criteria for sinus surgery in Guideline Note 35, SINUS SURGERY; OR

B) Septoplasty is performed in association with cleft lip or cleft palate repair or repair of other congenital craniofacial anomalies; OR

C) Septoplasty is performed as part of a surgery for a neoplasm or facial trauma involving the nose.

Septoplasty for other nasal obstruction not meeting the criteria above is included only on Line 562. Sept

Septoplasty is not included on these lines for treatment of obstructive sleep apnea or for improving ability to use CPAP. ~~and is not included on Line 201 SLEEP APNEA, NARCOLEPSY, INSOMNIA, HYPERSOMNIA, AND REM BEHAVIORAL DISORDER~~

The Effect of Nasal Surgery on Continuous Positive Airway Pressure Device Use and Therapeutic Treatment Pressures: A Systematic Review and Meta-Analysis

Macario Camacho, MD[1]; Muhammad Riaz, MD[2]; Robson Capasso, MD[3]; Chad M. Ruoff, MD[1]; Christian Guilleminault, MD[1]; Clete A. Kushida, MD, PhD[1]; Victor Certal, MD[4]

[1]Department of Psychiatry, Division of Sleep Medicine, Stanford Hospital and Clinics, Stanford, CA; [2]Department of Family and Community Medicine, University of California San Francisco, Fresno, CA; [3]Department of Otolaryngology-Head and Neck Surgery, Sleep Surgery Division, Stanford University Medical Center, Stanford, CA; [4]Department of Otorhinolaryngology, Hospital Lusiadas - Porto, Portugal; CINTESIS - Center for Research in Health Technologies and Information Systems, University of Porto, Porto, Portugal

Background: The relationship between nasal surgery and its effect on continuous positive airway pressure (CPAP) device therapeutic treatment pressures and CPAP device use has not been previously systematically examined.

Study Objectives: To conduct a systematic review and meta-analysis evaluating the effect of isolated nasal surgery on therapeutic CPAP device pressures and use in adults with obstructive sleep apnea.

Methods: MEDLINE, Scopus, Web of Science, and The Cochrane Library were searched through July 15, 2014. The MOOSE consensus statement and PRISMA statement were followed.

Results: Eighteen studies (279 patients) reported CPAP data after isolated nasal surgery. Seven studies (82 patients) reported preoperative and postoperative mean therapeutic CPAP device pressures and standard deviations, which reduced from 11.6 ± 2.2 to 9.5 ± 2.0 centimeters of water pressure (cwp) after nasal surgery. Pooled random effects analysis demonstrated a statistically significant pressure reduction, with a mean difference of −2.66 cwp (95% confidence intervals, −3.65 to −1.67); $P < 0.00001$. Eleven studies (153 patients) described subjective, self-reported data for CPAP use; and a subgroup analysis demonstrated that 89.1% (57 of 64 patients) who were not using CPAP prior to nasal surgery subsequently accepted, adhered to, or tolerated it after nasal surgery. Objective, device meter-based hours of use increased in 33 patients from 3.0 ± 3.1 to 5.5 ± 2.0 h in the short term (< 6 mo of follow-up).

Conclusion: Isolated nasal surgery in patients with obstructive sleep apnea and nasal obstruction reduces therapeutic CPAP device pressures and the currently published literature's objective and subjective data consistently suggest that it also increases CPAP use in select patients.

Keywords: continuous positive airway pressure, nasal surgery, obstructive sleep apnea, sleep apnea syndromes

Citation: Camacho M, Riaz M, Capasso R, Ruoff CM, Guilleminault C, Kushida CA, Certal V. The effect of nasal surgery on continuous positive airway pressure device use and therapeutic treatment pressures: a systematic review and meta-analysis. *SLEEP* 2015;38(2):279–286.

INTRODUCTION

Nasal continuous positive airway pressure (CPAP) was introduced by Sullivan et al.[1] in 1981 as treatment for obstructive sleep apnea (OSA) and treatment has been shown to have a mortality benefit.[2] Although CPAP is highly efficacious, the non-adherence rate (< 4 h of nightly use 70% of nights) is between 46–83%.[3] CPAP side effects include insomnia, claustrophobia, nocturnal awakenings, irritation of the upper airway, sneezing, nasal dryness, rhinitis, rhinorrhea, laryngitis, and epistaxis.[4–7] Nasal obstruction is a common complaint among CPAP users, with an estimated prevalence of 25–45%.[4,7,8] Decreased cross-sectional area and reduced volume of the nasal airway is associated with patients being less compliant with CPAP therapy.[9] Increased nasal resistance has also been associated with decreased CPAP therapy adherence.[10] Studies demonstrate that isolated nasal surgery in patients with nasal obstruction reduces therapeutic CPAP pressures and/or improves CPAP acceptance, compliance, tolerance, adherence, or use.[5,10–26] The objective of this study is to conduct a systematic review of the literature and perform a meta-analysis to evaluate the effect of isolated nasal surgery on therapeutic CPAP device pressures and CPAP use in adults with OSA.

METHODS

Search Strategy

A search of four databases (MEDLINE, Scopus, Web of Science, and The Cochrane Library) was performed from inception through September 1, 2013, with an update through July 15, 2014. Keywords, MeSH terms, and phrases searched included combinations of: "continuous positive airway pressure," "nasal obstruction," "nasal surgery," "nose surgery," "rhinoplasty," "septoplasty," "septorhinoplasty," "septoturbinoplasty," "sleep apnea," "sleep apnea syndromes," "surgery," "turbinate reduction," "turbinectomy," and "turbinoplasty". An example of a search on MEDLINE is: ((("Continuous Positive Airway Pressure"[MeSH]) OR ("Sleep Apnea, Obstructive"[MeSH])) AND (("Nasal Obstruction/surgery*"[MeSH]) OR ("Nasal Septum/surgery*"[MeSH]) OR "nasal surgery" OR ("Nasal Surgical Procedures*"[MeSH]) OR "nose surgery" OR "rhinoplasty" OR ("Rhinoplasty/methods*"[MeSH]) OR "septoplasty" OR "septorhinoplasty" OR "septoturbinoplasty" OR "turbinate reduction" OR ("Turbinates/surgery"[MeSH]) OR "turbinectomy" OR "turbinoplasty")).

The titles and abstracts for each of the results were reviewed for relevance. The full text versions of relevant articles were

Downloaded from https://academic.oup.com/sleep/article/38/2/279/2416975 by State of Oregon Law Library user on 16 January 2026

obtained for complete evaluation. The references of the obtained articles were also reviewed and any relevant studies in the reference lists were also obtained and included if they met criteria. As an additional step, each time a relevant article was encountered during the review of titles and abstracts, the "related citations/articles" and "cited by" features of the four databases and Google Scholar were searched to identify any additional potentially relevant articles.

Study Selection

Inclusion criteria for the studies consisted of adult patients with OSA who were treated with CPAP and underwent isolated nasal surgery. Additionally, the included studies needed to report quantitative outcomes data comparing prenasal and postnasal surgery therapeutic CPAP pressures and/or prenasal and postnasal surgery CPAP acceptance, compliance, tolerance, adherence, or use after nasal surgery, without regard to follow-up length. All languages and study designs were included. Exclusion criteria consisted of studies reporting qualitative data only and studies on children. If a study reported individual patient data for nasal surgeries and non-nasal surgeries, then the nasal surgery data were abstracted and included in this review.

Data Abstractions and Study Quality Assessment

Two authors (VC and MC) performed a literature search and screened titles and abstracts, and retrieved articles for further review. Data collected included the ages, body mass indices (BMI), therapeutic CPAP device pressures, and CPAP use data. After the data were collected, the National Institute for Health and Clinical Excellence (NICE) quality assessment tool, consisting of eight items for each study, was used to evaluate the quality of each of the included studies. Data were placed into an Excel 2013 spreadsheet. Authors of studies in which there were insufficient data reported (e.g., study means, standard deviations [SD], etc.) to include in the meta-analysis were contacted via email or phone, in an attempt to obtain these additional data. The corresponding authors were contacted for the following studies: Bican et al.,[19] Friedman et al.,[16] Nakata et al.,[10] Park et al.,[26] Pniak et al.,[24] Poirier et al.,[11] and Powell et al.[25] The raw data were no longer available for studies by Friedman et al. or Powell et al. Means and SD for CPAP pressures and use were provided by Rotenberg (Poirier et al. study). There was no reply from corresponding authors for Park et al., Bican et al., Nakata et al., and Pniak et al.

Statistical Analysis

The statistical analysis was performed with the Statistical Package for Social Sciences software (SPSS) version 20.0 and the Cochrane Collaboration's Review Manager (REVMAN) Software version 5.2. The prenasal and postnasal surgery means, mean differences (after - before), standard deviations, and 95% confidence intervals (CI) were calculated. If a study provided individual patient data, but did not report a P value, then the data were manually entered into SPSS in order to calculate the means, SD, and mean differences. The null hypothesis before initiating the study was that there is no difference between prenasal and postnasal surgery data. When combining data, a two-tailed, paired *t* test was performed and $P < 0.05$ was considered statistically significant. The REVMAN random effects model for pooling effects was applied if heterogeneity of treatment effects was present and a fixed-effects model was used if no heterogeneity was present. Forest plots were graphically inspected and heterogeneity was assessed with the I^2 statistic (low: 25%, moderate: 50% and high: 75%)[27] and the Cochran Q statistic (it is generally suggested to use a heterogeneity significance level of $P \leq 0.10$).[28] Additionally, a sensitivity analysis was performed by removing each study from the meta-analysis to investigate the effect the individual studies on the summarized effect and heterogeneity. Visual inspections of the funnel plots were performed to assess for publication bias. The Preferred Reporting Items for Systematic Reviews and Meta-Analysis (PRISMA) statement[29] and the Meta-analysis of Observational Studies in Epidemiology (MOOSE) consensus statement[30] were adhered to as much as possible.

RESULTS

The search identified a total of 792 articles after removal of duplicates. After the preliminary review of the titles and abstracts, a total of 29 studies were agreed to as being relevant and the full text was downloaded for further evaluation. Review of the articles' reference lists identified an additional 7 articles, which were also obtained. Of these 36 articles, a total of 18 were excluded for the following reasons: no quantitative CPAP data prenasal and postnasal surgery were presented in the article,[31,32] non-nasal surgeries were performed (i.e. uvulopalatopharyngoplasties, pillar implants or multilevel surgeries)[33–41] or no nasal surgery was performed.[4,7,9,42–45] Zonato et al.[13] reported individual data for nasal surgeries and multilevel surgeries; therefore, the data for nasal surgeries could be separated and included as part of the review. A total of 18 articles were included in this study, with a total of 279 patients identified within those articles, who underwent isolated nasal surgery and had quantitative data available.[5,10–25] Figure 1 demonstrates the flow diagram for the article selection. The mean patient age was 52.5 ± 8.7 y and the mean BMI was 29.5 ± 4.0 kg/m^2.

Methodological Quality of the Included Studies

The studies included in this review were all either retrospective or prospective case series (Level 4 evidence), except for one study by Powell et al.[25] that was a randomized, double-blind, placebo-controlled clinical trial (RCT), which is Level 1 evidence. The NICE quality assessment tool demonstrated that the included studies satisfied between three to six of the eight items, with most satisfying more than four items (presented in Table S1, supplemental material). The main limitations in general are that none of the studies were multicenter, patients were not recruited consecutively, and there was only one randomized controlled trial and the remaining studies were case series.

CPAP Results

Therapeutic CPAP Pressures

A total of 10 studies (135 patients) described therapeutic CPAP device pressures as an outcome after isolated nasal surgery.[5,10–16,20,21,24] Two studies reported the mean difference (MD) of the therapeutic pressures (Balcerzak et al.[20] reported a MD of

Downloaded from https://academic.oup.com/sleep/article/38/2/279/2416975 by State of Oregon Law Library user on 16 January 2026

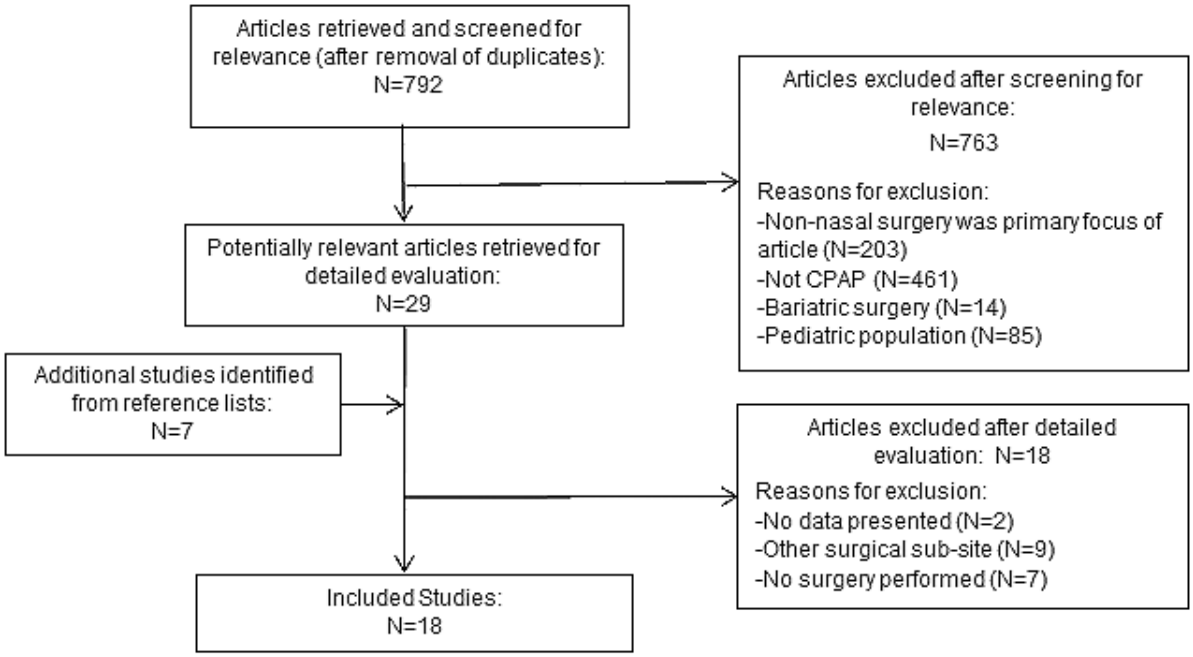

Figure 1—Literature search and study selection. CPAP, continuous positive airway pressure; N, number of studies.

−2.7 cwp and Ripberger and Pirsig[21] reported a MD of −5 cwp), but lacked the SD, therefore, were excluded from meta-analysis. Friedman et al.[16] reported the therapeutic CPAP means prenasal and postnasal surgery, but did not report the SD; therefore, the study was excluded from pooled meta-analysis calculations.[16] The remaining 7 studies (82 patients) reported both preoperative and postoperative therapeutic CPAP device pressures and SD, which were provided in the article or were obtained by contacting the authors of the original studies.[5,10–15]

With regard to determination of the therapeutic CPAP device pressures, Park et al.,[6] Poirier et al.,[11] and Mayer-Brix et al.[5] reported the therapeutic pressures based on the patients' CPAP devices, whereas in the remaining 5 studies in the meta-analysis reported therapeutic pressures based upon the in-laboratory polysomnography titrations.[5,10–15] Hypopnea scoring criteria for the studies included ≥ 10 sec for the hypopnea duration, in combination with: ≥ 3% oxygen desaturation with a 50% decrease in thermistor for Sufioglu et al.,[12] ≥ 3% oxygen desaturation or arousal associated with a hypopnea for Nakata et al.,[10] > 4% oxygen desaturation for Nowak et al.,[14] ≥ 4% oxygen desaturation with a ≥ 50% decreased effort to breathe for Katsantonis et al.,[46] whereas the remaining studies did not specify which hypopnea scoring criteria was used.[5,11,13,15,26]

The combined data for the 7 studies demonstrated a prenasal and postnasal surgery therapeutic CPAP device pressure that reduced from a mean ± SD of 11.6 ± 2.2 to 9.5 ± 2.0 centimeters of water pressure (cwp), with results shown in Table 1. The pooled random effects analysis (Figure 2) demonstrated a statistically significant reduction in the mean pressures, with a MD of −2.66 cwp (95% CI, −3.65 to −1.67; overall effect: Z score = 5.27 (P < 0.00001)). The I^2 (82%) and Cochran Q statistic (P < 0.00001) suggest significant heterogeneity across included studies, and therefore justified the need for a random-effects model. A sensitivity analysis showed that removing the Sufioglu et al.[12] study resulted in a low level of heterogeneity (I^2 = 27% and Cochran Q statistic = 0.23) but did not significantly affect the summarized effect size (MD: −3.00 cwp; 95% CI: −3.56 to −2.43, Z score = 10.39, and P < 0.00001). The study by Sufioglu et al.[12] states that a postoperative CPAP titration was not performed in five patients who were cured of OSA (apnea-hypopnea index [AHI] < 5/h).[12] Visual inspection of the funnel plot also demonstrated that the study by Sufioglu et al.[12] was slightly outlying when compared to the remaining studies.

A subgroup analysis was performed for studies that specifically stated in the article that nasal mask interfaces were used (studies did not specify nasal pillows versus nasal triangle masks), which resulted in the exclusion of studies by Sufioglu et al.[12] and Nakata et al.[10,12] When pooling the data from the remaining five studies (49 patients), the nasal CPAP pressures decreased from 11.3 ± 2.0 to 8.8 ± 1.9 cwp.[5,11,13–15] There was no heterogeneity across these studies, demonstrated by an I^2 of 0% and Cochran Q statistic of P = 0.54. The fixed effects analysis for this subgroup demonstrated a statistically significant decrease in the mean pressure with MD of −2.81 cwp (95% CI, −3.22 to −2.40; overall effect: Z score = 13.46, P < 0.00001 [see Figure 3]).

Individual patient therapeutic CPAP pressure data were reported for 20 patients, overall 85% (17 patients) decreased, 5% (one patient) remained the same, and 10% (two patients) increased their therapeutic CPAP pressures.[5,13,15]

Type of Nasal Surgery Performed and the Effect on Therapeutic CPAP Pressures

Data analyses were performed for the specific nasal surgery subsites: (1) septoplasty, (2) turbinoplasty, (3) septoplasty with turbinoplasty, and (4) unspecified; there were four

cwp, centimeters of water pressure; E, endoscopic sinus surgery; N, number of patients; R, septorhinoplasty; S, septoplasty; ST, septoturbinoplasty; T, turbinoplasty. * Statistically significant P value based on either the reported study value or a paired samples t-test and the calculated 2-tailed significance for the paired difference. ** Total calculations are based on studies providing both the means and standard deviations.

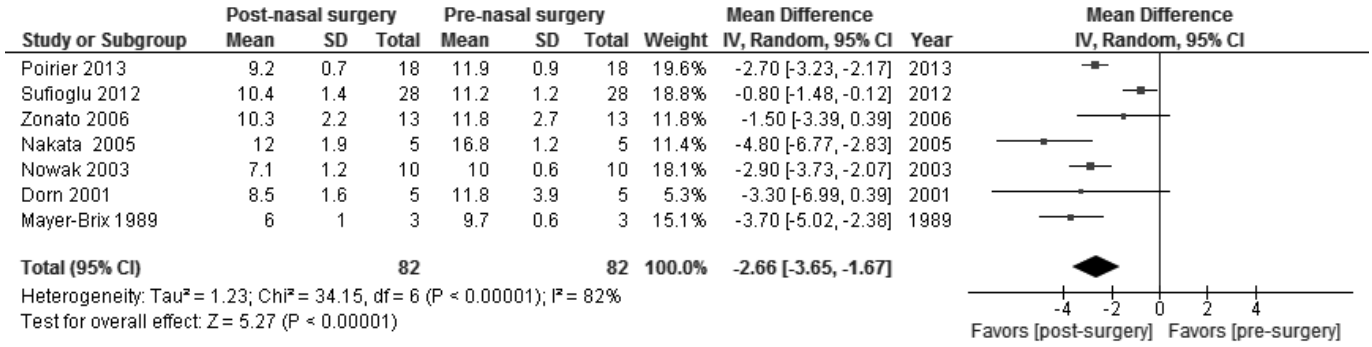

Figure 2—Prenasal and postnasal surgery random effects analysis. There was a statistically significant decrease in therapeutic continuous positive airway pressure device pressures with a mean difference of −2.66 cwp (95% confidence interval [CI], −3.65 to −1.67; P < 0.00001). SD, standard deviation.

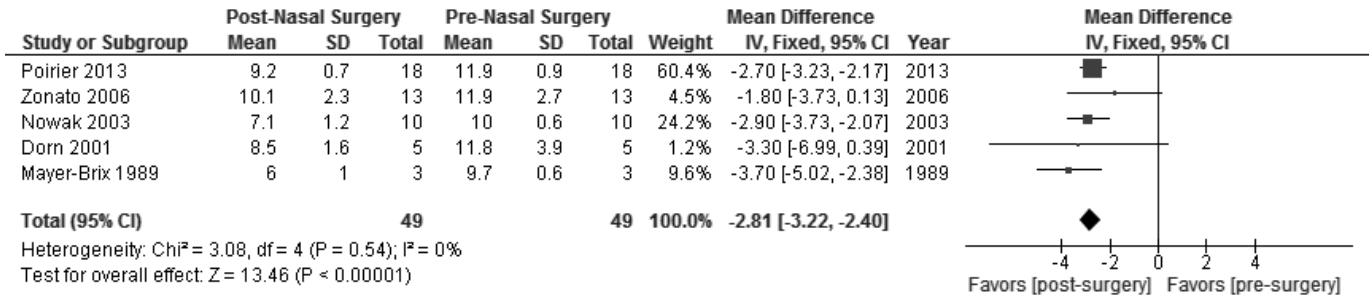

Figure 3—Subgroup analysis for studies in which continuous positive airway pressure (CPAP) was delivered by a nasal mask interface, prenasal and postnasal surgery. The fixed-effects analysis demonstrated a statistically significant decrease in therapeutic CPAP device pressures with a mean difference of −2.81 cwp (95% confidence interval [CI], −3.22 to −2.40; P < 0.00001). SD, standard deviation.

studies[10,12,14,15] during which multiple procedures such as septoplasties, turbinoplasties, rhinoplasties, and sinus surgeries, were performed but did not list individual patient data. Therefore the data are presented in the category of "unspecified." Overall, 2 studies reported individual patient data and the specific subsite,[5,13] and Poirier et al.[11] performed the same procedure in all patients, and therefore could be included in individual subsite data analyses. Outcomes for the combined nasal surgery subsites are presented in Table 2. The largest MD was observed in the septoplasty with turbinoplasty group (25 patients), demonstrating a MD of −2.60 cwp (95% CI −3.33, −1.87); overall effect: Z score = 5.52, P < 0.00001. The MD for the remaining nasal surgery sub-sites included: (1) unspecified (48 patients), −1.90 cwp (95% CI −2.80, −1.00); overall effect: Z score = 2.99, P = 0.0001; (2) turbinoplasty (8 patients), −2.2 cwp; paired *t* test P = 0.048; and (3) septoplasty (one patient), −2.0 cwp.

Table 2—Pre and postnasal surgery therapeutic mean CPAP pressure data stratified by nasal surgical sub-sites.

Nasal surgery performed	Study authors (number of patients in individual studies)	N	Mean CPAP pressure prenasal surgery (cwp)	Mean CPAP pressure postnasal surgery (cwp)	Mean difference	P value
Septoplasty	Zonato et al.	1	10.0	8.0	−2.0 cwp	–
Turbinoplasty	Zonato et al.	8	12.4 ± 3.3	10.2 ± 2.5	−2.2 ± 2.6 cwp	0.048*
Septoplasty with turbinoplasty	Poirier et al. (N = 18) Zonato et al. (N = 4) Mayer-Brix et al. (N = 3)	25	11.6 ± 1.1	9.0 ± 1.5	−2.60 cwp (CI −1.87, −3.33)	< 0.00001*
Unspecified**	Sufioglu et al. (N = 28) Nakata et al. (N = 5) Nowak et al. (N = 10) Dorn et al. (N = 5)	48	11.6 ± 2.4	9.7 ± 2.1	−1.90 cwp (CI −1.00, −2.80)	0.0001*

cwp, centimeters of water pressure; N, number of patients. *Statistically significant P value. Only three studies provided individual patient data that allow sub-site analyses. **The 4 nasal surgery studies that did not report individual patient data, however, the articles reported that septoplasties, turbinoplasties, rhinoplasties and/or sinus surgeries were performed.

CPAP Use After Nasal Surgery

Eleven studies (153 patients) evaluated CPAP acceptance, compliance, tolerance, adherence, or use before and after nasal surgery.[10,11,17–19,21–25] Three studies (n = 40) reported objective data from the CPAP devices themselves,[11,25,26] three studies (n = 49) reported subjective, patient self-reported use,[19,21,25] and six studies (n = 81) did not specify whether objective or subjective data was collected (Note: Powell et al. reported both objective and subjective data for all patients).[10,17,18,22–24]

The percentage of patients regularly using CPAP prior to nasal surgery was 38.7% (36 of 93 patients) and the percentage of patients who were adherent (synonymous with compliant), accepting, or tolerating CPAP after nasal surgery was 90.2% (92 of 102 patients). A subgroup analysis demonstrated that 89.1% (57 of 64 patients) who were not using CPAP prior to nasal surgery subsequently accepted, adhered to, or tolerated CPAP after nasal surgery. There were differences in the inclusion criteria between studies (i.e., six studies included patients not tolerating CPAP prior to nasal surgery,[10,11,18,22,24,26] two studies included patients already using CPAP, but with nasal obstruction present,[17,25] and three studies did not specify[19,21,23]). The CPAP device downloaded data for prenasal surgery hours of CPAP use mean and SD were 3.0 ± 3.1 h and postnasal surgery were 5.5 ± 2.0 h. The calculated treatment effect of nasal surgery based on Powell et al.'s RCT (difference between the treatment group and placebo controls) at 1 mo was 32 min (95% CI −21, 84), P = 0.22.[25] Table 3 summarizes prenasal and postnasal surgery objective and subjective CPAP use data.

DISCUSSION

There are five main findings in this study. First, there is a statistically significant relationship between nasal surgery and therapeutic CPAP pressures. Poiseuille's Law has demonstrated that resistance to airflow is directly proportional to the length and is inversely proportional to the fourth-power of the radius.[47] Therefore, a 10% increase in the cross-sectional area of the nasal airway can result in an increase of 21% of nasal airflow.[25] Thus, decreasing the size of the inferior turbinates or decreasing other sources of nasal obstruction (deviated septums, septal spurs, polyps, etc.) can provide a reduction in the nasal airway resistance, and therefore may lead to a decreased therapeutic CPAP pressure. In this meta-analysis, the pooled data for 82 patients demonstrates a MD of −2.66 cwp with a range of −0.8 to −4.8 cwp. The sensitivity analysis identified the study by Sufioglu et al.[12] as the source of heterogeneity, which is possibly caused by not performing a postoperative CPAP titration in five patients who were cured of OSA (AHI < 5/h), therefore the prenasal and postnasal CPAP device pressure MD is potentially smaller (0.8 cwp) than it would have been had those cured patients undergone a postoperative CPAP titration. The remaining studies' MD decreased by at least 1.5 cwp. Additionally, the visual inspection of the funnel plot for therapeutic CPAP device pressures demonstrated that the study by Sufioglu et al.[12] was slightly outlying when compared to the remaining studies. One difference in this study compared to the others is that this study reported the use of thermistors whereas the other studies did not specify whether thermistors or nasal cannulas were used.[12] Despite this difference, a similar MD prenasal and postnasal surgery would be expected because the same technique was used within the same study group. Because of publication bias against negative studies, it is possible that additional studies demonstrating minimal or no difference in CPAP device pressures after nasal surgery never made it to publication and therefore the study by Sufioglu et al.[12] would not be an outlier in that situation.[28]

Second, regardless of the nasal surgery subsite, there is at least a MD of −1.9 cwp between preoperative and postoperative CPAP device pressures (as outlined in Table 2). The greatest difference was seen in patients undergoing a combined septoplasty with turbinoplasty (MD of −2.6 cwp). It must be pointed out that only the study by Zonato et al.[13] reported outcomes for isolated septoplasty (one patient) and isolated turbinoplasty (eight patients). Additionally, only three of seven studies reported both preoperative and postoperative means and SD and also had individual patient data or performed the same procedure in all patients, which allowed the subsite data to be combined (34 patients). A significant limitation in the ability to subanalyze the data for the remaining four studies (48 patients) was

Table 3—Data regarding prenasal and postnasal surgery acceptance, adherence, tolerance, or use.

Study authors, Study year, Follow-up duration	# Pts	Prenasal Surgery: # Pts regularly using CPAP	Postnasal Surgery: # Pts adherent, accepting or tolerating CPAP	Prenasal Surgery: Objective hours of use	Postnasal Surgery: Objective hours of use	Postnasal Surgery: Subjective hours of use	Postnasal Surgery: Subjective hours of use	Additional information
Park et al.* 2014, 2 mo	7	0/7	7/7	0.0	≥ 4	–	–	RCS. Pressures reduced in 6 out of 7 patients.
Poirier et al.* 2013, 6 mo	16	0/16	16/16	0.5 ± 0.73	5.0 ± 2.37	–	–	PCS. 2 of 18 patients were cured.
Powell et al.*,** 2001, 1 mo	17	17/17	17/17	5.77 ± 2.08	5.97 ± 1.43	–	–	RCT. Treatment group used CPAP 32 min more at 1 mo compared to placebo controls.
Pniak et al.*** 2012, 3–6 mo	8	0/8	3/8	–	–	–	–	RCS. Improved subjective nasal patency.
Bican et al.** 2010, 2.5–6.5 mo	20	12/20	20/20	–	–	–	–	RCS. Tolerating CPAP device was easier. Mean postop pressure: 8.5 cwp.
Nakata et al.*** 2005	12	0/12	12/12	–	–	–	–	RCS: Nasal resistance decreased from 0.57 ± 0.31 to 0.16 ± 0.03 Pa/cm³/sec (P value < 0.01).
Esteller et al.*** 2004, > 12 mo	9	–	8/9	–	–	–	–	PCS. Tolerance was easier, and adherence increased (5 hours a day, 5 nights a week).
Biermann et al.*** 2001, 36 mo	39	–	–	–	–	–	6.7 ± 1.4	RCC. Treatment group used CPAP 48 min more at 3 years compared to control group.
Hollandt et al.*** 1997, 21 mo	6	0/6	2/6	–	–	0.0	5.85 ± 2.90	PCS. Two patients accepted PAP therapy after nasal surgery.
Ripberger et al.** 1994, 18 mo	12	–	–	–	–	–	–	PCS. Pressure decreased by an average of 5 cwp and the CPAP acceptance increased.
Series et al.*** 1992, 3 mo	7	0/7	7/7	–	–	–	–	RCS. 7 pts intolerant to CPAP due to discomfort, became tolerant after nasal surgery.
Total	153	36/93 (38.7%)	92/102 (90.2%)	3.0 ± 3.1	5.5 ± 2.0	–	–	57/64 pts (89.1%) not using CPAP subsequently accepted, adhered to or tolerated it after surgery.

Poirier et al.'s results exclude two patients who were cured of OSA. * Objective CPAP device data reported. ** Subjective, patient-reported data. *** Study did not specify if objective or subjective use data was reported. #, number; cwp, cm of water pressure; mo, months; PCS, prospective case series; Pts, patients; RCC, retrospective case-control; RCS, retrospective case series; RCT, randomized-controlled trial.

that multiple procedures were listed in these studies, without individual patient data. Therefore, it is possible that other procedures such as endoscopic sinus surgery for nasal polyposis or a functional rhinoplasty combined with septoplasty and turbinoplasty could be as effective or more effective in reducing CPAP device pressures; however, without stratified data, these conclusions cannot be made. Given that the currently published literature reporting outcomes for individual patient data is limited, we recommend that future researchers report outcomes for individual patients stratify the data for isolated subsites (i.e. septoplasty, turbinoplasty, etc.).

Third, overall CPAP use increased after nasal surgery and was demonstrated by 11 studies (153 patients). It should be noted that the patients in these studies were motivated enough to reattempt CPAP therapy. Two issues exist: first, only three studies specified that objective device data was used, whereas the remaining eight studies either reported subjective outcomes or did not specify. Second, one of the challenges in combining the "use" data is that studies refer to "use" by different terminology, such as: acceptance, compliance, adherence, tolerance, and use. We reviewed each of the study descriptions of "use" in order to organize the results into appropriate categories. The hours of use in each study reporting it varied significantly because of the differences in the inclusion criteria between studies, which ranged from including patients not tolerating CPAP prior to nasal surgery,[10,11,18,22,24] to including patients already using CPAP, but with complaints of nasal obstruction significant enough to warrant surgery.[17,25] Despite the differences in the inclusion criteria, there was an increase in objective and subjective CPAP use after surgery and there was a progressive increase in hours of use as the

Downloaded from https://academic.oup.com/sleep/article/38/2/279/2416975 by State of Oregon Law Library user on 16 January 2026

duration of follow-up from nasal surgery increased. There can be significant nasal crusting and edema after nasal surgery, and the healing phase may last 2–6 w. Therefore, studies reporting on pressure reduction and hours of use, should follow patients for 3–6 mo after surgery to ensure the healing is complete and the edema has resolved, because this can affect the results of CPAP use and therapeutic CPAP device pressures.

Fourth, in order to facilitate future research, we would like to recommend standardized terminology. Regarding the term "use", studies have demonstrated that self-reported CPAP usage overestimates the actual usage by approximately 1 h when compared to the CPAP device download data[8,48–50]; therefore, we recommend reporting the device download data as "use". The terms "adherence" and "compliance" have been used interchangeably,[3,50] and have been previously defined as "using CPAP for ≥ 4 h per night.[3,48,51]" When reporting the percentage of nights that patients are adherent, 70% is often used as a cutoff "regularly using" CPAP therapy.[48,51] The term "tolerance", as related to CPAP and nasal surgery, has been defined by the use of a visual analog scale (10 cm) with anchors 0 cm = "unable to tolerate or use" and 10 cm = "easily tolerated and use all 7 nights per week."[25] The term "acceptance", if used, should be defined by the authors reporting it to avoid ambiguity.

Fifth, there is a need for additional high-quality studies to allow for additional data analyses and to increase the power to draw more definitive conclusions. Most of the studies in this review were retrospective case series, with only five prospective case series and one randomized controlled trial. The study by Powell et al.,[25] which was very well planned, can serve as an example for future randomized, double-blind, placebo-controlled clinical trials. Two limitations with the study by Powell et al. were that only 22 patients were included, and the follow-up was short (1 mo, which is within the window of healing). When planning a study on nasal surgery and CPAP, important data to collect includes: the total number of nights of CPAP use versus nonuse, the percentage of nights with CPAP use versus nonuse, the percentage of nights with usage ≥ 4 h per night versus < 4 h per night, the average usage on nights CPAP was used and the average usage on all nights.[52] Additional important information to report includes: the 95th percentile leak, Epworth Sleepiness Scale questionnaire data,[53] the effect of treatment on quality of life, inferior turbinate sizes before and after surgery,[54] and information on nasal obstruction, which can be assessed with the Nasal Obstruction Symptom Evaluation (NOSE) scale questionnaire.[55]

CONCLUSION

Isolated nasal surgery in patients with OSA with nasal obstruction reduces therapeutic CPAP device pressures, and the currently published literature's objective and subjective data consistently suggest that it also increases CPAP use in select patients.

Treatment of Adult Obstructive Sleep Apnea with Positive Airway Pressure: An American Academy of Sleep Medicine Clinical Practice Guideline

Susheel P. Patil, MD, PhD[1]; Indu A. Ayappa, PhD[2]; Sean M. Caples, DO[3]; R. John Kimoff, MD[4]; Sanjay R. Patel, MD[5]; Christopher G. Harrod, MS[6]

[1]Johns Hopkins University, Baltimore, Maryland; [2]Icahn School of Medicine at Mount Sinai, New York, New York; [3]Mayo Clinic, Rochester, Minnesota; [4]McGill University Health Centre, Montreal, Quebec, Canada; [5]University of Pittsburgh, Pittsburgh, Pennsylvania; [6]American Academy of Sleep Medicine, Darien, Illinois

Introduction: This guideline establishes clinical practice recommendations for positive airway pressure (PAP) treatment of obstructive sleep apnea (OSA) in adults and is intended for use in conjunction with other American Academy of Sleep Medicine (AASM) guidelines in the evaluation and treatment of sleep-disordered breathing in adults.

Methods: The AASM commissioned a task force of experts in sleep medicine. A systematic review was conducted to identify studies, and the Grading of Recommendations Assessment, Development and Evaluation (GRADE) process was used to assess the evidence. The task force developed recommendations and assigned strengths based on the quality of evidence, the balance of clinically significant benefits and harms, patient values and preferences, and resource use. In addition, the task force adopted recommendations from prior guidelines as "good practice statements" that establish the basis for appropriate and effective treatment of OSA. The AASM Board of Directors approved the final recommendations.

Good Practice Statements: The following good practice statements are based on expert consensus, and their implementation is necessary for appropriate and effective management of patients with OSA treated with positive airway pressure:

1. Treatment of OSA with PAP therapy should be based on a diagnosis of OSA established using objective sleep apnea testing.
2. Adequate follow-up, including troubleshooting and monitoring of objective efficacy and usage data to ensure adequate treatment and adherence, should occur following PAP therapy initiation and during treatment of OSA.

Recommendations: The following recommendations are intended as a guide for clinicians using PAP to treat OSA in adults. A STRONG (ie, "We recommend…") recommendation is one that clinicians should follow under most circumstances. A CONDITIONAL recommendation (ie, "We suggest…") reflects a lower degree of certainty regarding the outcome and appropriateness of the patient-care strategy for all patients. The ultimate judgment regarding any specific care must be made by the treating clinician and the patient, taking into consideration the individual circumstances of the patient, available treatment options, and resources.

1. We recommend that clinicians use PAP, compared to no therapy, to treat OSA in adults with excessive sleepiness. (STRONG)
2. We suggest that clinicians use PAP, compared to no therapy, to treat OSA in adults with impaired sleep-related quality of life. (CONDITIONAL)
3. We suggest that clinicians use PAP, compared to no therapy, to treat OSA in adults with comorbid hypertension. (CONDITIONAL)
4. We recommend that PAP therapy be initiated using either APAP at home or in-laboratory PAP titration in adults with OSA and no significant comorbidities. (STRONG)
5. We recommend that clinicians use either CPAP or APAP for ongoing treatment of OSA in adults. (STRONG)
6. We suggest that clinicians use CPAP or APAP over BPAP in the routine treatment of OSA in adults. (CONDITIONAL)
7. We recommend that educational interventions be given with initiation of PAP therapy in adults with OSA. (STRONG)
8. We suggest that behavioral and/or troubleshooting interventions be given during the initial period of PAP therapy in adults with OSA. (CONDITIONAL)
9. We suggest that clinicians use telemonitoring-guided interventions during the initial period of PAP therapy in adults with OSA. (CONDITIONAL)

Keywords: obstructive sleep apnea, OSA, positive airway pressure, PAP

INTRODUCTION

Since the publication of the previous American Academy of Sleep Medicine (AASM) positive airway pressure (PAP) practice parameters,[1–3] the scientific literature has continued to expand regarding the effects of PAP on clinical outcomes in adults with obstructive sleep apnea (OSA). In addition, research on improving PAP adherence and advancements in device technology have continued to evolve. Given these advancements, updating the prior practice parameters was considered timely.

The AASM commissioned a task force (TF) of content experts to update and consolidate previous AASM PAP practice parameters and reviews relevant to the treatment of adult OSA with PAP modalities.[1,3,4] This guideline does not address the initiation and management of PAP in patients with obesity hypoventilation syndrome, sleep-related hypoventilation, or those with concurrent forms of obstructive and central sleep apnea. The efficacy of continuous PAP (CPAP), auto-adjusting PAP (APAP), bilevel PAP (BPAP), and other advanced PAP modalities for central sleep apnea and hypoventilation are addressed in other active AASM guidelines.[5,6] Furthermore, several prior

recommendations on the management of OSA with PAP were not readdressed in the present guideline. Nevertheless, the TF adopted and modified two prior statements as good practice statements, as they were considered essential to providing high quality care to patients with OSA who are treated with PAP.

This guideline, in conjunction with the accompanying systematic review,[7] provides a comprehensive update of the available evidence and a synthesis of clinical practice recommendations.

METHODS

The AASM commissioned a TF of both board-certified sleep medicine specialists and experts with proficiency in the use of PAP in adults with OSA to develop this guideline. The TF was required to disclose all potential conflicts of interest (COI) per the AASM's COI policy prior to being appointed to the TF, and throughout the research and writing of this paper. In accordance with the AASM's conflicts of interest policy, TF members with a Level 1 conflict were not allowed to participate. TF members with a Level 2 conflict were required to recuse themselves from any related discussion or writing responsibilities. All relevant conflicts of interest are listed in the disclosure statement.

The TF conducted a systematic review of the scientific literature to answer 11 PICO (Patient, Population or Problem, Intervention, Comparison, and Outcomes) questions regarding the initiation of PAP therapy in patients with OSA that focus on patient-oriented, clinically relevant outcomes (see systematic review, Table 1).[7] The purpose of the review was to determine the effectiveness of PAP, alternative PAP modes (ie, APAP, BPAP), and concurrent strategies designed to improve outcomes by enhancing acceptance and use of PAP for OSA treatment (eg, patient education and telemonitoring). The TF did not compare PAP against other treatment options (eg, oral appliance therapy, surgical therapy). Assessment of the evidence was performed according to the Grading of Recommendations Assessment, Development and Evaluation (GRADE) process.[8] The TF assessed the following four components to determine the direction and strength of a recommendation: quality of evidence, balance of beneficial and harmful effects, patient values and preferences, and resource use. Details of these assessments can be found in the accompanying systematic review.[7] Taking these major factors into consideration, each recommendation statement was assigned a strength (STRONG or CONDITIONAL). Additional information is provided in the form of remarks immediately following the recommendation statements, when deemed necessary by the TF. Remarks are based on the evidence evaluated during the systematic review and are intended to provide context for the recommendations to guide clinicians in the implementation of the recommendations in daily practice.

As this guideline focuses on the indications for PAP therapy for OSA in adults, rather than the use of specific components or accessories of the PAP device, recommendations for three of the PICO questions were not included. A summary of the systematic review and meta-analyses of the evidence for these PICO questions can be found in the additional considerations section, as these factors are still important for clinicians to consider in the context of their individual patient's circumstances, when initiating PAP therapy.

The AASM expects this guideline to have an impact on professional behavior, patient outcomes and, possibly, health care costs. This clinical practice guideline reflects the state of knowledge at the time of publication and will be reviewed and updated as new information becomes available.

GOOD PRACTICE STATEMENTS

The following are good practice statements, the implementation of which is necessary for appropriate and effective management of patients with OSA who are treated with PAP.

Treatment of OSA with PAP therapy should be based on a diagnosis of OSA established using objective testing.[9]

This good practice statement applies specifically to a new diagnosis of OSA, which should be established by either a home sleep apnea test or in-laboratory sleep testing prior to initiation of treatment for OSA. Patients with a previously established diagnosis of OSA who are currently on PAP therapy and have good symptom control should continue PAP therapy, even when prior testing results are not readily available.

Adequate follow-up, including troubleshooting and monitoring of objective efficacy and usage data to ensure adequate treatment and adherence, should occur following PAP therapy initiation and during treatment of OSA.

OSA is a chronic disease that rarely resolves except with substantial weight loss or successful corrective surgery. As with other chronic diseases, periodic follow-up by a qualified clinician (eg, physician or advanced practice provider) is necessary to confirm adequate treatment, assess symptom resolution, and promote continued adherence to treatment. Initial treatment of OSA requires close monitoring and early identification of difficulties with PAP use, as adherence over the first few days to weeks has been shown to predict long-term adherence.[10,11] Objective monitoring of PAP therapy should be performed to complement patient reporting of difficulties with PAP use, as patients often overestimate their use of PAP treatment.[12]

The timing of adequate follow-up after treatment is initiated will vary depending on patient circumstances. However, patients should be followed in the initial weeks to months after PAP initiation to promote adherence and assess response to treatment. Subsequently, yearly evaluation by a trained health care provider is reasonable, although longer periods of follow-up may be appropriate for selected patients who are highly adherent to PAP therapy, have sustained resolution of OSA-related symptoms, and have no concerns regarding their PAP therapy. In contrast, patients with persistent or recurrent sleep-related complaints or persistent difficulties with PAP use should receive more frequent follow-up to address their issues. Routine sleep testing to re-evaluate OSA status in patients

Table 1—Implications of STRONG and CONDITIONAL recommendations for users of AASM clinical practice guidelines.

User	STRONG Recommendations "We recommend…"	CONDITIONAL Recommendations "We suggest…"
Clinicians	Almost all patients should receive the recommended course of action. Adherence to this recommendation could be used as a quality criterion or performance indicator.	Most patients should receive the recommended course of action; however, different choices may be appropriate for different patients. The clinician must help each patient determine if the suggested course of action is clinically appropriate and consistent with his or her values and preferences.
Patients	Almost all patients should receive the recommended course of action, although a small proportion of patients may not.	Most patients should receive the suggested course of action, though some may not. Different choices may be appropriate for different patients. The patient should work with their clinician to determine if the suggested course of action is clinically appropriate and consistent with his or her values and preferences.
Insurance Providers	The recommended course of action can be adopted as policy for most situations. Adherence to the recommended course of action could be used as a quality criterion or performance indicator.	The ultimate judgment regarding the suitability of the suggested course of action must be made by the clinician and patient together, based on what is best for the patient. This decision-making flexibility should be accounted for when establishing policies.

AASM = American Academy of Sleep Medicine.

on PAP therapy with good symptom control and no change in clinical status (eg, significant weight loss or upper airway surgery) is considered low value care.

CLINICAL PRACTICE RECOMMENDATIONS

The following clinical practice recommendations are based on a companion systematic review, which evaluated the evidence using the GRADE methodology and should be read concurrently with this clinical practice guideline.[7] The recommendations in this guideline define principles of practice that should meet the needs of most patients in most situations. A STRONG recommendation is one that clinicians should follow for almost all patients (ie, something that might qualify as a quality measure). A CONDITIONAL recommendation reflects a lower degree of certainty in the appropriateness of the patient-care strategy for *all* patients. It requires that the clinician use clinical knowledge and experience, while strongly considering the individual patient's values and preferences to determine the best course of action. The ultimate judgment regarding any specific care must be made by the treating clinician and the patient, taking into consideration the individual circumstances of the patient, available treatment options, and resources.

The implications of the strength of recommendations for clinicians, patients, and policymakers are summarized in **Table 1.** Remarks are provided to guide clinicians in the implementation of these recommendations. A flowchart for the implementation of the recommendations is presented in **Figure 1**.

PAP Therapy

Recommendation 1: We recommend that clinicians use positive airway pressure, compared to no therapy, to treat OSA in adults with excessive sleepiness. (STRONG)

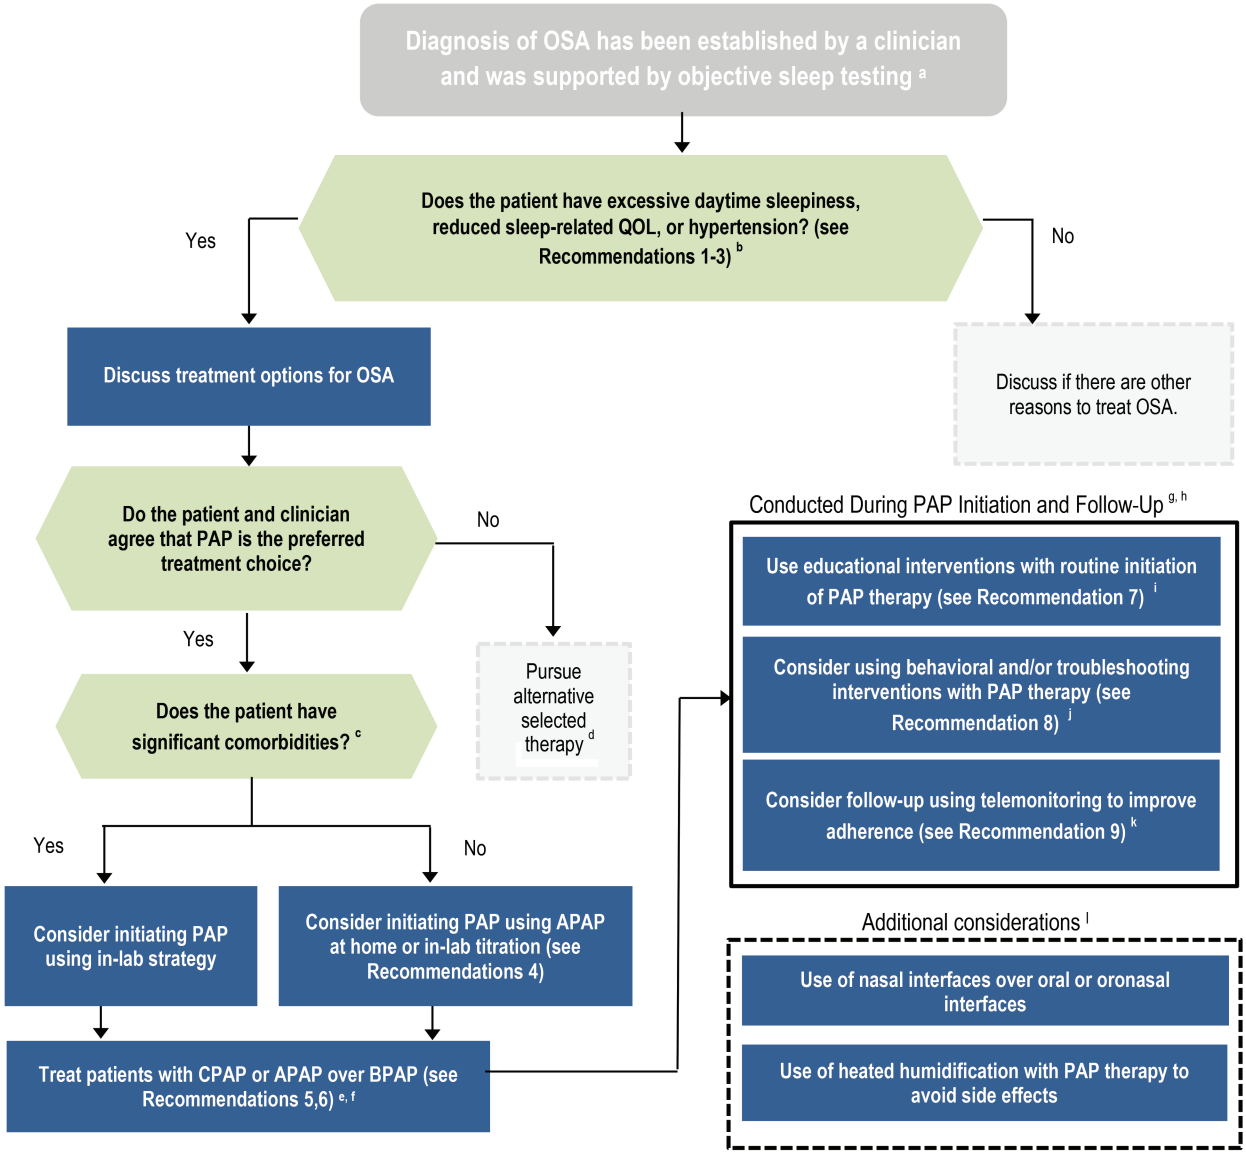
The TF assessed whether PAP should be offered to adult patients with OSA, based on improvements in the critical outcome of sleepiness, compared to no therapy. The TF identified 38 randomized controlled trials (RCTs) that assessed the efficacy of PAP to reduce excessive sleepiness. Meta-analyses demonstrated a clinically significant improvement in sleepiness with the use of PAP to treat adults with OSA as compared with no treatment. The overall quality of evidence, based on the critical outcome of sleepiness, was high. While a benefit of PAP use includes a reduction in daytime sleepiness, the potential harms include side effects such as nasal dryness or irritation, dry mouth, sore throat, and sinus infection as well as loss of intimacy,[4,9] all of which can be mitigated with appropriate interventions or are reversible with discontinuation of PAP. The potential burdens to the patient may include the costs of treatment and inconvenience such as maintaining the equipment and attending follow-up visits with the sleep clinician. The TF concluded that in adult patients with OSA and excessive sleepiness, the benefits of PAP therapy compared to no PAP therapy likely outweigh the potential harms and burdens, and that the majority of well-informed patients would choose the intervention over no treatment.

Recommendation 2: We suggest that clinicians use positive airway pressure, compared to no therapy, to treat OSA in adults with impaired sleep-related quality of life. (CONDITIONAL)

Remarks: Sleep-related quality of life (QOL) in adult patients with OSA may be adversely affected by OSA-related symptoms. Examples of such symptoms include: snoring, sleep-related choking, insomnia, disruption of bedpartner's sleep, morning headaches, nocturia, impairments in productivity or social functioning, and daytime fatigue.

The TF assessed whether PAP compared to no therapy should be offered to adult patients with OSA to improve the critical outcome of sleep-related QOL. OSA-related symptoms that can reduce sleep-related QOL include, but are not limited to; snoring, nocturnal choking, insomnia, disruption of their partner's sleep, morning headaches, nocturia, impairments in productivity or social functioning, and daytime fatigue. The TF identified 19 RCTs that assessed the efficacy of PAP to

Figure 1—Flow chart for implementation of clinical practice guideline.



a = Kapur et al., 2017.[9] b = symptoms that can impair sleep-related QOL include but are not limited to snoring, sleep-related choking, insomnia, disruption of bedpartner's sleep, morning headaches, nocturia, impairments in productivity or social functioning, and daytime fatigue. c = comorbidities may include: congestive heart failure, chronic opiate use, significant lung disease such as chronic obstructive pulmonary disease, neuromuscular disease, history of uvulopalatopharyngoplasty, those with known sleep-related oxygen requirements or expected to have nocturnal arterial oxyhemoglobin desaturation due to conditions other than OSA including hypoventilation syndromes and central sleep apnea syndromes. d = alternative therapies may include, but are not limited to, weight loss, positional therapy, oral appliance therapy or surgical interventions. e = BPAP is defined as a respiratory assist device that delivers inspiratory and expiratory positive airway pressure. f = BPAP devices may need to be used for patients with therapeutic pressure requirements greater than can be provided with CPAP or APAP; the decision to use BPAP should be based on the clinician's clinical judgement and needs of the individual patient. g = PAP therapy should be performed in conjunction with adequate follow-up to ensure adequate treatment and adherence. h = recommendations included within these boxes should be considered concurrently. i = educational interventions include those focused primarily on providing information about what OSA is, downstream consequences of untreated OSA, what PAP therapy is, how to use it, and the potential benefits of PAP therapy. j = behavioral interventions include those focused on behavior change related to use of PAP therapy using strategies such as cognitive behavioral therapy or motivational enhancement. Troubleshooting interventions include those focused on close patient communication to identify PAP-related problems and to initiate potential solutions. k = telemonitoring interventions include those that remotely monitor data obtained from a PAP device to identify PAP-related problems and to initiate potential solutions. l = when implementing the above recommendations, providers should consider additional strategies that will maximize the individual patient's comfort and adherence. APAP = auto-adjusting positive airway pressure, BPAP = bilevel positive airway pressure, CPAP = continuous positive airway pressure, OSA = obstructive sleep apnea, PAP = positive airway pressure, QOL = quality of life.

improve sleep-related QOL. Meta-analyses of sleep-related QOL, as assessed by the Calgary Sleep Apnea QOL Index (SAQLI) and the Functional Outcomes of Sleep Questionnaire (FOSQ), demonstrated a clinically significant improvement. However, meta-analyses of global QOL, as assessed by the SF-36 component scores, demonstrated no clinically significant

improvement. The overall quality of evidence, based on the critical outcome of sleep-related QOL, was moderate due to imprecision. The benefits and potential harms of PAP for patients with impaired sleep-related QOL are the same as for patients with sleepiness.[4,9] The TF concluded that in adult patients with OSA and impaired sleep-related QOL, the benefits of PAP therapy compared to no PAP therapy likely outweigh the potential harms and burdens, and that the majority of well-informed patients would choose the intervention over no treatment.

Recommendation 3: We suggest that clinicians use positive airway pressure, compared to no therapy, to treat OSA in adults with comorbid hypertension. (CONDITIONAL)

The TF assessed whether PAP should be offered to adult patients with hypertension and OSA, compared to no therapy to reduce the critical outcome of blood pressure (BP). The TF identified 5 RCTs that reported on the efficacy of PAP therapy on BP in this patient population. Meta-analyses demonstrated clinically significant BP reductions in nocturnal, daytime, and 24-hour systolic and diastolic BP when all patients in the studies were considered, with the largest effects seen for nocturnal measurements. When stratified by resistant hypertensive, hypertensive, and normotensive status, BP reduction was clinically significant in the meta-analyses for the group with hypertension and most BP measures in the group with resistant hypertension. The overall quality of evidence, based on the critical outcome of mean arterial BP, was moderate due to imprecision. The TF notes that the majority of studies evaluating the impact of PAP on BP recruited patients with predominantly moderate to severe OSA. (Note: studies did not systematically report BP based on OSA severity, which limited the ability to make recommendations specific to OSA severity.) The benefits and potential harms of PAP for patients with comorbid hypertension are the same as for patients with excessive sleepiness.[4,9] The TF recognized that patients experiencing symptoms of OSA (eg, excessive sleepiness) may be more accepting of PAP therapy, with the possibility of secondary benefits related to blood pressure reduction. Non-sleepy patients with OSA, however, may have a more nuanced view of whether to pursue treatment of OSA, particularly given the efficacy of standard antihypertensive treatments. The TF recognized that some non-sleepy patients will place a high value on any intervention that potentially reduces blood pressure, including PAP therapy. Nevertheless, the TF concluded that in adult patients with OSA and comorbid hypertension, the benefits of PAP therapy compared to no PAP therapy likely outweigh the potential harms and burdens, and that the majority of well-informed patients would choose the intervention over no treatment.

There is insufficient and inconclusive evidence to either recommend or withhold PAP to treat non-sleepy adults with OSA as a means to reduce cardiovascular events or mortality.

The TF assessed whether PAP compared to no therapy should be offered to adult patients with OSA to improve the critical outcomes of cardiovascular (CV) event and mortality risk. The TF identified 17 studies (11 observational studies and 6 RCTs) that assessed the impact of PAP therapy on cardiovascular events, and 13 studies (9 observational studies and 4 RCTs) that assessed the impact of PAP therapy on all-cause mortality. Meta-analyses of observational studies suggested a reduction in CV events and mortality with PAP therapy. In contrast, meta-analyses of randomized controlled trials demonstrated no clinically significant improvements in CV events or mortality. The quality of evidence for incident CV events and mortality ranged from very low to moderate due to study type and imprecision. Thus, the TF judged that the meta-analyses demonstrated insufficient and inconclusive findings regarding the impact of PAP therapy on incident CV events and mortality. Therefore, no recommendation is made regarding the use of PAP based on reduced incident CV events and mortality.

Some patients may, however; place a high value on any intervention that potentially reduces CV risk even when they are non-sleepy. In this situation, the patient and clinician should have a balanced discussion about the current state of the evidence about CV risk reduction with PAP therapy for OSA and the potential harms of PAP therapy when there are no other indications to treat the patient's OSA. Conversely, the uncertainty of any CV benefit, may lead some non-sleepy patients with OSA to decline treatment of their OSA. In these patients, conservative management of OSA, with monitoring for development of OSA symptoms over time, may be appropriate.

Initiation of PAP Therapy

Recommendation 4: We recommend positive airway pressure therapy be initiated using either APAP at home or in-laboratory PAP titration in adults with OSA and no significant comorbidities. (STRONG)

Remarks: When APAP is initiated in the home setting, therapy is maintained over the long-term by either using a fixed, continuous pressure setting determined from PAP monitoring data or continuing in the auto-adjusting mode. In-laboratory titration refers to both full-night and split-night titration. The choice of PAP initiation in the home or lab should be based on access, cost-effectiveness, patient preference, sleep clinician judgement, and other factors.

This recommendation is based on studies that excluded patients with the following comorbidities or conditions: congestive heart failure, chronic opiate use, significant lung disease such as chronic obstructive pulmonary disease, neuromuscular disease, history of uvulopalatopharyngoplasty, sleep-related oxygen requirements, or expectation for nocturnal arterial oxyhemoglobin desaturation due to conditions other than OSA, including hypoventilation syndromes and central sleep apnea syndromes.

This recommendation is based on the clinical trials reviewed, in which mask fittings and education on PAP use at a sleep center and/or close follow-up by trained staff during the treatment period were provided to the home APAP group. In some studies, daytime acclimatization to PAP was included.

The TF examined whether initiation of PAP using APAP at home (ie, without an in-laboratory titration) versus in-laboratory titration improved the critical outcomes of adherence, sleepiness, and QOL. The TF did not specifically assess patient outcomes with split-night titration testing as this was recently assessed by an AASM clinical practice guideline on diagnostic sleep testing and was deemed to be a reasonable approach under certain circumstances.[9] The guideline assumes that a diagnosis of OSA has already been established. The TF identified 10 RCTs that compared initiation of PAP using home APAP versus an in-laboratory PAP titration. Meta-analyses demonstrated no clinically significant differences in adherence, sleepiness, or QOL between APAP at home and in-laboratory PAP titration. The overall quality of evidence for this recommendation was high.

Potential benefits of using APAP in the home setting include lower cost, reduced time away from home, faster initiation of treatment, and greater access to care, whereas the potential harms may include inadequate patient education and the inability to identify and rectify problems related to mask fit, leak, or other PAP-related issues on the night of APAP use. The potential benefits of an in-laboratory PAP titration include providing education by a trained sleep technologist, real-time visual identification of efficacy of therapy, and the ability to provide immediate interventions to make PAP treatment more comfortable for the patient, whereas the potential harms include the need for an overnight stay away from home at the testing facility with the associated costs and patient time and the potential delay in initiation of therapy.

The TF concluded that the majority of well-informed adult patients with OSA and without significant comorbidities would prefer initiation of PAP using the most rapid, convenient and cost-effective strategy. This recommendation assumes that adequate education on PAP use and mask fittings with or without daytime acclimatization by trained staff are available. Furthermore, when APAP is implemented, the clinician is strongly encouraged to monitor the clinical response and PAP usage and therapy data within the first few weeks to make necessary PAP adjustments when indicated. Independent of payor restrictions, home APAP will be more rapid and convenient for most patients and has been shown to be more cost-effective.[13–15] Nevertheless, final determination of which strategy is ideal for an individual patient should be based on patient preferences and abilities, the sleep clinician's judgment, anticipated or known previous difficulty with PAP treatment, and availability of resources and cost of each strategy in a particular region.

PAP Modalities

Recommendation 5: We recommend that clinicians use either APAP or CPAP for ongoing treatment of OSA in adults. (STRONG)

Remarks: This recommendation is based on studies that mostly excluded patients with the following comorbidities or conditions: congestive heart failure, chronic opiate use, significant lung disease such as chronic obstructive pulmonary disease, neuromuscular disease, history of uvulopalatopharyngoplasty, sleep-related oxygen requirements or expectation of nocturnal arterial oxyhemoglobin desaturation due to conditions other than OSA, including hypoventilation syndromes and central sleep apnea syndromes.

The TF examined whether APAP versus CPAP improved the critical outcomes of adherence, sleepiness, and QOL. The TF identified 26 RCTs that investigated the effects of ongoing treatment with APAP compared with fixed CPAP. Meta-analyses demonstrated no clinically significant differences between APAP versus CPAP in adherence, self-reported and objective sleepiness, or QOL. The overall quality of evidence for this recommendation was moderate due to imprecision.

The TF judged that the benefits and harms of APAP and CPAP are similar, and the balance of effects does not favor either intervention. The main potential benefit of APAP to patients is the ability to automatically adjust pressure requirements over time in response to acute and chronic changes (eg, alcohol consumption, body position, or weight changes). No substantial differences in harms were identified for APAP versus CPAP use. Although meta-analyses demonstrated a lack of clinically significant differences in treatment adherence and outcomes, and patient preference varied between studies, the TF determined that individual patient tolerance of PAP, adherence, and symptom response may differ for one form of PAP or the other.

The TF concluded that either APAP or CPAP should be used for ongoing treatment of adult OSA, with the choice of therapy being tailored to patient tolerance and symptom response.

Recommendation 6: We suggest that clinicians use CPAP or APAP over BPAP in the routine treatment of OSA in adults. (CONDITIONAL)

Remarks: This recommendation is based on BPAP defined as a respiratory assist device that delivers inspiratory and expiratory positive airway pressure. This recommendation applies to all BPAP devices including flexible, modified, and auto-adjusting BPAP.

BPAP devices may need to be used for patients with higher therapeutic pressure requirements than can be provided by CPAP or APAP devices. The decision to use BPAP should be based on the clinician's judgement and needs of the individual patient. Furthermore, this recommendation is for the initial treatment of OSA and does not address management of patients who have previously failed CPAP or APAP. In addition, treatment of other forms of sleep-related breathing disorders associated with hypercapnia, which may require the use of BPAP, are covered in other AASM guidelines.[5,16]

To improve PAP adherence, BPAP has been used as an alternative to CPAP, in part due to issues of patient intolerance of high CPAP settings.[17] The TF examined whether BPAP versus CPAP improves the critical outcomes of adherence, sleepiness, and QOL (Note: while no direct evidence was available for the comparison of APAP to BPAP, the TF considers APAP to be equivalent to CPAP for the implementation of this recommendation. See recommendation 5 and **Figure 1**. The TF identified 5 RCTs that compared the use of BPAP to CPAP. Meta-analyses demonstrated no clinically significant differences in adherence,

self-reported sleepiness, and residual OSA with BPAP compared to CPAP. Studies reporting on sleep-related QOL and sleep quality also demonstrated no clinically significant differences. The overall quality of evidence for this recommendation was very low due to publication bias from industry funding and imprecision associated with small sample size.

The main potential benefit of BPAP over CPAP or APAP is improved comfort by lowering the pressure during exhalation, which may then increase adherence. The potential harms of BPAP over CPAP or APAP are a sub-optimally low expiratory pressure level that fails to prevent the occurrence of obstructive breathing events and the higher cost of BPAP. Furthermore, the historically perceived benefits of BPAP are less likely to be relevant since modified pressure profile technology, which also lowers expiratory pressures, has been integrated into modern PAP devices. The TF judged that although the benefits of treatment with BPAP versus CPAP or APAP are similar, the low quality of evidence and potential harms or burdens did not favor the regular use of BPAP for the routine treatment of OSA. Therefore, the TF concluded that the majority of well-informed adult patients with OSA would prefer initiation of treatment with CPAP or APAP over BPAP. However, there is a small subset of patients that require PAP treatment with pressures higher than 20 cm H_2O, which CPAP units are not typically capable of delivering. In these situations, BPAP devices may be needed for optimal treatment and can be utilized during an initial or subsequent in-laboratory PAP titration study. In addition, for specific patients who are unable to tolerate CPAP or APAP due to high pressure requirements and despite the use of modified pressure profiles, a trial of BPAP may be offered either during the initial in-laboratory titration or following a period of demonstrated non-acceptance.

Educational and Behavioral Interventions With PAP

Recommendation 7: We recommend that educational interventions be given prior to initiation of PAP therapy in adults with OSA. (STRONG)

Recommendation 8: We suggest that behavioral and/or troubleshooting interventions be given during the initial period of PAP therapy in adults with OSA. (CONDITIONAL)

Remarks: These recommendations are based on interventions defined as follows:

Educational interventions: Interventions focused primarily on providing information prior to initiation of PAP about what OSA is, its downstream consequences, what PAP therapy is, and the potential benefits of PAP therapy.

Behavioral interventions: Interventions focused on behavior change prior to and during the initiation and subsequent use of PAP therapy using strategies such as cognitive behavioral therapy or motivational enhancement.

Troubleshooting interventions: Interventions focused on close patient communication to identify PAP-related problems and to initiate potential solutions during the initial period of PAP therapy.

The intervention period may include interactions prior to, during and after PAP titration and follow-up.

The TF examined whether an educational, behavioral, or troubleshooting intervention versus no intervention prior to or during PAP treatment improves the critical outcome of adherence. QOL was initially considered a critical outcome; however, none of the accepted studies reported on this outcome. The TF identified 18 RCTs that evaluated the use of some combination of an educational, behavioral, or troubleshooting intervention as an adjunct to initiation of PAP therapy compared to PAP therapy with usual care. Meta-analyses demonstrated a clinically significant improvement in PAP adherence with all three types of interventions. The overall quality of evidence was moderate due to imprecision.

The potential harms of each of these interventions are minimal. The potential burdens to the patient are negligible for educational interventions but include the time required to receive the intervention and the cost of the additional care for the more intensive behavioral and troubleshooting interventions.

The TF judged that the benefits of educational interventions outweigh potential harms and burdens, while the benefits of behavioral and troubleshooting interventions likely outweigh the potential harms and burdens in most patients. As such, the TF concluded that the vast majority of well-informed adult patients with OSA would prefer that an educational intervention be provided with initiation of PAP therapy over initiation of PAP without education. In addition, the TF concluded that the majority of well-informed adult patients with OSA would likely prefer that a behavioral and/or troubleshooting intervention be given during the initial period of PAP therapy over no such intervention.

Monitoring During Treatment

Recommendation 9: We suggest that clinicians use telemonitoring-guided interventions during the initial period of PAP therapy in adults with OSA. (CONDITIONAL)

Remarks: This recommendation is based on interventions defined as follows: Telemonitoring includes the remote monitoring of PAP parameters such as PAP use, residual OSA severity, unintentional mask leaks, and PAP settings during treatment initiation and follow-up.

The TF examined whether behavioral, educational and troubleshooting interventions guided by remote monitoring of PAP therapy versus no remote monitoring improved the critical outcomes of adherence, sleepiness, and side effects. QOL was initially considered a critical outcome; however, none of the accepted studies reported on this outcome. The TF identified 5 RCTs that evaluated the use of remote monitoring of PAP variables to trigger early interventions versus no such system as an adjunct to PAP therapy. Meta-analyses demonstrated a clinically significant improvement in adherence, but not in sleepiness, with use of telemonitoring. PAP-associated side effect severity scores tended to be lower with a telemonitoring-guided intervention; however, these differences were not clinically

significant. The overall quality of evidence was moderate due to imprecision. The potential harms of remote monitoring interventions are small, primarily related to potential loss of privacy. How tele-monitoring guided interventions are implemented could lead to substantial increases in costs to healthcare systems, or conversely, may reduce costs if reductions in healthcare utilization substantially offset the investment in tele-monitoring systems. Nevertheless, the TF determined that the benefits of telemonitoring-guided adherence interventions likely outweigh the potential harms and burdens in most patients. Based on clinical experience, the TF concluded that the improvement in adherence would be valued by most patients. The TF concluded that the majority of well-informed adult patients with OSA would prefer enrollment in such a system compared to treatment without such an intervention.

ADDITIONAL CONSIDERATIONS

The AASM supports patient-centered care in which an individual patient's specific health needs and desired health outcomes are the driving force behind all health care decisions. When implementing the recommendations in this guideline, clinicians should consider strategies that will maximize the individual patient's comfort and adherence. The TF performed a systematic review of several interventions that aim to improve comfort and adherence including modified pressure profile, mask interfaces, and humidification. These are summarized below. A detailed evidence review can be found in the accompanying systematic review.[7]

Modified Pressure Profile PAP

Many PAP devices have now integrated modified pressure profiles, which lower the treatment pressure used during expiration. The potential benefit of using modified pressure profile PAP is increased patient comfort, while the potential harms of modified pressure profile PAP are similar to standard PAP. The TF identified 7 RCTs that investigated the use of modified pressure profile PAP to improve clinical outcomes and reduce side effects. Meta-analyses demonstrated no clinically significant differences in adherence, sleepiness, and QOL with modified pressure profile PAP versus standard PAP. Insufficient, standardized data were available to perform a meta-analysis on side effects; however, the reported data demonstrated no clinically significant differences. The data suggest that there are no systematic benefits to the routine initiation of treatment with modified pressure profile PAP, compared to standard PAP for OSA, despite perceived minimal potential harms and burdens. However, modified pressure profile PAP may have value in some patients in other contexts (eg, poorly adherent patients or patients with difficulty tolerating CPAP during in-laboratory titration studies) that have not yet been well studied.

Mask Selection

Appropriate mask selection will benefit patients by reducing side effects such as air leak and discomfort, which may then potentially improve adherence and subsequently patient outcomes. The TF identified 11 studies (3 observational studies and 8 RCTs) that evaluated the effects of different PAP interfaces on reducing the apnea-hypopnea index (AHI); improving adherence, sleepiness and QOL; and reducing side effects. Meta-analyses demonstrated a clinically significant improvement in adherence with nasal PAP versus oronasal interfaces, but there was no clinically significant difference in adherence between nasal or intra-nasal interfaces. With regards to self-reported sleepiness, meta-analyses demonstrated no clinically significant differences between interfaces. Studies reporting on QOL demonstrated no clinically significant differences between intra-nasal versus nasal interfaces. Finally, the studies analyzed indicated that there were fewer side effects with nasal compared with oronasal and oral interfaces. These data suggest that, for the routine initiation of PAP therapy in adults with OSA, clinicians should generally use nasal or intranasal mask interfaces over oronasal or oral interfaces. However, individual patient factors or preferences vary; therefore, the mask interface that minimizes side effects and optimizes efficacy and adherence should be used.

Humidified PAP

The use of humidification could also potentially reduce side effects from PAP therapy. The TF identified 9 RCTs that evaluated the use of PAP with humidification versus PAP without humidification to improve adherence, sleepiness, QOL, or PAP-related side effects. Meta-analyses demonstrated a clinically significant reduction in several side effects associated with the use of PAP, including dry mouth/throat, nasal discharge, nasal congestion, dry nose, bleeding nose, sinus pain or headache, sore throat, hoarse voice, and reduced smell. However, meta-analyses demonstrated no clinically significant improvement in PAP adherence, sleepiness, or QOL with the use of humidification compared with no humidification. The possibility of humidification causing "rain out" (ie, condensation of water into the PAP circuit, face, and nose or mouth of the patient) may deter its use. While the use of humidification may increase the ongoing costs (eg, purchasing distilled water, heated hoses) and maintenance requirements, these data suggest clinicians should generally use heated humidification with PAP devices to reduce side effects that may occur while treating adults with OSA.

SUMMARY

This clinical practice guideline provides recommendations for the use of PAP, approaches to the initiation of PAP treatment, and interventions to promote PAP adherence in adults with OSA. The recommendations are the result of the task force interpretation of evidence collected for the systematic review and application to the clinical care of adults with OSA. Four recommendations are strongly suggested and include: (1) using PAP to treat excessive sleepiness, (2) initiating PAP therapy with either APAP at home or an in-laboratory CPAP titration, (3) continuing PAP therapy for OSA with either CPAP or APAP, and (4) using educational interventions to initiate PAP therapy in adults with OSA. All other recommendations were conditional and include using PAP to treat impaired sleep-related QOL or

concomitant hypertension; implementing CPAP or APAP over BPAP in the routine treatment of OSA; and utilizing behavioral, troubleshooting, and telemonitoring interventions during the initial period of PAP therapy. The TF determined that a recommendation could not be made for the use or withholding of PAP therapy to treat non-sleepy patients to reduce incident cardiovascular disease. When implementing the recommendations, providers should consider additional strategies that will maximize the individual patient's comfort and adherence such as nasal/intranasal over oronasal mask interface and heated humidification, as discussed in the additional considerations section. Readers are strongly encouraged to read the companion systematic review[7] for a more detailed presentation and evaluation of the evidence. This clinical practice guideline reflects the state of knowledge at the time of publication and will be reviewed and updated as new information becomes available.

DISCLOSURE STATEMENT

Dr. Indu Ayappa disclosed that she receives royalties from patents held on some PAP devices. Dr. Ayappa's potential conflict was managed by requesting that she refrain from participation on any discussions pertaining to devices for which she may hold a patent. She was also asked to refrain from voting on recommendations pertaining to those devices. Dr. Sanjay Patel disclosed that he receives compensation from Bayer Pharmaceuticals to assess the impact of OSA and its treatment on pulmonary hypertension and other cardiovascular outcomes. He was asked to refrain from participation on any discussion pertaining to the use of PAP to treat hypertension. He was also asked to refrain from voting on recommendations pertaining to the use of PAP to treat hypertension. Mr. Harrod is employed by the American Academy of Sleep Medicine. No other task force members had any relevant conflicts of interest to disclose.

Tympanostomy Tube Coverage for Adults 2026 Re-Review

Plain Language Summary

Tympanostomy tubes are tiny tubes placed in the eardrum to help air and fluid move more freely in the middle ear, among other conditions. It's not clear when these tubes are covered for adults.

Staff recommend updating the ear tube guideline to explain when these are covered for adults.

This issue summary has not changed since the March 19 meeting materials

Staff Analysis Summary:

Significant proposed changes or discussion items:

1. The guideline about when ear tubes are inserted should be modified to clarify when these tubes are covered for adults.

Tympanostomy Tube Coverage for Adults 2026 Re-Review

Coverage Question: Should limited coverage be re-established for tympanostomy tubes in adults?

Question source: Mendy Maccabee, ENT in Hood River and Anthem medical director

Background:

Pressure equalization tubes (PE tubes, also known as tympanostomy tubes) are tiny tubes inserted into the eardrum to treat middle ear conditions, mainly middle ear infections (acute otitis media) and fluid collections (serous otitis media). The procedure to insert PE tubes is known as tympanostomy.

*CPT only copyright 2025 American Medical Association. All rights reserved.
** Current Dental Terminology © 2025 American Dental Association. All rights reserved

During the 2025 ENT BUP review, the two guidelines for tympanostomy tubes in acute otitis media and in chronic otitis media were combined. The acute otitis media guideline did not have any age restrictions for PE tube placement. The chronic otitis media guideline restricted PE tubes to patients "with specific higher risk conditions (including craniofacial anomalies, Down's syndrome, and cleft palate, or documented speech and language delay)" and "children up to and including age 7." The combined guideline does not have age mentioned in the acute otitis media section, and includes a restriction that PE tubes are only covered for children up to age 21 for chronic otitis media with a clause "note: tympanostomy tubes are not medically necessary for adults due to lack of impact on language acquisition." This BUP guideline was adopted early (January 1, 2026) as it was felt to be an improvement on the two previous guidelines.

From Dr. Maccabee:

> I also...must strenuously object to the cut off for tympanovstomy tubes at age 21. That makes no medical sense. There would be no data support for this. While the ICD10 code for requesting a tube for an adult would be different (OME, COME, SOME, ETD) it is a critical procedure for prevention of hearing loss, cholesteatoma and the need for much more invasive reparative interventions.....There are no adults jumping up and down for unnecessary tubes, no provider would request this for any reason other than necessary prevention of long term sequelae...

Previous HSC/HERC reviews:

This topic was discussed at the June and August 2025 VBBS and HERC meetings as part of the BUP review. "Members requested that the proposed new guideline be modified to include all children up to the age of 21 to correspond to EPSDT coverage. Wording should also be included in the guideline to indicate that coverage for adults is not included due to lack of issues with language acquisition. Members requested that HERC staff work on a proposal to have the guideline changes effective 10/1/2025."

Current Prioritized List/Coverage status:

PT tubes, tympanostomy and adenoidectomy are currently on lines:

*CPT only copyright 2025 American Medical Association. All rights reserved.

169 ACUTE MASTOIDITIS
308 HEARING LOSS - AGE 5 OR UNDER
372 CHOLESTEATOMA; INFECTIONS OF THE PINNA
386 ACUTE OTITIS MEDIA
444 HEARING LOSS - OVER AGE OF FIVE
472 CHRONIC OTITIS MEDIA

GUIDELINE NOTE 29, TYMPANOSTOMY TUBES

Lines 386,422,444,472

Tympanostomy tubes (CPT *69433, 69436) are only included on these lines as treatment for:

A) Patients with recurrent acute otitis media (three or more well-documented and separate episodes of acute otitis media in six months or four or more well-documented and separate episodes in the past 12 months with at least one episode in the past six months) in patients who have unilateral or bilateral middle ear effusion at the time of assessment for tube candidacy, OR
B) Chronic otitis media with a documented effusion for 3 months or longer in children under age 21 who are at high risk (note: tympanostomy tubes are not medically necessary for adults due to lack of impact on language acquisition):
    1) Children at high risk are defined as having one of the following:
        a) Permanent hearing loss of 25dB or greater independent of otitis media with effusion; OR
        b) Craniofacial anomalies; OR
        c) Syndromes that include cognitive, speech, or language delays; OR
        d) Blindness or uncorrectable visual impairment; OR
        e) Cleft palate; OR
        f) Developmental delay; OR
        g) Intellectual disability; OR
        h) Learning disorder; OR
        i) Attention-deficit/hyperactivity disorder; OR
        j) Speech and language delay

Formal audiometry is medically necessary for children with chronic otitis media with effusion present for 3 months or longer. Children with language delay, learning problems,

*CPT only copyright 2025 American Medical Association. All rights reserved.
** Current Dental Terminology © 2025 American Dental Association. All rights reserved

or significant hearing loss should have hearing testing upon diagnosis. Children with chronic otitis media with effusion who are not at risk for language delay (such as those with hearing loss <25dB in the better hearing ear) or developmental delay should be reexamined at 3- to 6-month intervals until the effusion is no longer present, significant hearing loss is identified, or structural abnormalities of the eardrum or middle ear are suspected.

Adenoidectomy is included on these lines at the time of tympanostomy tube insertion for children under age 4 with symptoms directly related to the adenoids (for example, ear infection associated with rhinorrhea and/or upper respiratory infection) OR in children aged 4 years or older.

Removal of retained tympanostomy tubes requiring anesthesia (CPT code *69424) or as an office visit, is included on Line 422 as a complication, pairing with ICD-10-CM H74.8.

The development of this guideline note was informed by a HERC coverage guidance. See https://www.oregon.gov/oha/HPA/DSI-HERC/Pages/Evidence-based-Reports.aspx

Evidence:

1) **AHRQ 2013**: Otitis Media With Effusion: Comparative Effectiveness of Treatments
    a. only limited research is available on treatment effectiveness in adults; we could identify only one study about treatments for adults

Submitted literature:

None received to date

Expert guidelines:

1) The American Academy of Otolaryngology-Head and Neck Surgery (AAO-HSN) only has clinical practice guidelines for children, not adults, regarding tympanostomy tube placement

Other payer policies:

1) Aetna 2025: Aetna considers myringotomy and tympanostomy tube (also known as ventilation tube and grommet) insertion medically necessary for *any* of the following indications:
    a. Autophony due to patulous eustachian tube; *or*

*CPT only copyright 2025 American Medical Association. All rights reserved.
** Current Dental Terminology © 2025 American Dental Association. All rights reserved

b. Barotitis media control; *or*
c. Children with cleft palate and history of otitis media with effusion and persistent hearing loss; *or*
d. Cholesteatoma; *or*
e. Chronic retraction of tympanic membrane or pars flaccida; *or*
f. Complications of otitis media such as meningitis, facial nerve paralysis, coalescent mastoiditis, or brain abscess; *or*
g. Otitis media with effusion after 3 months or longer and bilateral hearing impairment (defined as 20 dB hearing threshold level or worse in both ears) (tympanostomy tube); *or*
h. Recurrent episodes of acute otitis media (more than 3 episodes in 6 months or more than 4 episodes in 12 months) (tympanostomy tube); *or*
i. Severe otalgia in acute otitis media (myringotomy); *or*
j. To obtain a culture (diagnostic tympanocentesis/myringotomy) of the middle ear fluid prior to beginning or changing antimicrobial therapy (this may be necessary in situations such as otitis media that has failed to respond to appropriate antimicrobial therapy, or for otitis media in individuals or neonates who are immunocompromised)

2) Anthem BCBS 2025: The use of combined myringotomy and tympanostomy tube insertion is considered **medically necessary** for individuals who meet any of the following criteria:

a. Children or adults with recurrent acute otitis media (AOM) (more than 3 episodes in 6 months or more than 4 episodes in 12 months) with or without otitis media with effusion (OME) who have middle ear effusion at the time of assessment for tube candidacy; **or**
b. Children with unilateral or bilateral OME for greater than or equal to 3 months with hearing loss greater than 20 dB in one or both ears; **or**
c. Children with recurrent AOM or OME of any duration when the child is at risk for speech, language, or learning delay or disorder from OM based on baseline sensory, physical, cognitive, or behavioral factors
d. Children or adults with structural damage to the tympanic membrane (TM) or middle ear, such as cholesteatoma, chronic retraction of tympanic membrane or pars flaccida; **or**

*CPT only copyright 2025 American Medical Association. All rights reserved.
** Current Dental Terminology © 2025 American Dental Association. All rights reserved

e. Children or adults with barotitis (barotrauma); **or**
f. Children or adults with autophony due to patulous eustachian tube; **or**
g. Children or adults with middle ear dysfunction due to head and neck radiation or skull base surgery; **or**
h. Children or adults with a severe complication of acute otitis media including, but not limited to: meningitis, intracranial abscess, mastoiditis, or facial nerve paralysis; **or**
i. Adults with OME greater than 3 months and continued symptoms of aural pressure or hearing loss; **or**
j. Children or adults with persistent AOM despite at least 2 different courses of recommended empiric antibiotic therapy.

Expert input:

See Dr. Maccabee's comments in the background section

HERC staff summary:

PE tubes in adults with otitis media and effusion has been poorly studied. However, there are other rare indications for PE tubes in adults. Additionally, HERC has never intended to restrict PE tubes for acute otitis media to children and the current (2026) guideline does not appear to have that restriction. Based on expert input and private payer policies, HERC staff recommend modifying the tympanostomy tube guideline to clarify that adult PE tubes are not covered for chronic otitis media (consistent with HERC intent for 10+ years) but are covered for recurrent acute otitis media.

HERC staff recommendations:

1) Modify GN29 as shown below

GUIDELINE NOTE 29, TYMPANOSTOMY TUBES

Lines 386,422,444,472

Tympanostomy tubes (CPT *69433, 69436) are only included on these lines as treatment for:

A) ~~Patients~~ Adults and children with recurrent acute otitis media (three or more well-documented and separate episodes of acute otitis media in six months or four or

*CPT only copyright 2025 American Medical Association. All rights reserved.
** Current Dental Terminology © 2025 American Dental Association. All rights reserved

more well-documented and separate episodes in the past 12 months with at least one episode in the past six months) in patients who have unilateral or bilateral middle ear effusion at the time of assessment for tube candidacy, OR

B) Chronic otitis media with a documented effusion for 3 months or longer in children under age 21 who are at high risk (note: tympanostomy tubes are not medically necessary for adults for chronic otitis media due to lack of impact on language acquisition):
   1) Children at high risk are defined as having one of the following:
      a) Permanent hearing loss of 25dB or greater independent of otitis media with effusion; OR
      b) Craniofacial anomalies; OR
      c) Syndromes that include cognitive, speech, or language delays; OR
      d) Blindness or uncorrectable visual impairment; OR
      e) Cleft palate; OR
      f) Developmental delay; OR
      g) Intellectual disability; OR
      h) Learning disorder; OR
      i) Attention-deficit/hyperactivity disorder; OR
      j) Speech and language delay

Formal audiometry is medically necessary for children with chronic otitis media with effusion present for 3 months or longer. Children with language delay, learning problems, or significant hearing loss should have hearing testing upon diagnosis. Children with chronic otitis media with effusion who are not at risk for language delay (such as those with hearing loss <25dB in the better hearing ear) or developmental delay should be reexamined at 3- to 6-month intervals until the effusion is no longer present, significant hearing loss is identified, or structural abnormalities of the eardrum or middle ear are suspected. Adenoidectomy is included on these lines at the time of tympanostomy tube insertion for children under age 4 with symptoms directly related to the adenoids (for example, ear

Comparative Effectiveness Review
Number 101

Effective Health Care Program

Otitis Media With Effusion: Comparative Effectiveness of Treatments

Executive Summary

Background

Definition of Otitis Media With Effusion

Otitis media with effusion (OME) is defined as a collection of fluid in the middle ear without signs or symptoms of acute ear infection.[1] OME has several potential causes. The leading causes include viral upper respiratory infection, acute otitis media (AOM), and chronic dysfunction of the eustachian tube.[2,3] However, other potential explanations include ciliary dysfunction, proliferation of fluid-producing goblet cells, allergy and residual bacterial antigens, and biofilm.[4] More recent research suggests that mucoglycoproteins cause the hearing loss and much of the fluid presence that is the hallmark of OME.[5,6] The presence of fluid in the middle ear decreases tympanic membrane and middle ear function, leading to decreased hearing, a "fullness" sensation in the ear, and occasionally pain from the pressure changes.

Prevalence of Otitis Media With Effusion

OME occurs commonly during childhood, with as many as 90 percent of children (80% of individual ears) having at least one episode of OME by age 10.[7] OME disproportionately affects some subpopulations of children. Those with cleft palate, Down syndrome, and other craniofacial anomalies are at high risk for anatomic causes of OME and

Effective Health Care Program

The Effective Health Care Program was initiated in 2005 to provide valid evidence about the comparative effectiveness of different medical interventions. The object is to help consumers, health care providers, and others in making informed choices among treatment alternatives. Through its Comparative Effectiveness Reviews, the program supports systematic appraisals of existing scientific evidence regarding treatments for high-priority health conditions. It also promotes and generates new scientific evidence by identifying gaps in existing scientific evidence and supporting new research. The program puts special emphasis on translating findings into a variety of useful formats for different stakeholders, including consumers.

Effective Health Care

compromised function of the eustachian tube.[8] Individuals of American Indian, Alaskan, and Asian backgrounds are believed to be at greater risk,[9] as are children with adenoid hyperplasia. In addition, children with sensorineural hearing loss will likely be more affected by the secondary conductive hearing loss that occurs with OME.

Although rare, OME also occurs in adults. This usually happens after patients develop a severe upper respiratory infection such as sinusitis, severe allergies, or rapid change in air pressure after an airplane flight or a scuba dive. The incidence of prolonged OME in adults is not known, but it is much less common than in children.[10]

Many episodes of OME resolve spontaneously within 3 months, but 30 to 40 percent of children have recurrent episodes, and 5 to 10 percent of cases last more than 1 year.[1,11,12]

Despite the high prevalence of OME, its long-term impact on child developmental outcomes such as speech, language, intelligence, and hearing remains unclear.[7] The near universality of this condition in children and the high expenditures for treating OME (about $4 billion per year in the United States) make this an important topic for a comparative effectiveness review.

Diagnosis of Otitis Media With Effusion

Diagnostically, the core feature of OME is middle ear effusion (MEE), that is, fluid behind the eardrum in the middle ear. Tympanocentesis, which is the removal of fluid from behind the eardrum by using a needle to puncture the tympanic membrane, remains the gold standard for diagnosing MEE and OME. However, because tympanocentesis is an invasive procedure, it is rarely used for diagnosis. Tympanocentesis is not the same as myringotomy, in which the tympanic membrane is punctured to relieve pressure. A variety of supplemental examination techniques assist with identification. The most studied additional diagnostic method is pneumatic otoscopy, which is considered an accurate way to diagnose MEE by trained examiners.[7] To use this procedure, clinicians blow air through an otoscope, causing movement of the tympanic membrane that they can compare with normal movement of the membrane. Tympanometry is a supplemental diagnostic tool that indirectly measures middle ear pressure and tympanic membrane mobility. A "flat" tympanogram (Type B tympanogram) is consistent with OME. Additionally, children with OME often have a corresponding conductive hearing loss on pure-tone audiometry that measures 25 decibels (dB) or 10 dB above the IW hearing level of children with normal hearing.

Natural History and Treatment

Despite recent practice guidelines and systematic reviews,[8,13-20] the comparative benefits and harms of treatments and treatment strategies for OME are uncertain. The uncertainty stems from a lack of consensus regarding clinical and long-term functional outcomes of OME. Specifically, the authors of the most recent systematic review of the natural history of OME[8] found mixed evidence regarding the impact of OME in early childhood on later developmental outcomes. Although they concluded that children with early OME were at greater risk for temporary conductive hearing loss, they were unable to draw strong conclusions about the effect of early OME on later speech and language development. This lack of strong conclusions means it is not clear whether OME needs to be treated. Second, difficulty predicting the course of recurrence for individual patients, especially those with comorbid conditions, makes clinical decisions difficult. During topic refinement, the RTI-UNC Evidence-based Practice Center (RTI-UNC EPC) considered each of the known treatments in terms of uncertainty within the published literature (including gaps in the evidence), importance to clinicians, outcomes important to patients, and relevance to the U.S. population. Treatments examined in this review are indicated under Key Question 1.

Scope and Key Questions

The RTI-UNC EPC was charged with conducting this review because of the continuing uncertainty about efficacy, effectiveness, and particularly comparative effectiveness, as well as harms, for the included therapies. Providing more up-to-date and comprehensive comparative information will help many stakeholder groups make decisions about when and how to treat patients with this condition. This comparative review includes all interventions currently in use for treating OME—surgical, pharmacological, and nonpharmacological; we excluded antihistamines and decongestants, which have been extensively reviewed previously and demonstrated to have no benefit in this population. Antibiotics are the subject of a recent Cochrane review, and in cooperation with our Technical Expert Panel (TEP), we decided to not duplicate their work. We did not include this review as evidence because it was published in September 2012 after the deadline for including new reports in our

review.[21] For the most part, the treatments examined in the review are limited to those therapies that clinical guidelines recommended for managing OME.[20] However, we included several additional comparisons because more recent literature was available. Most notably, we included the findings of a recently published trial that examined adenoidectomy as an initial treatment with concurrent tympanostomy tubes (TT) placement in comparison with TT alone or watchful waiting because of the prominence of this large, carefully designed trial.[22]

The intent of our review was to cover the entire range of individuals who have OME; in particular, we sought evidence specific to populations who have not been examined in past reviews such as adults and children with comorbid conditions such as Down syndrome, cleft palate, or existing hearing loss. We did not limit the timeframe for outcomes, nor did we exclude any settings.

The EPC addressed five Key Questions (KQs) in this comparative effectiveness review.

KQ 1. What is the comparative effectiveness of the following treatment options (active treatments and watchful waiting) in affecting clinical outcomes or health care utilization in patients with OME? Treatment options include: tympanostomy tubes, myringotomy, oral or topical nasal steroids, autoinflation, complementary and alternative medical procedures, watchful waiting, and variations in surgical technique or procedures.

KQ 2. What is the comparative effectiveness of the different treatment options listed in KQ 1 (active treatments, watchful waiting, and variations in surgical procedures) in improving functional and health-related quality of life outcomes in patients with OME?

KQ 3. What are the harms or tolerability among the different treatment options?

KQ 4. What are the comparative benefits and harms of treatment options in subgroups of patients with OME?

KQ 5. Is the comparative effectiveness of treatment options related to factors affecting health care delivery or the receipt of pneumococcal vaccine inoculation?

We developed an analytic framework (Figure A) to guide our analysis. The populations of interest are in the box to the far left in the figure; the interventions appear in the middle; and the two sets of outcomes (for KQ 1 and KQ 2 on benefits, and also KQ 4 on important subgroups) appear on the far right. KQ 3 concerns harm (various types of adverse events). Finally, KQ 5 relates to a set of health care delivery or clinical factors (pneumococcal vaccination) that may influence choices of treatments or their clinical and quality-of-life outcomes.

Methods

Literature Search Strategy

Search Strategy

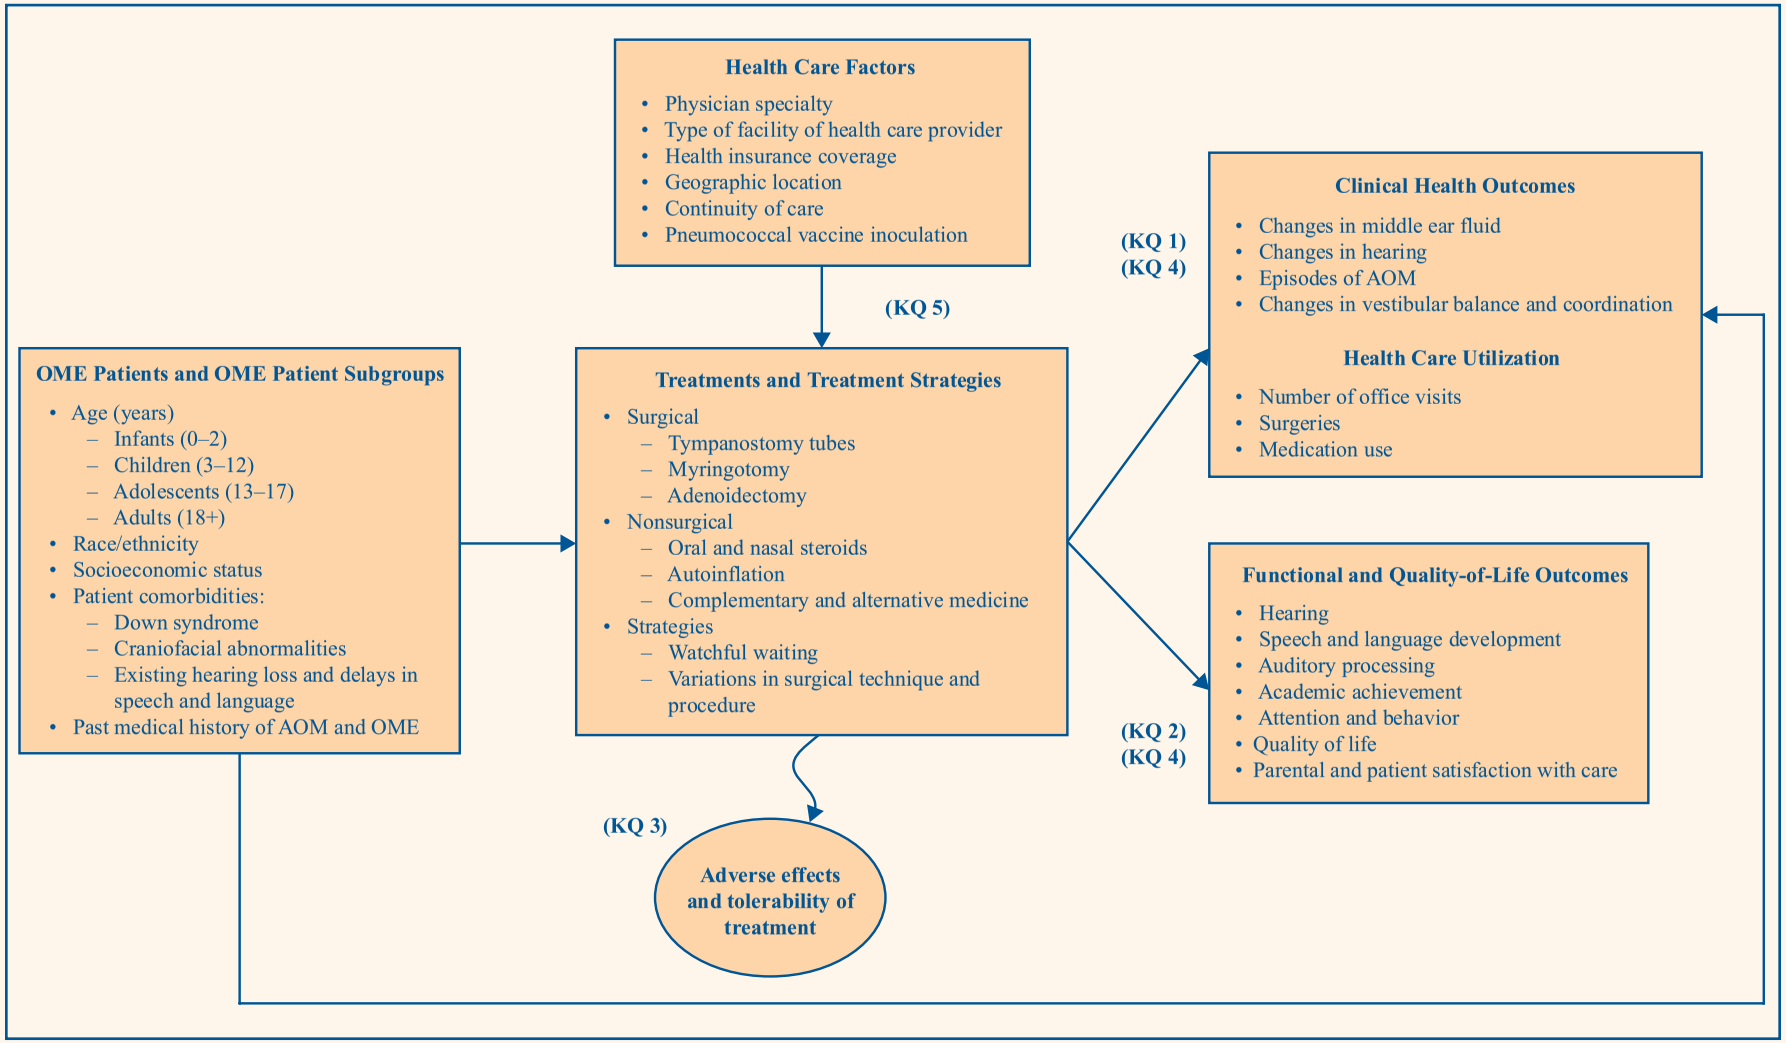
Five recently published systematic reviews on comparisons of interest (two on TT, one on adenoidectomy, one on steroids, and one on autoinflation)[13,15-18] were identified during the topic refinement stage of the review. An update of the steroid review[23] was added during peer review. As discussed in our review protocol, The Cochrane Collaboration conducted four of the reviews, and the Swedish Council of Technology in Health Care commissioned the fifth. The reviews covered the following treatment options for OME: TT, adenoidectomy, steroids, and autoinflation.

To avoid duplicating the work of these teams, we used these reviews as a starting point. We included evidence from these systematic reviews plus additional evidence that these reviews did not consider. The additional evidence included: additional outcomes data from studies that were included in the recent reviews but were not the focus of those reviews, observational studies done at any time, newer studies published since the last search dates in those reviews, and studies focusing on populations excluded from the reviews, such as adults with OME or children with Down syndrome or cleft palate, who may be differently affected by OME.

We searched MEDLINE® (via PubMed), Embase,® The Cochrane Library, and the Cumulative Index to Nursing and Allied Health Literature (CINAHL®) to identify studies not included in the systematic reviews. An experienced research librarian used a predefined list of search terms and medical subject headings (MeSH). We reviewed our search strategy with our TEP and incorporated their input into our search strategy. We limited the electronic searches to English-language materials. We completed the initial search on 1/8/2012, and we completed an update during peer review on 8/13/2012.

We searched unpublished and grey literature relevant to the review topic. Methods for identifying grey literature included a review of trial registries. In addition, AHRQ requested Scientific Information Packets (SIPs) from the developers and distributors of the interventions identified

Figure A. Analytic framework for comparisons of interventions for otitis media with effusion



AOM = acute otitis media; KQ = Key Question; OME = otitis media with effusion

in the literature review. We included unpublished studies that met all inclusion criteria and contained enough information on their research methods to permit us to make a standard risk-of-bias assessment of individual studies. Finally, we manually searched reference lists of reviews, including trials and background articles, to look for relevant citations that our searches might have missed and that addressed our KQs. We imported all citations into an electronic database (EndNote® X4).

Inclusion and Exclusion Criteria

We developed inclusion and exclusion criteria with respect to the PICOTS (i.e., populations, interventions, comparators, outcomes, timeframes, and settings) framework. The review included only English-language studies of individuals with OME. We included five systematic reviews that had been determined a priori to fit our PICOTS criteria and the relevant studies included in those reviews; we also retained eligible studies that the earlier reviews had not used, and these included randomized controlled trials (RCTs), nonrandomized controlled trials, and cohort studies. We imposed no other restrictions so that we could consider studies with individuals of any age, racial or ethnic background, or coexisting condition.

The treatments of interest were TT, myringotomy, adenoidectomy, oral or intranasal steroids, autoinflation of the eustachian tube, complementary and alternative medicine (CAM) procedures, watchful waiting, and variations in surgical technique or procedures. With two exceptions, included studies had to compare at least two of these treatments. We considered inactive controls in comparison with steroid treatment and usual care in comparison with autoinflation, based on the Cochrane review inclusion criteria. Based on discussions with our TEP, because the effectiveness of CAM treatments was unknown and there were concerns about the quality of nonrandomized studies, we limited studies of CAM to RCTs.

We specified a broad range of outcomes (see Figure A). We included clinical outcomes such as changes in middle ear fluid, episodes of AOM, and hearing thresholds; use of health care; functional and quality-of-life outcomes such as speech and language development, behavior, and parental satisfaction with care; and harms.

We were interested primarily in treatment outcomes of 3 months or longer, but we included outcomes of less than 3 months. We focused on end-of-intervention results when they were the only endpoint data available, such as in the autoinflation treatment studies.

We did not exclude studies based on geography or the setting of the service provision.

Study Selection

A total of six trained members of the team reviewed article abstracts and full-text articles. First, two members of the team independently reviewed each abstract using the inclusion/exclusion criteria. One reviewer was always a senior member of the review team. If both reviewers agreed that the study did not meet eligibility criteria, we excluded it; otherwise, we included the abstract for full article review. Two members of the team independently reviewed each full-text article. One reviewer was always a senior member of the review team. If both reviewers agreed that a study did not meet eligibility criteria, we excluded it. Each reviewer recorded the primary reason for exclusion. If the reviewers disagreed about whether an article should be excluded or about the primary reason for exclusion, they resolved conflicts by discussion and consensus or by consulting a third member of the team. We screened unpublished studies identified through a grey literature search and review of SIPs using the same title/abstract and full-text review processes.

Data Abstraction

We developed a template for evidence tables for data synthesis using the PICOTS framework. For the five systematic reviews and additional studies that met our inclusion criteria, we abstracted relevant information into these evidence tables: characteristics of study populations, interventions, comparators, settings, study designs, methods, and results. We directly reviewed individual studies included in the systematic reviews to capture additional outcomes data that were not the focus of the earlier reviews and to determine the availability of subgroup analyses not included in the reviews.

Six trained members of the team participated in the data abstraction. One of the reviewers initially abstracted the relevant data from each included article using Microsoft Excel® software and a second more senior member of the team reviewed each data abstraction against the original article for completeness and accuracy.

Risk-of-Bias Assessment

The risk-of-bias assessment was conducted using two tools, one appropriate for trials based on the Cochrane

risk-of-bias tool[24] and modified by our EPC to be used to evaluate observational studies (including instructions to reviewers that some questions concerning trial study design would be considered not applicable) and AMSTAR (assessment of multiple systematic reviews),[25] appropriate for systematic reviews. We did not reevaluate the risk of bias of the studies included in the previous systematic reviews,[13,15-18,23] but the original review study authors had determined these studies to be of low or medium risk of bias.

Two independent reviewers rated the risk of bias for each study. Disagreements between the two reviewers were resolved by discussion and consensus or by consulting a third member of the team. Results of this assessment were summarized in a rating of low, medium, or high risk of bias. High risk-of-bias studies were those that had at least one major issue that had the potential to cause significant bias and might invalidate the results.

Data Synthesis

Across all included studies, the populations, interventions, and outcome measures in the additional data were heterogeneous and did not lend themselves to a pooled analysis beyond what was currently available in the meta-analyses from the five earlier systematic reviews. Because we determined that additional quantitative analyses were not necessary or appropriate, we did all analyses qualitatively. Evidence used in the synthesis included the results from the earlier meta-analyses, additional data from individual studies contained in those systematic reviews, and data from the articles added from our own searches.

Strength of the Body of Evidence

We graded the strength of evidence based on the guidance established for the Agency for Healthcare Research and Quality Effective Health Care Program EPCs conducting comparative effectiveness reviews, as detailed in the paper by Owens and colleagues.[26] The EPC approach incorporates four key domains: risk of bias, consistency, directness, and precision of the evidence. The overall grade for strength of evidence is based on the scores for the four domains and reflects the strength of the body of evidence to answer the KQs on the comparative effectiveness, efficacy, and harms of the treatments and treatment strategies covered in this review.

A grade of high strength of evidence indicates that we have high confidence that the evidence reflects the true effect. Moderate strength of evidence implies that we have moderate confidence that the evidence reflects the true effect. Low strength or evidence suggests that we have low confidence that the evidence reflects the true effect. Insufficient strength of evidence signifies either that evidence is completely unavailable or that it does not permit estimation of an effect. Typically, evidence from just one study was considered insufficient to permit confidence in the estimation of an effect. Exceptions were single study bodies of evidence consisting of a relatively larger, low risk of bias trial, particularly if it showed a large magnitude of effect.

Two reviewers assessed each domain independently and assigned an overall grade for each treatment comparison for each key outcome listed in the framework. They resolved any conflicts through consensus discussion. If they did not reach consensus, the team brought in a third party to settle the conflict.

Applicability

We assessed the applicability of individual studies as well as the body of evidence. For individual studies, we examined factors that may limit applicability based on the PICOTS structure such as population characteristics, intervention characteristics, and comparators. We abstracted key characteristics of applicability into the evidence tables. During data synthesis, we assessed the applicability of the body of evidence using the abstracted characteristics. KQ 4 includes a detailed analysis of intervention effectiveness in population subgroups.

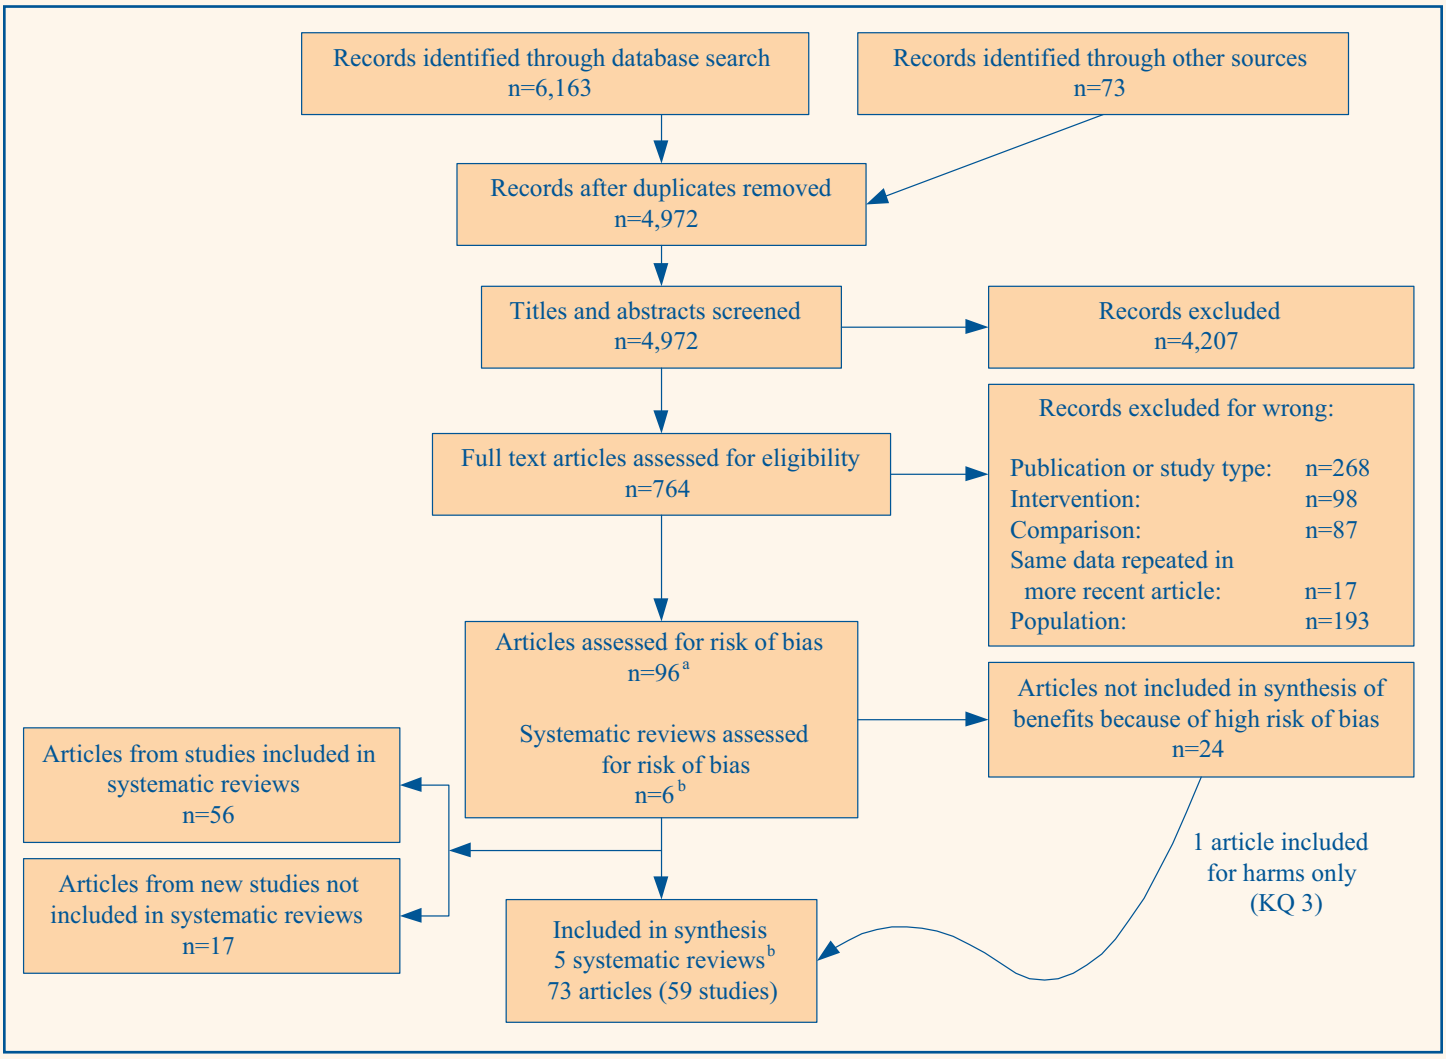
Results

This section is organized by KQ and then grouped by intervention comparison. The summaries of evidence findings are presented in Tables A–D by KQ. The full report contains summary tables. Appendix C contains evidence tables for included studies, and Appendix F has the strength of evidence grades for the main outcomes of each KQ. Except where otherwise noted, across KQs, the studies we included were limited to otherwise healthy children.

Literature Searches

We identified a total of 4,967 unduplicated citations and determined that 764 met criteria for full-text review (Figure B). We excluded 668 full-text articles based on our inclusion criteria and before risk-of-bias assessment. There were a total of 73 full-text articles, detailing 59 studies and five systematic reviews. Of the 59 studies, 42 studies were included in one of the five systematic reviews, and we included 17 additional studies. Of the 59 studies included in this review, 49 were RCTs (33 by person, 12 by ear, and 4 by person and ear), 6 were nonrandomized control trials

Figure B. Disposition of articles on otitis media with effusion



[a]We accepted the risk of bias assessment conducted by the review authors for the studies included in one of the 5 earlier systematic reviews (56 articles). We conducted our own risk of bias assessment for 17 new articles not included in one of those reviews.
[b]One of the 5 included systematic reviews was updated during our peer review period. We reviewed both the original report and the update.

(1 by person and 5 by ear), and 4 were cohort studies. Of the 17 articles not included in one of the five systematic reviews, we assessed 15 as medium risk of bias, 1 as low risk of bias and 1 as high risk of bias. Of the five included systematic reviews, four were limited to RCTs. We assessed four systematic reviews as low risk of bias and one as medium risk of bias.

We recorded the reason that each excluded full-text publication failed to satisfy the eligibility criteria and compiled a comprehensive list of such studies (Appendix B of the full report).

We did not include 23 high-risk-of-bias studies in our analyses (Appendix C of the full report). Virtually all lacked information on any baseline patient characteristics; of particular concern, unknown differences between groups based on age or time with OME could invalidate outcomes. Other serious concerns were a lack of control for selective concurrent treatment and lack of control for confounders in cohort studies.

Key Question 1. Comparative Effectiveness: Clinical Outcomes or Health Care Utilization

All but four of the 59 studies included in this review examined clinical outcomes. Thirty one studies and 12 meta-analyses examined signs and symptoms of OME. Thirty studies and six meta-analyses examined hearing as an outcome. Only three studies examined subsequent AOM as an outcome. No studies reported use of health services or balance outcomes. A description of the treatment comparisons and comparative effectiveness follows.

Tympanostomy Tube Comparisons

Six individually located studies[27-32] and eight studies[33-40] from one systematic review[13] addressed comparisons of TT. These studies compared different types of tubes (e.g., design, materials, size), approaches to insertion, or topical prophylaxis therapies. All comparisons were made between ears of the same individual.

Ten[27-31,33-37] of the 14 studies provided evidence for KQ 1; the other four provided evidence only for harms. Of these 10 studies, 7 were RCTs. Length of tube retention was higher in the longer term TT. Other TT comparisons and endpoints differed across studies. Because of sparse data, the diversity of comparisons, and inconsistent findings, the evidence is insufficient for comparisons of other design features or for hearing outcomes.

Tympanostomy Tubes Versus Watchful Waiting/Myringotomy

Two individual studies[41,42] and two systematic reviews[13,15] addressed comparisons between RCTs of TTs with either myringotomy or watchful waiting. The Browning et al.[15] systematic review reviewed 10 studies;[43-52] 7 were in comparison with watchful waiting or delayed treatment,[43-45,48,50-52] 2 were in comparison with myringotomy in the control ear,[46,49] and 1[47] included both myringotomy and watchful waiting arms. The Hellstrom et al.[13] systematic review included six of the studies that were in the Browning review; in addition, data on hearing outcomes from Gates et al. (1989)[53] were reported only in the Hellstrom review. We included as a companion study the Medical Research Council Trial of Alternative Regimens in Glue Ear Treatment (MRC TARGET)[22] that was a recently published version of the preliminary data included in the Browning review.[44] We also present additional reports of later followup of the cohorts of Maw and colleagues (1999),[43] Rovers and colleagues (2000),[45] and Paradise and colleagues (2001).[48]

TT placement decreased time with middle ear effusion by 32 percent compared with watchful waiting or delayed treatment (high strength of evidence) and up to 42 percent in comparison with myringotomy (moderate strength of evidence) at 1 year after surgery. Compared with watchful waiting or myringotomy (data combined), there was a 13 percent reduction through 2 years after surgery (moderate strength of evidence). Evidence was insufficient for longer followup. TT improved hearing through 9 months after surgery compared with watchful waiting (3–6 months: 8.8 dB; 6–9 months: 4.2 dB) (high strength of evidence); TT improved hearing by 10 dB at 4 to 6 months after surgery in comparison with watchful waiting or myringotomy (data combined) (high strength of evidence). Thereafter the differences in hearing became attenuated and were not significant at either 7 to 12 months compared with watchful waiting or myringotomy (low strength of evidence) or 12 to 18 months after surgery compared with watchful waiting (low strength of evidence). Evidence was insufficient for longer time periods and for other clinical outcomes or health utilization.

Tympanostomy Tubes Plus Adenoidectomy Versus Myringotomy Plus Adenoidectomy or Adenoidectomy Alone

Seven individually located studies[54-60] and four studies[53,61-63] reported in the Hellstrom review examined outcomes in relation to TT plus adenoidectomy as compared with myringotomy plus adenoidectomy or adenoidectomy alone. We included another report[64] that was a followup study to the Bonding and Tos report (1985)[61] included in the Hellstrom review. Four of the studies compared TT in one ear with an ear that received no surgery, in children who all had had adenoidectomies. Three studies (four articles)[59,61,63,64] compared ear outcomes between ears with TT and ears with myringotomy, among children who all had had adenoidectomies. The other four studies[53,57,58,60] compared TT with myringotomy among children who all had had adenoidectomies.

Two small studies found that TT conferred no additional benefit to adenoidectomy alone for reducing the recurrence of OME (insufficient strength of evidence); three studies comparing TT and adenoidectomy with myringotomy and adenoidectomy produced mixed results (insufficient strength of evidence). Five of six studies failed to find a difference in hearing at various endpoints between TT and myringotomy among children who had also received adenoidectomies (low strength of evidence). We found mixed results for hearing when comparing TT with watchful waiting in children who also received adenoidectomies (insufficient strength of evidence).

Myringotomy Comparisons

Only one RCT compared two different procedures for myringotomy on both middle ear and hearing outcomes.[65] The two procedures were radio frequency myringotomy with mitomycin C, a topical chemotherapeutic agent and radio frequency myringotomy alone. A majority of individuals in each arm received adenoidectomy (73% and 67%, respectively). There was insufficient evidence for concluding superiority of either myringotomy procedure for OME signs and symptoms or hearing outcomes.

Myringotomy Plus Adenoidectomy Comparisons

One retrospective cohort study compared two different procedures for myringotomy.[66] The comparison was between laser myringotomy and cold knife myringotomy. In both groups all individuals received an adenoidectomy. The evidence is insufficient for determining superiority for either myringotomy approach for OME signs and symptoms. No study examined hearing or any other clinical outcome.

Adenoidectomy Versus Other Interventions

Eight RCTs provided all the evidence for adenoidectomy in comparison to TT, myringotomy, watchful waiting, or no surgery among patients with OME. Seven of the RCTs were included in the Cochrane review by van den Aadweg et al.[16,46,49-51,67-69] and the eighth was the newly published MRC TARGET trial.[22] The trials examined adenoidectomy with and without myringotomy versus nonsurgical treatment or myringotomy only; adenoidectomy with unilateral TT versus a unilateral TT only (comparison by ears); adenoidectomy with bilateral TT versus bilateral TT only; and adenoidectomy plus TT versus watchful waiting.

Adenoidectomy was superior to no treatment for resolution of OME at both 6 months (risk difference of 0.27 [95% CI, 0.13 to 0.42] measured through otoscopy and 0.22 [95% CI, 0.12 to 0.32] as measured through tympanometry; high strength of evidence) and 12 months postsurgery (risk difference of 0.29 [95% CI, 0.19 to 0.39] through tympanometry; high strength of evidence). Adenoidectomy was superior to no treatment for hearing in one study at 6 months but not at 12 months; in a second study, no differences were detected between adenoidectomy and no treatment (insufficient strength of evidence for mixed findings). One single study found that adenoidectomy and myringotomy were superior to myringotomy alone for reducing time with effusion ($p<0.001$).and improving hearing at 24 months (better ear standard mean difference of -0.66 [95% CI, -0.93 to -0.40]; low strength of evidence). Because results were mixed, the evidence was insufficient for determining the effectiveness of adenoidectomy when added to TT in relation to effusion or hearing (insufficient strength of evidence). Hearing outcomes were superior with adenoidectomy and TT compared with watchful waiting at 24 months (low strength of evidence). There was insufficient evidence to determine the effectiveness of adenoidectomy compared with other treatments for recurrence of AOM.

Oral or Topical Nasal Steroids

The included evidence consisted of one systematic review conducted by The Cochrane Collaboration,[18] that was updated while we were conducting our review,[23] that examined oral steroids and topical intranasal steroids. The update review includes the studies included in the earlier review, nine RCTs of oral steroids[70-78] and three RCTs of topical intranasal steroids,[79,80] and adds one recent RCT conducted by Williamson et al.[80,81] All studies were in comparison with placebo controls; some of the oral steroid studies included antibiotics in both arms. All studies examined signs and symptoms of OME and hearing.

Results of a meta-analysis[18] comparing oral steroids with controls did not show differences in middle ear effusion at 1–2 months post treatment (low strength of evidence); nor did a meta-analysis comparing oral steroids with control along with adjunct antibiotics (moderate strength of evidence). Due to limited data, evidence was insufficient for determining the effectiveness of oral steroids with and without antibiotics for OME signs and symptoms at followup beyond 3 or more months. Topical intranasal steroids did not show differences in cure rate at various followup points with antibiotics (insufficient strength of evidence) or without antibiotics (low strength of evidence). The evidence was insufficient for determining the effectiveness of oral steroids with and without antibiotics for hearing at any time point. The RCT by Williamson et al.[80,81] comparing intranasal steroids with controls did not find differences in OME cure rate or in hearing at one or more months post treatment (low strength of evidence). There was insufficient evidence for comparing either oral or topical intranasal steroids with controls for any other clinical outcomes.

Autoinflation

One Cochrane review conducted by Perera et al.[17] summarized evidence from six RCTs of any form of autoinflation, a technique designed to increase pressure in the oropharynx forcing open the eustachian tube though a nasal balloon or other process. The review included five studies with children[82-86] and one study with adults, 16–75 years of age.[87] All studies were in comparison with no autoinflation, and other treatments (e.g., antibiotics, analgesics) were permitted as long as they were given equally to both arms. Meta-analyses comparing autoinflation with controls found an improvement in OME at 1 month or less, post treatment (low strength of evidence). Evidence was insufficient for drawing

conclusions regarding improvements in OME at longer time periods or for other clinical outcomes, including hearing.

Key Question 2. Comparative Effectiveness: Functional Outcomes or Quality of Life

Only a subset of the treatment comparisons reported functional or quality of life outcomes. These include TT versus watchful waiting, TT plus adenoidectomy versus myringotomy plus adenoidectomy, and steroids versus control. In general, there were no differences between the treatments. The studies included to address KQ 2 are described under KQ 1.

Tympanostomy Tubes Versus Watchful Waiting/Myringotomy

Meta-analyses reported by Browning et al.[15] did not find any differences in language development at 6 and 9 months post treatment between TT and watchful waiting (moderate strength of evidence for no differences). With one exception, studies examining children during preschool and elementary school years failed to find a difference in language skills. In the one exception where a difference favoring TT was reported, the investigators used a teacher rating of children's language; this difference disappeared at 8 years of age when they used a direct assessment of language (low strength of evidence for no difference). We did not find differences between TT and watchful waiting in any RCTs reporting cognitive development, academic achievement or quality of life at any time point (all low strength of evidence for no difference). Studies reported mixed findings for behavior outcomes at less than 1 year (insufficient strength of evidence); three studies reporting behavior at more than 1 year reported no difference (low strength of evidence). No studies comparing TT with myringotomy reported on functional or quality of life outcomes (insufficient strength of evidence).

Tympanostomy Tubes Plus Adenoidectomy Versus Myringotomy Plus Adenoidectomy

One study comparing TTs plus adenoidectomy with myringotomy plus adenoidectomy reported quality of life outcomes.[60] The two groups did not differ at any time point (insufficient strength of evidence). Strength of evidence was insufficient for all speech/language, cognitive, and behavioral outcomes because there were no studies including these outcomes.

Oral or Topical Nasal Steroids

Two studies comparing steroids to control (three reports)[79-81] examined functional outcomes. In one small study, patients receiving intranasal steroids plus oral antibiotics did not differ in parents' assessment of their children's symptoms from patients receiving placebo plus antibiotics (insufficient strength of evidence); nor did patients receiving intranasal steroids differ from controls in parent reported hearing outcomes (low strength of evidence). No studies comparing topical or oral steroids to control examined any other functional outcomes (insufficient strength of evidence).

Key Question 3. Harms or Tolerability

Six of the treatment comparisons included in the review reported on harms. These included comparisons between different types of TT, TT versus watchful waiting/myringotomy, TT plus adenoidectomy versus myringotomy plus adenoidectomy/adenoidectomy alone, steroids, and autoinflation. Only a limited range of harms was included for any comparison. Few significant differences in harms were reported.

Tympanostomy Tube Comparisons

We reviewed nine studies that reported on otorrhea.[27-32,37-39] Otorrhea rates differed by TT type, with placement of longer term TT related to a higher probability of otorrhea (low strength of evidence). For other harms such as perforation, cholesteatoma, occlusion, tympanosclerosis, and the presence of granulation tissue, the evidence was too limited to determine a direction of effect (insufficient strength of evidence).

Tympanostomy Tubes Versus Watchful Waiting/Myringotomy

We reviewed nine studies that compared side effects for TT with side effects for watchful waiting or myringotomy.[57,64,88-94] Otorrhea and tympanosclerosis occurred more frequently in ears that had TT than watchful waiting or myringotomy (low strength of evidence). Evidence was insufficient for other harms due to either conflicting results or data reported in only a single study.

Tympanostomy Tubes Plus Adenoidectomy Versus Myringotomy Plus Adenoidectomy/Adenoidectomy Alone

We reviewed nine studies that examined harms.[33-35,48,53,95-98] These included repeat TTs, otorrhea, perforation, and tympanosclerosis or myringosclerosis. The risk of tympanosclerosis was higher with TT than myringotomy or no surgery in addition to adenoidectomy (moderate strength of evidence). Results for other harms were either mixed, were reported in single studies, or were lacking precision (insufficient strength of evidence).

Adenoidectomy

Only two studies (three articles)[22,46,53] reported harms. In both studies, there was one report of a postoperative hemorrhage following adenoidectomy (low strength of evidence). Evidence was insufficient for other harms.

Oral or Topical Nasal Steroids

Evidence for harms of steroids comes from the systematic review and its update.[28,29] A meta-analysis of two RCTs in the updated review[29] comparing oral steroids plus antibiotics with control plus antibiotics reported no difference in mild to moderate adverse events at 2 weeks to 6 months. A second RCT[31,99] found no significant differences in mild adverse harms such as stinging nose, nose bleed, dry throat, or cough between those receiving nasal steroids and those receiving placebo control (low strength of evidence). Evidence concerning serious harms was sparse for either nasal or oral steroids (insufficient strength of evidence).

Autoinflation

None of the studies that compared autoinflation to control[17] provided quantitative information on rates of serious or mild harms, only verbal statements indicating there were few harms noted (insufficient strength of evidence).

Key Question 4. Comparative Effectiveness of Interventions for Subgroups of Patients

One of the explicit goals of this review was to examine treatment options for subgroups of patients including individuals defined by age groups and subpopulations at greater risk for OME such as individuals of American Indian, Alaskan, and Asian backgrounds and individuals with cleft palate, Down syndrome, and other craniofacial anomalies. Our search found very few studies of any subgroups that met our inclusion criteria. Two treatment comparisons examined comparative effectiveness of interventions for subgroups of patients—TT plus adenoidectomy versus myringotomy plus adenoidectomy/adenoidectomy alone and autoinflation.

Tubes Plus Adenoidectomy Versus Myringotomy Plus Adenoidectomy or Adenoidectomy Alone

One study[60] included children with sleep apnea and OME. The study did not find differences in hearing thresholds between children who received TT plus adenoidectomy and children who received myringotomy plus adenoidectomy (insufficient strength of evidence). Quality of life scores were measured in only one study (insufficient strength of evidence).

Autoinflation

One study[87] included in the systematic review of autoinflation[17] included adults 16 to 75 years of age. The autoinflation group was significantly more likely to experience a complete recovery than those in the control group at the end of treatment and 50 days later (low strength of evidence).

Key Question 5. Comparative Effectiveness by Health Care Factors

No included studies or systematic reviews examined effectiveness of intervention comparisons by any health care factors.

Discussion

Key Findings and Strength of Evidence

Key Question 1. Comparative Effectiveness: Clinical Outcomes or Health Care Utilization

Table A summarizes the strength of evidence for comparative effectiveness of treatments on clinical outcomes. We are able to draw some conclusions regarding surgical treatments.

We examined several design, placement, and material features of TTs. Longer acting TT such as Goode T-tubes and Paparella tubes were retained longer than shorter acting Shah and Shepard TTs; No other TT features were associated with clinical outcomes.

Compared with watchful waiting, TT decreased the number of children with MEE at 1 year after surgery (high strength of evidence); compared with myringotomy, TT decreased time with effusion at 1-year followup (moderate strength of evidence). TTs continued to improve MEE at 2-year followup (moderate strength of evidence), but the effect washed out thereafter. TT also improved hearing relative to watchful waiting or myringotomy, but the effect was shorter in duration, not lasting beyond 9 months after treatment (high strength of evidence). We found only limited evidence for drawing conclusions about the relative benefits of TT for other clinical outcomes such as OME recurrence or episodes of AOM.

We examined the evidence for whether TT or myringotomy differentially improved clinical outcomes when they were added to adenoidectomy. Based on finding no differences in hearing at any time point in five studies, we concluded that hearing outcomes do not differ (low strength of evidence); evidence was insufficient for all other clinical outcomes. However, TT plus adenoidectomy

Table A. Strength of evidence for interventions to improve clinical outcomes			
Intervention and Comparator	**Number of Studies (Sample Sizes)**	**Outcome and Results**	**Strength of Evidence**
TT vs. watchful waiting, delayed treatment, or myringotomy	MA of 3 RCTs (N=574)	TT had less persistent middle ear effusion at 1 year compared with watchful waiting or delayed treatment: 32% less time (95% CI, 17% to 48%).	High for benefit
	2 studies (N=294)	TT had less time with effusion through 1 year compared with myringotomy.	Moderate for benefit
	MA of 3 RCTs (N=426)	TT had less persistent middle ear effusion at 2 years compared with watchful waiting or myringotomy: 13% less time (95% CI, 8% to 17%).	Moderate for benefit
	MA of 3 RCTs (N=523) + 1 RCT (N=248)	TT had better measured hearing for up to 9 months than watchful waiting. MA results: -4.20dB (95% CI, -4.00 to -2.39).	High for benefit
	MA of 3 RCTs (by ears) (N=230)	TT had better measured hearing for up to 6 months than watchful waiting or myringotomy: -10.08 (95% CI, -19.12 to -1.05).	High for benefit
	MA of 3 RCTs (by ears) (N=234)	No difference between TT and watchful waiting or myringotomy in measured hearing at 7-12 months: -5.18dB (95% CI, -10.43 to 0.07).	Low for no difference
	MA of 2 RCTs (N=328); MA of 2 RCTs (N=283)	No difference between TT and watchful waiting in measured hearing at 12 months: -0.41dB (95% CI, -2.37 to 1.54) and 18 months -0.02 dB (95% CI, -3.22 to 3.18).	Low for no difference
TT + adenoidectomy vs. myringotomy + adenoidectomy	6 studies: 3 RCTs by person (N=431); 2 RCTs (by ears) (N=338); 1 NRCT (by ears) (N=193)	No difference in measured hearing between groups at 6 and 12 months and at more than 3 years.	Low for no difference
Adenoidectomy vs. no treatment	MA of 2 RCTs (by ears) (N=153); MA of 3 RCTs (by ears) (N=297)	Adenoidectomy had better OME resolution than no treatment at 6 months. The risk difference was 0.27 (95% CI, 0.13 to 0.42) measured through otoscopy and 0.22 (95% CI, 0.12 to 0.32) measured through tympanometry.	High for benefit
	MA of 3 RCTs (by ears) (N=298)	Adenoidectomy had better OME resolution than no treatment at 12 months. The risk difference was 0.29 (95% CI, 0.19 to 0.39).	High for benefit
Adenoidectomy + myringotomy vs. myringotomy	1 RCT (N=237)	Adenoidectomy and myringotomy had less mean time with effusion than myringotomy alone at 24 months: -0.76 standard mean difference (95% CI, -1.02 to -0.49).	Low for benefit
	1 RCT (N=237)	Adenoidectomy and myringotomy had better hearing than with myringotomy alone at 24 months measured as standard mean difference time with hearing level ≥ 20: worse ear: -0.65 (95% CI, -0.91 to -0.39); better ear: -0.66 (95% CI, -0.93 to -0.40).	Low for benefit
TT + adenoidectomy vs. WW	1 study (n = 250)	TT plus adenoidectomy improved hearing at 3 to 24 months.	Low for benefit
Oral steroids vs. controls	MA of 3 RCTs (N=106);	No difference in persisting OME at 1-2 months (no antibiotics provided in either group): OR=0.55 (95% CI, 0.21 to 1.48).	Low for no difference

Table A. Strength of evidence for interventions to improve clinical outcomes (continued)			
Intervention and Comparator	**Number of Studies (Sample Sizes)**	**Outcome and Results**	**Strength of Evidence**
Oral steroids + antibiotics vs. controls + antibiotics	MA of 3 RCTs (N=243)	No difference in persisting OME at 1-2 months (antibiotics provided to both groups): OR=0.75 (95% CI, 0.45 to 1.27).	Moderate for no difference
Topical intranasal steroids vs. controls	1 RCT (N=217)	No difference in OME cure rates at 1, 3, and 9 months.	Low for no difference
	1 RCT (N=217)	No difference in hearing loss at 3 and 9 months.	Low for no difference
Autoinflation vs. controls	MA of 2 RCTs (N=185)	Improvement in OME at <1month: RR=3.84 (tympanometry change C2 to C1 or A) and RR=2.72 (tympanometry change B to C1 or A).	Low for benefit

CI = confidence intervals; dB = decibels; MA = meta-analysis; NRCT = non-randomized controlled trial; N = number; OME= otitis media with effusion; OR = odds ratio; RCT = randomized controlled trial; RR = risk ratio; TT = tympanostomy tubes; vs. = versus

improved hearing at 3 to 24 months compared with watchful waiting (low strength of evidence). Adenoidectomy is superior to no treatment for improving the likelihood of OME resolution at 6 and 12 months after surgery (high strength of evidence). Adenoidectomy plus myringotomy was superior to myringotomy alone at 2 years after surgery for improving OME resolution and hearing (low strength of evidence). Evidence was insufficient for other outcomes. Evidence was also insufficient for comparisons between different approaches to myringotomy with and without adenoidectomy because of the limited number of studies.

We have reached some conclusions for nonsurgical interventions. Oral steroids do not offer any improvements in OME at 1 to 2 months after treatment (low strength of evidence). Similarly, oral steroids with antibiotics do not provide improvements in OME at 1 to 2 months (moderate strength of evidence). A recent study (low risk of bias) provided additional evidence that OME and hearing outcomes were not improved through the use of topical intranasal steroids through 9 months after treatment. These findings support the current clinical practice guidelines that recommend against the use of oral and intranasal steroids in treating OME in children. Although autoinflation improved MEE at less than 1 month after treatment (low strength of evidence), evidence was insufficient for reaching conclusions for other outcomes, largely because outcomes across studies testing autoinflation were not measured at consistent lengths of followup or through consistent measures.

Key Question 2. Health-Related Quality of Life and Functional Outcomes

Table B summarizes the strength of evidence for health-related quality of life and functional outcomes. We found only limited evidence regarding these outcomes. Language comprehension and language expression outcomes at 6 to 9 months were not significantly better among children with OME who received TT than among those who were limited to watchful waiting or delayed treatment (moderate strength of evidence). Results for cognitive development, behavioral competence, and academic achievement were similar; outcomes from TT versus watchful waiting or delayed treatment at various followup times did not differ (low strength of evidence). Evidence was insufficient to reach conclusions related to differences in either behavioral outcomes or quality of life for this treatment comparison.

Quality of life outcomes were measured in one small study comparing TT and adenoidectomy versus myringotomy and adenoidectomy, but we considered the evidence to be insufficient to reach conclusions. Topical steroids do not improve parent-reported hearing difficulties of their children at up to 9 months (low strength of evidence). However, evidence was insufficient to reach conclusions about other quality of life outcomes for oral steroids.

Key Question 3. Harms Associated With Interventions To Treat Otitis Media With Effusion

Table C summarizes the OME interventions on which we had low, moderate, or high strength of evidence about

Table B. Health-related quality of life and functional status			
Intervention and Comparator	**Number of Studies (Sample Sizes)**	**Outcome and Results**	**Strength of Evidence**
TT vs. watchful waiting or delayed treatment	MA of 3 RCTs (N=394) and 2 RCTs (N=503)	No difference in language comprehension at 6 to 9 months post-intervention (mean difference, 0.09; 95% CI, -0.21 to 0.39) or at preschool and elementary school age.	Moderate for no difference
	MA of 3 RCTs (N=393) and 2 RCTs (N=503)	No difference in language expression at 6 to 9 months post-intervention (mean difference, 0.03; 95% CI, -0.41 to 0.49) or at preschool and elementary school age.	
	2 RCTs (N=503)	No difference in cognitive development at 9 months post-intervention or at preschool and elementary school age.	Low for no difference
	3 RCTs (N=710)	No difference in behavior at 1 year or more.	Low for no difference
	2 RCTs (N=503)	No difference in academic achievement at elementary school age.	Low for no difference
Intranasal steroids vs. controls	1 study (N=144)	No difference in parent-reported hearing difficulties at 3 and 9 months or in median days with hearing loss at 3 months.	Low for no difference

N = number; NR = not reported; SR = systematic review; TT = tympanostomy tubes; vs. = versus

Table C. Strength of evidence for harms of interventions			
Intervention and Comparator	**Number of Studies (Sample Sizes)**	**Outcome and Results**	**Strength of Evidence**
TT vs. TT	1 RCT (N=30 ears); 2 observational studies (N=779 ears)	Otorrhea occurred more frequently in ears with longer-term TT than in ears with shorter-term TT after 1 year or more.	Moderate for harms of longer-term TT
TT vs. watchful waiting or myringotomy	5 studies (N=1,129)	Tympanosclerosis occurred more frequently in ears that had TT, based on examinations after the TT had been extruded.	Moderate for harms of TT
	4 studies (N=960)	Otorrhea occurred more frequently in ears with TT.	Low for harms of TT
TT plus adenoidectomy vs. adenoidectomy alone or with myringotomy	3 studies (N=485)	Tympanosclerosis occurred more frequently in ears with TT than ears with only adenoidectomy or myringotomy.	Moderate for harms of TT
Adenoidectomy vs. other treatments	2 studies (N=739)	Although rare, adenoidectomy increased the risk of postsurgical hemorrhage.	Low for harms of adenoidectomy
Oral nasal steroids vs. control	5 studies (N=637)	No difference in mild adverse events such as vomiting and diarrhea.	Low for no difference
Topical nasal steroids vs. control	2 studies (N=215)	No difference in mild adverse events such as nasal stinging, dry throat, and cough.	Low for no difference

N = number; NR = not reported; SR = systematic review; TT = tympanostomy tubes; vs. = versus

safety and harms. In relation to TT, we considered concerns such as otorrhea, tympanosclerosis, cholesteatoma, or surgical complications. In relation to steroid treatment, we considered problems such as diarrhea and nasal stinging.

Otorrhea was more common among ears with TT than those without (low strength of evidence), especially for those TT designed to stay in longer. Tympanosclerosis was more common in children who had TT than those who were actively monitored or who had myringotomy (low strength of evidence). Likewise, tympanosclerosis was more common when TT were added to adenoidectomy than for adenoidectomy alone or with myringotomy (moderate strength of evidence). Additionally, the risk of post-surgical hemorrhage, although rare, was associated with adenoidectomy, not any other comparison treatments.

We concluded that mild adverse events are not significantly higher with topical nasal steroids than with placebo (low strength of evidence). However, evidence was insufficient to reach conclusions related to oral steroids and serious adverse events from oral or topical steroids. Evidence was also insufficient concerning the surgical risks from the insertion of TT or those from myringotomy procedures with adenoidectomy.

KQ 4. Outcomes for Important Patient Subgroups

Table D provides the limited evidence we found for patient subgroups. Although we attempted to examine treatment effectiveness or harms for key subgroups characterized by clinical variables (e.g., cleft palate, Down syndrome, or sensorineural hearing loss) or sociodemographic factors (such as age), we could not identify studies that covered most of our subgroups of interest.

One study examined children with sleep apnea and OME, and one examined adults with OME. Among children with sleep apnea, all of whom had adenoidectomy to treat that condition, the addition of TT or myringotomy did not differ significantly in terms of any measured outcomes (insufficient strength of evidence). The study of autoinflation in one systematic review[17] found differences in rates of recovery between those receiving autoinflation and those who were in the control group. Individuals in the autoinflation group were significantly more likely to experience a complete recovery than those in the control group at both the end of treatment ($p<0.001$) and at 50 days after treatment ($p<0.001$). Similarly, the ears of the participants receiving autoinflation had better recovery rates than control ears at both time points ($p<0.001$). Strength of evidence was low for benefit.

Key Question 5. Health Care Factors

No studies examined issues related to health insurance coverage, physician specialty, type of facility of the provider, geographic location of patients, presence or absence of continuity of care, or prior use of pneumococcal virus inoculation. Evidence is thus insufficient for all such factors.

Applicability

This review was intended to apply to individuals with OME of all ages. Findings about all interventions are likely to be applicable to otherwise healthy children other than infants. In some cases, study authors did not provide sufficient information on age of the target population (e.g., provided only the average age without providing the age range) or included a wide age range of children, rendering it difficult to ascertain applicability of the tested intervention to specific age groups. The evidence base is clearly limited for adults and for infant children, and it is virtually nonexistent for children with major coexisting or congenital conditions, such as those with cleft palate, Down syndrome, and sensorineural hearing loss, who may be disproportionately affected by OME.

We provided evidence on all the commonly used treatments for OME, including TT, myringotomy, adenoidectomy and watchful waiting; we also examined outcomes from use of steroids upon the advice of our TEP, even though they are not recommended in current U.S. guidelines. We also provided evidence for autoinflation, an alternative noninvasive treatment strategy. We note the limitation in the evidence that not all studies comparing TT to other surgical or non-surgical treatments provided information regarding the type of TT used, limiting

Table D. Strength of evidence for subgroups

Intervention and Comparator	Number of Studies (Sample Sizes)	Outcome and Results	Strength of Evidence
Autoinflation vs. control	1 RCT (N=396 ears)	Adults (16–75) with OME: differences between groups in composite measure of recovery (otoscopy, tympanometry, audiometry) at end of tx and 50 days after tx.	Low for benefit (one study)

OME = otitis media with effusion; tx = treatment; RCT = randomized control trial

conclusions that can be made at this level of specificity. We also sought to include CAM procedures, but no RCTs met our inclusion criteria.

We did not limit the outcomes of interest. However, the bulk of the literature concerned reductions in OME and measured hearing. Only a few studies included quality-of-life outcomes, and none included satisfaction with care. Included studies were limited to head-to-head comparisons that collected a variety of harms, but they were not uniformly collected in all studies. We recognize that other study designs may have expanded our identification of possible harms. We did not limit the time frame for followup but were most interested in outcomes 3 months or more following treatment. Studies were conducted in clinical settings. They generally included populations from the United States and Western Europe, but a few studies were conducted in other countries including Egypt, Iran, and Japan.

Research Gaps

Research gaps in treatments for OME exist in several areas. We recommend the following for improving the research base.

The first area is to expand research in subgroups that were targeted in this review but for whom no evidence could be amassed. These groups include infants and toddlers who are developmentally vulnerable for language acquisition and for whom a mild conductive hearing loss over a shorter period of time may be more detrimental than for older children. Children with craniofacial anomalies such as cleft palate and other developmental disorders including Down syndrome and sensorineural hearing loss have not been a part of most treatment studies. When we did find studies on children with comorbid conditions, we excluded them for reasons such as having no valid comparison group (e.g., case series with no comparator) or data combined with children with acute AOM. Additionally, only limited research is available on treatment effectiveness in adults; we could identify only one study about treatments for adults.

The second area is to examine treatments that have heretofore not been subjected to rigorous research methods. For instance, despite the interest in CAM treatments, the lack of carefully designed investigations of these treatments is clear. While insertion of TT remains a common procedure, we have little evidence regarding different types of TT or routines for insertion. An ongoing Swedish trial plans to enroll a large cohort of children in an RCT comparing different TT; results from this trial may be able to provide the needed evidence regarding which TT are more (or less) beneficial. Some researchers are designing treatments to counteract the otological effects of gastroesophageal reflux disease; further research of promising treatments is welcome.

Methods deficiencies constitute a third gap. Measures are not uniform; investigators do not report on reoccurrence of AOM and functional outcomes; time points for collecting outcomes differ; and baseline measures are not always provided. Pain or discomfort resulting from OME was not measured in any studies. Studies do not routinely document effect sizes and many researchers fail to report their statistical power calculations of the sample size needed to find an effect (the RCTs of Williamson et al., the MRC, and Paradise et al. being notable exceptions). Missing data are often not addressed, and even if attrition is acknowledged, statistical procedures are rarely used to correct for this problem. We encourage investigators to give far more attention to their methods in the service of greatly improving the literature base.

Conclusions

Overall, we found a small and uneven body of evidence across treatment comparisons and outcomes. Compared with watchful waiting or myringotomy, we found strong and consistent evidence that TT decreased effusion and improved hearing over a short period but did not affect longer-term speech, language, or other functional outcomes. However, we found weaker evidence that TT placement also increases the rate of side effects such as otorrhea and tympanosclerosis. Although adenoidectomy decreases the number of children with OME in the short term relative to watchful waiting, less is known about its long-term effects particularly with respect to functional outcomes. Steroids were not found to provide a benefit. Additional research and better methods are needed to develop a comprehensive evidence base to support decisionmaking among the various treatment options, particularly in subpopulations defined by age and coexisting conditions.

May 2013

Hydrophilic Urinary Catheters

Plain Language Summary:

Urinary catheters drain urine when the bladder cannot empty on its own because of nerve damage or other disease or injury. Some catheters have a hydrophilic coating that becomes slippery in water.

Staff do not recommend covering hydrophilic catheters. Studies don't show these catheters work any better than normal catheters but cost more.

Staff Analysis Summary:

Staff propose 2 options for discussion:

1. Do not cover hydrophilic intermittent urinary catheters
2. Limit cover of hydrophilic catheters to situations where they do not cost more than another type of catheter

Changes after public comment period:

Nine public comments were received on this topic, all of which were in favor of covering hydrophilic intermittent urinary catheters. One was from an Oregon provider and several were from Oregon residents. The other comments were from individuals from advocacy groups or Coloplast. Multiple articles were submitted, but all of these articles were either included in the current or previous issue summaries or were previously excluded.

Most commentors cited the reduced risk of UTI with hydrophilic catheters compared to standard catheters which resulted in lower health care costs. Several commentors noted increased patient satisfaction with hydrophilic catheters. There were comments about hydrophilic catheters being more convenient as they do not have a separate lubricant package; however, patient convenience is not a coverage criteria under OHP.

Based on the submitted comments and the testimony heard at the March VBBS meeting, HERC staff have added an option to allow coverage of hydrophilic catheters if they are the least costly option and are medically necessary and appropriate for the patient.

Coverage Question: Should hydrophilic intermittent urinary catheters be covered?

Question source: HERC staff; OHA DME division

Background:

People who cannot empty their bladders due to neurologic diseases such as multiple sclerosis, neurologic injury such as spinal cord injury, or obstruction such as benign prostatic hypertrophy develop chronic urinary retention. This increases the risk of urinary tract infection, kidney disease and bladder damage. Patients with these conditions are generally treated with either permanent urinary drainage devices such as suprapubic catheters or with intermittent catheterization. There are many types of catheters used for intermittent catheterization, including plain plastic, silicone coated, Teflon coated or hydrophilic.

Hydrophilic catheters have a polymer coating that binds to the surface of the catheter. When the polymer coating is submersed in water, it absorbs and binds the water to the catheter. The catheter surface becomes smooth and slippery. This slippery surface remains intact upon insertion into the urethra and maintains lubrication through the length of the urethra. The hydrophilic coating is designed to reduce the friction as the catheter is inserted with the intention of reducing the risk of urethral damage. These types of catheters due not require additional lubricant. Because of their coating, hydrophilic catheters must be discarded after each use (i.e. are not reusable). They are marketed as causing a lower risk of urinary tract infections.

Effective for the dates of service on or after January 1, 2026, CMS has created 3 new HCPCS codes for hydrophilic catheters

*CPT only copyright 2025 American Medical Association. All rights reserved.
** Current Dental Terminology © 2025 American Dental Association. All rights reserved

A4295: Intermittent urinary catheter; straight tip, hydrophilic coating, each (CMS OR NR-$2.58)
A4296: Intermittent urinary catheter; coude (curved) tip, hydrophilic coating, each (CMS OR NR-$9.15)
A4297: Intermittent urinary catheter; hydrophilic coating, with insertion supplies (CMS OR NR-$9.99)

Before the creation of the new HCPCS codes, hydrophilic catheters were coded with HCPCS codes:

A4351: Intermittent urinary catheter; straight tip, with or without coating (teflon, silicone, silicone elastomer, or hydrophilic, etc.), each ($1.98 on OHP fee schedule 12/2025)

- As of 1/1/2026: Intermittent urinary catheter; straight tip, with or without coating (teflon, silicone, or silicone elastomer, etc.), each (CMS OR NR-$2.87)

A4352: Intermittent urinary catheter; coude (curved) tip, with or without coating (teflon, silicone, silicone elastomeric, or hydrophilic, etc.), each ($7.01 on OHP fee schedule 12/2025)

- As of 1/1/2026: Intermittent urinary catheter; coude (curved) tip, with or without coating (teflon, silicone, or silicone elastomeric, etc.), each (CMS OR NR-$9.15)

A4353: Intermittent urinary catheter, with insertion supplies ($7.65 on OHP fee schedule 12/2025) (CMS OR NR-$9.99)

Hydrophilic catheters typically cost $2.50-9.00 per catheter compared to non-hydrophilic catheters that cost approximately $1-1.50 each. Of note, Medicare has indicated that initially, both hydrophilic and non-hydrophilic catheter codes will receive the same reimbursement (based on current reimbursement level); however, Medicare has indicated that the reimbursement level of hydrophilic catheters will be part of their next review cycle. These catheters are typically allowed up to 200 units a month, making even small cost differences significant.

OHA DME policy staff as well as Washington Medicaid staff are interested in an evidence review of the effectiveness of hydrophilic catheters.

Previous HSC/HERC reviews:

This topic was discussed at the January 2026 VBBS and HERC meetings as a new HCPCS code review. The evidence review included a Ontario Health Assessment review, a CMS review, and a review by the Healthcare Infection Control Practices Advisory Committee of the CDC. The HERC staff summary was "Trusted evidence review sources (Ontario Health Technology Assessment) did not find evidence that hydrophilic urinary catheters reduced infection risk. The CDC concluded that "hydrophilic catheters might be preferable" as a weak recommendation. The CDC review noted that only 2 studies found significant change in UTI risk including one of bladder cancer patients; all other studies found no difference in risk. CMS has found sufficient support for hydrophilic catheters improving health outcomes and have moved to create specific HCPCS billing codes for these types of catheters."

Several members requested that HERC staff contact providers regarding use of these types of catheters. Specifically, Duty requested that HERC staff confer with the bladder cancer group at OHSU to see if that high risk group might need hydrophilic catheters. Hoffman requested that staff contact the OHSU spina bifida center regarding use in high risk children.

This topic was again discussed at the March 2026 VBBS/HERC meetings. Testimony was heard from a variety of industry and specialty society representatives who all recommended coverage. There was insufficient time for member discussion and this topic was tabled.

Current Prioritized List/Coverage status:

Urinary retention, neurogenic bladder, and similar diagnoses are on line 324 FUNCTIONAL AND MECHANICAL DISORDERS OF THE GENITOURINARY SYSTEM INCLUDING BLADDER OUTLET OBSTRUCTION

Urinary catheters are generally considered DME and are normally on the Ancillary file (covered for covered diagnoses).

Submitted literature:

1) **Ye 2021** Catheters for intermittent catheterization: a systematic review and network meta-analysis
    a. N=25 RCTs comparing at least 2 types of catheters (6 trials of children, 18 trials with adults)
        i. SNC: single-use non-coated catheter—a single-use uncoated catheter. After removing it from sterile packaging, the user needs to add some lubricant before insertion;
        ii. GSNC: gel-lubricated single-use non-coated catheter —a single-use uncoated catheter with pre-packaged lubricant, which is ready to use;
        iii. SHC: single-use hydrophilic-coated catheter —a single-use catheter with a hydrophilic polymer coating. The user needs to add sterile water for about 30 s to active the hydrophilic polymer coating; (iv)
        iv. CNC: clean reused non-coated catheter —a reusable uncoated catheter, which is usually washed with soapy water and air-dried after each use, but the user needs to add some lubricant before use each time;
        v. PSHC: pre-activated single-use hydrophilic-coated catheter —a single-use catheter with a hydrophilic polymer coating which has been activated, and is ready-to-use.
    b. N=16 trials reporting incidence of symptomatic UTI (916 patients)
        i. When SNC was used as the reference, only GSNC (OR 0.30, 95% CI 0.10–0.86) and PSHC (OR 0.41, 95% CI 0.19–0.83) were associated with a statistically significant lower incidence of symptomatic UTI
    c. N=8 trials reporting on hematuria
        i. No significant difference between catheter types
    d. N=9 trials reporting on patient satisfaction
        i. None of the catheters exhibited significant advantages compared with SNC
2) **Liao 2022** Effects of hydrophilic coated catheters on urethral trauma, microtrauma and adverse events with intermittent catheterization in patients with bladder dysfunction: a systematic review and meta-analysis

*CPT only copyright 2025 American Medical Association. All rights reserved.
** Current Dental Terminology © 2025 American Dental Association. All rights reserved

a. N=5 studies reporting on urethral stricture
    i. Diagnosis was made by endoscopic or radiographic examination, not be patient symptoms or other patient specific outcome
b. The incidence of urethral stricture was 3.1% (6/194) in patients using hydrophilic catheters and 11.5% (23/200) in patients using non-hydrophilic catheters (RR=0.28; 95% CI 0.13–0.60)

Expert input:

The OHSU group that treats bladder cancer patients uses standard urinary catheters.

Drs. Casey Seideman and Christopher Austin from OHSU pediatric urology strongly feel that hydrophilic catheters remain an option for certain pediatric patients.

From Dr. Austin:

> We do have a lot of patients who use hydrophilic catheters currently, many of which are covered by OHP. We prescribe hydrophilic catheters to patients, especially girls who catheterize themselves to make the process quicker and simpler for them (If you think about having to catheterize yourself 5-6 times a day for the rest of your life- you would agree that making it quicker and more convenient is not a luxury). Catheter manufactures have made catheters smaller and more discrete, especially for females. Having to carry packets or large tubes of lubricant is an added barrier to getting kids to comply with treatment recommendations. We also have some patients with challenging anatomy or discomfort with catheterizing that is safer or more comfortable when they use hydrophilic catheters. None of this will be reflected in published evidence. I would urge that you consider some exceptions to cover them. I would be happy to have some of my faculty and staff work with your committee in drafting what the exceptions should be. It is a great burden on me and my partners to be constantly writing letters requesting exceptions and filling out prior authorization paperwork for our patients that we are dedicated to caring for. I fear that this change will cause a great deal of distress for our many patients that use these products and my staff who care for them.

** Current Dental Terminology © 2025 American Dental Association. All rights reserved

HERC staff summary:

HERC staff conclude that the available evidence does not find that hydrophilic catheters are superior to other types of catheters for any health outcome for any condition. Expert local groups are not routinely using these catheters for patients undergoing treatment for bladder cancer but pediatric urologists recommended coverage for children without providing literature or other evidence. HERC staff were directed to consider drafting an Ancillary guideline outlining specific groups that might benefit more from coverage; however, based on expert input and submitted comments, HERC staff have been unable to determine which group(s) would benefit more from these catheters and therefore staff are not proposing a guideline at this time. Coverage for specific patients can be evaluated through the exceptions process. Based on the likely future higher cost for these catheters, HERC staff continue to recommend placing the new HCPCS codes on Excluded Services Guideline E1. Alternatively, limited coverage could be considered by placing the new HCPCS codes on the Ancillary file with a new Ancillary guideline limiting coverage to the situation in which these catheters are not most costly than other options.

HERC staff recommendation:

1) Option 1:
    a. Add an entry to Excluded Services Guideline E1 regarding hydrophilic catheters as shown below

EXCLUDED SERVICES GUIDELINE E1, INTERVENTIONS WITH MARGINAL CLINICAL BENEFIT OR LOW COST-EFFECTIVENESS FOR CERTAIN CONDITIONS

The following interventions result in marginal clinical benefit or have low cost-effectiveness and should be excluded from coverage:

Procedure Code	Intervention Description	Rationale	Last Review
A4295-A4297	Intermittent urinary catheter; hydrophilic coating	More costly than equally effective alternatives	March 2026

*CPT only copyright 2025 American Medical Association. All rights reserved.
** Current Dental Terminology © 2025 American Dental Association. All rights reserved

Option 2:

1) Advise Medicaid to add HCPCS A4295-A4297(Intermittent urinary catheter; hydrophilic coating) to the Ancillary file

2) Add a new Ancillary services guidelines as shown below

ANCILLARY GUIDELINE AX: INTERMITTENT URINARY CATHETERS

Hydrophilic intermittent urinary catheters (HCPCS A4295-A4297) may be covered as an alternative to non-hydrophilic catheters (HCPCA A4291-A4293) if they are no more costly than non-hydrophilic catheters.

Discussion Table

IDs/#s	Summary of Issue	HERC Staff Response
A, B, C, D, E1, F, G, H	Hydrophilic catheters result in superior clinical outcomes, including reduced urinary tract infections (UTIs) and urethral trauma as compared with standard catheters.	The evidence reviewed to date, including articles submitted by commentors, does not show a statistically significant reduction in UTI risk with use of hydrophilic catheters compared to other types of catheters.
E2, I1	There should be continuity of care that allows coverage for hydrophilic catheters for those currently using them using the new HCPCS codes. Non continuation of coverage represents a	Prior to 2026, there was no way to differentiate types of intermittent catheters based on coding. The lack of distinct billing codes also resulted in no difference in cost between catheter types. The new HCPCS codes effective in 2026 allow for distinguishing the type of catheter used. It is anticipated that CMS will give the new codes for hydrophilic catheters a higher reimbursement rate than the

IDs/#s	Summary of Issue	HERC Staff Response
	substantial reduction in Medicaid benefits that is not allowed.	older codes for non-hydrophilic catheters. The HERC review found no differences in outcomes between hydrophilic and non-hydrophilic catheters. With the expected increase in cost for the hydrophilic catheters, these catheters are no longer the least costly alternative. OHP allows a limited coverage of a non-covered DME item until a patient can transition to a covered item.
I2	Hydrophilic catheters result in reduced costs from complications such as UTIs when compared with standard catheters.	The evidence reviewed to date, including articles submitted by commentors, does not show a statistically significant reduction in UTI risk with use of hydrophilic catheters compared to other types of catheters. The economic modeling studies used a reduction in UTI risk to model cost savings; if there is no reduction in UTI risk then these models are not accurate.
A, B, G	Patients find hydrophilic catheters to be more convenient or comfortable.	Services provided solely for the convenience of the member are not medically necessary under OHP.
I	Hydrophilic catheters could be offered by OHA at the same cost as other catheters.	Staff have created a separate option to cover hydrophilic catheters if they are the least costly option for the health plan. This option would maintain access to hydrophilic catheters if costs remain comparable to other catheters.

A	Self-lubricated catheters are not the same as standard ones. Dropping Medicaid coverage for self-lubricated catheters will cause a definite and substantial reduction in quality of life and comfort for people with disabilities. The staff report does not adequately address the difference in these products. Self-lubricated catheters (often called hydrophilic or pre-lubricated catheters) are designed to make intermittent catheterization easier, safer, and more comfortable. Here are the main benefits:	Thank you for your comments. The HERC values patient input and experience. Unfortunately, patient or caregiver convenience cannot be taken into consideration for OHP coverage. There are self-lubricated catheters that are not hydrophilic. For example, there are catheters

ID/#	Comment	Disposition
	1. Greater Comfort The catheter is already coated or becomes slick when activated (often with water), reducing friction. This makes insertion and removal smoother and less painful compared to dry or manually lubricated catheters. 2. Reduced Risk of Injury Lower friction means less irritation to the urethra. Helps prevent micro-tears, which can otherwise lead to discomfort or complications over time. 3. Lower Risk of Urinary Tract Infections (UTIs) Many are designed for single use and come sterile. The smooth surface reduces the chance of bacteria sticking and entering the urinary tract. 4. Easier and More Convenient to Use No need to carry separate lubricant. Often come in ready-to-use packaging, making them more discreet and quicker to use—especially helpful when away from home. 5. More Consistent Performance Pre-lubrication ensures even coating every time, unlike manual lubrication which can be uneven. 6. Better for Frequent Use Particularly beneficial for people who need to catheterize multiple times a day, as they minimize cumulative irritation. When they're especially helpful: People with sensitive urethras Long-term catheter users Individuals with limited hand dexterity (simpler prep)	that are self-lubricated with silicon oil. These types of self-lubricating non-hydrophilic catheters will continue to be covered with the original HCPCS codes for OHP patients. Most types of intermittent urinary catheters are designed for single use and come in sterile packaging. B	I live in Portland, Oregon and have used a power wheelchair for the past 28 years after being paralyzed in a motor vehicle accident. I currently work full-time from home as the editor of New Mobility, the longest running magazine and website (newmobility.com) for active wheelchair users. Working in this position for the past 15 years has given me a unique perspective on the importance of having access to needed medical equipment and how being denied access to that equipment directly translates to often catastrophic health problems. You will receive plenty of eloquent emails and testimony about how hydrophilic catheters have been proven to reduce UTIs and the ER visits and hospitalizations that follow, so instead of repeating the same statistics, I want to share an experience that I hope will show why maintaining access to hydrophilic catheters is necessary. I recently had the chance to interview some of the designers of one of the leading hydrophilic catheters and ask them the very questions I imagine you are asking yourselves: are hydrophilic catheters worth the extra cost? Are hydrophilic catheters luxury or needed items? They showed me footage from inside multiple bladders as users tried regular catheters and hydrophilic catheters. On the video you could see the tiny droplets of blood created as the non-hydrophilic catheter went into the bladder to drain it. Even with ample lubrication, each user had some visible damage. Now imagine doing this to yourself 4-10 times a day. You are basically tearing yourself apart just to urinate. In addition to raising your chances of infection and other complications, you are inflicting great physical pain onto your body. I personally have no sensation, but many users do, and I've heard from countless friends that the cumulative discomfort can be unbearable. In the videos of the hydrophilic	Thank you for sharing perspective on this issue. We will share your comments with VbBS and HERC.

ID/#	Comment	Disposition
	catheters, the insertion was noticeably smoother thanks to the hydrophilic coating. I couldn't see any blood droplets. The bladder drained quickly and easily. My friends who rely on hydrophilic catheters say the process feels better and leads to better results in draining the bladder.*I came away convinced that not only are hydrophilic catheters needed, but they should become the standard for all catheter users. Instead of asking 'Is this worth the added cost?' or 'Is this needed?', we should be asking, 'Is it humane to not cover these?' Like I said before, ask yourself if you'd be willing to rip your urethral walls multiple times a day knowing there is a safer, healthier alternative? No one should have to endure this, and to deny Oregonians the option merely to save a few dollars is the modern day equivalent of advocating for bloodletting or using leeches despite the availability of all the superior and more proven options. I know you are faced with difficult spending decisions, but please — for the sake of all of us who depend on catheters, and the thousands of Oregonians who will in the future — do not cut coverage to hydrophilic catheters. Help us stay healthy, Ian Ruder *I do not use a hydrophilic catheter because I have an indwelling catheter and no major designer has released an indwelling hydrophilic catheter yet – in part because they fear insurance won't cover them. If one was available, I would switch instantly.	
C	Dear Oregon Medicaid Value-based Benefits Subcommittee:	Thank you for your comments. The HCPCS codes available before 2026 did not allow determination of the type of catheter being

	United Ostomy Associations of America, Inc. (UOAA) is a 501(c)(3) national nonprofit organization that supports, empowers, and advocates for people who have had or will have ostomy or continent diversion surgery. We have over 285 affiliated support groups across the United States with six (6) in the state of Oregon. There are between 725,000 to one million Americans living with an ostomy or continent diversion, and over 100,000 new life-saving ostomy surgeries occur in America yearly. As the voice and leading organization advocating for people living with an ostomy, we know first-hand how important access to ostomy and urological supplies are for this patient population. Many individuals in our community depend on both ostomy supplies and catheters to manage their health and daily bodily functions. On behalf of UOAA, our organization has serious concerns with Oregon Medicaid's proposal to remove coverage for hydrophilic intermittent catheters. Intermittent catheters (ICs) are covered by Medicare under the "prosthetic devices" benefit category which "replace all or part of an internal body organ". In 2024 the Centers for Medicare and Medicaid Services (CMS) made a decision to modify existing HCPCS codes and create three new codes (A4295, A4296 and A4297) to distinguish hydrophilic coating technology within the intermittent catheter product category. This decision recognizes the clinical benefits of hydrophilic coating technology and was also made to improve coding accuracy. These new codes went into effect in January 2026. Thirty-four state Medicaid plans have already implemented the new hydrophilic HCPCS codes, and all others are working on the finalization. UOAA has learned that Oregon Medicaid has decided that coverage is not medically necessary for A4295 A4296, and for A4297 and will not cover these	purchased. The new codes now allow identification of the hydrophilic catheters, which are not as cost-effective as non-hydrophilic catheters. OHP patients will continue to have access to medically necessary less expensive intermittent catheter supplies. The reviewed evidence did not find a significant reduction in infection, stricture or other outcomes with hydrophilic catheters. Staff have added an option for coverage of hydrophilic urinary catheters when they are equivalent in cost.

ID/#	Comment	Disposition
	products. Oregon Medicaid is the only state that is withdrawing coverage for hydrophilic intermittent catheters. We believe this must be a simple misunderstanding since prior to this coding update, Oregon Medicaid actually covered hydrophilic-coated catheters under HCPCS codes A4351, A4352, or A4353 (legacy codes- now used for non-hydrophilic catheter billing). It is critical that individuals who were using hydrophilic catheters previously continue to have access to their medically prescribed prosthetics as well as new patients going forward. Hydrophilic catheters are specifically designed to reduce friction during insertion and removal. The lubricated coating helps minimize trauma to the urethra, which lowers the risk of microtears, bleeding, and long-term urethral damage. Without access to these, individuals may be forced to use less advanced or reused catheters, increasing the likelihood of complications such as strictures or chronic irritation. For people who catheterize multiple times per day, even a small increase in infection risk can quickly escalate into recurrent UTIs, kidney infections, or even sepsis—conditions that are not only dangerous but also costly to treat. Our organization respectfully requests that HCPCS codes A4295, A4296, and A4297 be included in Oregon Medicaid coverage. Thank you for the opportunity to provide these comments and your consideration of our concerns to ensure access to these supplies.	
D	Dear Health Evidence Review Commission, Thank you for receiving my comments on Medicare's decision to no longer provide hydrophilic catheters. Seven years ago I survived a spinal cord injury. Many people who live with spinal cord injuries have	Thank you for your comments and sharing your personal experience. HERC is grateful for the input of those affected by issues under review. Your comments will be made available to members for review. The current review is

ID/#	Comment	Disposition
	neurogenic bladders, meaning the bladder cannot empty normally because the muscles controlling the bladder sphincter are paralyzed. Not emptying the bladder frequently using a catheter often results in bladder spasms and urinary tract infections (UTI). For the first four years of my injury I emptied my bladder using regular catheters and a separate packet of lubrication to ensure the catheter enters and exits the urethra without causing abrasians. The problem with using catheters that are not pre-lubricated, is that it opens the body to more bacteria and more frequent UTIs. It's incredibly difficult to handle separate packets of materials in a bathroom, and then insert the catheter into the bladder without introducing bacteria to a part of the body that is very sensitive to bacteria. During this four years of intermittent catheterization I lost count of how many UTIs I had and how often I needed to take antibiotics to clear the infection. It is quite common for people with SCIs to become antibiotic resistant because UTIs are so common. My urologist suggested I begin using hydrophilic catheters, which are pre-lubricated. This means only handling one package, and many of these catheters have a small device that the user can hold onto while inserting, so that virtually zero bacteria is introduced to the urinary tract. Since I switched to hydrophilic catheters, I have had zero UTIs. I went from having a UTI about every 2 months to never having a UTI again, purely because of the types of catheters I use. Since many people with SCIs become antibiotic resistant, it is quite common to be hospitalized with severe bladder infections. I am fortunate in that my infections were	focused only on Oregon Health Plan, Oregon's version of Medicaid, rather than Medicare (the federal program for older and disabled Americans). Thank you for the Ali 2024 reference. This study is a comparative cohort study. As RCT evidence is available, this was considered a lower quality of evidence based on the study design and therefore excluded from the coverage review. Thank you for your comments and sharing your personal experience. HERC is grateful for the input of those affected by issues under review. Your comments will be made available to members for review.

ID/#	Comment	Disposition
	never that severe. Because I no longer get UTIs, due to using hydrophilic catheters, I am able to maintain a part time job and run errands for my family. During my time of having frequent UTIs, I often did not leave the house at all, because UTIs often cause bladder spasms and heavy incontinence. For three years we had to wash my wheelchair cushion nearly daily, because even wearing Depends did not prevent urine from leaking everywhere. Living with a spinal cord injury is incredibly difficult, and hydrophilic catheters is one thing that makes life a little easier. My days of staying at home due to UTIs and incontinence left me incredibly depressed and almost unable to take care of myself, much less my family. If a urologist has prescribed hydrophilic catheters to a patient, it is due to the urologist's knowledge and experience with how to prevent infection. Please allow these doctors to help us remain healthy. Thank you, Katie Ciancetta Salem, Oregon	
E1	Dear Members of the Value-based Benefits Subcommittee, I am not a clinician, nor a policy maker, but as Interim CEO of the United Spinal Association I have the personal lived experience of over 20 years of catheterizations and that of the countless shared life experiences of	Thank you for your comments and sharing your personal experience. ID/#	Comment	Disposition
	our community members, many of whom are Oregon residents, to tell you: • Hydrophilic urological intermittent catheters absolutely can reduce urinary tract infections. • Hydrophilic urological intermittent catheters save healthcare costs. By taking away the coverage of hydrophilic catheters that people have depended upon for years, you are endangering lives. It took me twenty years to find a catheter that helps reduce UTIs. I struggled with many products until I found a closed hydrophilic-coated system that gave me safe independence with cathing. My journey is far, far from unique. Please gather more information before someone suffers a UTI that can lead not only to life threatening medical complications but can result in people dying. You simply must not to turn the clock back on individuals' health and innovation that provide significantly better healthcare outcomes. The cost savings achieved through preventive healthcare, saves precious dollars as well as lives.	outcomes with hydrophilic catheters. Your comments will be made available to members for review.
E2	As you will recall, the United Spinal Association previously commented on the critical need for coverage of hydrophilic catheters. To reiterate, the current access issue arises in the context of a CMS coding update that took effect on January 1, 2026. CMS established new HCPCS codes—A4295, A4296, and A4297—to clearly differentiate hydrophilic-coated intermittent catheters from non-hydrophilic products. These	Thank you for your comments. Under Oregon Administrative Rules (OAR 410-122-0080), OHP can only cover "...the least costly, medically appropriate item that meets the medical needs of the client." The HCPCS

ID/#	Comment	Disposition
	codes were created to improve coding accuracy and reflect established clinical distinctions. They did not signal a change in clinical evidence, medical necessity, or standard of care. Prior to this coding update, Oregon Medicaid covered hydrophilic-coated catheters when they were billed under HCPCS codes A4351, A4352, or A4353. As a result, individuals who had been stable and successful using hydrophilic catheters are now set to lose access solely because the products they use are billed under new codes that are not yet covered. From the patient perspective, this represents an administrative disruption rather than a clinically justified change. United Spinal respectfully urges Oregon Medicaid to reassess its current policy and align coverage with the updated CMS HCPCS structure by adding A4295, A4296, and A4297 to the state Medicaid fee schedule with appropriate reimbursement. Implementation of the hydrophilic HCPCS codes at the same rate as the existing non-hydrophilic HCPCS codes (A4351, A4352 and A4353) will not add additional cost to the state of Oregon. Additionally, this will retain coverage for hydrophilic-coated intermittent catheters protect continuity of care, support clinician-directed treatment decisions, and help prevent avoidable medical complications for individuals living with spinal cord injury and disorder. Thank you for your attention to this issue and for your continued service to Oregon Medicaid beneficiaries. Again, we welcome the opportunity to provide additional information, clinical perspectives, or patient input to support this review.	codes available before 2026 did not allow determination of the type of catheter being purchased. The new codes now allow identification of the hydrophilic catheters, which are not as cost-effective as non-hydrophilic catheters. Staff have added an option for coverage of hydrophilic urinary catheters when they are equivalent in cost.

	Sincerely, M. J. Castelluccio Matt Castelluccio Interim CEO United Spinal Association	
F	April 16, 2026 Dear Members of the Oregon Health Authority and Oregon Medicaid Program, My name is West Livaudais and I live in Portland, OR. Thank you for the opportunity to share my experience and why coverage of hydrophilic intermittent catheters is important for patients like me. I live with spinal cord injury and have a neurogenic bladder, which means I must use intermittent catheters 5-6 times every day to empty my bladder. Catheterization is not optional for me—it is a necessary medical treatment that allows me to stay healthy and avoid serious complications like UTIs. I currently use hydrophilic catheters, which are designed with a coating that becomes slippery when activated with water. These catheters are different from non-hydrophilic catheters because coating prevents micro-abrasions on my urethra that standard catheters cause. These abrasions make me more susceptible to UTIs.	HERC appreciates you sharing your personal experience as it values input from those affected by issues under review. Your comments will be available to members.

ID/#	Comment	Disposition
	Two years ago, I transitioned to hydrophilic catheters and immediately I stopped having UTIs every 60-90 days. It reduced my use of the ED. In the previous 5 years, I had used the ED 3 times and been hospitalized once for severe UTIs. They have reduced my need for antibiotics due to UTIs to almost zero. For patients like me, small differences in catheter design can make a big difference in health outcomes. With hydrophilic catheters, I have experienced: Fewer urinary tract infections Less irritation Fewer antibiotics due to UTIs Fewer ED and urgent care visits due to UTIs More consistent bladder management resulting in less incontinence When catheterization is more difficult or painful, patients may delay or avoid it, which can lead to serious complications such as infections, kidney damage, or hospital visits. This decision affects Medicaid beneficiaries directly and will affect whether we can access the products that work best for our medical needs. If hydrophilic catheters were not covered, it would mean a return to UTIs, antibiotics, ED visits - HIGHER COSTS for MEDICAID.	

ID/#	Comment	Disposition
	Ensuring coverage helps patients like me: Stay healthy Avoid infections and complications Remain independent Prevent more costly medical care in the future Hydrophilic catheters are not a convenience item—they are an important medical tool that helps people with bladder conditions manage their health safely and effectively. I respectfully ask Oregon Medicaid to continue to provide coverage for hydrophilic intermittent catheters so that patients like me can maintain our health, independence, and quality of life. Thank you for considering my experience and for the work you do to support patients in Oregon. Sincerely, West Livaudais, MPH Founder/Executive Director of Oregon Spinal Cord Injury Connection Portland, Oregon

H	Dear Members of the Oregon Health Authority and Medicaid Program, My name is Micki Kleven and I am an Occupational Therapist working with individuals with spinal cord injuries in the state of Oregon. I am writing on behalf of my patients, as well as my partner who is a C4-C5 incomplete quadriplegic, and all of our dear friends who we have met through the spinal cord injury community regarding the proposal to no longer fund hydrophilic intermittent catheters. These individuals living with spinal cord injury live with a secondary condition called neurogenic bladder that requires the use of	Thank you for sharing your personal and professional perspectives on this issue. Thank you for submitting literature for our review. • de Ridder 2005 was an RCT included in Ye 2021 which was in the March meeting materials • Vapnek 2003 was an RCT included in Ye 2021 which was in the March meeting materials

ID/#	Comment	Disposition
	catheterization to empty the bladder. These catheters must be used each time they use the restroom in order to safely evacuate the bladder fully and prevent urinary tract infections, which often lead to hospitalizations and more life-threatening conditions such as autonomic dysreflexia or sepsis. Hydrophilic intermittent catheters have been shown to decrease the risk of UTIs in individuals with spinal cord injury as cited in this research article by Ridder, et al., this research article by Vapnek, et al., this research article by Cardenas, et al., and many more. Decreased rates of UTIs means less Oregon Medicaid money going to ER or Urgent Care visits, antibiotics, caregivers, and hospitalizations. It means fewer individuals with spinal cord injuries out of the workforce while they treat UTI symptoms, and fewer individuals with spinal cord injuries dying from preventable causes. So, while cutting funding for hydrophilic catheters may seem like a good plan to save Medicaid dollars, it is short-sighted, and would ultimately lead to an increase in overall Medicaid spending to remedy the detrimental long-term effects this decision would have on Oregon Medicaid beneficiaries. I have personally witnessed the damage that uncontrolled UTIs can cause, as I recently lost a dear friend in December to a stroke that was brought on by autonomic dysreflexia. This bout of autonomic dysreflexia was brought on by a kidney infection that began as a UTI and traveled to	• Cardenas 2011 was an RCT included in Ye 2021 which was in the March meeting materials Staff have added an option for coverage of hydrophilic urinary catheters when they are equivalent in cost.

	his kidneys, ultimately killing him. He would have celebrated his 40th birthday this summer. Lack of access to appropriate equipment is, quite literally, life threatening to individuals with a spinal cord injury. For this reason, I respectfully ask that you continue covering hydrophilic intermittent catheters for your beneficiaries. I do not want to lose any further patients, friends, or my partner to something as preventable as a UTI because of lack of access. Thank you for considering my professional expertise, as well as my personal experiences on this matter. Thank you for your support of Oregon Medicaid beneficiaries and the hard work that you do. Sincerely, Micki Kleven, OTD, OTR/L, ATP/SMS Assistant Professor of Occupational Therapy Academic Fieldwork Coordinator	
I1	Federal Continuity of Pricing Requirements Federal Medicare payment policy regulates establishment of payment amounts for new HCPCS codes to maintain access when HCPCS coding changes occur. Federal regulations require continuity of pricing when the Centers for Medicare and Medicaid Services (CMS) establishes a new HCPCS code for an item that was previously included in a different HCPCS code. Under these regulations, the new HCPCS	Thank you for your comments. Under Oregon Administrative Rules (OAR 410-122-0080), OHP can only cover "...the least costly, medically appropriate item that meets the medical needs of the client." The HCPCS codes available before 2026 did not allow determination of the type of catheter being purchased. The new codes now allow identification of the hydrophilic catheters,

ID/#	Comment	Disposition
	code's Medicare payment amount is established at the same payment rate as the previous HCPCS code.[1] This framework reflects a clear federal policy principle: coding changes must not result in disruption of beneficiary access to medically necessary items. Accordingly, new hydrophilic catheter HCPCS codes are established and the item was previously included in another HCPCS code with an established payment amount, Medicare rules require the payment amount for the new HCPCS code to be the same as when the item was included in a different HCPCS code. Oregon Medicaid should follow the same principle by establishing payment rates for the A4295, A4296 and A4297 at the same rates, respectively, as A4351, A4352, and A4353. Oregon Medicaid previously covered and paid for hydrophilic intermittent catheters when they were included in A4351, A4352 and A4353; it should now cover and pay for these same items under their new HCPCS codes, A4295, A4296 and A4297. CMS approved State Plan Amendment (SPA) #24-0020 the rates for durable medical equipment and supplies are based on 80% of the 2024 Medicare fee schedule unless the 2012 rate is higher, in which case the rate will be frozen. Unless Oregon Health Authority submits a new SPA, the rates would be frozen at the current established fee schedules. The following chart summarizes the HCPCS codes changes as of January 1, 2026, and identifies Medicare's continuity of payment regulations as applied to the new HCPCS codes that include hydrophilic intermittent catheters.	which are not as cost-effective as non-hydrophilic catheters. HERC does not create fee schedules for the Oregon Health Plan. Staff have added an additional option so that hydrophilic catheters could be covered if equivalent in cost.

Federal Medicaid Due Process Requirements

Federal Medicaid regulations establish clear protections when coverage for a currently provided item is reduced or terminated. Under 42 C.F.R. § 431.201, an "action" includes the termination, suspension, or reduction of Medicaid services.[3] Any policy change that results in a previously covered catheter becoming non-covered constitutes a termination of service. By eliminating coverage for hydrophilic intermittent catheters when that coverage was previously available to Medicaid recipients, Oregon Medicaid is clearly reducing available Medicaid services. In these instances, federal regulations require the state to comply with due process procedures to provide some protections to the affected populations.

Therefore, if Oregon Medicaid continues with its decision to eliminate coverage for hydrophilic intermittent catheters, it must comply with the following requirements:• Advance written notice (42 C.F.R. § 431.211)[4]• Adequate notice content, including reasons and legal authority (42 C.F.R. § 431.210)[5]• Opportunity for a fair hearing (42 C.F.R. § 431.214)[6]• Notice of hearing rights (42 C.F.R. § 431.206)[7]• Managed care adverse benefit determination requirements (42 C.F.R. § 438.404)[8]• Notice of changes in services (42 C.F.R. § 435.917)[9]CMS has consistently made

ID/#	Comment	Disposition
	clear that states and managed care entities may not avoid these requirements by reclassifying services as "non-covered" when beneficiaries are actively receiving them. Federal Benefit Sufficiency Requirements and Clinical Impact Federal standards further require that Medicaid services be sufficient in amount, duration, and scope to reasonably achieve their intended purpose (42 C.F.R. § 440.230).[10] Restricting access to hydrophilic intermittent catheters—particularly where clinically indicated—may fail to meet this requirement and can lead to increased infections, complications, and higher downstream costs to the Medicaid program.	
I2	Fiscal Impact and Program Cost Considerations Eliminating coverage for hydrophilic intermittent catheters is unlikely to produce cost savings for the Oregon Medicaid program—and may instead increase total expenditures. Hydrophilic catheters are designed with surface coating that binds water to create a smooth, lubricious layer, eliminating the need for separate lubricant during use. Individuals using non-hydrophilic catheters require ongoing lubricant supplies to safely perform catheterization. Based on available estimates, if all current users were transitioned to non-hydrophilic catheters, Oregon Medicaid would incur approximately $656,640[10] annually in additional lubricant costs alone. This estimate does not include the well-documented downstream costs associated with increased urinary tract infections (UTIs), urethral	Thank you for your comments. The reviewed evidence did not find a significant reduction in infection, stricture or other outcomes with hydrophilic catheters. The economic studies that found cost savings used models that relied on reduced infection risk.

ID/#	Comment	Disposition
	trauma, emergency department visits, and hospitalizations that are more likely when hydrophilic catheters are not available. These avoidable complications can significantly increase total cost of care for intermittent catheter users. Given the previous coding structure and that Oregon Medicaid is unlikely to have a current breakdown of hydrophilic versus non-hydrophilic catheter utilization, this uncertainty further underscores the risk of unintended financial consequences from eliminating coverage. At a minimum, the program would be shifting costs rather than reducing them—potentially increasing overall spending. Maintaining coverage and applying continuity of pricing by crosswalking payment rates from the prior HCPCS codes would preserve access to clinically appropriate products without introducing new costs to the system. This approach aligns with federal policy, supports beneficiary health outcomes, and avoids unnecessary increases in both supply and medical expenditures.	
I3	Request to the Committee In light of these considerations, AAHomecare respectfully requests that the VBBS Committee: 1. Add and recognize current hydrophilic intermittent catheter HCPCS codes as covered services;	Thank you for detailing your recommendations which will be available to the members for review.

ID/#	Comment	Disposition
	2. Set payments for the new HCPCS codes that now include only hydrophilic intermittent catheters equal to those for the HCPCS codes that previously included hydrophilic intermittent catheters. 3. Ensure continuity of care for beneficiaries currently utilizing hydrophilic catheters; 4. Ensure compliance with federal notice and due process requirements; and 5. Engage stakeholders, including providers and patient advocates, to support implementation **Conclusion** Hydrophilic intermittent catheters are essential to maintaining patient health, independence, and dignity while reducing avoidable healthcare utilization. Federal law is clear that both coverage and payment policies must preserve continuity of care and protect beneficiary rights. AAHomecare stands ready to work collaboratively with the Oregon Health Authority and the HERC VBBS Committee to ensure that coverage policies are clinically appropriate, operationally feasible, and fully compliant with federal requirements. Thank you for your consideration. Sincerely,

Abstract

Study design Systematic review and network meta-analysis.

Objectives Intermittent catheterization (IC) is considered the standard treatment for neuro-urological patients who are unable to empty their bladders. The present study aimed to conduct a systematic evaluation and network meta-analysis of all available types of intermittent catheters, and determine which one is best suited for clinical use.

Methods We searched MEDLINE, EMBASE and Cochrane Central Register of Controlled Trials (CENTRAL) databases to identify relevant studies. Only randomized clinical trials (RCTs) were included. Five types of catheters were identified based on the included studies. A Bayesian network meta-analysis was then performed. The surface under the cumulative ranking (SUCRA) curve was used to determine the best catheter for each outcome.

Results A total of 25 RCTs, involving 1233 participants, were included. The pooled odds ratios of symptomatic UTI were lower for two ready-to-use single-use catheters (gel-lubricated non-coated catheter, OR: 0.30, 95% CI 0.095–0.86; pre-activated hydrophilic-coated catheter, OR: 0.41, 95% CI 0.19–0.83) as compared to single-use non-coated catheter. In terms of patient satisfaction, the SUCRA results showed that the pre-activated hydrophilic-coated catheter may the preferred option (SUCRA = 82.8%). However, there were no significant differences in all outcome measures between traditional single-use non-coated catheters and clean non-coated catheters.

Conclusion Ready-to-use single-use catheters are associated with lower rates of UTI compared to traditional catheters. Patients may be most satisfied with the pre-activated one. For traditional single-use non-coated catheters and clean non-coated catheters, there is still no convincing evidence as to which is better. Thus, more well-designed trials are needed.

Introduction

Intermittent catheterization (IC) is a procedure that involves using a urinary catheter to empty the bladder, which typically is done several times a day. IC is considered as a standard treatment for adults and children with incomplete bladder emptying due to neurological disorders [1]. However, with long-term IC usage, some life-threatening complications may occur. The most frequent complication is urinary tract infection (UTI) [2], which can result in bacteremia/sepsis. Urethral trauma, usually evaluated by haematuria, has also been reported and shown to affect the risk of UTI [3].

Since the first introduction of IC, the material, coating and design of the catheter have undergone continuous improvements to reduce the incidence of UTI, attenuate urinary tract injury and enhance patient satisfaction. IC was originally performed using sterile technique [4] (single-use catheter with sterile gloves and sterile containers). Lapides et al. [5] later proposed a clean reusable catheter, which is more cost-effective without increasing infection rates. Reused IC refers to the reuse of a catheter after washing with soap, boiling and/or soaking in disinfectants and air

drying, instead of discarding it. Coated catheters are now available for IC, which are only single-use and designed to improve lubrication and reduce urethral injury. The most widely used one is hydrophilic-coated catheter, with a layer of hydrophilic polymers that absorb water and bind to the catheter surface [6]. The friction of hydrophilic-coated catheter is greatly lower than that of the traditional plastic lubricated catheter [7].

IC can be done by caregivers or by the patients themselves after discharge from the rehabilitation facility. Several new designs, with the concepts of "No touch" or "Ready to use", have been developed to facilitate the procedure, reducing the risk of infection during the procedure, and improving patient comfort. For non-coated catheters, there are some designs such as a closed, touchless, self-contained catheter system that can be used in a sterile collection bag [8], and the catheters are pre-lubricated without a need to add gel manually [9]. For hydrophilic-coated catheters, the first design required immersion in water for 30 s to activate it before use; the later design is packed in water (pre-activated) and ready for use [10].

Although four meta-analyses [11–14] have suggested the benefit of hydrophilic-coated catheters over non-hydrophilic ones, the variety of catheters can make data synthesis challenging. The confounding factors may include sterile or clean technique, single-use or re-use, pre-lubricated, pre-activated and other design features.

Another comparison, single-use versus re-use catheters, is still controversial. Two cost-effectiveness studies [11, 15] demonstrated the economic advantage of re-use catheters, and the results suggest that re-use catheters may be more acceptable for long-term use to individuals in developing countries. A Cochran systematic review [13] in 2014 concluded that single-use catheters have no clear advantages over re-use catheters, and this potential endorsement of re-use catheters may have a strong impact on healthcare providers' decision-making. However, this Cochran review was withdrawn [16], since an independent appraisal [17] had found significant problems with data extraction and analysis.

Therefore, we undertook a network meta-analysis of all available types of catheters to identify the one that is most suitable for IC. This kind of analysis can reduce the confounding effects in pair-wise meta-analysis due to the variety of catheters, as well as integrate both direct and indirect comparisons.

Methods

Search strategy

This systematic review is reported based on the Preferred Reporting Items for Systematic reviews and Meta-analyses Statement (PRISMA) [18]. The PRISMA checklist is shown in supplementary information. MEDLINE, EMBASE and the Cochrane Central Register of Controlled Trials databases were searched to identify relevant articles published up to June 2020. The following search terms were used: *IC, urethral catheterization, self-catheterization, clinical trials as the topic* and *random*. The detailed search strategy is presented in Supplementary Table S1. Relevant references from the 2014 Cochrane review were also identified. Screening of titles and abstracts, as well as full-text reading if necessary, were done by two authors independently. Disagreements were resolved by a third reviewer. The study protocol was registered at PROSPERO (No. CRD42018114852).

Selection criteria

The inclusion criteria were as follows: (i) randomized controlled trials or randomized cross-over trials; (ii) participants who used some form of IC; (iii) comparison of different types of intermittent catheters; and (iv) outcomes were symptomatic UTI, asymptomatic bacteriuria, haematuria and/or patient satisfaction. Observational studies, editorials, commentaries and review articles were excluded. Based on the experimental groups in the included studies, we defined five types of catheters of interest for analysis, as follows: (i) single-use non-coated catheter (SNC)—a single-use uncoated catheter. After removing it from sterile packaging, the user needs to add some lubricant before insertion; (ii) gel-lubricated single-use non-coated catheter (GSNC)—a single-use uncoated catheter with pre-packaged lubricant, which is ready to use; (iii) single-use hydrophilic-coated catheter (SHC)—a single-use catheter with a hydrophilic polymer coating. The user needs to add sterile water for about 30 s to active the hydrophilic polymer coating; (iv) clean reused non-coated catheter (CNC)—a reusable uncoated catheter, which is usually washed with soapy water and air-dried after each use, but the user needs to add some lubricant before use each time; and (v) pre-activated single-use hydrophilic-coated catheter (PSHC)—a single-use catheter with a hydrophilic polymer coating which has been activated, and is ready-to-use. Only studies with at least two of the above-mentioned catheter types were included.

Data extraction

Data extraction was performed by two authors independently. Disagreements were resolved by a third reviewer when necessary. The following information was extracted from each qualified article: author list, publication year, study population, study design, study location, subject age range, sample size, study duration, catheter types, the number of participants who dropped out, and clinical outcomes.

Outcome assessment

The outcomes were symptomatic UTI, asymptomatic bacteriuria, urinary injury measured by haematuria, and patient satisfaction. The definitions of these outcomes were as follows: (i) symptomatic UTI—a positive urine culture of ≥ 10^3 cfu/mL with at least 1 symptom compatible with UTI, including fever, cloudy/malodorous urine, suprapubic/flank pain, worsening incontinence, malaise and/or pain associated with catheterization [19, 20]. Since some trials had discrepant definitions of symptomatic UTI, we also considered the definitions used in the trials, in a sensitivity analysis; (ii) asymptomatic bacteriuria—the presence of at least 1 bacterial species (≥10^5 cfu/mL) in a single catheter urine specimen without any symptoms compatible with UTI; (iii) haematuria—the presence of red blood cells in the urine, urethral bleeding, or gross and microscopic haematuria; and (iv) patient satisfaction—the subjective general opinion or preferences. All trials reporting satisfaction included a binary item of overall satisfaction, and the non-binary items were disregarded.

Data quality assessment

Two authors independently evaluated the quality of the studies using the Cochrane Risk of Bias tool covering selection bias, performance bias, detection bias, attrition bias, reporting bias and other potential sources of bias. The studies were classified into three grades: "high", "unclear" and "low" risk of bias.

Statistical analysis

A network meta-analysis was performed to compare all five types of IC catheters using a Bayesian approach [21], producing four networks with one outcome each. All analyses were performed in R 3.4.4 [22] using the 'GeMtc' package. The intervention efficacy or clinical impact are presented as odds ratios (ORs) and 95% confidence intervals (CIs). The ranking probabilities and the surface under the cumulative ranking curves (SUCRA) [23] are utilized to evaluate the relative ranking of different types of catheters for each outcome. Study heterogeneity was evaluated using the Higgins–Thompson I^2 method [24]. To evaluate inconsistency among the included trials in the networks, the Z test [25] and node splitting model [26] were used to quantify the degree of difference between direct and indirect comparisons. The level of statistical significance was set at $P < 0.05$.

As the definitions of symptomatic UTI varied between various studies, we conducted a sensitivity analysis assessing only studies with clear, detailed definitions and those which only met the standard provided by the Infectious Diseases Society of America (IDSA) 2009 consensus statement [19] and the American Academy of Pediatrics (AAP) guidelines for UTI [20].

Results

The literature search identified 2914 records, and 40 studies were selected for a full review after excluding duplicate publications and screening title and abstract. After full-text screening, 25 studies [9, 10, 27–49] were included. The PRISMA flow diagram is shown in Fig. 1.

Characteristics of the included studies

Table 1 lists the main characteristics of the studies. Fourteen were randomized controlled trials, and 11 were randomized cross-over trials. Among the 1233 participants, most were diagnosed with neurogenic bladder, while a few had other causes of urinary retention, such as prostatic hyperplasia. Six trials [30, 33, 44, 46, 48, 49] focused on children, and one [47] included individuals with myelomeningocele and involved a small number of children. In two [30, 33] of these seven trials, the children did self-IC, while in the remaining five [44, 46–49] they did it either themselves or IC was done by a trained caregiver. The remaining 18 trials included only adult subjects. In these 18 trials, IC was performed by the patients themselves [9, 10, 28, 32, 35, 39, 40, 42, 43, 45], by caregivers [29, 31, 34, 37, 38], or by both [27, 36, 41]. Males made up 75.9% of the total study sample. There were 16 trials [9, 27, 29–33, 36, 38–41, 45, 47–49] assessing the

incidence of symptomatic UTI, and 10 [27, 28, 30, 32–35, 38, 45, 49] assessing the incidence of asymptomatic bacteriuria. For haematuria, 8 trials [9, 30, 32, 35–37, 40, 41] were included; while for patient satisfaction, 9 trials [10, 32, 36, 37, 40, 42–44, 46] were included. The specific data of each comparison arm is shown in Supplementary Table S2. Cochrane tool risk of bias details are listed in Supplementary Fig. S1, which reveals a moderate risk of bias across trials.

Symptomatic UTI

Sixteen trials which reported the incidence of symptomatic UTI, comparing SNC, GSNC, SHC, CNC and PSHC (916 total participants) were included. When SNC was used as the reference, only GSNC (OR 0.30, 95% CI 0.10–0.86) and PSHC (OR 0.41, 95% CI 0.19–0.83) were associated with a statistically significant lower incidence of symptomatic UTI (Fig. 2A). According to the SUCRA values

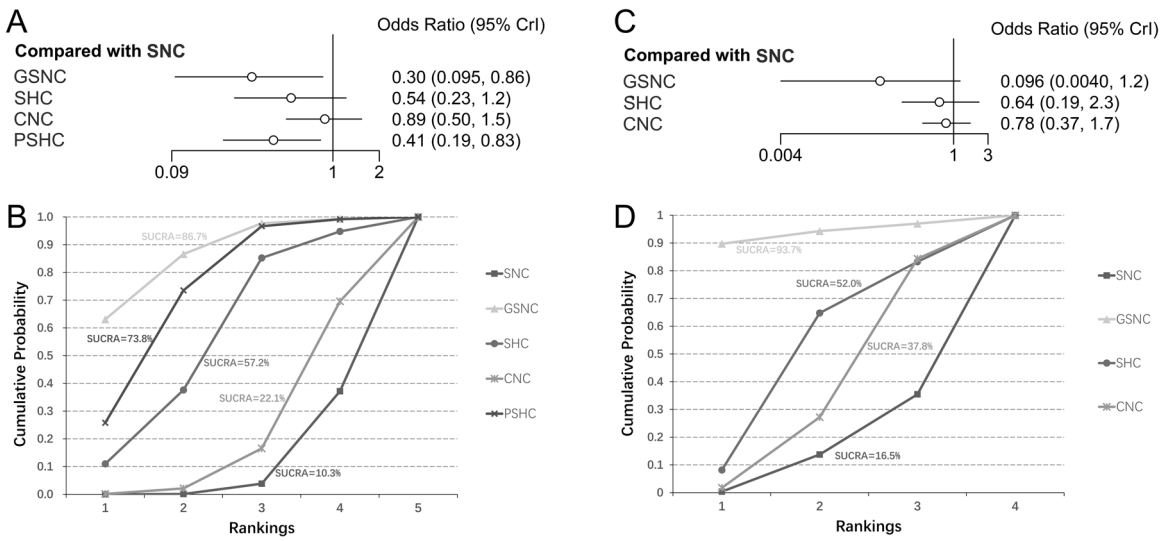

Fig. 2 Analysis of symptomatic UTI and asymptomatic bacteriuria. A Forest plot of symptomatic UTI, with single-use non-coated catheter as the comparator; **B** SUCRA plot of symptomatic UTI; **C** forest plot of asymptomatic bacteriuria, with single-use non-coated catheter as the comparator; **D** SUCRA plot of asymptomatic bacteriuria.

(Fig. 2B), GSNC (SUCRA = 86.7%) was the preferred option to decrease the risk of symptomatic UTI, followed by PSHC (SUCRA = 73.8%), SHC (SUCRA = 57.2%) and CNC (SUCRA = 22.1%). Assessment of heterogeneity (Supplementary Fig. S2) revealed $I^2 = 29.9\%$ for the comparison of GSNC versus SNC and $I^2 = 63.1\%$ for CNC versus GSNC; while the remaining comparisons showed no heterogeneity ($I^2 = 0\%$). Overall, we found no significant inconsistency ($Z = 3.99$, $p = 0.41$) in the analysis.

Sensitivity analysis of symptomatic UTI

The specific definition of symptomatic UTI described in each trial is given in Supplementary Table S3. We conducted a sensitivity analysis for symptomatic UTI assessing only studies with clear, detailed definitions and those that only met the standard of the IDSA 2009 consensus statement and AAP guidelines. Four trials [30, 36, 41, 47] were excluded, and PSHC was not included in this analysis due to the exclusion of two trials [36, 41]. The results of SUCRA-based analysis (Supplementary Fig. S3) showed a similar trend as in the initial analysis. Notably, the probability of GSNC being the preferred choice was 91.0% and that of SHC being the second preferred choice was 67.6%. The estimated risk for the comparison of GSNC versus SNC remained statistically significant (OR 0.29, 95% CI 0.09–0.86).

Asymptomatic bacteriuria

For asymptomatic bacteriuria, the network analysis comprised nine trials comparing SNC, GSNC, SHC and CNC (378 total participants). Base on the SUCRA results (Fig. 2D), GSNC (SUCRA = 93.7%) was the preferred choice to prevent asymptomatic bacteriuria, and SHC was likely (SUCRA = 52.0%) to be the second choice. No significant differences were observed for GSNC, SHC and CNC (OR 0.096, 95% CI 0.004–1.2; OR 0.64, 95% CI 0.19–2.3; and OR 0.78, 95% CI 0.37–1.7, respectively), when compared to SNC (Fig. 2C). In addition, there was no evidence of significant heterogeneity and no inconsistency between the studies (Supplementary Fig. S4).

Haematuria

Eight trials comparing SNC, GSNC, SHC, CNC and PSHC (643 total participants) with regards to haematuria or urethral bleeding were included. Although no significant difference in haematuria incidence was observed for the four catheters, the SUCRA results indicated that the hydrophilic-coated catheter may be the preferred option to decrease the risk of haematuria (OR: 0.19, 95% CI 0.01–1.5; SUCRA 87.7%; Fig. 3A, B). No significant inconsistency ($Z = 1.57$, $p = 0.67$) was observed between the studies. Assessment of heterogeneity gave $I^2 = 72.0\%$ for the comparison of PSHC with SNC and $I^2 = 57.3\%$ for PSHC versus GSNC; the remaining comparisons were not significant (Supplementary Fig. S5).

Patient satisfaction

Nine trials that reported patient satisfaction were included in the analysis (849 total participants). In six [10, 32, 37, 40, 42, 43] of these trials, the satisfaction was reported by the patients themselves; while in the other three

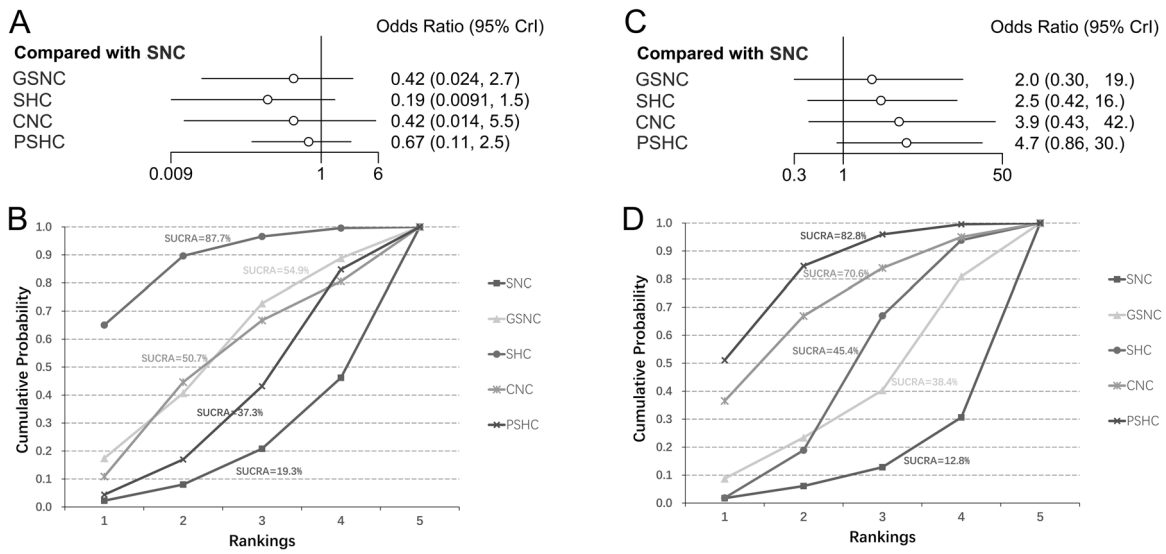

Fig. 3 Analysis of haematuria and patient satisfaction. A Forest plot of haematuria, with single-use non-coated catheter as the comparator; **B** SUCRA plot of haematuria; **C** forest plot of patient satisfaction, with single-use non-coated catheter as the comparator; **D** SUCRA plot of patient satisfaction.

[36, 44, 46], part of the evaluation was done by the patient and part by the care provider. SUCRA analysis indicated that in terms of overall patient satisfaction the catheters were ranked as follows: PSHC, CNC, SHC, GSNC and SNC (Fig. 3D). None of the catheters exhibited significant advantages compared with SNC (Fig. 3C). Assessment of heterogeneity (Supplementary Fig. S6) demonstrated no significant heterogeneity for the comparison of SHC versus SNC and GSNC; the remaining comparisons showed a slight but significant heterogeneity. There was no significant inconsistency ($Z = 3.46$, $p = 0.33$) observed between the studies.

Discussion

The types of catheters used in IC vary across the globe, including single-use or re-use, coated or uncoated, pre-lubricated, pre-activated and others. Previous pair-wise meta-analyses [12–14] have suggested the advantage of using hydrophilic-coated catheters for IC. However, these studies often clustered two different catheters (SNC and CNC) in the category of uncoated catheters when uncoated was compared to hydrophilic-coated catheters, and clustered two different hydrophilic-coated catheters (PSHC and SHC) in the same category. In the 2014 Cochrane review [13], when comparing single-use and re-use catheters, the hydrophilic-coated catheters, gel-lubricated catheters and traditional single-use catheters were classified in the same group (single-use), leading to possibly misleading conclusions. Therefore, the present study attempted to evaluate all available types of catheters as separate entities by performing a network meta-analysis. More importantly, the sample size (1233 total participants) of this meta-analysis and the number of included studies were greater than those of the previous meta-analyses [11–14]. It is hoped that the results will guide patients and healthcare providers when making treatment decisions.

Some findings are important based on pooled analyses and SUCRA results. First, GSNC and PSHC were associated with a significantly decreased risk of symptomatic UTI compared to SNC. The SUCRA results indicated the GSNC is the preferable option for UTI prevention. The results from asymptomatic bacteriuria gave a similar rank order, but did not reach statistical significance, probably because all patients on IC are at risk of asymptomatic bacteriuria. Asymptomatic bacteriuria has less clinical significance than UTI and requires no treatment. It was noteworthy that when subdividing the hydrophilic-coated catheters into PSHC and SHC, only PSHC shows a statistically significant reduction in UTI rate. These data can be explained by the fact that both GSNC and PSHC are ready-to-use and no-touch techniques, whereas the users need to add sterile water to the traditional hydrophilic-coated catheter (SHC) for about 30 s to active the hydrophilic coating, or manually add some lubricants and disinfectants to SNC before use. These operations may confer some risks. Goessaert et al. [50] reported that even in the hospital setting, nurses and nursing students might make more sterilization errors and spent more time performing the traditional method (sterile with a catheterization-set), than with the no-touch method. Moreover, as a non-hospital procedure, IC is widely performed by patients themselves in real-life circumstances. Many patients with spinal cord injury have decreased manual dexterity or are juveniles. The ready-to-use and no-touch technique that requires less

preparation and has less chance of making sterilization errors may be especially useful for those patients.

Previous studies have mentioned that the definitions of symptomatic UTI are not consistent across trials. Two previous meta-analyses [13, 14] used the definition taken from an outdated consensus statement [51], while the IDSA 2009 consensus statement [19] had already provided the latest definition of UTI. Considering the variation in the definitions, we conducted a sensitivity analysis focusing on trials with clear, detailed definitions, and those that approximately met the IDSA standard. The core definition of symptomatic UTI was significant bacteriuria plus the presence of symptoms or signs. The main differences between the two definitions are as follows: the National Institute on Disability and Rehabilitation Research (NIDRR) defined the significant bacteriuria of UTI as $\geq 10^2$ cfu/ml; while the IDSA standard defined the significant bacteriuria of UTI as $\geq 10^3$ cfu/ml. One trial [41] has applied the former definition, which may have led to a risk of overestimating the incidence of UTI. This study was excluded in the sensitivity analysis. The incidence of symptomatic UTI in this trial (82%) was higher than that in the remaining trials. Another three trials [30, 36, 47] were excluded due to the lack of a clear and precise description of the inclusion criteria and the definition of symptomatic UTI, especially the diagnostic standard of bacterial colonies in urine samples. Given the exclusion of the De Ridder [36] and Cardenas [41] studies, the PSHC arm was excluded from the sensitivity analysis. The sensitivity analysis revealed a similar rank order as the initial analysis, and the gel-lubricated catheter was still significantly superior to other catheters in terms of avoiding symptomatic UTI.

Regarding haematuria, the SUCRA results demonstrated the superiority of SHC compared to GSNC and other uncoated catheters. This may be attributed to the fact that hydrophilic catheters have a smooth and slippery surface with lower friction force and higher osmolality [7]. However, Stensballe et al. [37] measured the withdrawal friction and the incidence of haematuria for the hydrophilic catheter and the gel-lubricated catheter and reported that there is no direct relationship between friction force and haematuria, which may partially explain our insignificant results. Haematuria is an acute form of urethral trauma, and trauma to the urethral mucosa can lead to long-term complications such as urethral stricture, which was rarely reported in most trials. The reason may be that a great number of patients might only have mucosal irritation symptoms, which indicate a very slight urethral trauma that cannot be detected by laboratory tests.

Some subjective indicators should be paid more attention than objective ones, such as the overall patient satisfaction and other related parameters. Patient satisfaction or preference is affected by comfort, ease of handling, convenience, cost and insurance reimbursement. The SUCRA analysis revealed that with respect to patient satisfaction PSHC and CNC were the top two. The advantage of PSHC is that it has a slippery surface and is ready-to-use, which offer comfort and ease of operation at the same time. Traditional single-use hydrophilic catheters can make some individuals feel that 'lubricant [water in the packaging] would leave a mess on the bathroom floor', and make them prefer to use multi-use catheters [44]. The evaluation criteria of satisfaction varied greatly; however, we noted that all trials reporting satisfaction include a binary measure of overall satisfaction. The remaining non-binary items could not be used for network analysis at present. It is hoped that there will be a unified scale to measure IC satisfaction in the future, which is convenient for accurate evidence synthesis.

Another important issue nowadays is whether the SNC or the multi-use non-coated catheter is preferred. Our meta-analysis showed that if hydrophilic-coated and gel-lubricated catheters were left out of comparison, there were no significant differences for the four outcomes between the SNC and CNC. The 2014 Cochrane review [13] reached a similar conclusion and stated that no benefit was proven for single-use catheters compared to re-use catheters. However, such a statement strongly encourages healthcare insurers to carefully consider the cheaper re-use catheters, thus leading to great potential risks. There still is no general consensus whether the healthcare insurers should cover the cost of single-use catheters.

A cost-effectiveness analysis, which represents a key to interpret the clinical and financial trade-offs, was not included in the current meta-analysis. Two previous cost-effective studies [11, 15] obtained different conclusions based on two probabilistic Markov models with various groups and health states. Bermingham et al. [11] reported that clean re-use catheters were more cost-effective than single-use catheters, whereas Clark et al. [15] supported the use of SHCs, especially when long-term UTI complications were included in the analysis. However, these two studies were both performed based on the National Health Service drug tariff in the UK, and data from developing countries are still missing. More rigorous trials with cost-effectiveness analyses are needed for adequate decision-making, especially in developing countries.

This study has some limitations. First, the variety of definitions of clinical outcomes in the included studies might contribute to statistical heterogeneity. The above sensitivity analysis was an attempt to address this issue. Second, most studies had limitations of high dropout rate, which in turn resulted in a low quality of evidence. That is, the clinical outcomes of various IC options could be different for individuals who did not complete the study than for those who had completed the study, which may have resulted in an underestimate of UTI risks. Third, most studies had a short follow-up period, hence, some long-term complications such

as urethral stricture and renal failure were not observed and reported. Forth, due to the obvious differences in the operation of diverse catheters, the blinding method was not used in any of the included studies. Fifth, the cleaning technique is another variable that should be considered. Cleaning technique is the procedure of IC with or without a rigorous aseptic technique (sterile gloves, container and asepsis of genitals), and it can be performed with a single-use catheter or a reused catheter. Unfortunately, few trials have evaluated cleaning techniques, which may introduce confounding. Finally, most of the study subjects included were male, and seven trials [29, 30, 32, 35–37, 40] enroled only males, which could reduce the significance of the results in guiding IC use by female. Despite these limitations, the present network meta-analysis is the first to integrate all current literature and thus determine the most suitable type of catheter for IC.

Conclusion

Our network meta-analysis indicated that GSNC and PSHC reduce the risk of UTI. The ready-to-use and no-touch technique showed significant advantages compared to traditional techniques. For reasons such as ease of use and comfort, patients were most satisfied with PSHC. In terms of urethral injury measured by haematuria, the hydrophilic-coated catheter seemed to perform best. However, based on the present analysis and previous cost-effective studies, there is still no convincing evidence whether SNC or CNC is better. Further well-designed and high-quality RCTs with a strict definition of outcomes, adequate sample size, follow-up periods and cost-effectiveness analysis, are necessary to obtain more conclusive results.

UROLOGY - REVIEW

Effects of hydrophilic coated catheters on urethral trauma, microtrauma and adverse events with intermittent catheterization in patients with bladder dysfunction: a systematic review and meta-analysis

Abstract

Background Hydrophilic coated catheters are recommended to reduce the side effects of intermittent catheterization (IC) in patients with bladder dysfunction. However, there is lack of Level one evidence to support the use of this intervention.

Search methods Several electronic databases were systematically searched to evaluate complication incidences for hydrophilic coated (HC) and non-hydrophilic catheters (NHC).

Results Twelve studies were eligible for inclusion in the review. The meta-analyses exploring microscopic hematuria frequencies (RR = 0.69; 95% CI 0.52–0.90) and urethral stricture frequencies (RR = 0.28; 95% CI 0.13–0.60) showed a lower risk ratio associated with HC in comparison to NHC, whereas gross hematuria was no statistically significant difference in two groups. Subgroup analyses of gross hematuria which was grouped according to "catheterization frequency", "single/multiple catheterization" and "self/other catheterization" were performed and the values of combined RR were also no statistically significant difference.

Conclusions Compared with non-hydrophilic catheters, the hydrophilic coated catheters have positive significance in reducing the incidence of urethral microtrauma and the urethral stricture. However, more studies are warranted for evaluating effects of hydrophilic coated catheters on the incidence of gross hematuria.

Keywords Hydrophilic catheters · Intermittent catheterization · Hematuria · Urethral stricture · Adverse events

Introduction

Causes of bladder dysfunction are neurogenic or non-neurogenic. Neurogenic bladder dysfunction is often secondary to spinal cord injury and central nervous system disease (multiple sclerosis or spina bifida), of which complications often manifest as urinary tract infections (UTI), urinary incontinence and upper urinary tract lesion [1]. Common non-neurogenic bladder dysfunction includes outlet obstruction, such as benign prostatic hyperplasia and postoperative urinary retention, which probably leads to vesicoureteral reflux. Bladder dysfunction hinders urine discharge, increases pressure in bladder, eventually causes urinary retention, which aggravates the risk of renal failure [2]. The treatment of bladder dysfunction is aimed at alleviating urinary incontinence, protecting the upper urinary tract, and improving bladder function as well as patients' quality of life.

Intermittent catheterization (IC) is a preferred treatment for patients with significant urination problems [3] which is used in 56% spinal cord injury patients for bladder management in the United States [4]. IC makes the bladder store a reasonable amount of urine at low pressure and empty it at appropriate intervals, which simulates physiological urinary function. Thereby, IC prevents overdistention and decreases pressure of bladder [5], improves blood circulation in bladder wall [6], reduces the incidence of urinary retention, and ultimately prevents deterioration of upper urinary tract [7].

2 West China Hospital, Sichuan University, Sichuan 61004, China

However, there are non-negligible side effects of IC, such as inducible urethral trauma, microtrauma, urethral stricture, bladder stone and false passages formation [8–10]. In recent years, several types of conduits are gradually available for IC to solve these disadvantages, including especially gel pre-lubricated polyvinyl chloride (external lubricant at most) and hydrophilic-coated catheter (polyvinylpyrrolidone coated at most) [10]. Compared with gel pre-lubricated polyvinyl chloride, HC is increasingly used to reduce intubation friction, urethral injury and urethral adhesion due to its special hydrophilic lubrication characteristics and non-sensitization [11].

Three previously published meta-analyses investigated the effects of HC and non-hydrophilic catheters (NHC) on urethral bleeding morbidity in IC patients [3, 12, 13], however, the results were contradictory. In addition, these studies provide few reliable evidence of urethral microtrauma and urethral stricture which are also important outcomes in the early and late stages of IC, respectively, except for gross hematuria. Consequently, the aim of our study is to evaluate whether HC improves the direct adverse effects compared with NHC, especially in urethral trauma, microtrauma, urethral stricture and rare adverse events.

Materials and methods

Inclusion/exclusion criteria

Population Studies considering adults (over 18 years old), adolescents (12–18 years old) and children (less than 12 years old) population with bladder dysfunction requiring IC.

Intervention Hydrophilic catheters—single-use.

Control Non-hydrophilic catheters—single-use or multiple-use.

Outcomes Gross hematuria, urethral microtrauma (microscopic hematuria), urethral stricture, false passages, bladder stone.

Study Randomized controlled trials, controlled before-and-after study, prospective cohort studies and cross-over trials.

Availability English; full text.

Data sources

We searched the following electronic databases to identify studies: Embase, PubMed, The Cochrane Central Register of Controlled Trials (CENTRAL), Web of Science, Medline, the Cumulative Index to Nursing and Allied Health Literature (CINAHL), British Nursing Index and three Chinese databases (The CNKI, Wan Fang Database and the VIP). The database has been established until December 31, 2021 and the search has been carried out by combining subject words with free words. English search terms include: 1. hydrophilic urethral catheters, hydrophilic-Coated Catheters, hydrophilic coated catheter. 2. Self-lubricated urethral catheters, pre-lubricated catheter, ultra-slippery, aqueous lubrication, surface wettability and lubrication, lubricant, aqueous lubrication, hydrogel coatings hydrogels, aqueous. 3. Reducing friction. 4. Urethra trauma, urethral micro trauma, urinary tract trauma, urethral epithelial micro-trauma. 5. Long-term follow-up study, long-term follow-up, reduce treatment-related complications, adverse events, false passages, urethral stricture, bladder stone. At the same time, the references of the included literatures have been manually retrieved to supplement the relevant literatures.

Literature screening

Two evaluators read the obtained literature independently. After excluding the trials that clearly did not meet the inclusion criteria, the full text of the trials that might meet the inclusion criteria was read to determine whether they really met the inclusion criteria. After the cross-check, if there is a disagreement, a third party will assist in adjudication. Data extraction was performed using standardized forms of the Cochrane Collaboration. The extracted contents include: ① basic information of the included study, ② baseline characteristics included in the study, ③ specific details of the intervention including catheter material/catheter brand, the coating type and the lubrication mode, ④ key factors for the risk of bias include catheter size, self-catheterization or other-catheterization, single-use or multiple-use of catheterization, daily frequency of intubation, ⑤ Outcome indicators and outcome measures.

Bias risk assessment for included studies

Methodologic quality was independently assessed by 2 reviewers using Cochrane.

Statistical analysis

Risk Ratios (RRs) were used as a measure of the relationship between hydrophilic or non-hydrophilic catheters and outcome indicators. The 95% confidence interval (CI) for the dichotomous data was calculated. The pooled RRs were adopted the Mantel–Haenszel method. If there were no events in one or both arms, the Peto method was used. The percentage of variability of each study attributable to heterogeneity beyond chance was evaluated by the chi-square test ($P < 0.10$) and I^2 statistics. According to heterogeneity test, we adopted the random effects model ($I^2 > 50\%$, $P < 0.10$) or the fixed effects model. Then, the

probability of publication bias was evaluated with Egger's test and funnel plots. All statistical analyses were conducted with Stata15.0.

Results

Literature screening process and results

Figure 1 shows the selection process at each step and the reasons for excluded studies. Finally, 12 papers containing 850 participants met the inclusion criteria [14–25], including 9 randomized controlled trials [14, 15, 17, 19, 21–23, 25], 1 controlled before-and-after study [20], 1 prospective cohort studies [18], and 1 cross-over trials [16]. Table 1 illustrated patients' characteristics (age and gender), catheter materials and catheter size. Meta-regression was performed with the year of publication, male proportion and age as independent variables, and the results showed that the regression equation had no statistical significance ($p > 0.05$).

Risk bias assessment form for included studies

In these studies, blinding of participants and interveners were not possible, but even unblinded methods were considered unlikely to have an impact on objective evaluation indicators. Therefore, they were classified as low risk. Patient withdrawal (an average of 17.71%) was common in the literature [14–17, 19, 22–25], which was an unbalanced and potentially biased factors (Fig. 2).

The results of the study

Gross hematuria

Studies have used different terms such as urethral bleeding, hematuria and gross hematuria to describe the same condition. A total of eight trials reported the number of patients with gross hematuria [14–17, 19–22]. The incidence of gross hematuria was 17.9% (57/318) in patients using hydrophilic catheters and 21.0% (73/347) in patients using non-hydrophilic catheters (RR = 0.80; 95% CI 0.45–1.42) (Fig. 3). The risk of gross hematuria was not statistically significant between two groups. As "catheterization frequency", "single/multiple catheterization" and "self/other catheterization" are key indicators for gross hematuria incidence, we performed subgroup analysis for the three aspects. Figure 4 shows that there was still no statistically significant difference in the risk of gross hematuria incidence. In addition, the proportion of male was found that it did not affect the results of the final forest plot of gross hematuria by meta-regression (additional Fig. 3④). Moreover, there was also no evidence of heterogeneity ($p = 0.060$; $I^2 = 55.8\%$) or publication bias ($t = -1.94$, $P = 0.148$) (additional Fig. 3②). For the results of the sensitivity analysis, all the included studies were within the confidence interval except one study at the lower limit of the 95% CI (additional Fig. 3③). In brief, HC did not significantly improve the incidence of gross hematuria compared with NHC.

Microscopic hematuria

In this study, we considered microscopic hematuria as the following definition: the presence of red blood cells (RBC)

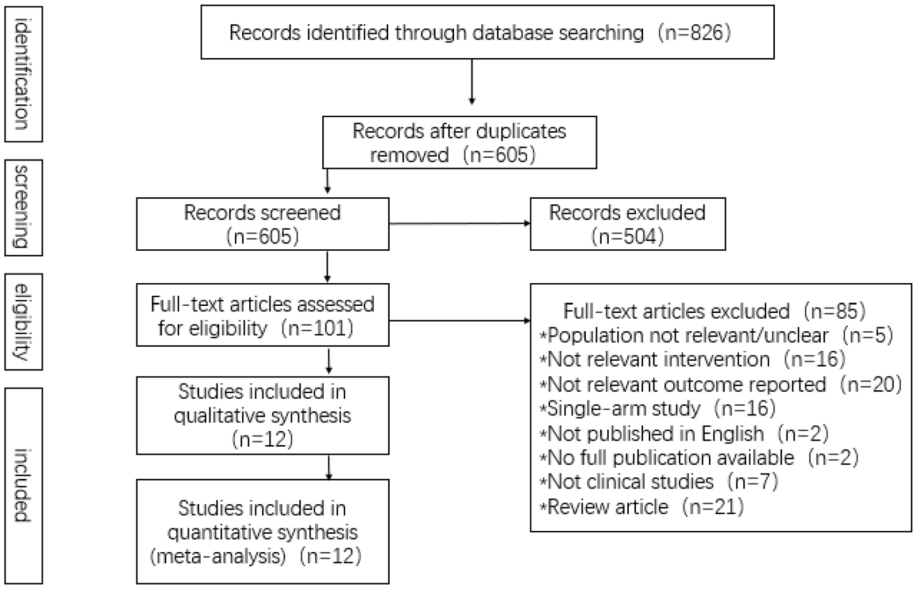

Fig. 1 PRISMA flow diagram—clinical search strategy

[e]PE: polyethylene

in high power field under the microscope. There were 3 trials in 12 studies for microscopic hematuria in our study [19, 23, 24]. The incidence of microscopic hematuria was 41.7% (53/127) in patients using hydrophilic catheters and 56.3% (49/87) in patients using non-hydrophilic catheters (RR = 0.69; 95% CI, 0.52–0.90) (Fig. 5). The difference between two groups was statistically significant, indicating that the risk of microscopic hematuria with hydrophilic catheters was only 69% of that in non-hydrophilic group. There was also no evidence of heterogeneity ($p = 0.678$; $I^2 = 0.0\%$) or publication bias ($t = -0.65$, $P = 0.633$) (additional Fig. 5②). For the results of the sensitivity analysis, the included studies were all within the CI (additional Fig. 5③). In short, HC significantly improved the incidence of microscopic hematuria compared with NHC.

Urethral stricture

The method for stricture evaluation is maximum flow rate < 14 mL/s or endoscopic or radiographic examination. A total of five trials reported the number of patients with urethral stricture [14, 15, 21, 22, 25]. The incidence of urethral stricture was 3.1% (6/194) in patients using hydrophilic catheters and 11.5% (23/200) in patients using non-hydrophilic catheters (RR = 0.28; 95% CI 0.13–0.60) (Fig. 6). The difference between two groups was statistically significant,

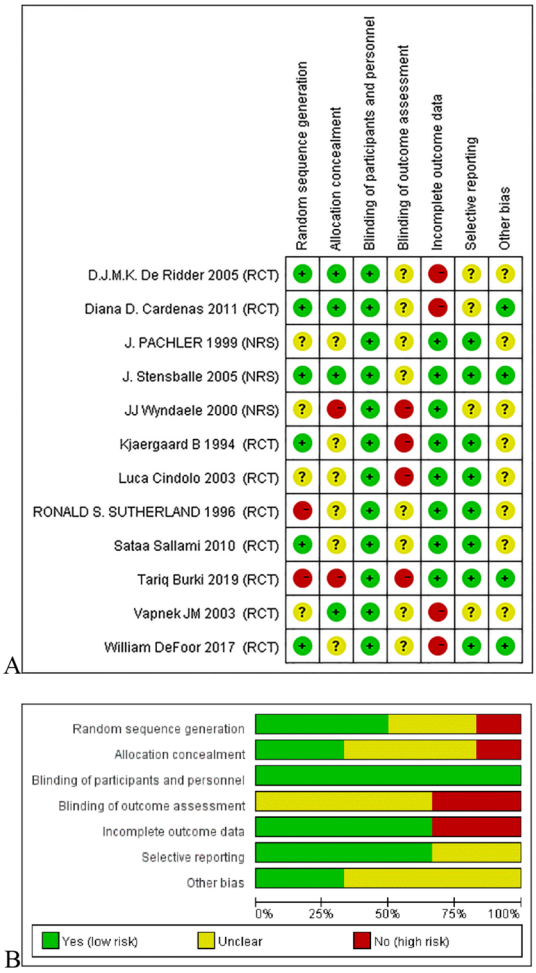

Fig. 2 **A** Risk of bias summary for RCT ($n=9$) and NRS ($n=3$); **B** risk of bias graph for all included studies ($n=12$). *RCT* randomized controlled trials, *NRS* non-randomized controlled trials

suggesting that the risk of urethral stricture with hydrophilic catheters was only 28% of that in the non-hydrophilic group. There was also no evidence of heterogeneity ($P=0.983$; $I^2=0.0\%$) or publication bias ($t=0.69$, $P=0.617$) (additional Fig. 6②). Five studies were all within the 95% CI about the sensitivity analysis (additional Fig. 6③). In a word, HC significantly improved the incidence of urethral stricture compared with NHC.

Rare adverse events

In addition to hematuria and urethral stricture, false passages and bladder stone are also rare adverse reactions after intubation in patients with bladder dysfunction. There were two studies focusing on the incidence of false passages [14, 20] and another two studies on bladder stone morbidity [18, 23]. Wyndaele [20] enrolled 39 patients who had been using NHC for IC over a number of years and switched to urocath-gel hydrophilic lubricated catheter for 1 month. It was found that only NHC group had one false passage. William [14] included children with neurogenic bladder dysfunction and divided them into 41 patients with NHC and 37 patients with HC. There were no false passages patients found in both groups. Jonathan [23] included 30 patients with HC and 31 patients with NHC for neurogenic bladder dysfunction, and found that one patient in each group had bladder stone. Tariq [18] included 101 children with spina bifida and divided them into HC and NHC groups. There were no bladder stones in the two groups. The incidences of both indicators were low after IC, and there was no difference between the two groups.

Discussion

Since Dr. Lapides proposed that using of IC as an alternative way to urinary diversion in 《Urology》 in 1972 [6], IC has become the globally recognized standard for the treatment of neurogenic bladder dysfunction and has been usually used in managements for various urinary system disease [26]. Generally, IC improves the quality of patients' life through removing long-standing drainage tubes and drainage bags [2]. Initially, catheters for IC were mainly made of latex and rubber. However, these catheters were gradually taken placed by polyvinyl chloride (PVC) catheters due to their sensitization, hardness and difficulty in catheterization [27]. In addition, the practice of re-using catheters with same tube in IC has changed over the past 10 years, for example most patients with intermittent self-catheterization (ISC) were required to use disposable catheters during catheterization [2].

Under the guidance of healthcare workers, almost all patients with bladder dysfunction could get benefits from IC [2]. IC changes the pattern of urinary management in patients with bladder dysfunction because of its various advantages. In addition to decreasing mortality caused by kidney deterioration [28], IC also reduces the harmful effects of long-term indwelling urinary catheters, including urinary tract infections (UTIs) [29], traumatic hypospadias, urinary fistula and even bladder cancer [30]. However, there are still unavoidable complications including mechanical stimulation and mucosa injuries for IC, such as pain and urethral injury. Applying external lubricant is a traditional method to reduce mucosa friction and adhesion during catheterization. Common external lubricants cover Vaseline, paraffin oil, gel, lidocaine cream, amiodarone and ketamine [31]. Nevertheless, the application of external lubricant on the surface of urinary duct has plentiful limitations such as uneven application, cumbersome operation, weak lubrication effect and short residence time. In addition, anesthetic lubricant such as

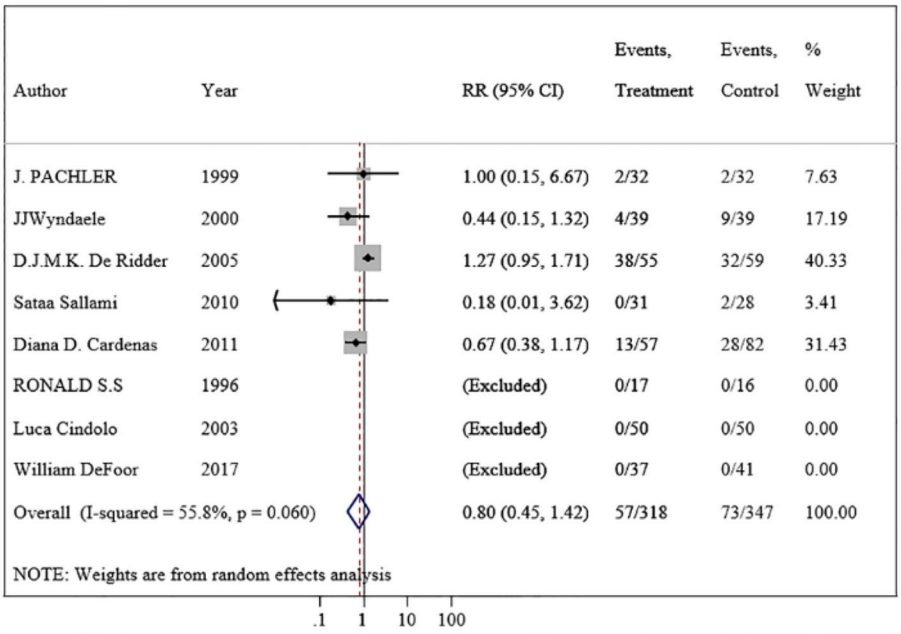

Fig. 3 Meta-analysis comparing hydrophilic catheter with non-hydrophilic catheter, evaluating gross hematuria

lidocaine cream contains additives that cause allergic reactions [32].

In recent years, water lubrication, which is an ideal solution to ultralow friction of medical catheter has received growing attentions. Hydrophilic coated catheters are usually made of PVC material and polyvinylpyrrolidone coated (PVP coated). PVP is a polymer with hydrophilic groups [33]. After the PVP hydrophilic groups are combined with a lubricating fluid (such as water or saline), the interface between the surface of catheter and the urethral mucosa forms a smooth area composed mainly of water molecules [24]. Direct contact between the surfaces is avoided during sliding process, thus greatly reducing friction coefficient and mucosal injury [24, 34, 35]. Furthermore, PVP coated possibly reduce a potential risk of urethral stricture caused by repeatedly intubation [22, 36]. Meanwhile, PVP coated is able to reduce the adsorption of fibrinogen and fibronectin, as well as the deposition of hydroxyapatite on the tube surface [34], potentially resulting in lower incidence of bladder stone.

Generally, gross hematuria is used as an indicator to estimate urethral trauma. However, the results of previous researches were contradictory in regard to whether gross hematuria could be reduced by HC [3, 12, 13]. Two meta-analyses concluded that HC was associated with a reduced risk of urethral bleeding compared with NHC [12, 13], but another research suggested a higher risk of hematuria in the HC group [3]. Simultaneously, the results from the three meta-analyses were challenged due to their inclusion, heterogeneity and bias risk analysis.

Gross hematuria is a more serious outcome indicator, so it is not a favorable indicator for reflecting the early condition of urethral damage. Innovatively, our study assessed urethral microtrauma using microscopic hematuria. Except for urethral bleeding, there are few studies evaluating whether HC reduce the incidence of adverse events, such as urethral stricture, false passages and bladder stone. In our study, HC made positive contributions to reducing the incidence of urethral microtrauma and urethral stricture compared with NHC, whereas gross hematuria was no significant difference. More studies are needed to further confirm the association between HC and these indicators in the future.

Implications for clinical practice

Due to the limitations of the study population and relevant intervention measures, the results of previous studies were contradictory and difficult to be generalized. Our study included a broad population of men and women of all ages with IC. There were no strict restrictions on the influencing factors, including catheterization frequency, self-catheterization or other-catheterization, single-use or multiple-use and the intubation environment. Therefore, our results regarding the complications of HC have broad adaptability to guide clinical practice.

Call for future studies

More high-quality, large-scale RCT studies are urgently needed. Recommendations for future research are as follows: ① The inclusion and exclusion criteria of study subjects should be clarified; ② The specific details of the intervention should be clarified including catheter material/catheter brand, the coating type and the way of lubrication; ③ key

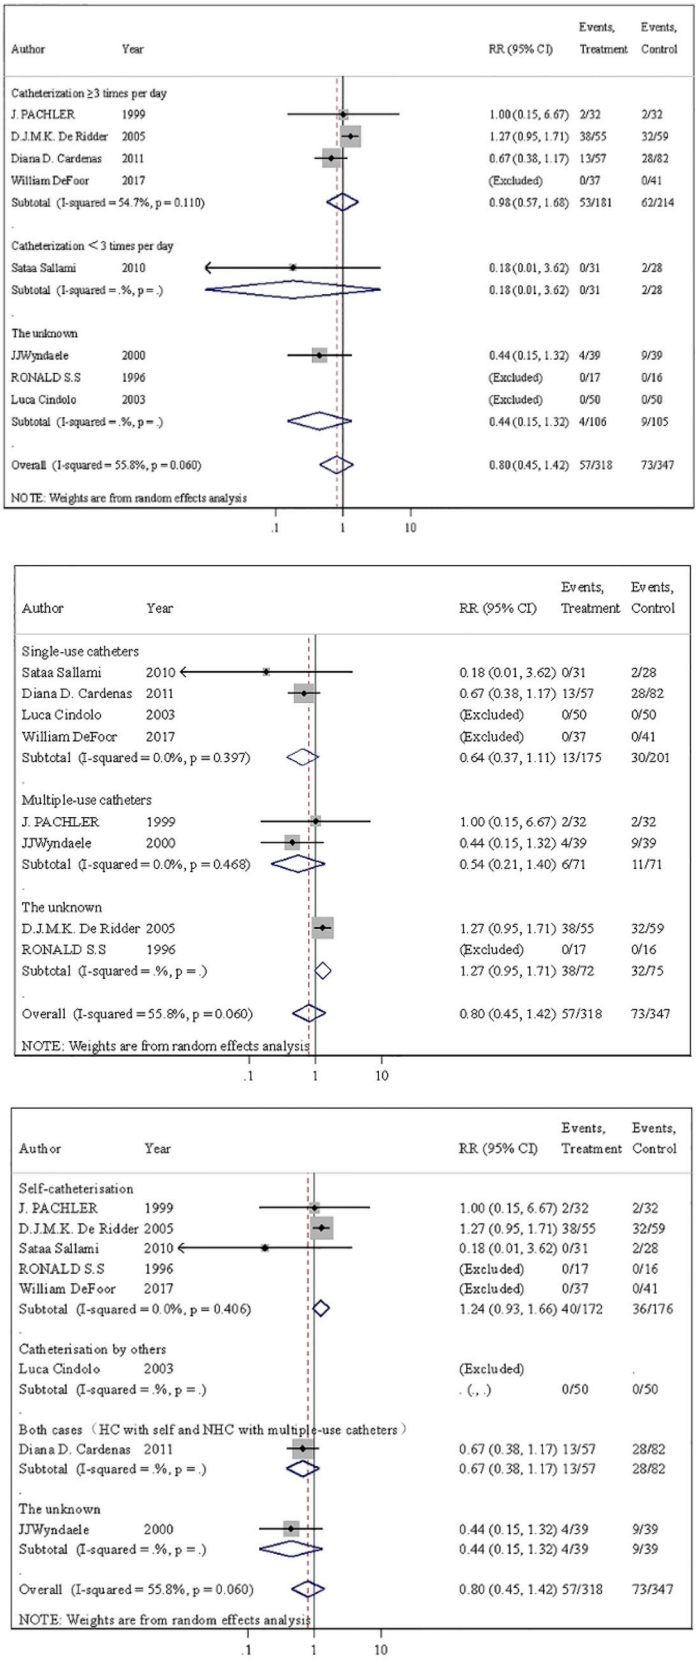

Fig. 4 Meta-analysis comparing hydrophilic catheter with non-hydrophilic catheter, evaluating subgroup analysis of gross hematuria

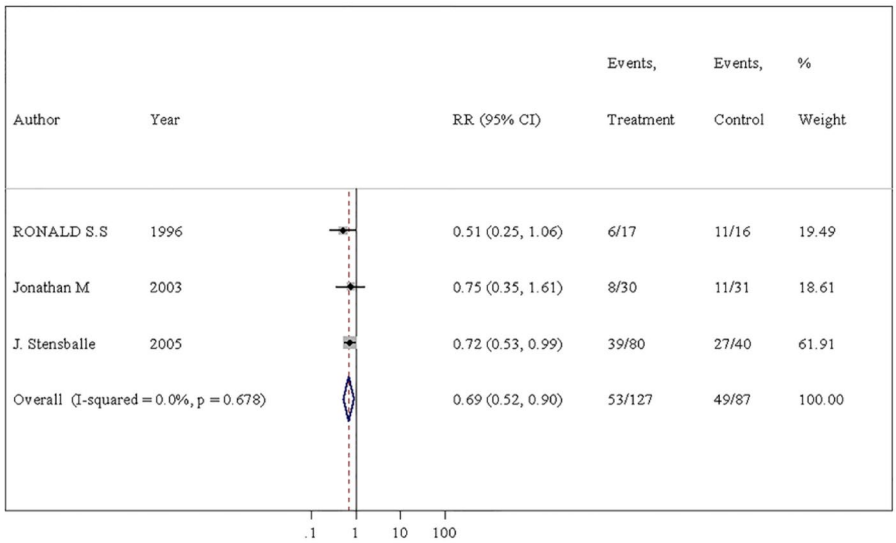

Fig. 5 Meta-analysis comparing hydrophilic catheter with non-hydrophilic catheter, evaluating microscopic hematuria

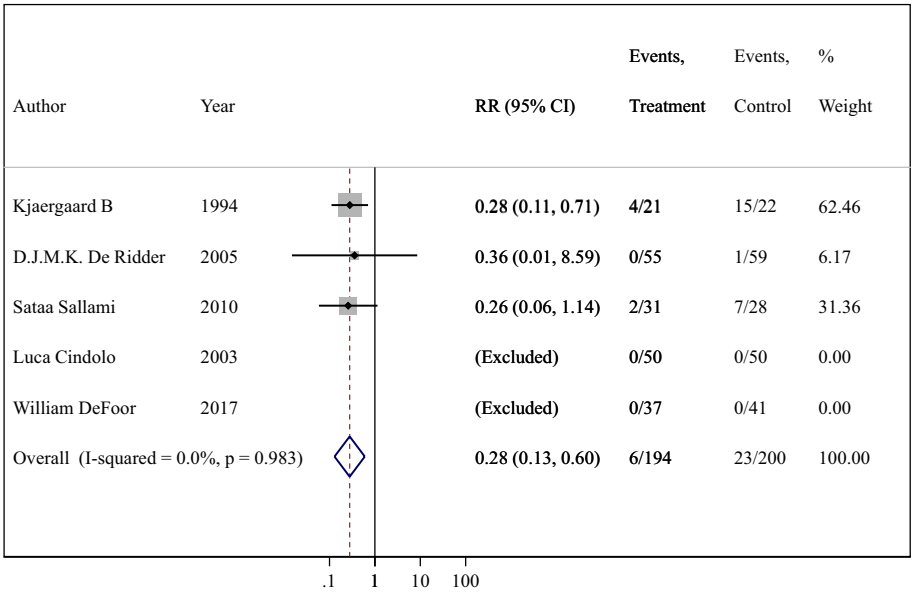

Fig. 6 Meta-analysis comparing hydrophilic catheter with non-hydrophilic catheter, evaluating urethral stricture

factors for the risk of bias need to be controlled including catheter size, total duration of intubation, time to start catheterization, self-catheterization or other catheterization, single-use or multiple-use of catheterization and catheterization frequency; ④ Call for clear definition of outcome indicators and specification of outcome measures.

Limitations

Our study still had some aspects for improving: ① Due to the wide heterogeneity of study subjects, study design, outcome measurement methods, as well as the small number of included literatures, it was difficult to conduct meta-subgroup analysis about long term adverse events such as urethral stricture. Therefore, we only performed subgroup analysis for gross hematuria; ② Risk of bias covers "little blinding of participants and interveners" and "the differences in patient drop-off between the two groups", which perhaps impact study results; ③ The majority of our data was in males and it would be a non-negligible influence factor for IC. However, the objects are only men in the current literature which was eligible for inclusion in these two indicators of microscopic hematuria and urethral stricture.

Conclusion

This meta-analysis supports the benefits of using hydrophilic coated catheters for IC in patients with bladder dysfunction, including reduced incidence of microscopic hematuria and urethral stricture. However, whether HC reduces the risk of gross hematuria has not been proven. While waiting for more evidence, it is recommended to select a more appropriate catheter type of IC combined safety, efficacy, cost effectiveness and patient satisfaction. Patients are advised to use hydrophilic coated catheter as the first treatment option when the condition permits to reduce urethral complications and offers higher comfort [20]. In this study, we evaluated the effects of HC and NHC on urethral trauma, microtrauma, urethral stricture and rare adverse events, demonstrating that HC is a better intubation method for patients with bladder dysfunction.

Acupuncture for Depression May 2026

Plain Language Summary:

Depression is treatable. Many people get better with talk therapy, medication, or both. Acupuncture is proposed as a therapy to help other treatments for depression work better.

Western medical studies show acupuncture is not helpful when treating depression. Staff recommends not adding acupuncture coverage for depression.

Staff Analysis Summary:

Significant proposed changes or discussion items:

1. Do not add acupuncture for treatment of depression based on studies done in Western healthcare settings

Changes after public comment period:

Six public comments were received on this topic from Oregon patients and providers. All commentors described their personal and/or professional benefits of acupuncture for mental health conditions. One submitted study was added to the issue summary which did not find a significant impact of auricular acupuncture on depression. These comments did not change the HERC staff assessment that acupuncture is not more clinically beneficial than control in the western medical setting.

Coverage Question:

What does the literature from studies performed in medical systems similar to the US indicate about acupuncture for depression?

Question source:

HERC

*CPT only copyright 2025 American Medical Association. All rights reserved.
** Current Dental Terminology © 2025 American Dental Association. All rights reserved

Background:

At the March 2026 HERC meeting, HERC staff discussed a recent listening session at which two Oregon acupuncturists presented information on acupuncture for depression, anxiety and PTSD. The HERC requested that staff research the studies included in the meta-analysis presented at the May 2025 VBBS/HERC meeting that were conducted in health systems similar to the US (western Europe, Australia, Canada, or similar).

HERC staff reviewed the NICE 2022 systematic review of acupuncture for depression which concluded that there was a clinical effect, but that it was unclear whether this effect would translate into the UK medical system. The references from this NICE review were individually reviewed. 6 publications were conducted in health systems similar to the US.

Current Prioritized List/Coverage status:

Acupuncture is paired with a variety of conditions but not with depression

Evidence:

Studies included in the NICE 2022 systematic review

1) **Allen 2006** Acupuncture for Depression: A Randomized Controlled Trial
    a. United States
    b. N=157 patients
        i. N=53 specific acupuncture (N=42 at 8 weeks, 34 at 16 weeks)
        ii. N=52 non-specific acupuncture (points not intended to treat depression) (N=45 at 8 weeks, 37 at 16 weeks)
        iii. N=52 waitlist (N=44 at 8 weeks, 38 at 16 weeks)
        iv. All patients given specific acupuncture after 8 weeks
    c. Intensity of intervention: 12 acupuncture sessions over 8 weeks
    d. Hamilton rating scale for depression
        i. All subjects had significant reduction at 8 weeks
        ii. 22% of patients in specific acupuncture group, 39% of non-specific acupuncture group and 17% of waitlist group rated as responders at 8 weeks

*CPT only copyright 2025 American Medical Association. All rights reserved.
** Current Dental Terminology © 2025 American Dental Association. All rights reserved

   e. Authors conclusions: results fail to support [TCM manual acupuncture] as a monotherapy for MDD

2) **Andreescu 2011** Acupuncture for the Treatment of Major Depressive Disorder: A Randomized Controlled Trial
   a. Australia
   b. N=53 patients
      i. N=28 electroacupuncture
      ii. N=25 control (sham acupuncture)
      iii. "Subjects remained free of psychotropic medications during the duration of the study"
   c. Intensity of intervention: 2 sessions a week for 6 weeks
   d. Both groups improved, with mean (SD) absolute HDRS score decreases of −6.6 (5.9) in the verum group and −7.6 (6.6) in the control group, corresponding to 37.5% and 41.3% relative decreases from baseline. There were no serious adverse events associated with either intervention
   e. Authors conclusions: We were unable to demonstrate a specific effect of electroacupuncture.

3) **MacPherson 2013** Acupuncture and Counselling for Depression in Primary Care: A Randomised Controlled Trial
   a. United Kingdom
   b. N=564 patients
      i. N=233 acupuncture + usual care
      ii. N=222 counseling + usual care
      iii. N=119 usual care
      iv. Usual care defined as "according to need" in the NHS system
   c. Intensity of intervention
      i. Average 8.7 acupuncture sessions over 3 months
      ii. Average 7.5 counseling sessions over 3 months
   d. The majority (68.7%) of all patients were taking antidepressants at baseline
      i. Rate comparable across study arms
   e. Compared to usual care, patients in the acupuncture arm experienced an average additional reduction in depression of -2.46 points on the PHQ-9 (p,0<001, 95% CI -3.72 to -1.21)

*CPT only copyright 2025 American Medical Association. All rights reserved.
** Current Dental Terminology © 2025 American Dental Association. All rights reserved

f. Compared to usual care, patients allocated to the counselling arm experienced an average additional reduction in depression of -1.73 points (p = 0=008, 95% CI -3.00 to -0.45)
g. The difference between acupuncture and counselling, -0.76 points on the PHQ-9 (p= 0.41, 95% CI -0.77 to 0.25), was not statistically significant.
h. NOTE: the MCID for the PHQ-9 is -5 points
i. Authors conclusions: In this randomised controlled trial of acupuncture and counselling for patients presenting with depression, after having consulted their general practitioner in primary care, both interventions were associated with significantly reduced depression at 3 months when compared to usual care alone
j. HERC staff note: none of the PHQ-9 reductions were clinically meaningful

4) **Quah-Smith 2005** Laser acupuncture for mild to moderate depression in a primary care setting – a randomised controlled trial
    a. Australia
    b. N=25 patients
        i. N=11 inactive or sham laser
        ii. N=14 active laser
    c. Beck Depression Inventory scores
        i. Inactive group at 12 weeks: -9.1 (-14.1 to -4.1)
        ii. Active group at 12 weeks: -13.9 (-17.5 to -10.4)
        iii. Inactive group at 20 weeks: -9.4 (-13.7 to -5.1)
        iv. Active group at 20 weeks: -15.8 (-18.3 to -13.2)
        v. HERC staff note: the confidence intervals overlap between groups, indicating no significant difference
    d. Hospital Anxiety and Depression Scale (HADS) scores not significantly different at 12 or 20 weeks
    e. Authors conclusions: Conclusion Laser acupuncture may be worth further investigation as a treatment for mild to moderate depression in primary care
5) **Quah-Smith 2013** Laser acupuncture for depression: A randomised double blind controlled trial using low intensity laser intervention
    a. Australia
    b. N=43
        i. N=22 active laser

*CPT only copyright 2025 American Medical Association. All rights reserved.
** Current Dental Terminology © 2025 American Dental Association. All rights reserved

ii. N=21 inactive laser
iii. Patients required to be “free of psychotropic drugs and herbal remedies for at least four weeks prior to trial entry”

c. Intensity of intervention: Twelve sessions of the intervention were performed: twice weekly for four weeks and once a week for another four weeks.
d. Respectively) and for QIDS-CL (P¼ o0.001 and 0.016). For QIDS-SR, although there was an overall statistically significant decrease in depression scores over time (F1, 39=4.63, p= 0.038 and F1, 42=0.013, respectively), there were no differences between groups (P=0.571 and 0.390).

Additional studies done in Western medical settings provided by experts (note: these studies were included in submitted systematic reviews)

1) **Whiting 2008** Using acupuncture to treat depression: A feasibility study
   a. United Kingdom
   b. N=19 (13 acupuncture and 6 sham acupuncture)
   c. Intensity of intervention: 12 sessions (time period not given)
   d. There was a decrease in mean scores on the BDI in both study groups, which indicates a reduction in depressive symptoms. There was also a slight increase in mean scores on the RAND in both study groups, which indicates an improvement in quality of life; however, a reduction in mean scores for the RAND categories of ‘physical functioning’ and ‘pain’ was seen in the sham-control group only
2) **Allen 1998** The Efficacy of Acupuncture in the Treatment of Major Depression in Women
   a. United states
   b. N=38 women
      i. N=12 specific acupuncture
      ii. N=11 non-specific acupuncture (control)
      iii. N=11 waitlist
      iv. Significant differences in scores existed at baseline between groups
   c. Treatment intensity: 2 sessions a week for 4 weeks then 1 session a week for 4 weeks

d. At the conclusion of the acute (8-week) phase of treatment, by DepHRSD criteria, 50% of the participants in the specific-treatment group had remitted, whereas only 27% in the nonspecific-treatment group and 27% in the wait-list group had remitted.
    i. Remitted defined as a 50% decrease in the Hamilton Rating Scale for Depression (DepHRSD) score
e. Authors conclusions: Results from this small sample suggest that acupuncture can provide significant symptom relief in depression, at rates comparable to those of psychotherapy or pharmacotherapy.

3) **Roschke 2000** The benefit from whole body acupuncture in major depression
    a. Germany
    b. N=70 patients
        i. N=22 acupuncture
        ii. N=24 placebo acupuncture
        iii. N=24 control
        iv. All three groups were treated with an antidepressant (mianserin)
    c. Treatment intensity: three times a week over 4 weeks
    d. Both treatment and sham acupuncture groups improved slightly more than antidepressant alone group. No difference found between the treatment and sham acupuncture groups
    e. Authors conclusions: The results of our study suggest that the effect of acupuncture is unspecific and might be due to additional attention provided three times a week for nearly half an hour
4) **De Oliveira Rodigues 2023** Efficacy and Safety of Auricular Acupuncture for Depression A Randomized Clinical Trial
    a. Brazil
    b. N=47 patients
        i. N=24 specific auricular acupuncture
        ii. N=23 nonspecific auricular acupuncture (control)
    c. Treatment intensity: twice a week for 6 weeks
    d. Three months after randomization, 14 of the 24 participants (58%) randomized to the specific acupuncture group had a reduction of at least 50% in the PHQ-9 score compared with 10 of 23 participants (43%) in the

nonspecific acupuncture group. The result was not statistically significant (risk ratio [RR], 1.34; 95% CI, 0.76-2.45; P = .38)

e. Authors conclusions: The results of this randomized clinical trial suggest that SA over 6 weeks is safe. Although there was no statistically significant difference between groups for the primary efficacy outcome, patients receiving SA did experience greater symptom remission at 3 months. A larger sample size and longer intervention are needed to further evaluate the efficacy of SA for depression

HERC staff summary:

The NICE systematic review included 5 studies in Western medical settings, 3 in Australia, 1 in the US and 1 in the UK. All 5 studies did not find a significant impact of acupuncture on depression when compared to sham acupuncture, counseling, usual care or wait list. The "dose" of acupuncture (1-2 times per week) was typical for the US healthcare system.

Four additional small studies conducted in Western medical settings (UK, US, Germany and Brazil) were found through review of references in the systematic reviews submitted by experts or were submitted by commentors. All four studies found beneficial effects of acupuncture; however, statistical significance was not reported or was not significant. Therefore, the statistical or clinical significance of the results were not determinable.

Based on the 9 studies identified conducted in Western medical settings, acupuncture does not appear to be more effective than control. The statistically and clinically significant impact seen in meta-analyses therefore was driven by studies conducted in the Chinese medical system.

HERC staff recommendation:

1) Do not add coverage for acupuncture for depression

A	I fully support the Oregon Health Authority's coverage of acupuncture for depression based on both the strength of the research and clinical outcomes/experiences I have had both personally as a patient and directly with patients as an acupuncture provider. I initially sought acupuncture for women's health issues in 2004. As a person with a history of severe injury due motor vehicle accident at age 12 and someone with congenital musculoskeletal imbalances (transitional segment L4/L5 to sacrum and scoliosis) that were exacerbated by the car accident causing lifelong chronic pain, I soon realized acupuncture could help with body pain. Yet, the thing that really intrigued me about acupuncture is that it soothed my emotional experience of life. Acupuncture has effectively treated my own anxiety and depression, which are core components of PTSD. As an acupuncture practitioner working in substance use treatment, one of the	Thank you for your comments. The HERC values the perspectives of patients and providers.

ID/#	Comment	Disposition
	main benefits that I see with SUD clients is that acupuncture relieves their depression, anxiety, and PTSD, giving them the much needed resilience needed to tackle the day to day life of being substance free. Many SUD clients use substances to deal with depression, anxiety, and PTSD. They are assisted in their process of recovering from these conditions by getting regular acupuncture treatments, which in turn allows them to recover from substance use. I want to emphasize that mental health and substance use are both beneficially treated with acupuncture. Please consider OHP insurance coverage for depression, anxiety, and PTSD; this decision will beneficially impact so many Oregonians.	
B	I first received acupuncture treatment at the age of 14. Even at that early stage, I experienced a notable reduction in symptoms of social anxiety and early-onset depression. Over the years, I returned to acupuncture intermittently, particularly during periods when conventional treatments—including pharmaceutical interventions, individual psychotherapy, and group therapy—did not sufficiently address both my psychological and physical symptoms. The majority of these treatments were conducted at Working Class Acupuncture facilities. After a nine-year hiatus from therapeutic care, I reached a point where severe depression, anxiety, and accumulated complex post-traumatic stress disorder (C-PTSD) significantly impaired both my mental and physical health. At that time, I	Thank you for sharing your experiences. The HERC values patient input.

ID/#	Comment	Disposition
	began treatment at Quest Center for Integrative Health, which offers a multidisciplinary approach combining acupuncture with individual and group therapies. I enrolled in an outpatient program at Quest that incorporates acupuncture treatments two-three times per week. Within the first week of treatment, I observed meaningful improvements in both my mental state and physiological symptoms. I was able to attend group therapy sessions without experiencing debilitating social anxiety and noticed a reduction in depressive episodes during non-treatment days. Within the first month, my physical health improved substantially, and I developed the capacity to set and pursue both short- and long-term goals. My C-PTSD symptoms also showed significant improvement, and I began to experience a renewed sense of stability and hope. In addition to supporting my mental health, acupuncture has played a critical role in regulating my nervous system and mitigating the physiological effects of chronic stress. I have developed several autoimmune-related conditions that are exacerbated by stress. Through ongoing acupuncture treatment, I have experienced a marked decrease in the frequency of flare-ups, and when they do occur, both their duration and severity are significantly reduced. Overall, acupuncture has been a central component in my recovery and long-term health management. It has contributed not only to symptom reduction but also to an improved quality of life, enabling me to	

ID/#	Comment	Disposition
	function more effectively and engage meaningfully with my personal and social environment.	
C	I have worked with PTSD depression and anxiety for many years. My capstone project in 2016 was on acupuncture and PTSD. Since then, I have seen many patients dealing with all sorts of trauma related issues and helped them work through it. Aspects that have improved are self perception, sleep quality, managing emotional swings and relational dynamics, and of course pain of any kind.	Thank you for sharing your clinical experience.
D	I believe that Acupuncture can help those who suffer from anxiety and depression (including PTSD). Having this service covered by OHP will enable more folks to benefit from acupuncture. I work with a non profit who helps breast cancer patients. We have partnered with local health care providers who provide acupuncture and have seen first hand how acupuncture has helped them first hand. Many breast cancer survivors/thrivers have anxiety/depression and some PTSD before and after treatment and acupuncture has helped ease those for many of the people we serve. We have been lucky that the health providers have partnered with us and offer low to no cost but so many others are not as lucky. If OHP covered acupuncture for anxiety, depression and PTSD, imagine the amount of people who could be helped.	Thank you for sharing your experiences and for sharing your thesis on acupuncture and PTSD. Unfortunately, the HERC cannot accept reports of professional experience as evidence.

ID/#	Comment	Disposition
E	I have been an acupuncturist for nearly 20 years. Before that I was a patient who's life was dramatically improved by acupuncture for the treatment of anxiety and PTSD. That's how I decided I wanted to study it. In 2001, I was in my early twenties living in New York City. After 9/11 many of us were suffering from PTSD, anxiety, grief, and depression. At times, the PTSD was so bad it was impacting my ability to function. This went on for months and months. I sought help from various sources: EMDR therapy led me to Acupuncture and Chinese Medicine. I cannot begin to express to you the impact of acupuncture on my body. My panic attacks resolved. I was able to sleep again. I got my energy back. It felt like my soul was healing. In a sense, I had become soulsickened. It was like my nervous system had gotten fried. With acupuncture it was coming back to life and healing. After six months of acupuncture regular acupuncture, I felt enormously better and was so moved and wowed by the experience that I left my career and enrolled in graduate school for acupuncture and herbal medicine. I have practiced in Portland, Oregon since 2009, and done thousands of sessions for emotional pain as well as physical pain. This medicine is exemplary for people struggling with significant mental health issues with few options that effectively bring improvement. Pharmaceuticals can treat the symptoms and reduce them, but they do not treat the root issue in the nervous system. Acupuncture is repairative	Thank you for sharing your personal and professional experiences.

ID/#	Comment	Disposition
	by nature. It restores the body and mind and heals rifts in the soul. It helps keep people off of opioids and other dangerous drugs people reach for to numb their feelings. It has been proven over and over in studies that it statistically reduces suicide rates and symptoms of Anxiety, Depression, and PTSD. By making it billable for OHP, you are providing deep and meaningful access to this valuable medicine. Oregon has the opportunity here to be a leading state, modeling the need to prioritize mental-emotional health care, employing methods that are unconventional (to some) and that are proven time and time again to work. People need effective mental health care. What we currently have is not enough. Imagine a society where people have less anxiety, depression, and PTSD. What would you do to make that happen?	
F	As an acupuncturist, I have treated depression and seen the benefits for patients and their families. Outside of anecdotal evidence, there is research that shows acupuncture performing as well as standard practice. Also, the safety of acupuncture provides an alternative to medication, which often carries unwanted side effects. I am not asking for acupuncture to replace other therapies, but that is is offered as an option alongside allopathic practices. Oregon should set a standard of best practices utilizing evidence-based medicine, for which acupuncture has shown to be as beneficial as any other medical care.	Thank you for your comments and for the provided literature. The first link provided is the website for the American Academy of Medical Acupuncture. The de Oliveira Rodrigues 2023 RCT was added to the issue summary. The Armour 2019 article was a systematic review and meta-analysis of acupuncture for depression. The included studies had a high

ID/#	Comment	Disposition
		degree of overlap with the NICE 2022 systematic review already considered by the Commission. The Wong 2021 study was conducted in Hong Kong and this review was focused on non-Chinese type medical system studies.

Abstract

Background: Over 50% of patients with major depressive disorder (MDD) either do not tolerate or do not respond to antidepressant medications. Several preliminary studies have shown the benefits of acupuncture in the treatment of depression. We sought to determine whether a 2-point

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

electro-acupuncture protocol (verum acupuncture) would be beneficial for MDD, in comparison to needling at nonchannel scalp points with sham electrostimulation (control acupuncture).

Method: Fifty-three subjects aged 18–80 years, recruited via advertisement or referral, were included in the primary analysis of our randomized controlled trial, which was conducted from March 2004 through May 2007 at UPMC Shadyside, Center for Complementary Medicine, in Pittsburgh, Pennsylvania. Inclusion criteria were mild or moderate MDD (according to the Structured Clinical Interview for *DSM-IV* Axis I Disorders) and a score of 14 or higher on the Hamilton Depression Rating Scale (HDRS). Exclusion criteria included severe MDD, seizure disorder or risk for seizure disorder, psychosis, bipolar disorder, chronic MDD, treatment-resistent MDD, and history of substance abuse in the prior 6 months. Patients were randomized to receive twelve 30-minute sessions of verum versus control acupuncture over 6 to 8 weeks. The HDRS was the primary outcome measure. The UKU Side Effect Rating Scale was used to assess for adverse effects.

Results: Twenty-eight subjects were randomized to verum electroacupuncture and 25 to control acupuncture. The 2 groups did not differ with regard to gender, age, or baseline severity of depression. Both groups improved, with mean (SD) absolute HDRS score decreases of −6.6 (5.9) in the verum group and −7.6 (6.6) in the control group, corresponding to 37.5% and 41.3% relative decreases from baseline. There were no serious adverse events associated with either intervention, and endorsement of adverse effects was similar in the 2 groups.

Conclusions: We were unable to demonstrate a specific effect of electroacupuncture. Electro-acupuncture and control acupuncture were equally well tolerated, and both resulted in similar absolute and relative improvement in depressive symptoms as measured by the HDRS.

Depression is a common problem affecting as much as 20% of the adult population during their life-time.[1] Depression is associated with reduced quality of life, increased suicide risk, and increased morbidity and mortality of common conditions such as heart disease[1] and is often resistant to treatment, with over 50% of patients either not tolerating or not responding to antidepressant medications.[2,3] In addition, many Americans refuse conventional treatments for depression, or they discontinue them prematurely.[4,5] Other barriers to adequate antidepressant treatment involve perceived stigma associated with mental illness and minimization of the need for somatic treatment.[6]

Thus, a growing number of Americans have been turning to complementary and alternative modalities for the treatment of depression.[7] In a large survey, depression was among the 10 most frequently reported medical conditions for which respondents sought alternative treatments.[8]

These alternatives might be used as adjuncts to, or substitutes for, conventional acute treatments or as maintenance or preventive treatments following remission. A 2005 Cochrane review[9] found 7 published reports[10–16] on controlled studies of the efficacy of acupuncture for major depressive disorder (MDD). Overall, these 7 trials included a total of 547 patients, but they used a variety of designs and acupuncture interventions, and most of them had significant methodological flaws.[9] We identified 2 additional reports[17,18] published since 2004, for a total of 9 published studies: In 5 studies, all conducted in China, acupuncture or electroacupuncture was as efficacious as, or more efficacious

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

than, amitriptyline (150–400 mg/d)[10–13] or maprotiline (75–250 mg/d).[15] By contrast, in the 2 US studies,[14,18] acute response and remission rates did not differ significantly among subjects randomized to depression-specific acupuncture protocols according to the principles of traditional Chinese medicine (TCM), nonspecific ("control") acupuncture, or a wait-list condition.[14,18] Finally, in a small Australian study[17] (N = 30), there was greater improvement in depressive symptoms with active laser acupuncture than with control laser acupuncture.

In a recent meta-analysis,[19] the efficacy of monotherapy acupuncture was comparable to that of an antidepressant alone—and not different from control acupuncture. A recent update of the Smith et al Cochrane review[20] included all randomized controlled trials comparing acupuncture with control acupuncture, no treatment, pharmacologic and psychotherapeutic treatment, or standard-of-care treatment. On the basis of a total of 30 trials involving over 2,800 participants, the authors concluded that there was insufficient evidence of a consistent beneficial effect of acupuncture.[20] However, a recent randomized controlled trial[21] found depression-s pecific acupuncture to be more beneficial than nonspecific control acupuncture in depressed pregnant women,[21] supporting the possibility that acupuncture could be a valuable alternative to pharmacotherapy given the risks and side effects of antidepressants during pregnancy.[21,22]

We used a randomized parallel-group design to compare the efficacy and tolerability of electroacupuncture and control ("sham") acupuncture for the treatment of mild or moderate MDD. We hypothesized that (1) depressed subjects randomized to 12 sessions of electroacupuncture would have a significantly higher decrease in their scores on the Hamilton Depression Rating Scale (HDRS)[23] than subjects randomized to control acupuncture, (2) a higher proportion of subjects randomized to electroacupuncture would experience clinical response, (3) a significantly higher proportion of depressed subjects randomized to electro acupuncture than to control acupuncture would experience an improvement in functioning, and (4) there would be no significant difference between subjects randomized to electroacupuncture and control acupuncture with regard to adverse events.

METHOD

Subjects

Patients aged 18–80 years who met the criteria for mild or moderate MDD, according to the Structured Clinical Interview for *DSM-IV* Axis I Disorders (SCID),[24] and who presented with an HDRS score of 14 or above were recruited via advertisement or referral. Patients with severe MDD (as per SCID criteria) or with acute suicidality were excluded from the study. Other exclusion criteria included (1) a seizure disorder or significant risk factors for a seizure disorder (history of brain trauma, recent stroke, brain tumor); (2) psychosis; (3) bipolar disorder; (4) chronic MDD (as per SCID criteria, ie, duration of 2 years or longer); (5) treatment-resistant MDD, defined as having failed at least 1 prior adequate antidepressant trial according to the criteria of the Antidepressant Treatment History Form[25]; and (6) history of substance abuse in the 6 months prior to enrollment.

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

The trial was conducted from March 2004 through May 2007 at UPMC Shadyside, Center for Complementary Medicine, in Pittsburgh, Pennsylvania, and was registered at www.clinicaltrials.gov (Identifier: NCT00071110). The protocol was approved by the Institutional Review Board of the University of Pittsburgh, Pittsburgh, Pennsylvania, and all subjects provided written informed consent.

Active and Control Interventions

Treatment regimen.—Both the active and control intervention consisted of 12 sessions (2 sessions/wk), with each session lasting 30 minutes.

Cointerventions.—All antidepressants and other psychotropic medications were tapered prior to randomization. Subjects remained free of psychotropic medications during the duration of the study. No other cointerventions (eg, herbs, exercises, life-style advice) were used.

Needling procedures.—For subjects randomized to the active electroacupuncture intervention, 0.22 × 30-mm sterile stainless steel needles were inserted at the following 2 points: Du 20 (top of the scalp, located at the intersection of the midsaggital plane and an imaginary line drawn between the apexes of the ears) and Yintang (midpoint between the eyebrows). These points were selected on the basis of the protocol reported by Luo et al.[26] At Du 20, the needle was inserted obliquely in the frontal direction beneath the scalp for 2 cm. At Yintang, the needle was inserted obliquely and downward for 2 cm. An Electro-Stimulator 4-C (Pantheon Research, Venice, California) was connected to the needles with a current of 3–5 mA and a frequency of 2 Hz. At this current intensity, subjects typically felt a slight but not uncomfortable twitching. Current was applied for 30 minutes.

The control intervention consisted of needling at nonchannel scalp points with sham electrostimulation. For subjects randomized to this control acupuncture intervention, the procedures closely followed the procedures used for the active electroacupuncture intervention except that (1) needles were inserted at 2 points that are remote from any classically described meridian or extraordinary acupuncture point and (2) no current was applied to the needles. These 2 points were located as follows: the anterior superior aspect of each ear where the helix meets the temporal region was identified, and the 2 control points were 3 cun (a Chinese word that translates to “anatomical inch”) superior bilaterally. These points correspond to the area of the coronal suture and the inferior temporal line. The location of these points on the head enhanced the similarity between the control acupuncture and the electroacupuncture and the believability of the control procedures.[27,28] The needles were inserted obliquely approximately 1 cm, which was the minimum needed to allow a stable connection to the electroacupuncture leads. We used a control electro-stimulator identical to the one used for the electroacupuncture intervention, with the lead modified so that no electrical stimulation was administered when the stimulator was turned on.

Practitioner background.—A licensed acupuncturist provided both the active and controlled interventions. The acupuncturist had 4 years of schooling, completing a Masters of Acupuncture and Traditional Chinese Medicine, was certified by the National

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

Certification Commission for Acupuncture and Oriental Medicine (NCCAOM), was a licensed acupuncturist, and had been in the practice of acupuncture and TCM for 5 years prior to the start of the study. His clinical practice included the treatment of anxiety disorders and depression. He monitored the subjects periodically throughout the session for both active and control conditions, but he did not engage the subjects in conversation.

Outcome Measures and Other Assessments

Ratings were performed at the initial screen, at baseline prior to the first intervention session, weekly during the intervention, and 2 weeks postintervention. All ratings were performed by a trained research associate who was blind to the subject's randomized assignment.

The primary outcome measure was defined a priori as the absolute change in HDRS score. In addition, we also compared the proportions of responders in each group, with response defined as both a final HDRS score of 10 or less and a relative decrease of at least 50% from baseline. The UKU Side Effect Rating Scale (UKU)[29] was used weekly to assess tolerability. The Medical Outcomes Study 36-Item Short-Form Health Survey (MOS-SF-36)[30] was used at baseline and completion to assess functional improvement. Response rates, the UKU, and the MOS-SF-36 were a priori–defined secondary outcome measures. The Global Assessment of Functioning[31] was also completed at baseline and 2 weeks postintervention. In addition, an exploratory analysis was conducted to determine whether acupuncture had a meaningful impact on anxiety or sleep symptoms that have been shown to be frequently present with MDD and to respond to antidepressant treatment.[32,33] We assessed the change in scores for 2 HDRS subscales: HDRS anxiety (items 9, 10, 11, and 15 for agitation, psychic anxiety, somatic anxiety, and hypochondriasis, respectively) and HDRS sleep (items 4, 5, and 6 for early, middle, and late insomnia, respectively).[33]

At baseline, the Cumulative Illness Rating Scale[34] was completed to assess for comorbid physical illnesses, and the Mini-Mental State Examination[35] was complete to assess cognitive status.

Statistical Analysis

Randomized subjects who completed at least 1 follow-up assessment were included in the intent-to-treat analysis. We used a hierarchical linear model to assess the difference in baseline mean HDRS scores between the 2 groups (electro-acupuncture and control acupuncture). The significance of the treatment effect and rate of change was compared using a mixed-effects model with random intercepts to detect time and group-by-time differences that were treated as fixed-effects study factors in the mean-response mixed-model analysis. The dependent variable was the HDRS score at each time point. We assumed an unstructured covariance structure to account for correlation among different intervention assessment points. The significance of the treatment effect was assessed using the likelihood ratio statistic using a type I error of $\alpha = .05$. The analysis was performed using SAS Version 9.2 PROC MIXED.[36] Proportions of responders in each group were compared with χ^2 statistics; tolerability (measured by the UKU) and functional improvement (measured by the MOS-SF-36) were compared using 2-sample *t* tests. Changes

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

in the scores for the HDRS anxiety and sleep subscales were analyzed using a hierarchical linear model as described above.

On the basis of the results of studies that had been published at the time this study was designed,[12,14] we predicted that we would observe a mean (SD) improvement in HDRS scores of approximately 12.2 (5.4) points in the electroacupuncture group and 2.9 (7.9) points in the control acupuncture group. Thus, we estimated that with at least 20 subjects in each group we would have a 91% power to detect a significant difference between the 2 groups.

RESULTS

Figure 1 summarizes the recruitment and retention of study subjects. Of 83 persons screened, 57 subjects who met all eligibility criteria were randomized—28 to electro-acupuncture and 29 to control acupuncture. Over the first 4 months of the study, the primary acupuncturist erred in treating the first 4 control acupuncture subjects. Although he correctly used the control electricity procedure (ie, no current was applied to the needles), he placed needles into the verum electroacupuncture points of Du 20 and Yintang for these 4 subjects randomized to control acupuncture. Therefore, we excluded them from the primary analysis, resulting in the inclusion of 28 subjects treated with electro-acupuncture and 25 treated with control acupuncture in the intent-to-treat analysis. Of these, 24 subjects in the electro-acupuncture group completed the protocol (21 of whom received at least 10 sessions), and 22 in the control acupuncture group completed the protocol (all of whom received at least 10 sessions).

Table 1 presents the demographic and baseline clinical characteristics of the 53 subjects included in the analysis. The 2 groups did not differ with regard to gender, age, education, baseline HDRS scores, and cognitive or functional status.

The absolute and relative decreases in mean (SD) HDRS scores observed in the 2 groups did not differ significantly (Table 2). In the mixed-model analysis including all subjects, the absolute decreases were −6.6 (5.9) for electroacupuncture versus −7.6 (6.6) for control acupuncture (t_{48} = 0.59, P = .56); the mean relative decreases were 37.5% (32.8) vs 41.3% (34.3), respectively (t_{48} = 0.41, P = .69). The mixed model revealed no differences between the rates of change (group-by-time interaction estimate = 0.13, SE = 0.23; P = .47), and there was no statistically significant difference between the HDRS scores in the 2 groups at end-point or at any evaluation point (Figure 2). Similarly, the proportion of responders did not differ significantly in the 2 groups (40.0% for electro-acupuncture vs 44.0% for control acupuncture; χ^2_1 = 0.08, P = .77).

We also conducted a sensitivity analysis that included in each study group the 4 subjects who were randomized to control acupuncture but who had the needles inserted into the verum points. Again, the absolute and relative decreases observed in the 2 groups and the proportion of responders did not differ significantly between the groups: (1) When we included these 4 subjects in the control acupuncture group, the mean HDRS absolute decreases were −6.6 (5.9) for electroacupuncture and −8.3 (6.4) for control

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

acupuncture (t_{52} = −0.96, P = .34); the mean relative decreases were 37.5% (32.8) versus 45.9% (34.4), respectively (t_{52} = 0.91, P = .36); and the proportions of responders were 40.0% versus 48.3%, respectively (χ^2_1 = 0.37, P = .54). (2) When we included these 4 subjects in the electroacupuncture group, the mean absolute decreases were −7.3 (5.9) for electroacupuncture and −7.6 (6.6) for control acupuncture (t_{52} = −0.19, P = .85); the mean relative decreases were 42.5% (33.6) versus 41.3% (34.3), respectively (t_{52} = −0.13, P = .90); and the proportions of responders were 44.8% versus 44.0%, respectively (χ^2_1 = 0.0037, P = .95).

There were no serious adverse events in either group. Endorsement of adverse effects and endpoint UKU scores did not differ between the 2 groups (see Table 2). Similarly, there was no difference in functional improvement, as measured by the MOS-SF-36 (see Table 2). The 2 groups had similar baseline HDRS sleep subscale scores (see Table 1), and a second mixed model revealed that both groups experienced a significant decrease in their HDRS sleep subscale scores over time (t_{253} = −2.04, P = .04), with no difference between the groups. The 2 groups had similar baseline HDRS anxiety subscale scores (see Table 1), and both groups also experienced a significant decrease in their HDRS anxiety subscale scores over time (t_{253} = −4.99, P < .001), with no significant difference between the groups.

DISCUSSION

We conducted a randomized controlled trial to compare the efficacy and tolerability of electroacupuncture and control acupuncture for the treatment of mild or moderate MDD. Electroacupuncture was well tolerated and resulted in close to a 50% reduction in depressive symptoms as measured by the HDRS. However, there was no significant difference between the absolute or relative changes in HDRS score observed in the electroacupuncture and the control acupuncture groups. Similarly, the 2 groups did not differ with regard to functional improvement or improvement in anxiety or sleep symptoms. These results differ from the reports in the Chinese literature[10–12,26] but are similar to reports from other trials conducted in North America.[14,18,37]

Our negative results need to be considered in the context of some potential limitations in the design and conduct of our study: an error in the treatment of 4 subjects, the selection of our control (“sham”) condition, and a standardized protocol using only 2 needles.

Inadvertently, the acupuncturist treated the first 4 subjects in the control group with the verum points without electricity. As a result, these subjects did not fit with either group, and they were excluded from the analysis. A sensitivity analysis showed that including them in either group would not appreciably change the study results.

One possible interpretation of our results is that the beneficial effect of electroacupuncture we observed is due solely to a placebo effect. However, there are many complexities in conducting acupuncture research. Similar to research on pharmacotherapy, studies of acupuncture commonly find that a believable control intervention improves clinical outcomes comparably to the active (verum) acupuncture treatment but to a greater extent than no-treatment, wait-list, or other nonneedle controls.[38,39] A placebo is defined as being

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

inert and *believable*.[40] Extensive studies and commentaries have indicated problems with both of these assumptions.[41] As with the use of placebo pills, needling at nonacupuncture points can be associated with physiologic effects that can be detected by functional neuroimaging.[42] Even sham or nonpenetrating needles display these properties. For our control condition, the needles were inserted far from any specific acupuncture meridian. However, in both TCM and Japanese approaches, the entire scalp is considered a microsystem, with any point corresponding to an area of the body and having some effect.[38,43] The control points we used are located on the scalp and thus might not offer a viable inert control to the verum points. Therefore, we might have in fact tested 2 potentially effective treatments, explaining why we did not detect any differences between our active and control interventions. Also, care was taken in our study and other studies to maintain the blind; however, given the difference in technique and the fact that the treating acupuncturist cannot be blinded, it is difficult to have the same level of concealment as in a placebo-drug study.

There has been extensive research and discussion in the literature regarding the optimal design of acupuncture trials, including the above issues pertaining to placebo.[40,41,43,44] Considerations include the use of nonpenetrating, telescoping needles; the use of a multigroup design with comparison of verum acupuncture, a needle control, and some other control such as wait-list; and options for providing a more individualized acupuncture intervention.[28,40,43]

Another factor that has an impact on acupuncture trials is the use of a standardized treatment. In clinical practice, an acupuncturist will individualize treatment on the basis of the TCM diagnosis, which includes evaluation of constitutional symptoms, pulses, and the tongue. This evaluation leads to the use of specific points for treatment and to modulation of the intensity of stimulation of the needles, all based on the TCM diagnosis. Conversely, most Western-designed randomized controlled trials, including this study, have utilized a standardized protocol for all subjects, which may minimize the treatment efficacy.

Finally, dosage of the treatment may also have contributed to this study's negative results. The use of only 2 acupuncture points reflects a minimalist approach. We selected this approach on the basis of the positive results of previous studies published by Luo et al[11,26] that used the same 2 acupuncture points. However, their study used a much higher dose of electroacupuncture (6 sessions per week for 6 weeks) than our protocol, which consisted of twelve 30-minute sessions—a dosage that has been commonly used in other studies and that is considered adequate to determine an acute effect. A number of other acupoints have been described in the TCM literature as being useful for the treatment of depression, anxiety, and sleep problems. Consequently, one could consider a "dose-finding study" comparing our active protocol, 1 or 2 additional conditions with a greater number of points to be treated, and a control condition. However, such a multigroup design would require a much larger sample size. Moreover, recruitment into our study was hindered by the exclusion of anyone taking any psychotropic medications. To conduct a larger study, investigators could include and stratify subjects who are currently taking a selective serotonin reuptake inhibitor or other antidepressant.

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

In conclusion, our data support the tolerability of electro-acupuncture in the treatment of mild or moderate MDD. Both the subjects treated with electroacupuncture and those who received control acupuncture experienced a significant and comparable decrease in HDRS scores from baseline to end-of-intervention. Thus, we were not able to demonstrate a specific effect of electroacupuncture. Future studies might consider different designs, such as a 3-group design com paring our 2-acupoint protocol, a more extensive TCM-based acupuncture intervention, and a control condition using noninserted placebo needles.

Abstract

Background: Depression is a significant cause of morbidity. Many patients have communicated an interest in non-pharmacological therapies to their general practitioners. Systematic reviews of acupuncture and counselling for depression in primary care have identified limited evidence. The aim of this study was to evaluate acupuncture versus usual care and counselling versus usual care for patients who continue to experience depression in primary care.

Methods and Findings: In a randomised controlled trial, 755 patients with depression (Beck Depression Inventory BDI-II score ≥20) were recruited from 27 primary care practices in the North of England. Patients were randomised to one of three arms using a ratio of 2:2:1 to acupuncture (302), counselling (302), and usual care alone (151). The primary outcome was the difference in mean Patient Health Questionnaire (PHQ-9) scores at 3 months with secondary analyses over 12 months follow-up. Analysis was by intention-to-treat. PHQ-9 data were available for 614 patients at 3 months and 572 patients at 12 months. Patients attended a mean of ten sessions for acupuncture and nine sessions for counselling. Compared to usual care, there was a statistically significant reduction in mean PHQ-9 depression scores at 3 months for acupuncture (−2.46, 95% CI −3.72 to −1.21) and counselling (−1.73, 95% CI −3.00 to −0.45), and over 12 months for acupuncture (−1.55, 95% CI −2.41 to −0.70) and counselling (−1.50, 95% CI −2.43 to −0.58). Differences between acupuncture and counselling were not significant. In terms of limitations, the trial was not designed to separate out specific from non-specific effects. No serious treatment-related adverse events were reported.

Conclusions: In this randomised controlled trial of acupuncture and counselling for patients presenting with depression, after having consulted their general practitioner in primary care, both interventions were associated with significantly reduced depression at 3 months when compared to usual care alone.

Introduction

Depression will be the second leading cause of disease burden worldwide by 2020, according to the Global Burden of Disease Study [1]. An estimated 2·6 million cases of depression were reported in England in 2000 [2]. It is the third most common reason for primary care consultations [3]. The economic burden is estimated to exceed UK£9 billion per annum in England, with direct costs of treatment being approximately UK£370 million [2]. Anti-depressants are the front-line treatment in primary care, yet an inadequate response to antidepressant treatment has been reported in up to 60% of patients [4] and lack of adherence to medication in 30% [3]. The effectiveness of newer anti-depressants for mild to moderate depression has recently come under question [5]. Patients have been concerned about an over-reliance on prescribed antidepressant medications and are keen to have access to non-pharmacological treatment options [6].

Acupuncturists commonly treat depression [7], but it is rarely provided within the UK's mental health services or primary care [8]. A Cochrane review found insufficient data on whether or not acupuncture is an effective intervention for depression, in part because of the high risk of bias in the majority of studies [9]. This review recommended the use of comparative designs in future research, comparing acupuncture to structured psychotherapies such as counselling or standard care. A widely used intervention for patients with depression is counselling, which is provided in approximately half of the 9,000 primary care practices in England [10]. Most counsellors provide a humanistic style of counselling. Recent National Institute for Health and Care Excellence (NICE) guidance is equivocal in recommending counselling for mild to moderate depression, identifying uncertainty regarding its effectiveness [11]. A Cochrane review, which identifies short-term but not long-term benefits from counselling, recommends extending the evidence base to include comparisons not just with usual care but also other interventions, including acupuncture, as this would have the potential to increase patient choice [12].

The primary aim of this study was to determine the clinical effectiveness and cost-effectiveness of short courses of either acupuncture or counselling when compared to usual care for patients with moderate to severe depression, with the secondary aim to compare acupuncture and counselling on the basis that there is structural equivalence regarding time and attention. The health economic results will be reported separately.

Methods

Ethics Statement

Ethical approval was obtained on 21st September 2009 from the York NHS Research Ethics Committee (ref: 09/H1311/75).

Design

The design was that of an open parallel-arm randomised controlled trial with patients randomised by the York Trials Unit to one of three arms using the allocation ratio of 2:2:1, respectively: acupuncture plus usual care; counselling plus usual care; and usual care alone, as detailed in the published protocol [13]. Patient details were recorded by the Trials Unit prior to using Structured Query Language (SQL) software for computer-generated block randomisation, with block sizes of five and ten, conducted by an investigator with no clinical involvement in the trial. This ensured that the allocation was securely concealed from the researchers who subsequently informed patients of their allocation.

Population

Patients who had consulted with depression in primary care within the past 5 years, and were continuing to experience moderate to severe depression were recruited. Identified from general medical practice databases, potential participants were aged 18 or over. Patients returned written consent forms and baseline questionnaires and were eligible if scoring 20 or above on the Beck Depression Inventory-II [14]. Thus all participants would be recognised as having depression. We used a different screening questionnaire from our chosen outcome measurement of depression, PHQ9 [15], because we did not want to use a screening questionnaire with a cut-off as the baseline measure in our analysis, to avoid problems of regression towards the mean. We did not want to give people the same questionnaire twice in fairly rapid succession, hence our choice of a second, also well-established, questionnaire for screening. We excluded patients who were receiving acupuncture or counselling at the time, who had terminal illness, significant learning disabilities, haemophilia, hepatitis, HIV, were pregnant, or who had confounding psychiatric conditions (bipolar disorder, postpartum depression, adjustment disorder, psychosis, dementia, or personality disorder). Patients who had suffered a close personal bereavement or given birth during the previous 12 months were excluded. Spoken English was a requirement.

Interventions

Patients allocated to the acupuncture and counselling groups were offered up to 12 sessions usually on a weekly basis. Participating acupuncturists were registered with the British Acupuncture Council with at least 3 years post-qualification experience. An acupuncture treatment protocol was developed [16] and subsequently refined in consultation with participating acupuncturists. It allowed for customised treatments within a standardised theory-driven framework. Counselling was provided by members of the British Association for Counselling and Psychotherapy who were accredited or were eligible for accreditation having completed 400 supervised hours post-qualification. A manualised protocol, using a humanistic approach, was based on competences independently developed for Skills for Health [17]. Practitioners recorded in logbooks the number and length of sessions, treatment provided, and adverse events. Further details of the two interventions are presented in Tables S2 and S3. Usual care, both NHS and private, was available according to need and monitored for all patients in all three groups for the purposes of comparison.

Outcome Measures

Our primary outcome measure was the PHQ-9 [15] at 3 months. In addition, we evaluated the overall impact over a 12-month period. PHQ-9 scores range from 0 to 27, with depression considered mild (5–9), moderate (10–14), moderately severe (15–19), or severe (20 and above). The EQ-5D was used as a preference-based measure of health outcome [18]. The use of medication was ascertained by asking patients whether they had taken any prescribed medication for depression or any prescribed analgesics/painkillers. Patients were asked to report health service use, including the number of times they had consulted a health professional because of their depression. Out-of-pocket costs included patient reports on spending on acupuncture, counselling, or psychotherapy including cognitive behavioural therapy. These data were collected at baseline and by postal questionnaire at 3, 6, 9, and 12 months These data were self-reported by patients

independent of the research team, thereby avoiding problems of potential differentials between trial arms, such as unblinding, that could lead to bias. BDI-II was collected at baseline and 12 months. We collected baseline demographic data and patients' prior preferences and expectations of the interventions. For both acupuncture and counselling groups, we measured patients' perceptions of their practitioners' empathy at 3 months using the Consultational and Relational Empathy (CARE) measure [19]. A reimbursement of UK£5 was enclosed with the final questionnaire to enhance response rate [20]. In-depth interviews were used to explore the experiences and perspectives of patient and practitioner, the results of which will be reported separately.

Sample Size

An effect size of 0·39 on the PHQ-9 was sought when comparing either acupuncture versus usual care alone or counselling versus with usual care alone. An allocation ratio of 2:2:1 was chosen in order to increase power to detect statistically significant differences between acupuncture and counselling. As a result, a smaller effect size of 0·32 was sought when comparing acupuncture and counselling. Anticipated differences between the treatments were likely to be smaller but not clinically meaningful. With 90% power and a two-sided significance level of 5%, the required group sizes were 204, 204, and 102 participants in the acupuncture, counselling, and usual care alone arms, respectively. Allowing for 20% attrition, the total sample size required was 640 (i.e., groups of 256, 256, 128, respectively).

Analysis

The primary effectiveness comparisons were between acupuncture plus usual care versus usual care alone, and counselling plus usual care versus usual care alone. A secondary comparison was between acupuncture plus usual care versus counselling plus usual care. The primary outcome was PHQ-9 at 3 months, for which we used analysis of covariance (ANCOVA), with baseline PHQ-9 score as covariate. Multiple imputation by chained regression was used for missing data using treatment group, baseline measures (PHQ-9, BDI-II, SF-36, EQ-5D Anxiety/Depression), and demographics (age and gender). The primary analysis was based on the imputed rather than raw data in order to take account of the profile of non-responders.

To assess the overall clinical impact at 12 months, we evaluated area under the curve (AUC) for PHQ-9 over that period by linear regression, predicting average AUC while controlling for baseline PHQ-9. We also explored PHQ-9 outcomes across all time points in more detail using random intercept linear mixed models with fixed effects for treatment arm, time, and arm by time interaction for each treatment comparison. The models nested time points within patients and controlled for baseline PHQ-9 and potential mediators including patients' prior expectations and preferences regarding the treatments. These were identified by univariate regressions ($p<0·1$) of PHQ-9 at 3 months for the whole patient sample, controlling for baseline PHQ-9. When comparing acupuncture and counselling, we controlled for treatment time (combined length of sessions) and quality of attention (CARE empathy score). Treatment differences between BDI-II depression scores at 12 months were analysed by ANCOVA, controlling for BDI-II baseline scores and covariates for depression as identified above. Missing data were multiply imputed as for the PHQ-9.

All analyses were carried out in Stata (version 12.1) on an intention-to-treat basis. Statistical tests were at a two-sided 0·05 significance level. Analysis of residuals was undertaken for all regression models in order to assess model assumptions.

Results

Participants

Patient flow in the trial is presented in Figure 1. In total 755 patients were recruited, 18% over target, from 27 general medical practices between December 2009 and April 2011 in Yorkshire and northeast England. General practices recruited an average of 28 patients (range 0 to 122). Baseline patient characteristics were balanced between the trial arms and are presented in Table 1. These characteristics included data on expectations of the treatments, which were lowest for acupuncture (68% were undecided) and preferences, for which the majority (58%) would have preferred to have been allocated acupuncture. These variations were taken into account in the linear mixed model analysis. Comparison of baseline data between patients with and without missing data at 3 months is presented in Table S1.

Interventions

In the acupuncture arm, 266 patients (88.1%) received one or more treatment sessions (mean = 10.3, standard deviation [SD] 3.14) with one of 23 acupuncturists. By the 3-month time point, the average number of sessions received was 8.7 (SD = 3.34), with 133 patients (50.0%) having completed all of their sessions. In the counselling arm, 231 patients (76.5%) received one or more treatment sessions (mean = 9.0, SD = 3.74) with one of 37 therapists. By the 3-month time point, the average number of sessions received was 7.5 (SD = 3.60), with 114 patients (49.4%) having completed all of their sessions. The mean time from randomisation to last treatment was 117 days in both treatment arms (SD = 47.0 and 51.2, respectively), a period that included time to first appointment. Acupuncturists were allocated an average of 13 patients each (range two to 45), and counsellors an average of eight patients each (range one to 27).

In the logbooks, we collected data on acupuncturists' and counsellors' self-reports of intervention protocol violations. We received reports of four cases of violations of the acupuncture protocol (which incidentally did not involve counselling), one of which was deemed a true case involving prescription of a herbal lotion application to reduce swelling and pain. We received seven reports of violations of the counselling protocol, of which two were deemed true cases; one case involved goal setting and in another the counsellor reported being analytical and interpretative beyond the scope of humanistic counselling.

Details of medication use over the period of the trial is reported below, and further details of all three interventions are summarised for acupuncture (Table S2) and counselling (Table S3), and, respectively, and for usual care: patients seeing a health professional (Table S4); patients attending hospital accident and emergency departments (Table S5); patients admitted to hospital (Table S6); and patients paying for private health care (Table S7). A more complete report on the acupuncture provision has now been published [21] and one on the counselling provision will follow shortly.

Clinical Outcomes

Unadjusted mean scores for the PHQ-9 at all time points are presented in Table 2 and Figure 2. For the primary outcome, Table 3 gives results for between-group differences in PHQ-9 depression at 3 months using ANCOVA. Patients for whom no data were available at that point tended to be younger with higher levels of baseline depression, and imputed data were used to take their profile into account. Compared to usual care, patients in the acupuncture arm experienced an average additional reduction in depression of −2·46 points on the PHQ-9 ($p<0·001$, 95% CI

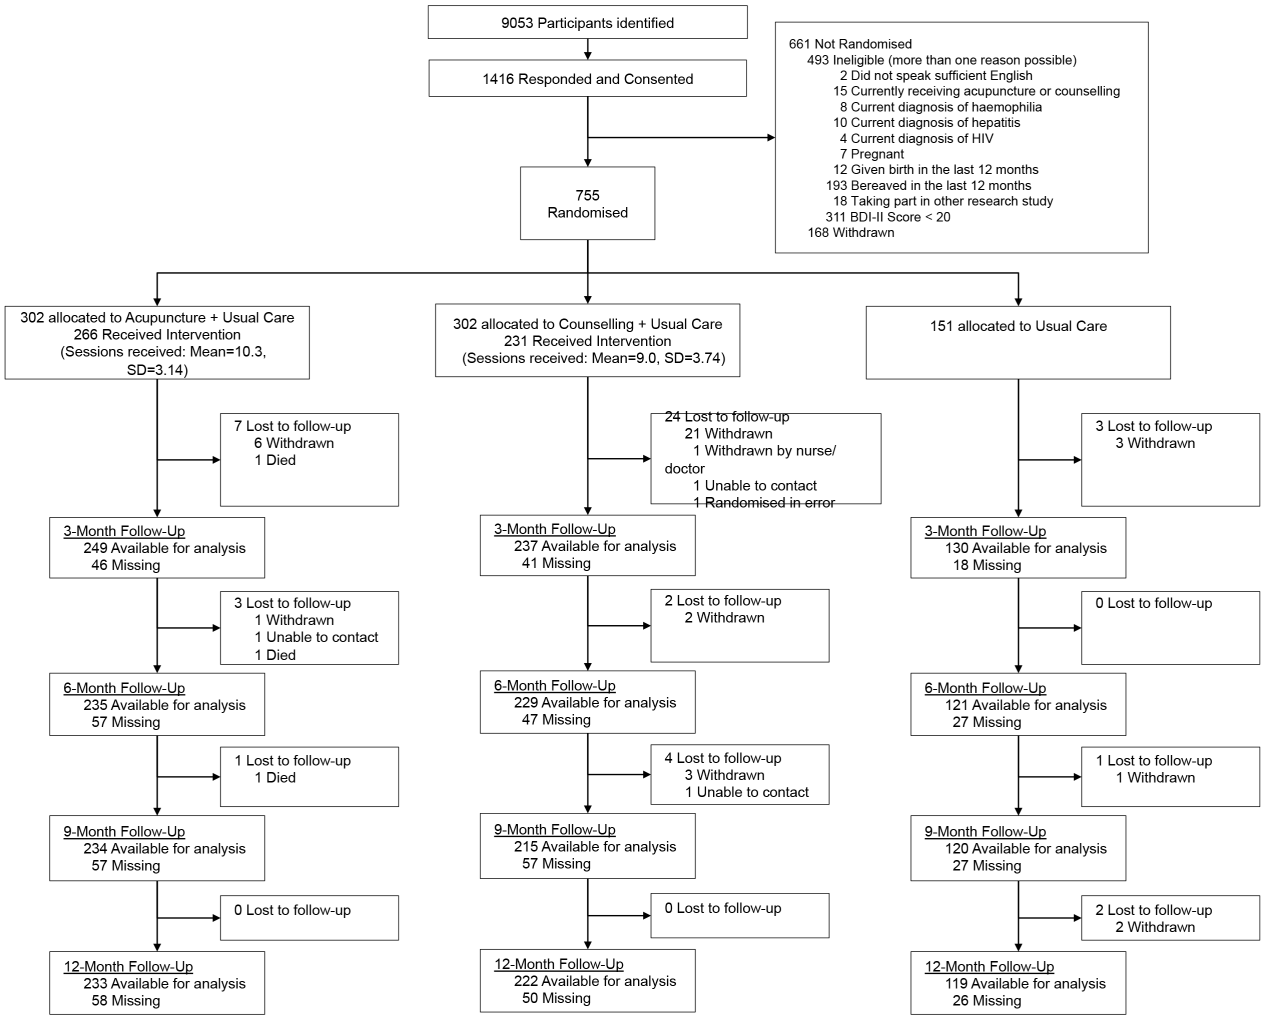

Figure 1. CONSORT flow diagram.
doi:10.1371/journal.pmed.1001518.g001

−3·72 to −1·21), an observed effect size equivalent to a Cohen's *d* of −0·39 (95% CI −0·58 to −0·19). Compared to usual care, patients allocated to the counselling arm experienced an average additional reduction in depression of −1·73 points ($p = 0·008$, 95% CI −3·00 to −0·45), equivalent to a Cohen's *d* of −0·27 (95% CI −0·47 to −0·07). The difference between acupuncture and counselling, −0·76 points on the PHQ-9 ($p = 0.41$, 95% CI −1·77 to 0·25), was not statistically significant. These data are conservative, as non-imputed data showed slightly larger treatment effects (see Table S8).

In the AUC analysis of PHQ-9 scores over 12 months, the benefit of acupuncture and counselling over usual care alone in terms of score reduction seen at 3 months remained when averaging over the 12-month trial period: acupuncture reduced PHQ-9 scores by −1·55 (95% CI −2·41 to −0·70); counselling by −1·50 (95% CI −2·43 to −0·58) (Table 3).

In secondary analyses, PHQ-9 at 3 months was associated with two factors: expectations of counselling ($p = 0·064$) and expectations about the treatment that patients were allocated to ($p = 0·015$). These factors were included as potential mediators of the effect of trial arm in further analyses. Within the acupuncture and counselling arms, additional significant factors were total session time at 3 months ($p < 0·001$) and perceived empathy of practitioners ($p < 0·001$), which were added as further covariates.

Linear mixed modelling showed reduced PHQ-9 depression in the acupuncture and counselling groups as compared to usual care at 3 and 6 months (Table 3). The scores in the usual care group continued to reduce over time, such that differences were no longer statistically significant at 9 and 12 months. There was no evidence of significant differences between acupuncture and counselling throughout.

Unadjusted mean scores for the BDI-II at baseline and 12 months are shown in Table 2. Results using ANCOVA show that depression scores on the BDI-II were reduced in the acupuncture arm (−2·88, 95% CI −5·68 to −0·08) and counselling arm (−2·74, 95% CI −5·50 to 0·02) to a greater extent than by usual care alone at 12 months, but with no statistically significant differences between the two interventions (Table 4).

Prescribed Medication

The majority (68·7%) of all patients were taking antidepressants at baseline (Table 5). The use of prescribed antidepressants decreased steadily by an average of 12% over the 12-month study period, the rate of which was comparable between trial arms. Around half (47·9%) of patients were taking analgesics at baseline,

which decreased on average to 41·0% over 12 months. Patients in the acupuncture arm showed a marked decrease in the use of analgesics in the first 3 months, which was not sustained following the end of the intervention.

Adverse Events

The number of patients experiencing a serious adverse event (SAE) over the 12 months, as judged by a clinician (IW), was 16 (5·3%) of 302, 26 (8·6%) of 302, and nine (6·0%) of 151 from the acupuncture, counselling, and usual care groups, respectively, of whom nine had more than one SAE (range 2–4). No SAEs, including three deaths, were known to be related to treatment. The number of patients experiencing a non-serious adverse event (NSAE) was 56 (18·5%), 47 (15·6%), and 40 (26·5%), respectively, of whom 17 had more than one NSAE (range 2–4).

Discussion

Principal Findings

In this first randomised trial of acupuncture and counselling for patients continuing to experience depression in primary care, we found statistically significant benefits at 3 months associated with both interventions when provided alongside usual care. This population can be characterised as having experienced recurring bouts of depression (76% having had four or more episodes), with the first episode on average at age 25, some 19 years previously, and 69% were on anti-depressant medication. Moreover significant benefits were observed over the 12-month period as a whole in an AUC analysis. Over time, the usual care group improved such that by 9 and 12 months the benefits of acupuncture and counselling were no longer significantly better than usual care in our primary outcome measure, the PHQ-9. No serious adverse events related to treatment were reported.

Strengths and Limitations

This study had a clear and practical research question with an appropriate trial design, namely a pragmatic randomised controlled trial, which modelled closely what would happen if patient referrals to acupuncturists and counsellors were routine. Pragmatic trials have an emphasis on external validity with the intention that findings are generalisable to typical patients and settings. We recruited patients in primary care from those who had consulted with depression and continued to be moderately or severely depressed, thereby excluding patients whose symptoms had been

alleviated sufficiently by other treatment. Using a different screening measure (BDI-II) from the one we used for measuring outcome (PHQ-9) had the advantage that we avoided the well-known problems of regression towards the mean that occur when we choose people as being above a cut-off. The natural variation in responses to questionnaires produced a few scores below the cut-off for depression on the PHQ9 measurement, 0.8% of participants being below 5, which would have them classified as not depressed, and 11.5% between 5 and 9, which would be mild depression. This is an inevitable consequence of the difficulty of measuring depression. A single PHQ9 below 5 does not mean that someone is not depressed and a single BDI above 20 does not mean that they are depressed, these scores occurring in the same individuals for six participants. Each of these scores is only an uncertain estimate of the person's position on a continuum.

The attrition between invitation to participate and randomisation at baseline was typical of trials that recruit via primary care databases. Multiple imputation was used to compensate to some degree for the limitations related to the loss of follow-up data. The randomisation into groups provided a control for temporal effects and other factors across all patients that might have influenced outcomes beyond the treatment itself. We provided standardised treatment protocols for the acupuncturists and counsellors that were designed to reflect routine practice, allowing individualisation to match patient variability, while ensuring all practitioners met appropriate standards of qualification and experience. While no attempt was made to standardise usual care, it was however provided to patients in all arms of the trial, with a majority of patients continuing with anti-depressants, and differences between groups in usual care at all time points were minimal (see Tables S4–S7). Accordingly, we can assume that the differences between arms can largely be ascribed to the treatments provided by the acupuncturists and the counsellors.

Pragmatic trials, however, tell us less about which aspects of the interventions might be most or least beneficial. Such trials are not designed to separate out relative contributions from treatment components that are specific or non-specific to the intervention. With regard to two treatment components in the acupuncture and counselling groups that are often considered "non-specific," namely session time and quality of therapist attention, we found that specific treatment effects remained when these were accounted for. Despite the limitation that a pragmatic approach has in ascribing outcomes to different treatment components, exacerbated by some loss to follow-up, this design nevertheless provides a useful estimate of overall effects of complex interventions, an estimate of most interest to patients, practitioners and providers.

Relationship to the Literature

In a recent Cochrane review of acupuncture for depression, no studies focussed on moderate to severe depression. The only comparator equivalent to the usual care of our study was a wait list comparator, which involved two trials by the same research team [22–23]. The Cochrane review's meta-analysis involving 94 patients in these two trials showed a reduction in standardised mean difference (SMD) of −0·73 (95% CI −1·18 to −0·29). This is a larger effect size than we found, however we need to be cautious in the interpretation of the result, as the patients were less depressed and the numbers analysed were small. Regarding counselling, we found no trial based in primary care that evaluated counselling for moderate to severe depression. From a Cochrane review, there is evidence from six trials of counselling for mild to moderate depression with 772 patients that counselling is more effective than usual care in terms of mental health outcomes over 1 to 6 months (SMD −0·28, 95% CI −0·43 to −0·13). These advantages were not shown to endure over the longer term from 7

to 12 months (SMD −0·09, 95% CI −0·27 to 0·10). Their number-needed-to-treat for short-term benefit was 6, somewhat less than the 10 we found for moderate to severely depressed patients. In another review of psychological interventions, four cognitive behaviour therapy studies based in primary care covering 259 patients with depression found a similar short-term effect (SMD −0·33, 95% CI −0·60 to −0·06) [24]. In our rigorously conducted large-scale trial, we present the first evidence on acupuncture and counselling for patients in primary care who are representative of those continuing to experience symptoms of moderate to severe depression. Both interventions are shown to be effective treatments at 3 months when compared to usual care

alone, with evidence that there are benefits over the 12-month period in terms of clinical symptoms.

Implications for Clinical Practice and Future Research

If treatment success is defined as improvement from a depressed PHQ-9 score (≥10) to a non-depressed score (≤9) with an improvement of at least 50% [25], then 33% of acupuncture patients, 29% of counselling patients, and 18% of usual care patients achieved this. These percentages apply to the total number of patients with a baseline PHQ-9 score of 10 or above and for whom data were available at 3 months. The number-needed-to-treat for one additional treatment success, as defined above, was 7 for acupuncture (95% CI 4·3–17·4) and 10 for counselling (95% CI 5·3–47·3). The patient experience can be further illustrated in terms of "depression free days" [26], an approximate summary measure derived from PHQ-9 cut-off scores averaged over the period between measurements. The mean number of depression free days over 3 months was 34 (95% CI 31–38) for the acupuncture group, 27 (95% CI 24–30) for the counselling group, and 23 (95% CI 19–27) for the usual care group.

Further research into the optimal populations and treatment regimens for acupuncture and counselling is merited. The characteristics of patients one recruits to trials of interventions for depression in primary care will depend on the recruitment methods used. Patients recruited at the point of consultation will be different from those recruited via databases, as we did in this trial, and different again from those with depression who are not consulting at all. In the trial we report here, what was important was that patients had consulted in primary care, continued to be depressed, and were seeking other interventions that might help with their depression. A different recruitment method could be used to assess whether the interventions would be more effective for patients referred at the onset of their first episode of depression, rather than after many episodes, as was the case in the present study in which 76% had had four or more previous episodes.

We recruited patients using the Beck Inventory (BDI-II) with scores greater or equal to 20, which is classified by this measure as "moderate to severe." However other classifications systems, such as DSM, have different categories of severity. What our trial does not tell us is whether acupuncture or counselling performs better or worse for the more mild forms of depression. Nor do we know whether patients not receiving anti-depressant medication (one third of our sample) do better or not, or whether fewer sessions would be sufficient for mild to moderate depression, or more sessions would improve outcomes for those with severe depression (approximately 60% of our sample). For those randomised to acupuncture, it was usually their first experience of this intervention, whereas many randomised to counselling had received this intervention before; however, it is not clear whether this difference impacted on outcomes.

With regard to the acupuncture provision, there is some evidence from the literature that a uniform combination of points can work for depressed patients [27,28]; however, a head-to-head trial or large individual patient data meta-analysis would be required to determine whether a uniform approach was more beneficial than an individualised approach.

A full economic analysis is needed to combine the costs and effects of each treatment option to determine the cost-effective treatment. Although no other trial data are available on the costs and effects of acupuncture for these primary care patients, other trials exist for counselling in primary care and, to guide policy, these should be synthesized into cost-effectiveness estimates.

Conclusion

To our knowledge, our study is the first to rigorously evaluate the clinical and economic impact of acupuncture and counselling for patients in primary care who are representative of those who continue to experience depression in primary care. We have provided evidence that acupuncture versus usual care and counselling versus usual care are both associated with a significant reduction in symptoms of depression in the short to medium term, and are not associated with serious adverse events.

Editors' Summary

Background. Depression–overwhelming sadness and hopelessness–is responsible for a substantial proportion of the global disease burden and is a major cause of suicide. It affects more than 350 million people worldwide and about one in six people will have an episode of depression during their lifetime. Depression is different from everyday mood fluctuations. For people who are clinically depressed, feelings of severe sadness, anxiety, hopelessness, and worthlessness can last for months and years. Affected individuals lose interest in activities they used to enjoy and sometimes have physical symptoms such as disturbed sleep. Clinicians can diagnose depression and determine its severity by asking patients to complete a questionnaire (for example, the Beck Depression Inventory [BDI-II] or the Patient Health Questionnaire 9 [PHQ-9]) about their feelings and symptoms. The answer to each question is given a score and the total score from the questionnaire ("depression rating scale") indicates the severity of depression. Antidepressant drugs are usually the front-line treatment for depression in primary care.

Why Was This Study Done? Unfortunately, antidepressants don't work for more than half of patients. Moreover, many patients would like to be offered non-pharmacological treatment options for depression such as acupuncture–a therapy originating from China in which fine needles are inserted into the skin at specific points of the body–and counseling–a "talking therapy" that provides patients with a safe, non-judgmental place to express feelings and emotions and that helps them recognize their capacity for growth and fulfillment. However, it is unclear whether either of these treatments is effective in depression. In this pragmatic randomized controlled trial, the researchers investigate the clinical effectiveness of acupuncture or counseling in patients with depression compared to usual care in primary care in northern England. A randomized controlled trial compares outcomes in groups of patients who are assigned to different interventions through the play of chance. A pragmatic trial asks whether the intervention works under real-life conditions. Patient selection reflects routine practice and some aspects of the intervention are left to the discretion of clinician, By contrast, an explanatory trial asks whether an intervention works under ideal conditions and involves a strict protocol for patient selection and treatment.

What Did the Researchers Do and Find? The researchers recruited 755 patients who had consulted their primary health care provider about depression within the past 5 years and who had a score of more than 20 on the BDI-II–a score that is defined as moderate-to-severe depression on this depression rating scale–at the start of the study. Patients were randomized to receive up to 12 weekly sessions of acupuncture plus usual care (302 patients), up to 12 weekly sessions of counseling plus usual care (302 patients), or usual care alone (151 patients). Both the acupuncture protocol and the counseling protocols allowed for some individualization of treatment. Usual care, including antidepressants, was available according to need and monitored in all three groups. Compared to usual care alone, there was a significant reduction (a reduction unlikely to have occurred by chance) in the average PHQ-9 scores at both 3 and 6 months for both the acupuncture and counseling interventions. The difference between the mean PHQ-9 score for acupuncture and counseling was not significant. At 9 months and 12 months, because of improvements in the PHQ-9 scores in the usual care group, acupuncture and counseling were no longer significantly better than usual care.

What Do These Findings Mean? These findings suggest that, compared to usual care alone, both acupuncture and counseling when provided alongside usual care provided significant benefits at 3 months in primary care to patients with recurring depression. Because this trial was a pragmatic trial, these findings cannot indicate which aspects of acupuncture and counseling are likely to be most or least beneficial. Nevertheless they do provide an estimate of the overall effects of these complex interventions, an estimate that is of most interest to patients, practitioners, and health care providers. Moreover, because this trial only considers the effect of these interventions on patients with moderate-to-severe depression as classified by the BDI-II; it provides no information about the effectiveness of acupuncture or counseling compared to usual care for patients with mild depression. Importantly, however, these findings suggest that further research into optimal treatment regimens for the treatment of depression with acupuncture and counseling is merited.

Laser acupuncture for mild to moderate depression in a primary care setting

– a randomised controlled trial

Joo Im Quah-Smith, Wai Mun Tang, Janice Russell

Abstract

Objective Depression is a major public health problem. There is some evidence supporting the effectiveness of needle acupuncture in its treatment. Laser stimulation, regarded here as a modality of acupuncture, is non-invasive and therefore free of infection risk; and it is acceptable to patients with needle phobia. The technique is relatively easily learned by community-based general practitioners. It is also amenable to sham control and therefore double-blinding in clinical trials. A double-blind randomised controlled trial was conducted to test the efficacy of low level laser acupuncture in mild to moderate depression.

Methods Thirty patients with depression were randomised to receive either active or inactive laser treatment. The laser unit could be switched to one of two settings. One switch position delivered active laser acupuncture and the other was inactive (sham). In the active mode, 0.5J was delivered to each of six to eight individually tailored acupuncture sites per visit. All patients were treated twice weekly for four weeks then weekly for a further four weeks. The patients and the acupuncturist were both blinded to conditions. Outcome was assessed using the Beck Depression Inventory at baseline, weeks four and eight during treatment, and at 4 and 12 weeks following the treatment.

Results At the end of the treatment period, Beck Depression Inventory scores fell from baseline by 16.1 points in the intervention group and by 6.8 points in the sham control group ($P<0.001$). The difference showed only a trend four weeks later, but was again significant after 12 weeks ($P=0.007$). Laser acupuncture was well tolerated with transient fatigue as the most common adverse effect.

Conclusion Laser acupuncture may be worth further investigation as a treatment for mild to moderate depression in primary care.

Introduction

Clinical depression is defined as a syndrome with symptoms of low mood, loss of pleasure and interest, sleep disturbances, weight and appetite changes, fatigue, feelings of worthlessness or guilt, poor concentration and (when severe) suicidal thoughts and gestures, that persist for at least two weeks.[1] Depression commonly impacts not only on the patient but their families, workplace and the community. In 2000 the World Health Organisation assessed the global burden of unipolar depressive disorders, and estimated that depression accounted for 11.9% of years lived with a disability, compared with 10.7% in 1990. Depression remained the fourth leading cause of total disease burden accounting for 4.4% of Disability Adjusted Life Years, a measure of future lost years of healthy life.[2;3] The economic burden of depression in the USA has been estimated at $83.1 billion annually, 30% in direct health care and the remainder from impaired workplace productivity and premature death. Depressed workers have an estimated 20% decrease in productivity.[4;5]

Only 40% of people with depressive symptoms seek professional help, and less than half of these receive evidence-based treatments.[6] The National Institute of Mental Health (NIMH) has published the largest study to date on pharmacological and

psychotherapy treatments of depression in which health outcomes of known clinical interventions were examined.[7] Thirty two percent of patients dropped out of therapy prior to completion and of those who did complete 16 weeks of active treatment, 30% to 49% failed to respond. A significant proportion of responders were found to be depressed again within 18 months. Premature termination of treatment was attributed to adverse effects, dissatisfaction with treatment effectiveness or preference for other therapies, particularly use of complementary therapies.[8;9] Thus, there is need to explore these clinical alternatives and to establish their effectiveness in primary and tertiary care settings.

A review of the available evidence on acupuncture for depression was recently conducted within the framework of the Cochrane Collaboration.[10] Seven trials fulfilled inclusion criteria and were evaluated to determine whether acupuncture was more effective than sham acupuncture, no treatment, standard treatments (pharmacotherapy and psychological intervention) and to determine the adverse effects of acupuncture. One included study tested the effectiveness of overall acupuncture and specific acupuncture points in the management of depression.[11] Acupuncture was shown to be effective in the management of depression with a significant effect of specific acupuncture points. Six months later, relapse rates were comparable to those of established therapies.[12] There was adequate randomisation and blinding of the participant, acupuncturist and outcome assessor but no mention of blinding of the statistical analyst. There was no intention-to-treat analysis performed and the sample population was small. In the trials by Luo et al and Han et al, electroacupuncture was found to be as effective as pharmacotherapy,[13-16] although the group treated with pharmacotherapy alone in the trial of Luo et al (1998) reported a greater reduction in depression compared to the combined acupuncture and pharmacotherapy group.[16] Roschke compared pharmacotherapy with needle acupuncture, pharmacotherapy with placebo acupuncture, and pharmacotherapy alone. Acupuncture intervention was superior to pharmacotherapy alone but there was no measurable difference between the effects of placebo and true acupuncture.[17] Xiujuan found classical needle acupuncture to be no different from pharmacotherapy in the reduction of depression.[18] Together, these trials demonstrate that acupuncture may be effective in depression management but methodological issues are of major concern. Outcomes were confounded by small sample sizes, randomisation and blinding issues, lack of specific inclusion and exclusion criteria, statistical analytical issues and variable dosages of pharmacotherapy. Adverse events were not always reported.

The efficacy of laser acupuncture has been demonstrated in a variety of medical conditions,[19-28] but not in depression. Again methodological issues including the depth of transmission of the laser beam have been problematic.[29] The generalisability of results is limited due to the relatively small number of studies performed, and the lack of widespread clinical experience. Laser acupuncture was selected for this study as it allows blinding of treatments more easily than does needle acupuncture. Other advantages of laser acupuncture over needling include the facts that it has shorter treatment times, is not invasive, has no infection concerns, is ideal for the needle phobic patients, and should be relatively easy for primary care doctors to use as a treatment option for depressed patients.

The aims of this study were to examine the efficacy of laser acupuncture in the treatment of mild to moderate depression in a double blind controlled trial and to report on any adverse effects from the treatment.

Methods

Recruitment and Study Design

We performed a randomised controlled trial comparing laser acupuncture with sham laser acupuncture. Patients were invited to participate through advertisements placed in local newspapers and referral from medical practitioners in the North Shore area of Sydney. Interested participants were then interviewed via telephone by a research assistant to assess their eligibility. Details recorded included age, sex, marital status, previous diagnoses with depression and treatment received. Those who fulfilled the recruitment criteria then completed the Beck Depression Inventory (BDI) and Hospital Anxiety and Depression Scale (HADS) by mail. Potential participants with BDI scores between 12 and 30 were then examined by a psychiatrist (JR or WMT) to confirm the diagnosis of mild to moderate depression. Those with scores outside this range were referred to a general practitioner.

The treatment period was eight weeks. Treatment commenced within two weeks of completion of the screening BDI, which also served as baseline score. The BDI was then completed by participants after four weeks and eight weeks of treatment, and four and a further eight weeks following termination of the treatment course, ie 12 and 20 weeks from randomisation. Participants were given a $20 rebate upon completion of the final post intervention questionnaire in order to offset their travel expenses.

Instruments

The BDI is a self-reporting questionnaire with 21 questions relevant to depression.[30] Each question has four options scoring 0 to 3. The clinical threshold score for 'caseness of depression' (ie a diagnosis of depression in an individual) is 12, with scores of 12-20 signifying mild depression, 20-30 moderate depression and over 30 severe depression. The HADS is a self-reported questionnaire with 14 questions concerning anxiety and depression.[31] The scores for anxiety and depression are scored separately on a four point Likert scale (0-3). Scores of less than eight are considered below the clinical threshold for anxiety, 8-10 doubtful and 11 and above indicative of definite anxiety. Patients who scored 11 or more for anxiety at baseline were treated with an additional, anxiety specific acupuncture point (see below). HADS was administered at baseline and postal follow ups at 12 and 20 weeks. An Adverse Events Questionnaire was sent to all participants who completed the final treatment session.

Inclusion criteria

Participants were suitable for inclusion in the trial if they had depressive symptoms with a BDI score of 12 to 30, if they agreed to being included and to participate in follow up for three months after the completion of acupuncture intervention, and if they were able to give informed consent.

Exclusion criteria

Participants were excluded if they were diagnosed as suffering from chronic dysthymia, ie chronic depression of over two years duration, hypomania, psychosis or substance abuse, if they had been taking psychotropic drugs including prescribed drugs or herbal supplements for depression within the last three months. Other exclusion criteria were history of neurological disorders, endocrine disorders, pregnancy or active suicidal tendencies.

Withdrawal criteria

Participants were withdrawn from the study if any of the aforementioned exclusion criteria became apparent, as decided by the participant or treating doctor.

Randomisation and blinding

Equal numbers of red and green beans were placed in a closed jar with a small hole in its lid. Upon entry into the study, the research assistant randomly selected one of the coloured beans from the jar to indicate group allocation. The colour corresponded to position 1 or 2 on the laser, as decided by a flip of a coin and only known to the manufacturer until the data had been analysed.

The participants and the acupuncturist were both blinded. The laser did not cause any sensory effect and the indicator light on the control panel flashed during treatment for both the inactive and active laser. The acupuncturist was not allowed access to the BDI scores during the eight week intervention. At the outset, she was told when the baseline HAD-A (anxiety) was equal to or greater than 11. She was not allowed to interact with the participant apart from greeting them. The time spent with each participant at each treatment was less than five minutes. The research assistant collecting the data and the statistical analyst were blind to group assignment.

Intervention

Practitioner background and acupuncture point selection

The medical acupuncturist is a fellow of the Australian Medical Acupuncture College (AMAC). She is in full time medical acupuncture practice. Her training was with AMAC, Professor Jean Bossy (Montpelier University), Associate Professor Steven Aung (University of Alberta), Dr Stephen Birch (LA, PhD) and Dr Raphael Nogier of Groupe Lyonnaise d'Etudes Medicale (GLEM).

Acupuncture point selection was based on classical syndromes as defined in Traditional Chinese Medicine. The treatments were individualised, and the predominant syndromes were found to be either liver Qi stagnation or liver Qi deficiency. To facilitate recovery, classical 'alarm points' were chosen for

treatment as these are traditionally believed to be the fastest acting points. Six primary acupuncture points were routinely used for all participants: LR14 on the right, CV15 and CV14 in the anterior midline (all being alarm points), HT7 at the wrists (for calming) and LR8 on the left (Liver Yin). LR8 was also believed to be a faster-acting acupuncture point. Secondary acupuncture points were selected by the acupuncturist and were only used when the HADS anxiety score was 11 or greater. The most important site was KI10. Other acupuncture points infrequently used were LI4, SP6, GV20.

Treatment regimen

Twelve laser acupuncture sessions in total were given, twice weekly for the first four weeks then weekly for the following four weeks. There were no co-interventions. The participants were made aware at initial telephone interview that herbal or pharmaceutical psychotropic preparations were not permitted during the study, and reminded at the first session. The participants were also told to check with the research assistant if there were other therapies being considered and that these should be avoided until the final assessment.

Laser unit

The low level infrared laser acupuncture unit was adapted for the study. A flick switch was installed, numbered '1' and '2' by the manufacturer. One of these two options was sham laser, but at both positions the laser would beep and flash at the control panel during 'treatment'. None of the participants in either group reported any sensation when the laser was applied to the skin.

The low level laser acupuncture unit used was the Meyer 100mW, (Meyer, Melbourne, Australia) which is in common use by medical practitioners in Australia. The laser was applied to each acupuncture point for five seconds to deliver 0.5J per point. The instrument was recalibrated during preparation for this research project. At each acupuncture point, the probe was held lightly in contact with the skin for five seconds to deliver 0.5J of laser energy so each participant received in total 3-4J of laser energy per session.

Ethical approval

The study was approved by the Monash University Standing Committee on Ethical Research on Humans. All participants gave written informed consent at study entry and were also given information regarding the clinical use of laser acupuncture, the mechanism of action and its safety. They were also assured of the confidentiality of their participation and their right to withdraw at any stage.

Statistical Analysis

A multivariate analysis of variance (MANOVA) was performed on all completers to compare group effects. The main effects were time (baseline, weeks 4, 8, 12 and 20), switch setting (1 or 2) and the interaction term was time by switch setting. The primary outcome measure was the change in BDI score at each assessment point (baseline minus the BDI at each time point). In addition, caseness (ie BDI score >11) in the active laser and sham control groups was compared using chi square analysis. An intention-to-treat analysis (ITT) was also carried out using the last observation carried forward method for imputing missing values.

Results

Of the 234 people who responded to advertisements, 129 did not meet inclusion criteria when screened by telephone (see Figure 1). Of the 105 participants sent an invitation package, 30 participants (29%) were eligible to participate with BDI scores between 12 and 30. Seventy five respondents with BDI scores suggesting they had major depression (>30) were referred to a general practitioner.

Of the 30 participants entering the study, 16 patients were allocated to receive active laser treatment and 14 were randomised into the control arm. The mean age was 38.5 years (range 21-49 years) and women comprised 77% of the participants (13 active arm and 10 in the inactive arm). Other baseline data are presented in Table 1. For half the patients, the patient's general practitioner or psychiatrist had made the diagnosis of depression, in 10% there was a history of postpartum depression and in 37% antidepressants had been used previously. Four patients (13%) dropped out of the study before completing the eight week intervention, two from each arm of the study. The reasons giving for dropping out were acute illness, relocation or deterioration in mood. No patient dropped out because of adverse effects from the treatment. One control participant did not return the questionnaires

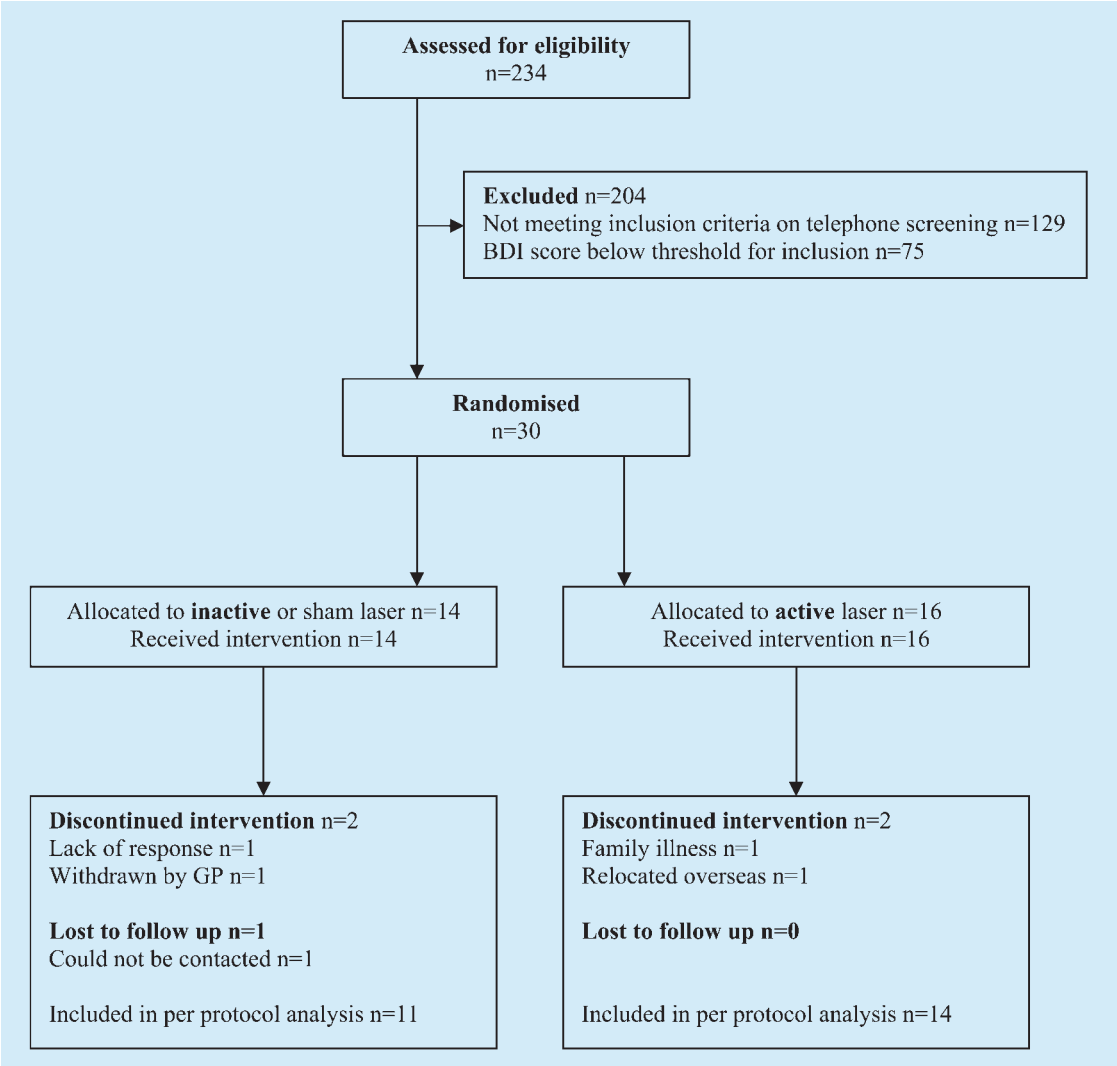

Figure 1 Patient flow through RCT of laser acupuncture for depression.

post treatment. Thus, 25 participants completed the study as per protocol (14 participants from the active group and 11 participants from the inactive arm).

Table 2 shows the baseline and change in BDI scores over the study period. A repeated measures ANOVA of BDI scores for the completers (n=25) demonstrated a significant effect of time (F=44.23, DF=4, 92, P<0.001) and switch setting by time interaction (F=4.30, DF=4, 92, P=0.003) but not for the switch setting (F=2.70, DF=1, 23, P=0.114). Subsequent post-hoc tests at each time point showed significantly improved BDI scores for the active laser group at eight weeks (P=0.006) and a strong trend at week 20 (P=0.07).

With reference to Table 2, change in BDIs from baseline were calculated and compared between active and control groups in a per protocol analysis. The changes in BDI ratings were not significantly different at four weeks, but at eight weeks the difference was significantly different between the groups receiving active versus the inactive laser treatment (P<0.001). At 12 weeks the change in BDI was not significantly different (P=0.088). However at 20 weeks the change in BDI was significantly different between groups (P=0.007). An intention to treat analysis using the last observation carried forward showed a significant group difference for change in BDI scores at the eight weeks (P=0.003) and a trend three months after the intervention (P=0.046).

Table 2 also presents the numbers of patients in each group with BDI scores greater than 11 (ie caseness of probable depression) at each time point. For the inactive laser group, 64% fulfilled the criteria for depression at the end of the study (20 weeks)

Table 1 **Baseline characteristics of patients included in RCT of laser acupuncture**

Variable	Inactive laser group (n=14)	Active laser group (n=16)	Total (n=30)
Females (n)	10	13	23 (77%)
Mean age, years (SE)	38.1 (2.3)	38.9 (1.5)	38.5 (1.3)

20 weeks	7/11 (64%)	2/14 (14%)	

BDI scores at baseline, changes (95% CI) at each measurement point, and numbers of patients scoring >11 in each group. Negative scores indicate an improvement in depression.

whilst in the active group only 14% had BDI scores greater than 11 (chi square 6.51, df=1, P<0.025).

The main aim of administering the HADS was to identify patients with anxiety and treat them at additional acupuncture points. The change in depression and anxiety subscales were not significantly different between the active and inactive laser groups (Table 3).

In response to the Adverse Effect Questionnaire, 17% of the placebo group recorded adverse effects and 29% of the active laser group. Fatigue was the main complaint in the active group. Insomnia, dry mouth and headache were also recorded. Participants reported that the side effects were mild and transient, resolving in less than 24 hours after treatment.

Table 3 **Hospital Anxiety and Depression Scale (HADS) scores**

	Inactive laser group	Active laser group	Between group comparison
HADS Depression at baseline, mean ± SEM	9.1 ± 0.6 (n=14)	9.5 ± 0.6 (n=16)	
Change at 12 weeks	-2.3 (-5.5 to 0.8) (n=11)	-4.9 (-6.7 to -3.0) (n=14)	P=0.113

HADS scores at baseline, changes (95% CI) and numbers of patients in each category at various measurement points.

Discussion

Laser acupuncture was shown to be effective in the treatment of mild to moderate depression at the end of treatment and at the three month follow up. The findings were supported by a trend in reduced caseness for depression from 100% at baseline to 36% at eight weeks and 14% at 12 weeks post intervention, compared to 64% of controls at this time point.

Limitations of this study include: small sample size; recruitment method; use of a single assessment instrument; short time period of the trial; and lack of acceptability assessment. The selection of laser acupuncture facilitated the conduct of a randomised double blind controlled trial. In planning the study, the simplicity of recruitment by advertisement was thought to outweigh the risk of selection bias. In order to compensate for this, the potential participants who passed both the telephone interview and the BDI screening were interviewed by a team psychiatrist. The small study population was of concern, as was the brevity of the trial period due to lack of funding. There were difficulties with recruitment: the large numbers of respondents (234) did not translate into a large number of participants (13%). To increase recruitment numbers, a longer recruitment period over 12 months or more or a multicentre trial might have been preferable. The dropout rate was low at 13% compared to the 30% reported by Elkin et al.[7] This might have been partly due to acceptability of the modality used and partly to the fact that the participants had the regular attention of a single practitioner resulting in a better therapeutic alliance.

The improvement in BDI score was not significant at four weeks post intervention even though it was significant at the end of the study and at 12 weeks post intervention. This suggests that the positive effect was delayed until the completion of treatment, or that the sample size was too small. In the follow up phase of the study by Allen,[9] the positive effect from needle acupuncture was no longer present by six months post intervention. If this study indicated that the effect was still present at three months, further follow up questionnaires at four, five and six months would have been useful. This would be of practical utility in making maintenance treatment plans to improve the quality of life of the depressed patient.

The HADS was poorly utilised. It would have been useful to explore anxiety as a co-morbidity and to have applied the HADS alongside the BDI at each time point. Another, possibly better measure could have been the Beck Anxiety Index, an observer rated instrument. However, the simplicity of the self-reporting BDI was a major advantage in this primary care based study.

It is not clear why the BDI was more sensitive to change than the HAD. There are two possibilities to

be considered. First, that the HADS may have been more appropriate for measuring the interrelationship between depression and anxiety, and not so appropriate for measuring depression changes alone. Secondly, as the acupuncture points were specific for depression, the BDI may have been the more sensitive instrument. One anxiety related acupuncture point was used regularly (KI10) but only in those participants who had a positive HADS scale for anxiety. Another problem identified was the lack of recording of the number of participants needing the anxiety specific acupuncture points. This should be addressed in future studies.

The adverse effect profile was reassuring in that although 29% experienced adverse effects in the active laser group, 60% of these being fatigue, the effects were transient and persisted for less than 24 hours. When compared to adverse effects from pharmacotherapy which may persist and affect patient compliance, these transient adverse effects were better tolerated .

Conclusion

Persisting alleviation of mild to moderate depressive symptoms was demonstrated in a randomised controlled sample of a primary care population treated with an eight week course of laser acupuncture. In order to confirm this positive result, a study with a larger sample is required using an observer rated depression instrument. The fact that the BDI produced a significant result but not the HADS needs to be further evaluated. This form of laser acupuncture was not designed to treat anxiety, so the HADS scale might not be as appropriate. More research is warranted to investigate acupuncture point specificity in both depression and anxiety. The prevalence of poorly managed depression in the population highlights the need for a safe, effective and well tolerated treatment appropriate for use in primary care. With minimal adverse effects, a time frame of efficacy comparable to conventional methods and high user friendliness, laser acupuncture could prove to be an important addition to the clinical armamentarium for the treatment of depression in primary care.

Acknowledgements

The author wishes to thank Dr Glenn Hunt for his advice and statistical analysis on the project; Ms Helen Bezer, research assistant, for her patience and diligence; Associate Professor Peter Schattner for his help toward completion of this study.

Summary points

- Mild to moderate depression is commonly under treated
- A double blind RCT tested the efficacy of an eight week course of laser acupuncture
- Laser acupuncture was significantly superior to sham at two measurement points
- Adverse effects were minimal, mostly transient fatigue
- The conclusions from this study are limited by small sample size

ABSTRACT

Introduction: Trials of acupuncture for the treatment of depression have produced mixed results. We examined the effectiveness of laser acupuncture compared with placebo acupuncture for the treatment of major depression.

Methods: A randomised, double blinded, placebo controlled trial was conducted in Sydney, Australia. Participants aged 18–50 years with DSM-IV major depressive disorder were eligible to join the study. Forty-seven participants were randomised to receive laser acupuncture or placebo laser at acupoints LR14, CV14, LR8, HT7 and KI3. The intervention was administered twice a week for 4 weeks and once a week for another four weeks, for a total of 12 sessions. The primary outcome assessed the change in severity of depression using the Hamilton-Depression Rating Scale (HAM-D), and secondary outcomes assessed the change in severity of depression using the Quick Inventory for Depression-Self Reporting (QID-SR), the Quick Inventory for Depression-Clinician (QIDS-CL), with outcomes assessed at eight weeks. The treatment response (greater than 50% improvement in HAM-D) and remission (HAM-D <8) were analysed.

Results: At eight weeks participants showed greater improvement in the active laser group on the primary and clinician-rated secondary outcome measures (HAM-D (mean 9.28 (SD 6.55) vs. mean 14.14 (SD 4.78 $p<0.001$); QIDS-CL (mean 8.12 (SD 6.61 versus 12.68 (mean SD 3.77)) $p<0.001$). The self-report QIDS-SR scores improved in both groups but did not differ significantly between the groups. In the active laser group, QIDS-SR scores remained significantly lower than baseline at 3 months follow-up. Response rates (active laser, placebo laser) on ITT (intention to treat) analyses were 72.0% and 18.2% ($p<0.001$), respectively. Remission rates on ITT analyses (active laser, placebo laser) were 56.0% and 4.5% ($p<0.001$). Transient fatigue was the only adverse effect reported.

Limitations: There was no follow-up for the placebo group at one and 3 months.

Conclusion: Laser acupuncture showed a clinically and statistically significant benefit with reducing symptoms of depression on objective measures.

1. Introduction

Clinical depression has been identified as one of the top health priorities worldwide. The World Health Organization quantifies unipolar depression as the fourth leading cause of total disease burden worldwide (Lopez, 2005). In addition to lost productivity, depression has a major impact on the quality of life of the sufferer. In spite of growing community awareness and attempts to destigmatise depression, 60% of the depressed population avoids professional help, seeking only symptomatic relief. Of the remainder, less than half receive evidence-based care (Ellis and Smith, 2002). Many patients with depression either refuse antidepressant drugs or discontinue them owing to side-effects, and turn to complementary and alternative medicines (CAMs) (MacPherson et al., 2006). The latter are perceived as being "natural", holistic, free of adverse effects and more nurturing than standard medical therapies. Amongst CAMs, herbal remedies such as St John's Wort and acupuncture are two of the most popular therapies (Kessler et al., 2001; Jorm et al., 2002).

Recent evaluation of the use of pharmacotherapy in depression found that only 7% of patients remitted on antidepressants (Pigott et al., 2010). The majority discontinued due to adverse effects. There was also concern that, for those who continued pharmacotherapy, the adverse effects actually increased the placebo response (Pigott et al., 2010). This sobering report raises concerns for the future

management of major depression in the community. There is therefore some urgency to evaluating non-drug treatments of depression.

There been much clinical interest in acupuncture for the treatment of depression over the last decade, with the current scientific evidence base being inconclusive. Four systematic reviews (Mukaino et al., 2005; Leo and Ligot, 2007; Halbreich, 2008; Smith et al., 2010) found acupuncture to be no more effective than sham or waitlist control strategies. The efficacy of acupuncture as an adjunct to standard treatment is also unclear. Methodological issues have plagued many of these investigations.

There are many acupuncture techniques, most of which traditionally use needle puncture. However there are other modalities utilised such as acupressure and low intensity laser. Laser acupuncture (LA) has emerged as a well-accepted technique due to its ease of application, and being both needle and pain-free, it is non-invasive and presents no risk of infection.

Laser is an acronym for Light Amplification by Stimulated Emission of Radiation. In brief, the chosen lasing medium (in this study, this is a semiconductor made from gallium–aluminium-arsenide or GaAlAs) is excited by an external energy source (battery pack consisting of AA alkaline batteries) to a higher energy state and a portion of this is released as the laser output from the laser unit (Baxter, 1994). The laser output is usually measured in milliwatts in low intensity laser acupuncture units.

Being pain-free and non-invasive, low intensity laser lends itself to clinical applications in paediatrics. LA in the treatment of children with headaches significantly reduced the number of headache days ($p < 0.001$) with active laser compared to placebo laser ($p < 0.22$) (Gottschling et al., 2008). LA to acupoint PC 6 also significantly reduced postoperative vomiting in children undergoing strabismus surgery (Schlager et al., 1998) and when this modality was used in school age children with asthma, there were significantly less days of febrile infections and reduction in bronchial hypersensitivity (Stockert et al., 2007). An earlier study on low intensity laser (with lasing medium GalAlAs) described the relationship between pain attenuation and significant change ($p < 0.001$) in serotonin plasma ratios after laser application (Mizokami et al., 1993). Endogenous opiate like peptides and serotonin plasma levels were found to increase with laser puncture analgesia (Zhong et al., 1989).

There has been one pilot laser acupuncture study (Quah-Smith et al., 2005) that reported LA as efficacious compared to placebo laser (PA) ($p < 0.001$) in the treatment of mild to moderate depression in a primary care setting, and the treatment response persisted for 3 months following laser intervention ($p < 0.01$). This improvement in mood was more significant at the end of the series of LA, with data showing only a trend for improvement at 4 weeks post LA and then was very significant again at 12 weeks post LA. This fluctuation may be attributable to, possibly, a delay before the longer- term effect of acupuncture (in this case, mood improvement) was evident (Quah-Smith et al., 2012). There were no significant adverse effects. It has also been shown, using functional magnetic resonance imaging (fMRI), that LA produces significant activation and deactivation in fronto-limbic-striatal brain regions compared to placebo (Quah-Smith et al., 2010). In this study, we examined the efficacy of acupuncture with reducing the symptoms of depression compared with a placebo control Fig. 1.

2. Methods

A double blinded, randomised, placebo controlled clinical trial was undertaken at the Black Dog Institute and a private acupuncture clinic in Sydney, Australia. Participants were recruited from the media and online advertising. Individuals aged 18–50 years were eligible to join the trial if they were diagnosed with major depressive disorder meeting DSM-IV (American Psychiatric Association, 1993) criteria for current major depression, a score of ≥ 14 on the Hamilton Depression Rating Scale (HAM-D_{17}) (Hamilton, 1960), and a score > 10 on the Quick Inventory of Depressive Symptomatology – Clinician (QIDS-CL) and Quick Inventory of Depressive Symptomatology – Self Reporting (QIDS-SR) (Rush et al., 2003). Participants needed to be free of psychotropic drugs and herbal remedies for at least four weeks prior to trial entry, and no co-interventions were permitted during the trial. Participants were not eligible if the duration of depression was greater than two years, or there was a history of hypomania or mania, substance abuse disorders, known central nervous system lesions, known uncontrolled endocrine disorders, pregnancy or potential pregnancy, or active suicidal tendencies. Suitability was confirmed by clinician screening. Participants provided written informed consent and the study was approved by the Human Research Ethics Committee of the University of New South Wales (HREC No. 07258).

Following recruitment, participants were randomised to either laser acupuncture (LA) or placebo acupuncture (PA). Randomisation was computer-generated. Only the project manager (JAH) was privy to this sequence to allow allocation of participants to LA or PA. Switch 'A' or 'B' was identified for each participant and this was kept in an envelope in each participant's folder (identifiable by the recruitment code alone of initials and recruitment number). The medical acupuncturist was not allowed access to each participant's folder.

All participants received treatment at selected putative 'depression' acupoints (unilateral right sided Qimen LR14, Juque Ren14, left sided Ququan LR8, left sided Shenmen HT7) and unilateral (right side) Taixi KI3. Twelve sessions of the intervention were performed: twice weekly for four weeks and once a week for another four weeks. The choice of acupoints administered to both groups included – Qimen LR14, Ququan LR8, Juque CV14, Shenmen HT7 and Taixi KI3 – was based on the principles of TCM (Macioca, 1994; Aung and Chen, 2007), No TCM differential diagnosis was undertaken as the selected acupoints have been trialled successfully in our pilot study (Quah-Smith et al., 2005). Qimen LR14 and Juque CV14 are "alarm points" empirically known to act rapidly. LR14 and LR8 are useful in mood disorders and stressful states. CV14 is useful where somatic changes occur including pectoral pain, headaches, epigastric pain and nausea. HT7 is a classical acupoint used to calm the individual and help in insomnia. KI3 is useful for addressing fatigue and reducing anxiety.

KI3 replaced CV15 in the pilot study, for the purposes of treating the anxiety component found in 85% of depressives (Tiller, 2012). Empirically, CV14 is used more frequently than CV15 and the former is the "alarm point" as previously mentioned on the Heart meridian (Aung and Chen, 2007).

This clinical study is part of a series of clinical and biological investigations into LA in depression: KI3 on the right had side was treated and LR8 on the left hand side so laterality could be tested (whether acupoint stimulation with LA activates ipsilateral or contralateral brain regions) in our associated functional magnetic resonance (fMRI) investigations mentioned above (Quah-Smith et al., 2010, 2012).

Acupoint location followed the guidelines documented by the World Health Organisation were applied (World Health Organization, 2008). IQS administered the LA: she is a Fellow of the Australian Medical Acupuncture College and has been teaching and practising acupuncture for 21 years.

For those receiving LA, 100 mW low intensity infra red (808 nm) units were produced, based on the Moxla^{R} protocol, by Advantage Health Care, Victoria, Australia for this study. The

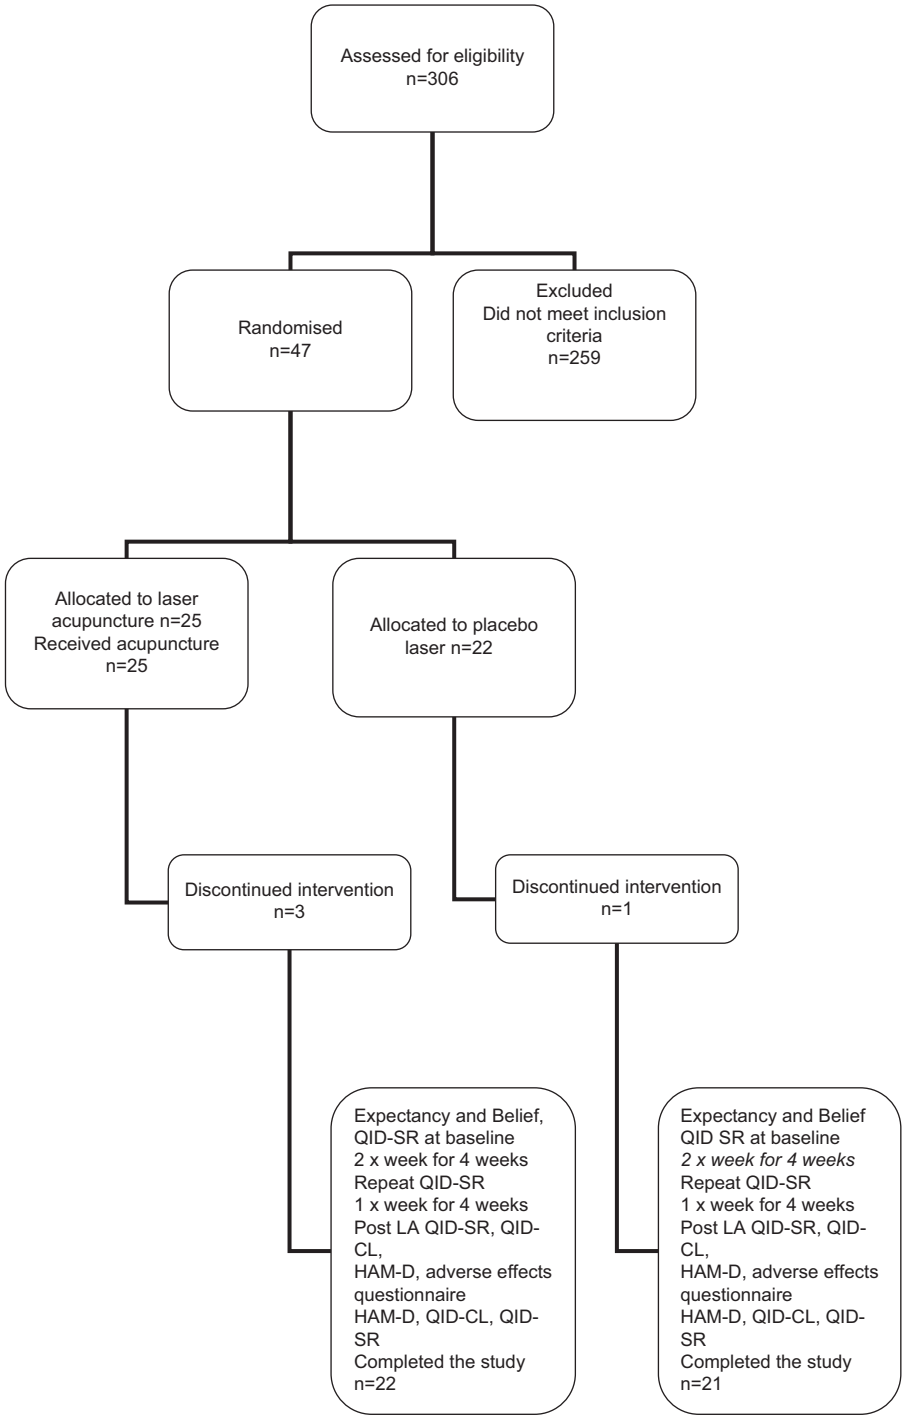

Fig. 1. Recruitment and participant flow through the trial.

laser beam is infra-red in frequency range (808 nm) and is not visible to the naked eye. The laser probe is fully in contact (perpendicular to the skin surface) to avoid scatter of the laser beam. Both laser units had a concealed section with a flick switch numbered by the manufacturer as 'A' and 'B', one of which was the placebo option, known only to the project manager (JAH) and the manufacturer. The control panel of the laser units beeped and a red light flashed when the laser probe button was on either A or B. Each unit was separately set up for placebo or laser options.

None of the participants reported any sensation apart from a light touch of the laser probe when it was applied to the skin. The flick switches were concealed with wide fabric strip (velcrose) bands. The prepared unit was handed to the medical acupuncturist at the time of treatment and retrieved immediately after.

The laser was applied to each acupoint for 10 s to deliver one joule of laser energy at each acupoint, giving a total of 5 J for 5 acupoints per session. For those in the placebo group the laser infra- red beam did not come on when the switch was pressed. Each participant wore black lensed laser protective glasses supplied by the manufacturer and was treated in a brightly lit environment. The laser probe was in direct contact with the participant's skin surface perpendicularly before commencement of laser delivery. The participants and acupuncturist were blind to group allocation.

The primary endpoint was measured at the 2 months mark after the last treatment (HAM-D). Secondary endpoints were measured at the one month mark (QID-SR), at the two months mark after the last treatment (QID-SR, QID-CL), one month post treatment (QID-SR) and three months post treatment (QID-SR). The primary outcome measured a reduction in the severity of depression defined as a $>50\%$ reduction in score, of the 17-item HAM-D. The secondary outcome measured remission at the end of treatment defined as a score of ≤ 7 on HAM-D or ≤ 5 on QIDS-CL and QIDS-SR. The structured interviews for rating were conducted by trained clinicians blind to group allocation. Inter-rater reliability of the rating clinicians was high prior to trial commencement. Practice ratings were conducted to ensure reliability. The raters were (MH designated main rater), IQS (for emergencies) and for screening only, JAH.)

We evaluated the baseline expectations and beliefs of the participants and whether there might be any contributory bias (positive effect) to their scores, using a self report 6-item Expectancy and Belief scale, adapted from the University of Michigan study on acupuncture and fibromyalgia (Harris et al., 2005). Upon completion of the 12 sessions of acupuncture, JH asked all participants to complete a 6-item scale with score range of 0 to 6 (6 being maximum intensity) to assess any adverse effects:1. dizziness, 2.aches, 3.transient fatigue, 4.prolonged fatigue, 5.vagueness, and 6.nausea). An assessment of blinding was made from each participant and the medical acupuncturist.

The results of the pilot study showed a large effect size (Cohen's d) of approximately 0.90, based on differences between the placebo and active groups in the change in the Beck Depression Inventory (BDI) scores (Beck et al., 1961). To detect a similar effect size for measures used in the present study, with power of 80% and $\alpha=0.05$, we estimated that a total sample of 44 participants would be required, assuming approximately equal number of participants in placebo and active groups.

The analysis was carried out by JC. Repeated measures ANCOVA was used to examine differences between the active and placebo groups in changes in the HAM-D, QIDS-CL and QIDS-SR measures. Control variables were age, sex and expectancy. The Expectancy variable was calculated as the first principal component (Question1: "In general, do you think acupuncture works?") of the six expectancy items and was rated from 1 (very negative) to 7 (very positive). The remaining 5 questions in the Expectancy and Beliefs Questionnaire were rated 0% to 100% by the participants: (Questions 2: Do you want LA to improve your mood and help your depression; Question 3: Do you want LA to help your general wellbeing: Question 4: How confident are you that LA will improve your mood; Question 5: How confident are you that it will improve your fatigue; Question 6: How confident are you LA will alleviate your other symptoms for (physical complaints).). Mean values were calculated for Questions 2 to Question 6.

Per-protocol analyses were performed using only those participants with both pre- and post-treatment ratings, as well as Intention to Treat (ITT) analyses in which last observed value carried forward for missing post-treatment ratings. In order to better understand which domain of depression was most affected by the laser acupuncture intervention, the repeated measures ANCOVA was also performed with each of the items in HAM-D and QIDS-CL as dependent variables. Only the clinician based assessments were selected for the latter analysis in order to better evaluate items such as somatic symptoms, psychomotor agitation and retardation, as well as general interaction. Response and remission rates based on HAM-D and QIDS scores at post-test were calculated. Remission was at HAM-D <8 or QIDS-CL <6 and QID-SR <6 (Insel, 2006). The statistical significance of differences between active and placebo groups in response and remission rates were investigated using the chi-squared test. Number-needed-to-treat (NNT) values were calculated for remission rates. An assessment of blinding was examined using the Chi-square test.

3. Results

Recruitment commenced in mid-August 2007 and continued until the end of August 2009. In total, 306 potential participants were assessed for eligibility. The majority of those excluded had chronic depression of more than 2 years or were on antidepressant therapy and did not wish to stop their medication. Forty-seven were randomised. Twenty-two recruited subjects completed laser acupuncture (LA) and 21 completed the placebo acupuncture (PA). There were four dropouts (LA 3; PA 1). The reasons for dropout were: LA group—one participant withdrew after 2 weeks LA, the subject felt her mood was not improving and may be deteriorating and chose to return to pharmacotherapy, one was unable to keep up attendance and withdrew, and the last completed the series of LA but was too unwell to continue with post LA QID-SR. The dropout in the PA group withdrew for personal reasons after completing the treatment series.

The baseline characteristics are presented in Table 1. Thirty-four participants were female (72%), thirty-five were working (74%). Twenty-six (55%) had previously sought needle acupuncture treatment. Participants had clinically significant depression with a DSM-IV diagnosis of major depressive disorder and were drug free or drug naive at the time of their entry into the trial. Clinical depression scores included mean scores on the HAM-D of 20.03 (SD 4.2), QIDS-CL 20.6 (SD 4.3), and QIDS-SR 18.40 (SD 4.6). Twenty-seven participants reported duration of depression of greater than three months (57%), and thirty-two reported a previous episode of depression (68%). No statistically significant differences between LA and PA were found at baseline. There was no statistical difference between groups for expectancy ($p=0.412$). All participants completed all scheduled intervention sessions.

In addition to the baseline characteristics, mean values for the remaining questions in the expectancy and belief questionnaire were: wanting LA to help their depression (92.0%), wanting LA to help their general wellbeing (42.7%), confident that LA will improve their mood (30.5%), confident that LA will alleviate their fatigue (28.8%) and confident that LA will alleviate all their other physical complaints (28.0%).

3.1. Treatment effects

Table 2 Statistically significant group by occasion interactions were found with both per-protocol and ITT analyses for HAM-D ($P=0.001$ and 0.013, respectively) and for QIDS-CL ($P=<0.001$ and 0.016). For QIDS-SR, although there was an overall statistically significant decrease in depression scores over time (F1, $39=4.63$, $p=0.038$ and F1, $42=0.013$, respectively), there were no differences between groups ($P=0.571$ and 0.390). In these analyses, no statistically significant interactions with occasion were observed with any of the control variables, sex, age or expectancy, except for the per-protocol analysis for changes in QIDS-CL, in which greater reductions in scores were found for those with higher expectancy scores (F1, $38=5.61$, $p=0.023$).

3.2. Ancillary analyses

In the analyses of depression symptoms HAM-D item-by-item analyses, five items showed statistically significant group by occasion interactions, after controlling for age, sex and expectancy. These were: depressed mood ($P=0.044$), late insomnia

Table 1

F and p values are for statistical tests for interactions between group and occasion, with control variables age, sex and Expectancy. 17-item Hamilton-Depression Rating Scale HAM-D; Quick Inventory for Depression-Self Reporting QIDS-SR; Quick Inventory for Depression-Clinician QIDS-CL.

(P=0.014), anorexia (P=0.035), somatic symptoms (P=0.00021), somatic anxiety (P=0.013) and agitation (P=0.035). [Supplementary Table 1]. In the QIDS-CL, five items with significant group by occasion interactions. These were: waking up too early (p=0.002), increased or decreased appetite (p=0.002), view of self (p=0.042), general interest (p=0.007) and energy level (p=0.021). After Bonferroni's correction for multiple comparison, somatic symptoms (heaviness in limbs, back and head; backache, headache and muscle aches; loss of energy and fatigability) were still highly significant (p=0.00021). [Supplementary Table 1].

Statistical analyses were undertaken to ensure there was no significant difference between raters. Statistical analyses were undertaken on pre- and post-LA-treatment scores only. In the rater comparisons, there was a constant trend for MH to rate lower than QS but the only statistically significant difference was for pre treatment QID-CL (means 18.17 and 21.13, p=0.041) [Supplementary Table 2].

Table 3
Response and remission rates, and numbers needed to treat (NNT) for per-protocol and intention to treat (ITT) analyses by treatment group.

	Placebo laser n/N (%)	Laser acupuncture n/N (%)	χ^2 ($df=1$)	P	NNT
Per-protocol analyses					
HAM-D > 50% reduction	4/21 (19.0%)	18/22 (81.8%)	18.94	.00005	1.59
HAM-D < 8 at post-test	1/21 (4.8%)	14/22 (63.7%)	16.40	.00005	1.70
QID-CL < 6 at post-test	0/21 (0.0%)	12/22 (54.5%)	15.89	.00006	1.83
QID_SR < 6 at post-test	1/21 (4.8%)	5/23 (21.7%)	2.69	.188	5.89
ITT analyses					
HAM-D > 50% reduction	4/22 (18.2%)	18/25 (72.0%)	13.61	.0004	1.86
HAM-D < 8 at post-test	1/22 (4.5%)	14/25 (56.0%)	14.26	.0001	1.94
QID-CL < 6 at post-test	0/22 (0.0%)	12/25 (48.0%)	14.18	.0001	2.08
QID_SR < 6 at post-test	1/22 (4.5%)	5/25 (20.0%)	2.51	.194	6.47

Hamilton-Depression Rating Scale (HAM-D_{17}); Quick Inventory for Depression-Self Reporting (QIDS-SR); Quick Inventory for Depression-Clinician (QIDS-CL).

3.3. Treatment response rate, treatment Effects on remission Rates, and Numbers needed to treat (Table 3)

Response rates (> 50% reduction in HAM-D scores) were 81.8% in the active group and 19.0% in the placebo group ($p < 0.001$) for the per-protocol analysis, and for the ITT analyses these were 72.0% and 18.2% ($p < 0.001$), respectively. The numbers needed to treat (NNT) to achieve a response over 8 weeks of LA were 1.59 for per-protocol analysis and 1.86 for the ITT analysis. Remission rates were significantly different between the two groups based on a criteria of HAM-D < 8 or QIDS-CL < 6, for both per-protocol and ITT analyses ($p < 0.001$), but not based on a criteria of QIDS-SR < 6 ($p=0.188$ and 0.194). For HAM-D < 8 criteria, remission rates in the active group were 63.7% and 56.0% for the two types of analyses, and for the placebo group, 4.8% and 4.5%. Based on the criterion of QIDS-SR < 6, remission rates in the active group were 21.7% and 20.0%, and in the placebo group 4.8% and 4.5%, respectively. NNT for remission based on the HAM-D < 8, QIDS-CL < 6 and QIDS-SR < 6 criteria were 1.70. 1.83 and 5.89, respectively, for the per-protocol analyses, and 1.94, 2.08 and 6.47, for the ITT analyses, respectively Table 3.

3.4. Follow up at one and three Months post treatment for laser acupuncture group

QIDS-SR follow-up scores were obtained for the laser acupuncture group at one month ($n=18$), and at 3 months after study completion ($n=16$). Repeated measures ANCOVA, controlling for age, sex and expectancy, showed statistically significant differences between pre-test scores and each of end of LA, and 1-month post LA and 3 months post LA follow-up scores (all $P=0.001$). No statistically significant differences were found between the post-test and 1 and 3 months QID-SR scores.

3.5. Integrity of blinding

The percentage of participants in the active group that offered guesses 'active', 'placebo' and 'unsure' were 65.2%, 30.4% and 4.3%. For participants in the placebo group, the corresponding percentages were 60.0%, 30.0% and 10.0%. These differences were not statistically significant between groups (Chi-square=0.537, $df=2$, $p=0.765$). Overall, the acupuncturist's patterns of response for the three options (active vs. placebo vs. unsure) were evenly distributed with no significant difference in proportion of guesses (Chi-squared=0.125, $df=1$; $p=0.723$).

3.6. Adverse effects

There were no significant inter-group differences in adverse effects. Out of a maximum score of 6, the only adverse effects with mean scores > 0.50 were: in the LA group, minimal transient fatigue (0.67); and in the PA group, aches (0.11), transient fatigue (1.0), days of fatigue (0.71) and vagueness (0.52).

4. Discussion

This is the first adequately sized double blind controlled trial of LA in depression. LA was associated with a clinically and statistically significant reduction in HAM-D scores, and a significant number of patients with major depression responded or remitted on this measure after 8 weeks of treatment. This result was supported by analysis of the secondary clinician-rated measure, but not by the self-rated measure. Although this positive effect was found in the earlier pilot study at 3 months post LA compared to PA (as recorded using the self reporting Beck Depression Inventory Scale (BDI)), we cannot make any conclusive comments that this was the case in this study. In the LA group, the positive effect was still measurable at the third month post treatment (QID-SR $p < 0.001$ compared to baseline) but we did not follow up the QID-SR in the PA group after completion of intervention due to our ethical responsibility (a condition of our ethical approval) to break the blinding and offer the PA group active laser upon completion of intervention. Clinician ratings at the 3-month post treatment mark, which were not carried out due to resource limitations, would have overcome this limitation. There were no significant adverse effects of LA.

The results of this trial must be examined in light of the accumulating literature on acupuncture in depression. A recent Cochrane Review (Smith et al., 2010) examined 30 trials of acupuncture in depression and concluded that the evidence of the effectiveness of acupuncture in depression, relative to sham acupuncture, was inconclusive. The majority of trials compared acupuncture with drug treatment and found no group differences. Two trials found acupuncture to have an additional beneficial effect when co-administered with medication. Most studies used either manual acupuncture or electro-acupuncture, with the exception of one small study that examined laser acupuncture (Quah-Smith et al., 2005), the latter finding LA to be superior to placebo in its anti-depressant effect. There are three possible explanations to justify the large clinical effect observed in this trial. First, the double blind study design allowed an evaluation of the efficacy of laser acupuncture compared with a placebo and therefore reduced the potential for effects arising from the use of

active sham points seen in manual acupuncture studies. Our findings have been supported by our fMRI study (Quah-Smith et al., 2005) on healthy subjects where we demonstrated significant brain activation patterns greater than rest or placebo with active laser. Second, there was a significant improvement in the debilitating somatic changes that accompany depression including somatic symptoms (muscle aches and pains, headaches, digestive changes), and sleep patterns. Consequently participants' quality of life improved. Third, there were little or no adverse effects using the low intensity laser. This clinical study returned a transient mild fatigue (for only a few minutes after each laser session which appeared and resolved within the couple of hours after the laser intervention).

The lack of significant inter-group difference in the self-report measure in our study is worthy of comment. The high expectancy of being in the LA group by all subjects (60% in both LA and PA groups thought they were in the LA group when asked by JH which group they were in upon completion of the intervention) may be a factor. Also at baseline, the mean Expectancy Score for wanting LA to improve their mood and help their depression (Question 2) by all the subjects was very high (mean score of 92%). This desire for LA to work did not, however, carry through to wanting LA to help their wellbeing (42.7%), confidence their mood will improve (30.5%), confidence their fatigue will get better (28.8%) nor alleviate other physical symptoms they might also have (28.0%). Another factor may be that the HAM-D and QID-CL rated different items of depression to the QID-SR and the acupuncture effect in depression is better measured by the first two scales. We did not foresee that changing the self-rating instrument from BDI in our pilot study to the QID-SR in this study would be of concern. Unfortunately, this was not the case. The BDI correlated well with the HAM-D in the assessment of depression (Schotte et al., 1997; Hotopf et al., 1998; Kim et al., 2009). For this reason, we used the BDI as the primary measure in the pilot study as we did not then have the resources to use the HAM-D. Our finding in the pilot study that the change in score for BDI from baseline was significant ($p < 0.001$) in the LA group has been replicated in this study with the change in score of the HAM-D ($p < 0.001$). Our secondary measure in the pilot study, the Hospital Anxiety and Depression Scale (HADS) did not record this significant improvement at all (Zigmund and Snaith, 1983).

Upon further evaluation at the item-by-item level, we examined items of depression in the HAM-D, the BDI (as it was our primary measure in the pilot study) and the QID-SR: the HAM-D measured somatic changes (Questions 8, 9, 13) and the QID-SR had no clearly defined somatic symptoms questioning. Irritability is measured in the HAM-D (Question 12) and interestingly, also by the BDI (Question 11) in the pilot study, but does not feature as an item in the QID-SR. Although psychomotor agitation is measured by all three instruments, psychomotor retardation is only measured by the HAM-D (Question 16). Furthermore, the QIDS-SR did not correlate well with its sister scale the QIDS-CL in this study and the primary measure the HAM-D, while the latter two correlated well. The somatic items (Q 3,Q 6,Q 7,Q 14 in QIDS-CL) (Supplementary Table 1) were found to show a significant change in LA; these items were measures of pain, appetite, speech and agitation, which are possibly better assessed by a clinician. In the QIDS-CL, improvement in sleep (Q 1) and appetite (Q 7) were greater in the LA group. These differences may be attributed to laser acupuncture induced somatisation effects as described previously, including autonomic modulation (Haker et al., 2000; Agelink et al., 2003; Wu et al., 2009; Napadow et al., 2012; Quah-Smith et al., 2012). After correction for multiple comparisons, the HAM-D item on change in somatic symptomatology was still highly significant ($p = 0.00021$) reflecting the most important positive physical changes from active laser acupuncture resulting in improved quality of life. In spite of the participants' lack of confidence in LA alleviating their fatigue or their physical symptoms such as headaches and back aches, those who received active laser certainly benefited as measured by the HAM-D item on somatic changes. It is apparent now that the choice of primary and secondary measures including the self-reporting measure is important if we want to better measure the acupuncture effect.

In this study, not being able to follow up at one and three months post intervention with the QID-SR in the PA group imposes a limitation- if there was a delayed or prolonged effect of LA we have missed the opportunity to measure this effect compared to the PA group. However there is emerging evidence of this prolonged or delayed effect as measured by fMRI (Rheu et al., 2011; Quah-Smith et al., 2012).

An important strength of the trial was that blinding was successfully maintained for study participants. Not only does LA lend itself to blinding easily because of the lack of skin sensation from laser stimulation, the allocation, administration and evaluation aspects of the trial were kept separate. Unforeseen circumstances necessitated IQS to be a rater as well. However analysis of the ratings by MH and IQS did not show any significant difference between the two raters for the post treatment scores, only a tendency for MH to overall rate a lower baseline QID-CL compared to IQS. This lower baseline QID-CL would have exerted a conservative effect by lowering post treatment scores. Post-treatment questioning of participants and IQS did not suggest that blinding had been compromised.

We therefore explain the discrepancy between objective and subjective ratings to be due two possibilities: (a) the objective measures of depression improved to a greater extent than the subjective measures. An item-analysis of HAM-D revealed 5 items as being significantly affected by treatment: depressed mood, late insomnia, anorexia, somatic symptoms, somatic anxiety and agitation, partially supporting this possibility; (Supplementary Table 1). (b) our choice of self rating scale the QID-SR in this study did not measure some of the items of depression which improve with LA (for example, irritability and psychomotor retardation). In addition, the somatic symptoms changes with LA were also highly significant ($p = 0.00021$) in the HAM-D item-by-item analysis.

In studies of major depression, it has been found that the placebo response is significant regardless of the treatment type being tested and is related to the study design and study population (Brunoni et al., 2009). The frequent visits for treatment and the contact with the supportive research team are likely to have exaggerated the placebo effect, especially at a subjective level. JAH also recorded the relatively long periods of time (20–30 min) some of the subjects would stay on in her office to chat (unsolicited by JAH) or arrange appointment times. The conditioning effects of repeated visits leading to increased learning and increased placebo response have previously been described (Colloca et al., 2010).

The mechanism of action of LA, and indeed all acupuncture as a potential anti-depressant treatment, is poorly understood. Various mechanisms have been suggested for needle acupuncture, which include stimulation of large peripheral nerves, neurovascular bundles, mechanoreceptors, or free nerve endings, but no neuroanatomical structure or pathway has been clearly established as mediating the therapeutic effect (Napadow et al., 2008). More recent attention has been on the intermuscular/intramuscular loose connective tissue, as many meridians and acupuncture points align with this (Langevin and Yandow, 2002). Acupuncture meridians have also been reported to have lower electrical impedance and higher capacitance compared to adjacent controls, which may justify the use of electroacupuncture, although the data on this are not conclusive (Ahn et al., 2008). In relation to the use of laser, the mechanisms are poorly understood.

The choice of acupoints for this trial was based on recommendations in TCM for the treatment of depression (Macioca, 1994; Aung and Chen, 2007), the highly significant results of our pilot study and the neuroimaging evidence we have gathered with regards to this suite of acupoints in depression (Quah-Smith et al., 2012). In practice, acupoint efficacy is not specific, and one acupoint can be used for several different conditions, just as one medical condition can be managed with several acupoint locations. Empirical basis for the choice of acupoints is therefore weak and requires further evaluation. There is however some emerging evidence for acupoint specificity (Jin et al., 2004; Yan et al., 2005; Campbell, 2006). For example, in a functional magnetic resonance imaging (fMRI) investigation of acupoints considered to be useful in depression performed in a healthy sample, HT7, considered to be an anti-anxiety acupoint in TCM, did not have any significant brain response (Quah-Smith et al., 2010). The neuroanatomical pathways by which laser stimulation produces its effect are also not known, although a role has been postulated for unmyelinated C fibres (Olausson et al., 2002).

There is further evidence that acupuncture produces brain changes that are consistent with a potential therapeutic effect. Some neuroimaging and neuroendocrine studies have suggested that needle acupuncture affects hypothalamic as well as extra-hypothalamic functions and modulates mood (Hsieh et al., 2001; Napadow et al., 2007). Laser acupuncture of a foot acupoint, classically used for treating visual problems, was demonstrated to cause activation of the occipital cortex (Siedentopf et al., 2002). More recently, our group showed in an fMRI study that LA stimulation of the acupoints used in the current study lead to activation of frontal-limbic-striatal brain regions, with the pattern of neural activity being somewhat different for each acupuncture point (Quah-Smith et al., 2010). This argued for the plausibility of LA as an anti-depressant treatment, although the relative merits of the various acupoints, or their combinations, are unknown.

The promise of improved efficacy, in particular, the clinically and statistically significant improvement of somatic symptomatology and lack of adverse effects is a potent combination for improving the quality of life for the depressed. The efficacy of LA relative to established treatments is not known, and it is therefore difficult to suggest a place for it in today's repertoire of anti-depressant treatments. A recent study did however use acupuncture as augmentation therapy in antidepressant partial and non-responders (Yeung et al., 2011). Our study also does not further our understanding of potential mechanisms by which the response occurs.

5. Conclusion

Low intensity laser acupuncture was associated with objective improvement in depression. Further studies are needed to replicate this finding, and larger trials will help determine the predictors of good response. It is also important to examine longer-term effects, and whether repeated applications are necessary to maintain such benefit.

Role of funding source

This study was funded by the Black Dog Foundation and a grant from a private philanthropist.

Conflict of interest

The authors have no conflict of interest to declare.

Acknowledgements

We wish to thank Scientia Professor Gordon Parker, the Black Dog Foundation and Mr Charles Scarf for their support and generosity, Scientia Professor Perminder Sachdev for his support, Associate Professor Vijaya Manicavasagar for her counsel, Julie Ann Ho (JAH) for her role as the research project manager, Dr. Mark Horowitz for his role in pre and post acupuncture assessments, Matthew Hyett (BDI) for his role in helping establish inter-rater reliability for the project, BDI staff for their kind support and enthusiasm always and the staff at Albert Medical Acupuncture for their support. Thanks also to Professor Rick Harris (University of Michigan) for his permission to modify his expectancy and belief measures for acupuncture in pain for our study.

SHORT COMMUNICATION

Using acupuncture to treat depression: A feasibility study

KEYWORDS
Depression;
Acupuncture;
Sham control

Summary
Objectives: To establish the feasibility of conducting a randomised controlled trial to evaluate the efficacy of acupuncture in the treatment of mild-to-moderate depression. Control group intervention, blinding of treatment, outcome measures and the acceptability of such a trial amongst participants were key factors to be addressed. The findings from this study will be used to determine the design of a phase III randomised controlled trial.
Design: Nineteen participants were recruited through general practices in London, UK. Participants were randomly assigned on a 2:1 basis to either 12 sessions of verum acupuncture or 12 sessions of sham acupuncture (control). Sham acupuncture involved actual needling but at sites considered to be unrelated to depression.
Main outcome measures: The Beck's Depression Inventory (BDI) and the RAND 36 Item Health Survey 1.0 (RAND) were completed at baseline and at the end of treatment or at treatment dropout. All participants also attended a brief qualitative interview at the end of the study.
Results: Treatment dropout was low and there were high levels of patient enthusiasm for a study of acupuncture. Referrals from General Practitioners (GPs) were lower than expected. The sham control method successfully maintained participant blinding to treatment and enabled the specific (or active) component of an acupuncture intervention to be isolated and its efficacy assessed. The outcome measures were sensitive enough to record changes in depressive symptoms and quality of life and are appropriate for use in a larger trial.
Conclusions: This feasibility study has provided important information that can be used to guide the design and methodology of a full-randomised controlled trial.

Introduction

Depressive disorders are expected to become the second highest cause of disease burden worldwide by 2020.[1] Around 70% of all primary care consultations are reported to involve individuals with depressive disorder.[2]

Acupuncture may be a promising treatment in primary care for individuals with depressive disorders[3–5]; however, the evidence for use of this technique in such cases is inconsistent or inconclusive, and further trials are required.[5–7] The objective of this study was to establish the feasibility of conducting a randomised controlled trial to evaluate the efficacy of acupuncture in the treatment of mild-to-moderate depression. Previous report has highlighted the need for greater methodological rigour in acupuncture trials[6]; therefore, this feasibility study was designed to focus on patient recruitment, to identify a suitable control group intervention, to explore treatment blinding, and to ascertain suitable outcome measures.

Materials and methods

Accrual of participants

Participants were recruited in seven general practices in North London, UK. General Practitioners (GPs) provided information to eligible participants during routine consultations and posters and leaflets describing the study (and inviting contact) were displayed in practice waiting rooms. Participants were screened using a self-completion Beck's Depression Inventory (BDI) and those who scored at least 14 were contacted.

Following referral or expression of interest, the participants were screened for eligibility.

Inclusion criteria

(1) Aged at least 18 years; (2) ''mixed anxiety and depression'' or ''mild-to-moderate depressive episode with or without somatic syndrome''[8] as diagnosed using the Clinical Interview Schedule—Revised.[9]

Exclusion criteria

(1) Pregnancy; (2) history of substance abuse or brain damage; (3) other psychiatric disorder preceding the onset of depression; (4) in receipt of concurrent alternative treatments or a talking therapy for repression; (5) in receipt of pharmacological treatments for more than 3 months in the past year.

Randomisation and treatment blinding

Participants with confirmed eligibility attended a diagnostic session with the acupuncturist and were then randomised. The acupuncturist elicited the underlying imbalances of the participants without reference to 'depression'. A member of the research team (S.A.) was independently responsible for randomisation off-site, and used a block method on a 2:1 ratio with two-thirds of participants receiving verum acupuncture.

The member of the research team responsible for randomisation informed the acupuncturist by telephone of each patient's randomisation after they had completed their diagnostic session. All other researchers, including assessors, and the participants were blinded to treatment. The acupuncturist received training from a member of the research team who has extensive clinical trial experience. The training included advice on how to maintain professionalism and confidentiality about assignment of treatment.

Intervention

Participants were randomised to receive either 12 sessions of manual verum acupuncture or 12 sessions of manual sham acupuncture (control). Each session lasted 40 min and was provided during usual clinic hours by an accredited TCM Healthcare practitioner with 10 years' clinical experience.

Verum acupuncture—rationale and method

A formula combined with two additional discretionary points was used in the acupuncture treatment. Box 1 (published in online version at http://sciencedirect.com/ as supplementary data) shows the points used in the verum group, the range of needling depth, and the dimensions of the needles used. Choice of points and needling depth was individualised according to TCM Healthcare principles[10] and body mass of the participant.

Sham acupuncture—rationale and method

Sham acupuncture involves actual needling but at sites considered to be unrelated to depression. The same sham points were used on all participants in the sham group (Box 1, published in online version at http://sciencedirect.com/ as supplementary data). In addition, only shallow needling was undertaken, there was no needle stimulation after insertion and *de-qi* was avoided.

Needle retention time was 20 min for both verum and sham control treatments.

Outcome assessment

The primary outcome measure was the BDI.[11] The secondary outcome measure was the RAND 36 Item Health Survey 1.0 (RAND).[12] Both the BDI and the RAND were completed at baseline and at the end of treatment or at treatment dropout. All participants also attended a brief qualitative interview at the end of the study. The interview was designed to explore the participant's experiences of the study. The participants were also asked to indicate to which study group they believed they had been assigned. All baseline outcome measures were assessed face-to-face at the participant's general practice. Where possible, end point assessments were also conducted face-to-face. In cases where this was not possible, end point assessments were conducted by telephone.

Analysis

Brief descriptive analysis of the BDI and the RAND was used to examine changes in mean scores. Qualitative data were coded into the categories 'acupuncture treatment had a positive impact', 'acupuncture treatment had a negative impact' and 'acupuncture treatment was ineffective'.

Ethical approval was obtained from Barnet, Enfield and Haringey Local Research EthicsCommittee. All participants provided signed informed consent.

Results

Enrolment

Twenty patients were recruited into the study over a period of 15 months. One patient withdrew from the study before randomisation. Thirteen participants were randomised into the verum group and six into the sham-control group. Endpoint data were available for all 13 participants in the verum group and for four of the six participants in the sham-control group. The flow of participants through each stage of the study is shown in Fig. 1. Most participants were self-referred.

Baseline characteristics

The mean age of participants was 39.9 years (S.D. = 12.1) in the verum group (nine female, four male) and 48.5 years (S.D. = 10.2) in the sham-control group (five female, one male). Participants in the verum group had slightly higher depression scores on the BDI and slightly lower wellbeing scores on the RAND than participants in the sham-control group (Table 1). The TCM Healthcare diagnosis of each participant's condition at enrolment is given in Box 2 (published in online version at http://sciencedirect.com/ as supplementary data).

Adherence to treatment

Treatment adherence was good: 11 of 19 participants (58%) completed all 13 study sessions and 16 of 19 participants (84%) completed at least 6 study sessions (Table S1, published in online version at http://sciencedirect.com/ as supplementary data). There was no correlation between early treatment dropout of participants and the treatment they were receiving.

Outcome scores

There was a decrease in mean scores on the BDI in both study groups, which indicates a reduction in depressive symptoms. There was also a slight increase in mean scores on the RAND in both study groups, which indicates an improvement in quality of life; however, a reduction in mean scores for the RAND categories of 'physical functioning' and 'pain' was seen in the sham-control group only.

Qualitative interviews

All participants welcomed the opportunity to participate in the current study. There were no differences between the verum and sham-control groups with regard to self-

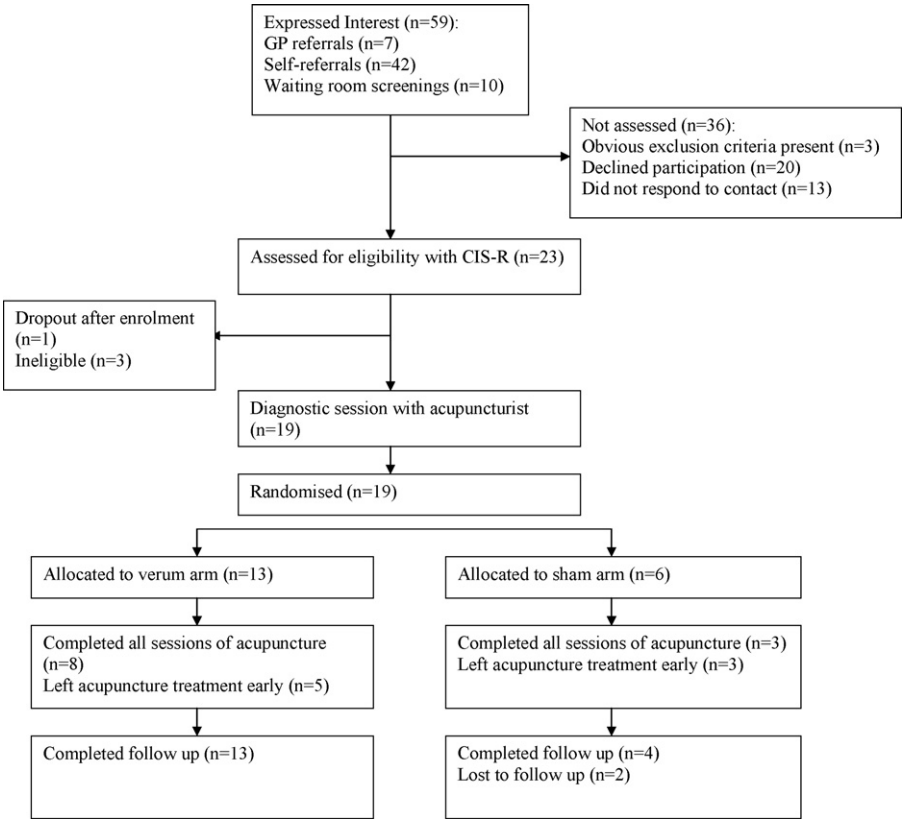

Figure 1 Flow of participants through the trial.

Table 1 Mean scores (S.D.) in BDI and RAND 36 Item Health Survey 1.0 at baseline and end point

	Verum baseline ($n = 13$)	Verum end point ($n = 13$)	Sham baseline ($n = 6$)	Sham end point ($n = 4$)
BDI	30.7 (5.3)	21.3 (10.5)	24.7 (8.4)	13.5 (11.6)
RAND 36 Item Health Survey				
Physical functioning	63.2 (27.8)	64.6 (33.9)	73.5 (24.2)	61.1 (41.8)
Role limitations physical	26.9 (29.8)	50.7 (48.5)	54.2 (40.1)	75.0 (35.4)
Role limitations emotional	2.6 (9.6)	47.2 (43.7)	27.8 (39.0)	73.3 (43.5)
Energy/fatigue	21.0 (12.5)	35.3 (22.9)	25.3 (33.2)	62.3 (23.0)
Emotional well-being	29.8 (11.1)	50.2 (23.7)	30.7 (13.5)	55.2 (29.3)
Social functioning	25.0 (15.3)	46.9 (23.9)	31.3 (29.5)	55.0 (36.0)
Pain	51.7 (32.3)	63.3 (35.5)	63.3 (29.3)	56.0 (21.0)
General health	34.2 (16.1)	46.3 (15.8)	50.8 (28.9)	60.0 (12.4)

reported positive or negative impacts of acupuncture. Eleven participants (eight verum, three sham) reported that the acupuncture treatment had a positive impact on their wellbeing, particularly on levels of stress and energy. One participant in the verum group reported that needle insertion caused pain, and two participants in the verum group reported that the acupuncture process had made their depressive symptoms worse. Three other participants (two verum, one sham) considered acupuncture to be ineffective.

Treatment blinding

There was no correlation between a participant's ability to judge correctly their study group and the treatment they were receiving.

Discussion

This feasibility study has increased our understanding of the challenges associated with conducting a full trial of the efficacy of acupuncture in the treatment of depression, and has provided important guidance on how to proceed. The study has been particularly useful in providing information about recruitment, control group design and outcome measures. The outcome measures used in this study appear to be suitable for use in a larger trial. In such a trial, the BDI and RAND will be completed following an extended follow-up period to clarify the long-term efficacy of verum acupuncture. The main purpose of this feasibility study was to provide methodological guidance for future work. The study comprised only a small population; therefore, the findings of the study need to be treated with caution and no definitive conclusions about the efficacy of acupuncture in the treatment of depression can be drawn. The number of GP referrals into this study was lower than expected, which is consistent with other trials,[13] and may be a problem related to time pressures and workload priorities[14,15] rather than a lack of commitment to the study. Most participants were self-referred after seeing an advertisement for the study in their practice waiting rooms. More consistent referral channels will need to be established for recruitment of participants into a full trial. Retrospective recruitment methods have been used successfully in Complementary and Alternative Medicine (CAM) trials[16]; however, these methods were not used in the current study because many recorded patients may be on alternative treatments that would exclude them from the study, and retrospective recruitment would exclude patients who have not yet been diagnosed with depression by the GP. Recruitment of participants into a large phase III trial is recommended to occur through a combination of patient screening in general practice waiting rooms and targeted advertising in primary care settings.

The use of a sham control method is recommended in a definitive randomised controlled trial. However, non-acupuncture points should also be used to show that the sham control needling sites are completely ineffective in the treatment of depression.

There are several concerns about the use of sham control interventions in acupuncture studies. For example, sham control methods may be perceived to reduce the experience of acupuncture solely to needling, rather than enabling the holistic nature of acupuncture to be assessed.[17] Also, the possibility that 'expectation' of treatment has a physiological effect on the brain, thus mediating a potentially powerful non-specific clinical response to acupuncture, has been suggested during pain trials.[18]

The study described here was designed to separate the non-specific effects of the intervention from the effects of needling at the correct depth in the correct place and with manual stimulation, all of which are specific to acupuncture treatment. Furthermore, the study showed that the sham method was a plausible intervention for the control group and successfully maintained participant blinding to treatment, an issue that is central to improving the methodological quality of trials assessing the effects of acupuncture in individuals with depression.[6]

The use of a sham-control group also enabled the specific (or active) component of an acupuncture intervention to be isolated and its efficacy assessed.

Although practitioner engagement is an essential part of acupuncture,[19] correct needling must be considered the most important factor. Examination of the impact of inserting needles into specific energy points in the body is imperative and will provide valuable evidence about the efficacy of acupuncture.

Conclusion

This feasibility study has provided important information that can be used to guide the design and methodology of a full-randomised controlled trial.

Acknowledgements

The authors would like to thank the acupuncturist, study participants and GPs. The North Central London Community Research Consortium funded this study.

Research Report

THE EFFICACY OF ACUPUNCTURE IN THE TREATMENT OF MAJOR DEPRESSION IN WOMEN

John J.B. Allen,[1] Rosa N. Schnyer,[2] and Sabrina K. Hitt[1]

[1]*Department of Psychology, University of Arizona, and* [2]*Kwan Yin Center for the Healing Arts, Tucson, Arizona*

Abstract—*The effectiveness of acupuncture as a treatment for major depression was examined in 38 women, randomly assigned to one of three treatment groups. Specific treatment involved acupuncture treatments for symptoms of depression; nonspecific treatment involved acupuncture for symptoms that were not clearly part of depression; a wait-list condition involved waiting without treatment for 8 weeks. The nonspecific and wait-list conditions were followed by specific treatment. Five women terminated treatment prematurely, 4 prior to the completion of the first 8 weeks. Following treatments specifically designed to address depression, 64% of the women* (n = *33) experienced full remission. A comparison of the acute effect of the three 8-week treatment conditions* (n = *34) showed that patients receiving specific acupuncture treatments improved significantly more than those receiving the placebo-like nonspecific acupuncture treatments, and marginally more than those in the wait-list condition. Results from this small sample suggest that acupuncture can provide significant symptom relief in depression, at rates comparable to those of psychotherapy or pharmacotherapy. Acupuncture may hold sufficient promise to warrant a larger scale clinical trial.*

Depression is an unfortunately common condition for which people often seek alternative treatment (Eisenberg et al., 1993). Lifetime-prevalence estimates of major depression (American Psychiatric Association, 1994) have ranged from 3% to 6% (Horwath & Weissman, 1995; Myers et al., 1984; Robins et al., 1984), with recent estimates (Kessler et al., 1994) notably higher, in the range of 17%. The costs of major depressive disorder exceed those of other chronic diseases such as diabetes and hypertension in terms of personal distress, lost productivity, interpersonal problems, and suicide (Gotlib & Beach, 1995; Hirshfield & Schatzberg, 1994).

Conventional treatments for depression, such as psychotherapy and pharmacotherapy, provide significant relief for approximately 50% to 70% of patients who complete treatment. Unfortunately, of those enrolling in treatment, about one third terminate treatment prematurely (Elkin et al., 1989), citing factors such as dissatisfaction with their current treatment or intolerable side effects. If both noncompleters and nonresponders are taken into account, more than half of all depressed persons who enter treatment fail to recover. Even among those who recover from an episode of major depression, more than one third show clinical relapse within 18 months (Shea et al., 1992).

These statistics suggest that alternative treatments may be welcomed by individuals with depression. Such alternatives might serve as adjuncts to or substitutes for existing treatments, or as maintenance or preventive treatments following remission. A recent survey (Eisenberg et al., 1993) revealed that depression was among the 10 most frequently reported medical conditions for which respondents sought treatment, and among those with self-reported depression, seeking alternative treatments (with or without traditional treatment) was more common than seeking the services of a traditional provider alone.

The present study therefore sought to assess the efficacy of an alternative treatment—acupuncture—for major depression. Although abstracts of several reports from China and the former Soviet Union suggest that acupuncture may assist in the treatment of emotional disorders, including those for which depression is a prominent symptom (Chengying, 1992; Cherkezova & Toteva, 1991, 1993; Dudaeva, 1990; Frydrychowski, Landowski, Watrobski, & Ostrowska, 1984; Han, 1986; Polyakov, 1988; Suobin, 1991), there exist no controlled studies of acupuncture's effectiveness for depression in the refereed literature in English.

Acupuncture treatments derive from the principles of Chinese medicine. Strictly speaking, depression does not exist as a disease category in Chinese medicine, because Chinese medicine does not focus on the diagnosis and treatment of disease, but rather on the detection of energetic imbalances. Chinese medicine views health as a balance between the yin and the yang forces, which depends on the proper circulation of the vital energy Qi (pronounced "chee") along energetic pathways or meridians. Within the Western framework, many different symptom patterns are subsumed under the diagnosis major depression (e.g., a depression with overeating, hypersomnia, and psychomotor retardation vs. a depression with loss of appetite, insomnia, and psychomotor agitation); by contrast, these different symptom constellations would signify different patterns of disharmony from the perspective of Chinese medicine, and would require different treatments. The rationale of Chinese medicine has been well described (Kaptchuk, 1983), and we have elsewhere discussed in greater detail its application to assessing and treating depression (Allen & Schnyer, 1998). In brief, acupuncture can be seen as providing a framework for understanding heterogeneous symptom patterns, and for providing treatments individually tailored to address these distinct patterns.

In the present study, patients with major depression received acupuncture treatments that were individually tailored, according to the principles of Chinese medicine, to specifically address each individual's pattern of symptoms. Some patients, prior to receiving these specific treatments, received superficially similar placebo-like treatments designed to treat symptoms other than depression (nonspecific treatments) or entered a wait list. This design allowed us to test whether acupuncture designed to specifically treat symptoms of depression would demonstrate efficacy compared with a wait-list control and nonspecific acupuncture treatments.

METHOD

Patients

Thirty-eight women between the ages of 18 and 45 were recruited through newspaper advertisements. Advertisements mentioned treatment for depression, but not acupuncture. Patients were included if they met the diagnostic criteria for current major depression as outlined in the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV; American Psychiatric Association, 1994). They were assessed using the Structured Clinical Interview for DSM-III-R (SCID; Spitzer, Williams, Gibbon, & First, 1990), which was administered by interviewers with a master's in psychology under the supervision of the first author. Patients were excluded if any of the following criteria were present: (a) dysthymia or chronic (duration greater than 2 years) major depression, (b) any current Axis I diagnosis besides major depressive disorder, (c) history of psychosis or mania, (d) substance abuse or dependence within the past 4 months, (e) any current treatment, (f) endocrine abnormalities, (g) history of central nervous system lesions or any medical disorder or treatment that could cause depression, (h) active suicidal potential necessitating immediate treatment, or (i) pregnancy. Five women (13%) dropped out of the study prior to completing it,[1] resulting in a final sample of 33 women who received treatment specifically for depression.

To assess the women's depression, we administered a 31-item, modified version of the Hamilton Rating Scale for Depression (HRSD) modeled after the revision of the HRSD by Gelenberg et al. (1990). Because only 19 of the items in this version address DSM-IV symptoms of depression, we report in this article scores for this subset of items, which we refer to as the DepHRSD.[2] The 33 women in the final sample had mild to moderate depression, with a mean DepHRSD score of 25.1 (SD = 6.8, range: 13–41). The mean duration of their current episodes was 9.2 months (SD = 6.9), and they had on average 2.5 (SD = 2.9) prior episodes. Additionally, 82% of the patients reported having previously received psychotherapy, 53% reported previous trials of antidepressants, and 11% reported no previous treatment. Fifty-nine percent of these patients reported that one or more first-degree relatives also had depression of comparable severity. All participants provided informed consent to participate, and had their rights protected by procedures approved by the University of Arizona's human subjects committee.

General Design and Data Analysis

Factors not specific to acupuncture or the points selected can have therapeutic impact. Such factors include, among others, the patient–acupuncturist relationship and actively engaging in activity believed to improve depression. Our design therefore provided for the development of two types of acupuncture treatments for each patient: a treatment individually tailored to treat the patient's specific symptoms of depression (specific treatment) and a placebo-like treatment designed to treat a pattern of disharmony that was not related to the individual's depression, but was characteristic of the individual (nonspecific treatment; e.g., targeting back pain). The nonspecific treatment was not, strictly speaking, a placebo because it was an active treatment and may therefore have had more impact than a truly inert placebo treatment. We reasoned that if specific treatments outperformed these active nonspecific treatments, it is likely that they would also outperform a truly inert placebo treatment. Active nonspecific treatments were employed, however, to keep the acupuncturists' expectancies of efficacy comparable between the two treatments. Moreover, the specific and nonspecific treatments were similar from the perspective of the patients—involving points in the same general body regions—and patients were unaware of which treatment they were receiving. If specific treatments demonstrated greater efficacy than nonspecific treatments, it would be reasonable to conclude that the effect of acupuncture per se was responsible.

The specific and nonspecific treatment plans were developed according to our treatment manual (Schnyer & Allen, 1998) by an assessing acupuncturist (R.N.S.), and were administered by four other trained and board-certified acupuncturists. Because the nonspecific treatments involved valid acupuncture points, the treating acupuncturists perceived that they were providing a valid treatment, a belief that they would not have held if sham points had been used as a control. The treating acupuncturists were blind to the experimental hypotheses and the method by which the specific and nonspecific treatments were devised, and were not informed of which treatment plan they received. Nonetheless, it may not be appropriate to consider this study fully double-blind because it remains possible that the acupuncturists developed some awareness of the differences between the treatments. There is evidence, however, that the acupuncturists were effectively blinded. They rated their beliefs about the efficacy of the treatment[3] following the first treatment session, and these ratings did not differ between specific and nonspecific treatments, $F(1, 22) < 1$, n.s.

Patients were randomly assigned to one of three conditions (specific treatment: n = 12, nonspecific treatment: n = 11,[4] or wait list: n = 11) and to one of the acupuncturists. All women received the specific treatment. Patients in the specific-treatment group received 8 weeks of specific treatment immediately. Patients in the nonspecific-treatment group received 8 weeks of nonspecific treatment first, and then 8 weeks of specific treatment. Patients in the wait-list group waited 8 weeks before receiving 8 weeks of specific treatment. Each 8-week treatment regimen (both specific and nonspecific) comprised 12 treatment sessions: 2 sessions a week for the first 4 weeks followed by 1 per week thereafter.

1. Two dropped out for reasons unrelated to treatment (pregnancy, moving out of state), 2 left because of discomfort with the treatment, and 1 left because she was not losing weight and believed that she would lose weight with a pharmacological treatment.

2. The 19 items included in the DepHRSD are depressed mood, suicidal thinking, suicidal behavior, difficulty falling asleep, middle-of-the-night awakening, early-morning awakening, hypersomnia, loss of interest, loss of pleasure, psychomotor retardation, psychomotor agitation, loss of energy, appetite change, weight change during the past month, loss of sexual interest, decreased concentration, helplessness, hopelessness, and worthlessness-failure. The non-included items on the HRSD reflect symptoms such as anxiety (psychic anxiety, somatic anxiety, obsessive-compulsive symptoms) and other nondepressive symptoms (e.g., paranoia, depersonalization).

3. The acupuncturists used a 9-point Likert scale to rate the following two items: "To what extent do you feel you have helped this client?" and "Predict the extent to which the client will benefit from the specific treatment we are offering."

4. Among the 5 patients who left the study prematurely, 2 dropped out from specific treatment, 2 from nonspecific treatment, and 1 from the wait list. The patient who dropped out because she wanted to lose weight had completed nonspecific treatment but had not begun specific treatment, and is therefore included in analyses involving the nonspecific treatment.

Assessments

Interviews

All patients were interviewed by trained raters blind to treatment condition using the previously described 31-item version of the HRSD. Patients were interviewed before treatment (baseline), after 4 weeks, after 8 weeks, and if in the wait-list and nonspecific groups, after 12 weeks and after 16 weeks. An intraclass correlation of .96 was obtained for a sample of 22 interviews comparing the original interviewers' HRSD scores with consensus (original interviewer excluded) HRSD scores. The questions from the depression section of the SCID were also administered at the end of each 8-week treatment regimen.

Self-report measures

The Inventory of Depressive Symptomatology (IDS; a self-report version of the HRSD; Rush, Giles, Schlesser, & Fulton, 1986), the Beck Depression Inventory (BDI; Beck, Rush, Shaw, & Emery, 1979), and the Beck Hopelessness Scale (BHS; Beck, Weissman, Lester, & Trexler, 1974) were filled out weekly by patients during treatment, but not during the wait-list period. Although the interview data were available for all 33 patients, self-report data were available for 29 women.

RESULTS

First, to test for the efficacy of the specific treatment compared with the nonspecific treatment and the wait list, we examined the reduction in depressive symptoms after Week 8 for all three groups. Second, to estimate the clinical significance of treatment, we calculated the percentage of patients experiencing remission. In all cases, parametric tests are reported, unless the test could not be run because of violations of the normality assumption, in which case the comparable nonparametric test is reported (χ^2 with Friedman repeated measures analysis of variance [ANOVA] on ranks for repeated measures analyses, H with Kruskal-Wallis ANOVA on ranks for nonrepeated measures analyses). All post hoc tests used the Student Newman-Kuels procedure.

Comparative Efficacy of Specific Acupuncture Treatments

To determine whether specific treatment was comparatively more effective than nonspecific treatment or the wait list, we examined change scores from baseline to Week 8. Change scores were selected because, despite random assignment to group, there were significant differences between the groups at baseline on the DepHRSD, $F(2, 31) = 4.6$, $p < .05$: The nonspecific group (mean score = 20.5, $SD = 4.5$) was significantly less depressed ($p < .05$) than both the wait-list group (mean score = 27.7, $SD = 6.8$) and the specific group (mean score = 26.9, $SD = 6.7$), which did not differ from one another.

Figure 1 shows the mean change in DepHRSD scores for the three groups over the course of the study. A one-way ANOVA revealed a significant difference in symptom reduction between the groups on the DepHRSD, $H(2) = 7.2$, $p < .05$. The symptom reduction in the specific group ($M = -11.7$, $SD = 7.3$) exceeded that of the nonspecific group ($M = -2.9$, $SD = 7.9$). In addition, there was a nonsignificant trend ($p < .12$) for symptom reduction in the specific group to exceed

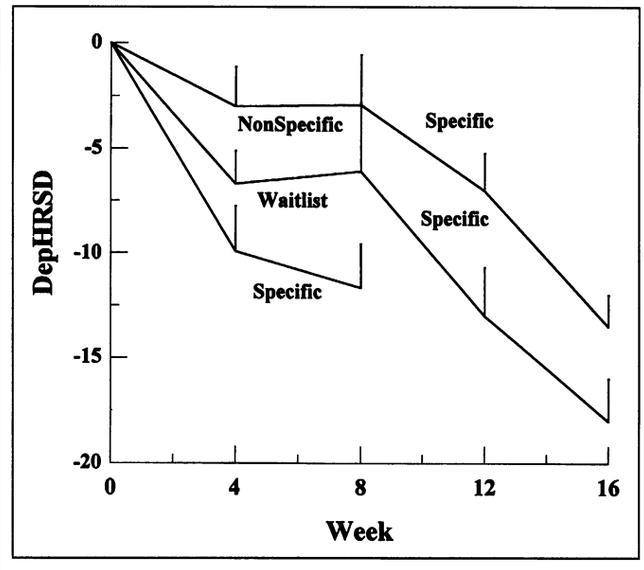

Fig. 1. Mean (±*SE*) change on the depression items from the Hamilton Rating Scale for Depression (DepHRSD) for patients in the specific-treatment ($n = 12$), nonspecific-treatment ($n = 11$), and wait-list ($n = 11$) groups by week. Note that after 8 weeks, patients in the nonspecific-treatment and wait-list groups began receiving specific treatment.

that of the wait-list group ($M = -6.1$, $SD = 10.9$). Similar results were obtained over the 8-week interval with the self-report measures for those patients undergoing treatment. On the BDI, patients in the specific group demonstrated larger changes ($M = -10.7$, $SD = 7.8$) than those in the nonspecific group ($M = -3.4$, $SD = 7.4$), $F(1, 20) = 5.2$, $p < .05$. On the IDS, patients in the specific group also demonstrated larger changes ($M = -18.5$, $SD = 11.8$) than those in the nonspecific group ($M = -8.5$, $SD = 9.0$), $F(1, 20) = 5.0$, $p < .05$. No differences emerged on the BHS, $F(1, 20) = 1.3$, n.s. Because self-report measures were completed only in the context of treatment, no comparisons with the wait-list condition were possible using self-report measures.

To determine whether the results would be the same for the original intent-to-treat sample, we conducted two analyses. The simple intent-to-treat analysis took the last available DepHRSD score of each participant who dropped out and carried that score forward to count as the subsequent observation. DepHRSD scores again differed significantly between participants in the three treatment groups, $H(2) = 6.4$, $p < .05$. The second strategy used a random regression model (Gibbons et al., 1993, implemented with BMDP 5V), which imputes missing values based on maximum-likelihood estimates of missing parameters, thereby allowing for the analysis of all intent-to-treat subjects. The model examined DepHRSD scores at intake, 4 weeks, and 8 weeks, and revealed a significant Group × Time interaction ($\chi^2[4, N = 38] = 9.70$, $p < .05$), which indicated that the rate of change differed significantly between the specific- and nonspecific-treatment groups ($\chi^2[2, N = 26] = 9.95$, $p < .01$), but not between the nonspecific-treatment and wait-list groups ($\chi^2[2, N = 24] = 0.76$, n.s.). The specific-treatment and wait-list groups showed a trend for rates of change to differ, $\chi^2(2, N = 26) = 4.28$, $p < .12$.

Clinical Significance

We used two measures to ascertain whether treatment resulted in clinically significant remission: DSM-IV diagnoses and at least a 50% reduction in scores on the DepHRSD. Full remission in terms of DSM-IV diagnoses was defined as absence of both core symptoms of depression (depressed mood and anhedonia).

At the conclusion of the acute (8-week) phase of treatment, by DepHRSD criteria, 50% of the participants in the specific-treatment group had remitted, whereas only 27% in the nonspecific-treatment group and 27% in the wait-list group had remitted. By DSM-IV criteria, 42% of those in the specific-treatment group, 9% of those in the nonspecific-treatment group, and 20% of those in the wait-list group had experienced full remission.

After completion of specific treatment (pooled across all patients), by DepHRSD criteria, 70% of women had remitted. Using the DSM-IV remission criteria, 64% of women experienced full remission.

DISCUSSION

These findings from a small sample of women with major depression suggest that acupuncture may hold sufficient efficacy to warrant a larger clinical trial. Moreover, it appears that acupuncture induces remission at rates roughly comparable to those of conventional treatments[5] (Elkin et al., 1989). Additionally, the dropout rate of 13% in this sample compares favorably with the rates of more than 30% reported in other studies (Elkin et al., 1989), although such a finding could be due to many factors that may or may not be related to the modality of treatment. It is important to note that all women in this study were outpatients, free of psychosis or acute suicidal ideation. However, 29% of them met criteria for suicidal ideation (but without acute risk), based on the SCID. The efficacy of acupuncture for more severe depressions is unknown.

The present data also suggest that acupuncture has a specific effect above and beyond the nonspecific therapeutic factors related to regular visits to an acupuncturist. Patients receiving specific treatment improved more over 8 weeks than patients receiving nonspecific treatment. Although expectancy effects cannot be completely ruled out as a factor in the comparative efficacy of the treatments, the design minimized the possible role of these effects. Patients were blind to which treatment they received. Moreover, the treating acupuncturists implemented treatment plans provided by the assessing acupuncturist, and both the specific and the nonspecific treatments involved active and valid acupuncture points. Furthermore, the acupuncturists' beliefs about the efficacy of the treatment—which were assessed following the first treatment session—did not differ between specific and nonspecific treatments, reducing the likelihood that the acupuncturists' expectancies were responsible for the observed superiority of the specific treatment. Although it remains possible that the treating acupuncturists' expectations changed across the 8 weeks of delivering treatment, it would be impossible to determine whether differential beliefs about the effectiveness of specific and nonspecific treatment—if such beliefs had been assessed later in the progression of treatment—would indicate unblinding or simply be the result of differential improvement in the specific- and nonspecific-treatment groups.

Because specific treatment did not produce significantly greater improvement than the wait list, it remains possible that the improvement during specific treatment was due to spontaneous remission. Several findings suggest, however, that the specific treatment may have provided improvement above and beyond that expected by spontaneous remission alone. First, spontaneous remission was equally likely to affect patients in all groups, and specific treatment provided greater improvement than nonspecific treatment. Moreover, an examination of the effect sizes[6] indicates that the relative advantage of the specific treatment over the wait list ($d = 0.61$) is similar to what has been observed when other treatment modalities have been compared with a wait-list control in depression (Robinson, Berman, & Neimeyer, 1990). With greater statistical power, specific treatment would likely prove significantly more effective than a wait-list control, as the power to detect a significant difference between these two groups with the present sample size is only .31. Finally, among participants in the wait-list group, comparing the change observed during the specific-treatment phase and the wait period preceding it yields an effect size ($d = 0.52$) of similar magnitude. In other words, even after 8 weeks of a wait list, specific treatment provided change that was notably larger than that seen in these same patients during the wait period. Similarly, specific treatment produced larger change than the nonspecific treatment preceding it ($d = 0.79$) for patients in the nonspecific-treatment group (see Fig. 1).

These findings are, of course, preliminary. Larger scale studies are required to provide corroboration. If additional research corroborates that acupuncture is an effective treatment for depression, further research should address several issues. First, acupuncture's effectiveness remains to be determined for severe or chronic depressions (e.g., chronic major depression, dysthymia), as well as for persons with comorbid disorders (e.g., anxiety disorders, substance dependence). Second, the long-term prognosis of patients who respond to acupuncture treatment is unknown. Therefore, future research can address whether the treatment gains are maintained or whether less-frequent continuation or maintenance treatments are required after the initial set of treatments. Evidence from studies of other treatments for depression suggests the importance of maintenance treatments (Hirshfield & Schatzberg, 1994). Third, a direct comparison of the efficacy of acupuncture and psychotherapy or pharmacotherapy—within the same study—needs to be performed. Fourth, investigation of the mechanisms by which acupuncture achieves its effects is required. Finally, and perhaps most important, future research is required to determine whether acupuncture can assist individuals who fail to respond to traditional treatments, and whether traditional treatments will assist those who fail to respond to acupuncture.

5. Remission criteria vary somewhat from study to study. Very few studies have used interview-based DSM diagnoses as a measure for remission because the interviews are expensive and labor-intensive. Most studies use a joint criterion of reduction of 50% in HRSD score and a final score less than or equal to 6. The present data cannot be compared with data from studies using this criterion because we used a version of the HRSD that is different from the version most studies use. BDI scores, however, can provide a clear comparison between the results in this study and those reported in the literature. After the 33 patients had completed specific treatment, their mean BDI score was 12.1, which compares favorably with the mean score of 11.8 from 22 studies of psychotherapy (Robinson, Berman, & Neimeyer, 1990).

6. Effect sizes were calculated using Cohen's (1977) d, which expresses the differences in treatment means as a proportion of the pooled standard deviation: $(\bar{x}_1 - \bar{x}_2)/s$, where $\bar{x}_1$ is the first treatment mean, $\bar{x}_2$ is the second treatment mean, and s is the pooled standard deviation.

Research report

The benefit from whole body acupuncture in major depression

J. Röschke*, Ch. Wolf, M.J. Müller, P. Wagner, K. Mann, M. Grözinger, S. Bech

Abstract

Background: In a single-blind placebo-controlled study design we investigated the efficacy of acupuncture additionally applied to drug treatment in major depression. *Methods:* We randomly included 70 inpatients with a major depressive episode in three different treatment groups: verum acupuncture, placebo acupuncture and a control group. All three groups were pharmacologically treated with the antidepressant mianserin. The verum group received acupuncture at specific points considered effective in the treatment of depression. The placebo group was treated with acupuncture at non-specific locations and the control group received pharmacological treatment plus clinical management. Acupuncture was applied three times a week over a period of 4 weeks. Psychopathology was rated by judges blind to verum/placebo conditions twice a week over 8 weeks. *Results:* Patients who experienced acupuncture improved slightly more than patients treated with mianserin alone. *Conclusions:* Additionally applied acupuncture improved the course of depression more than pharmacological treatment with mianserin alone. However, we could not detect any differences between placebo and verum acupuncture. © 2000 Elsevier Science B.V. All rights reserved.

Keywords: Acupuncture; Depression; Mianserin

1. Introduction

In various different records and books acupuncture (Mann, 1973; Zhang, 1988; Bullock et al., 1989; Youbang and Liangyue, 1989), an ancient Chinese art of healing, is considered to alleviate or cure physical or mental diseases by simply piercing the skin with a fine needle at defined acupuncture points. In detail, symptoms of depression reoccur frequently in traditional Chinese works (Hubei Zuhonggyi Xueyuan, 1979; Nguyen Van Nghi, 1983) as well as newer literature on acupuncture (Porkert, 1983; Ross and Zang, 1985; Requena, 1989; Ots, 1990), suggesting whole body acupuncture is beneficial in the treatment of depressive patients.

The present study was designed to explore the efficacy of acupuncture in treating depression. Up to now, a single placebo-controlled clinical study of acupuncture as a treatment for depression has been reported. Yang et al. (1994) published data on acupuncture employed in the case of 41 patients suffering from various types of depression. The

diagnostic assignment was quite heterogeneous ranging from bipolar affective disorders and dysthymia to involutional depression of in- and outpatients. One group received acupuncture with individually determined needle points, the controls were pharmacologically treated with amitriptyline ranging between 150 and 300 mg/day. After 6 weeks no significant difference in psychopathology between the two methods of treatment was found, suggesting acupuncture to be as effective as antidepressant medication.

The aim of our study was to evaluate the efficacy of whole body acupuncture additionally applied to drug treatment of depression in a single-blind placebo-controlled study design. The hypotheses tested were: (a) additionally applied acupuncture improves the course of the illness more than pharmacological treatment by itself; (b) the effect of needling defined acupuncture points is specific, meaning in the case of verum acupuncture, the improvement of the course of depression is much higher than in the case of placebo acupuncture.

2. Methods

2.1. Study design

From October 1993 to October 1995 we studied 70 consecutive inpatients suffering from a major depressive episode and randomly assigned the patients to one of three different treatment groups:

1. mianserin treatment (90–120 mg/day);
2. mianserin treatment (90–120 mg/day) plus verum acupuncture; and
3. mianserin treatment (90–120 mg/day) plus placebo acupuncture.

In all treatment groups a benzodiazepine comedication up to 20 mg/day diazepam was allowed if required. The criteria for inclusion into the study were: cross-sectional diagnosis of a major depressive episode according to DSM-III-R (American Psychiatric Association, 1987), a score ≥ 18 points on the 21-item Hamilton depression scale (HAMD, Hamilton, 1976), and age of the patients between 20 and 70 years. Entry into the study was limited to patients without acute suicidality, longitudinal diagnosis of schizoaffective or bipolar affective disorder as well as delusions. Furthermore, patients with coagulation-disease, wound healing disease, emphysematous thorax, abnormal blood cell count, serious liver and kidney diseases, and epilepsy were excluded.

Because of the wide range of age for participants, we selected mianserin as the standardized antidepressant medication, which is not accompanied by anticholinergic side effects (Swinkels and de Jonghe, 1995). The dosage regimen was 30–30–30 or 30–30–60 mg/day. Written informed consent was obtained from all patients.

Psychopathology was rated at entry to the study and twice a week over a period of 8 weeks by two independent experienced judges not informed about verum/placebo acupuncture. The following observer rating scales were used to determine the psychopathological course of the illness: Global assessment scale (GAS, Endicott et al., 1976), Bech–Rafaelsen Melancholia scale (BRMS, Bech and Rafaelsen, 1980), Clinical global impressions scale (CGI, National Institute of Mental Health, 1976). For evaluation of depressive states in longitudinal studies we employed a self-rating scale (Bf-S, von Zerssen et al., 1974).

2.2. Subjects

Table 1 summarizes the age, gender and psychiatric diagnosis according to DSM-III-R of the patients participating in the study. The DSM-III-R number 296.2 represents a single episode, 296.3 a recurrent episode of a major depressive disorder.

2.3. Acupuncture protocol

Acupuncture was practised by two clinicians experienced in traditional Chinese acupuncture. They were excluded from the clinical management. For both groups, verum and placebo acupuncture, each patient was treated with a standardized whole body acupuncture treatment, applied three times a week over four consecutive weeks at 18 different locations. The duration of each acupuncture session was nearly 30 min. Each individual patient was needled over the treatment period by the same clinician. However, both clinicians did the acupuncture in both groups. The distribution verum/placebo acupuncture

296.3	37	f	–	–	–	296.2	50	f

was equal for both clinicians. In case of verum acupuncture we needled bilaterally at the positions: U.B.15, U.B.17, U.B.18 (back), H7 (wrist), P6 (forearm), St40 (lower leg), Sp5, Sp6 (foot), and Lu1 (upper part of the body). Skin was pierced at the acupuncture points with a fine stainless steel needle (0.3×25 mm) to a depth of a few millimeters which was withdrawn after the lapse of a few minutes (Nguyen Van Nghi, 1983; Ross and Zang, 1985; Bullock et al., 1989). The electric skin resistance was measured to accurately determining the acupuncture points where resistance was reduced. In the case of placebo acupuncture we needled at non-specific locations in the neighbourhood of the loci cited above merely pricking the skin superficially.

2.4. Statistical analysis

Values in tables are presented as means±S.D. Categorical variables were analyzed by means of χ^2-tests. Baseline differences were evaluated with one-way ANOVA. Between group differences in outcome parameters were analyzed following an intention-to-treat-analysis with repeated measures ANOVA using treatment as between subjects factor (control vs. placebo vs. verum acupuncture) and assessments 1–16 (week 1–8) as repeated measures. For adjustment of degrees of freedom due to heterogeneity of variance–covariance matrices the procedure of Huynh and Feldt (1976) was applied. The level of statistical significance was set at $\alpha = 0.05$.

3. Results

3.1. Patients' characteristics

Table 2 summarizes the number of patients, gender, mean age and the HAMD score at the beginning of the study for the different treatment groups. According to χ^2-test (gender) and ANOVAs (age, HAMD), no differences between the groups under study could be found. It is obvious that all

Table 2
Number, sex ratio, mean age and HAMD score of the patients

Group	Number	Male:female	Mean age	HAMD
Control group	24	10:14	49±11	28±7
Verum acupuncture	22	3:19	49±13	28±5
Placebo acupuncture	24	9:15	47±9	29±5

patients suffered from a severe depression (mean score on HAMD = 28). An additionally applied one-way ANOVA did not show any difference in the number of former hospitalizations between the groups. Thus, the distribution of the patients' severity score, age, and gender ratio was quite homogeneous across the groups.

3.2. Differences between the three different treatments under study

Figs. 1–5 show the course of the depression according to the observer rating scales GAS, BRMS, CGI, and the self rating scale Bf-S over a time period of 8 weeks. In all cases there was greater improvement when acupuncture (placebo or verum) was applied compared to plain pharmacological treatment. In case of GAS (the higher the score, the better the psychopathology) the different groups under study improved homogeneously within the first 4 weeks of treatment (Fig. 1). However, during the last 4 weeks patients who had experienced acupuncture reached a higher score than patients treated with mianserin alone. For the observer ratings BRMS and CGI, respectively, again the three groups improved equally during the first half of the study (the lower the scores the better the psychopathology), whereas during the second half patients previously treated with acupuncture showed greater benefit (Figs. 2–4). According to the self rating scale Bf-S (the lower the score the better the psychopathology) we observed the same course of depression over time: patients who had experienced acupuncture showed more rapid progress than patients with mianserin alone (Fig. 5).

For each rating instrument Table 3 summarizes the results of the two-way ANOVA with between subjects factor group (control vs. placebo vs. verum acupuncture) and within-subject factor time (repeated measure design of ratings 1–16). We could not detect any statistically significant main effect for the factor group, but in all instruments a highly significant

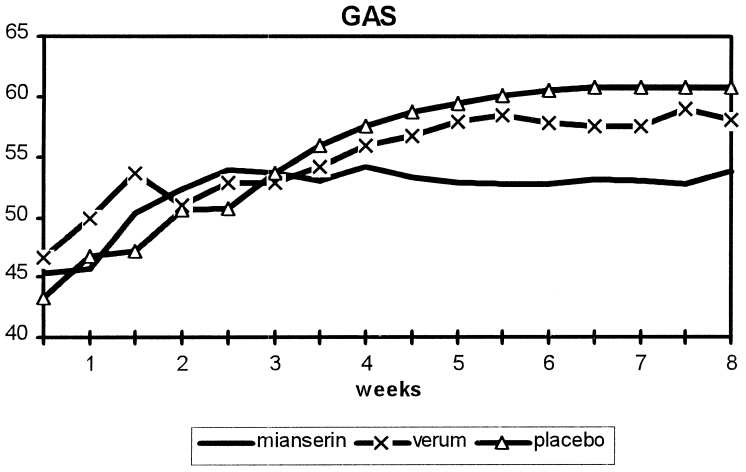

Fig. 1. GAS ratings (global assessment) over time (the better the score, the better the psychopathology).

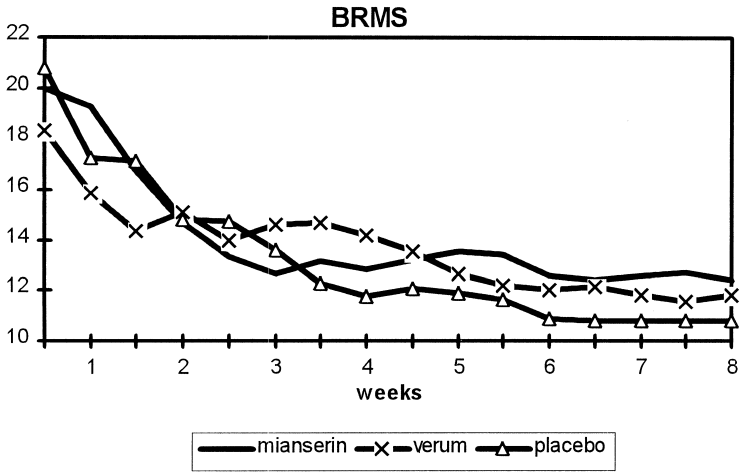

Fig. 2. BRMS ratings (melancholia scale) over time (the lower the score, the better the psychopathology).

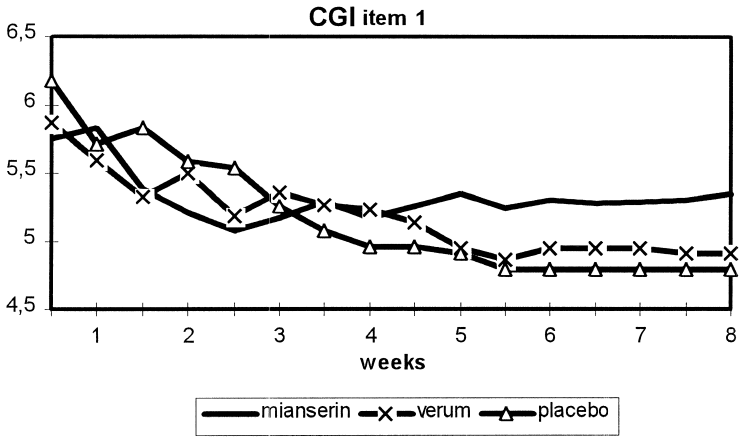

Fig. 3. CGI ratings (item 1 = psychopathological state) over time (the lower the score, the better the psychopathology).

effect for the factor time. In case of CGI item 2 (measuring the improvement of psychopathology) we found a statistically significant interaction of group by time ($P = 0.048$).

Additionally, we investigated the differences in mianserin dosage and diazepam comedication (if required) between the three treatment groups. Fig. 6 shows the mianserin medication and the diazepam dosage during the study period. Table 4 summarizes the results of a two-way ANOVA for both mianserin and diazepam. No main effect for the factor group nor any statistically significant interaction of group by time could be observed. Thus, the significant interaction of group by time for CGI (item 2) is not due to influence by different medication.

3.3. Differences between control and acupuncture treatment

In order to detect differences between the drug treatment and both acupuncture conditions (placebo as well as verum acupuncture), we performed a

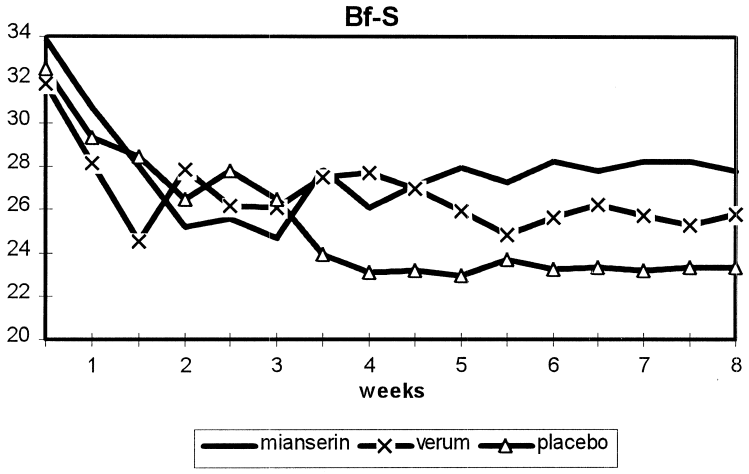

Fig. 5. Bf-S self ratings (depressive mood) over time (the lower the score, the better the psychopathology).

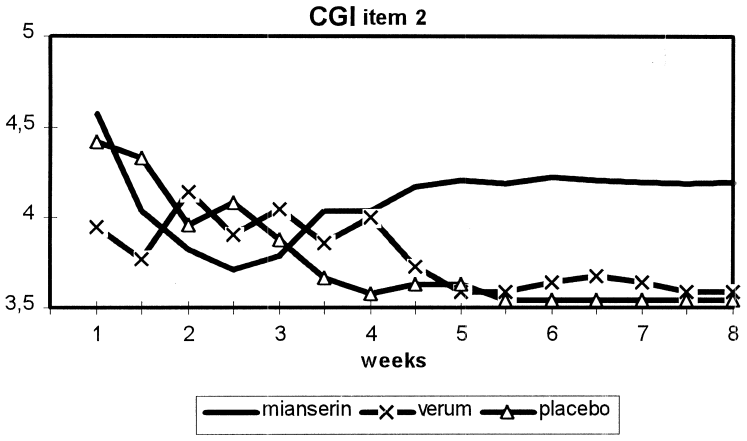

Fig. 4. CGI ratings (item 2 = improvement) over time (the lower the score, the better the psychopathology).

Table 3
Summary of two-way ANOVA for each of the rating instruments (Huynh–Feldt adjusted P values)

Instrument	ANOVA (between the three treatment groups)		
	Group	Time	Interaction
CGI item 1	$F_{2,67} = 0.12$ $P = 0{,}889$	$F_{15,1005} = 12.36$ $P = 0.0001$	$F_{30,1005} = 1.94$ $P = 0.092$
CGI item 2	$F_{2,67} = 0.84$ $P = 0.435$	$F_{15,1005} = 48.23$ $P = 0.0001$	$F_{30,1005} = 2.36$ $P = 0.048$
BRMS (sumscore)	$F_{2,67} = 0.10$ $P = 0.906$	$F_{15,1005} = 23.79$ $P = 0.0001$	$F_{30,1005} = 1.39$ $P = 0.226$
GAS	$F_{2,67} = 0.65$ $P = 0.525$	$F_{15,1005} = 19.18$ $P = 0.0001$	$F_{30,1005} = 2.16$ $P = 0.052$
Bf-S	$F_{2,67} = 0.25$ $P = 0.782$	$F_{15,1005} = 4.99$ $P = 0.0001$	$F_{30,1005} = 1.22$ $P = 0.296$

two-way ANOVA with between-subject factor group (control vs. acupuncture) and within-subject factor time. Table 5 summarizes the results. No main effect for the factor group could be found. However, for the instruments CGI (item 2) and GAS statistically a significant interaction was shown.

Therefore, according to the observer ratings CGI (item 2) and GAS patients treated with acupuncture (placebo or verum) showed higher benefit than patients treated only with mianserin. However, we could not detect any difference between patients who had experienced verum acupuncture and those who had placebo acupuncture. A two-way ANOVA with

Results of ANOVA for mianserin and diazepam medication

Medication	ANOVA (between the three treatment groups)		
	Group	Time	Interaction
Mianserin	$F_{2,67} = 0.06$ $P = 0.940$	$F_{15,1005} = 201.28$ $P = 0.0001$	$F_{30,1005} = 0.65$ $P = 0.693$
Diazepam	$F_{2,67} = 0.70$ $P = 0.502$	$F_{15,1005} = 6.07$ $P = 0.001$	$F_{30,1005} = 1.25$ $P = 0.288$

Table 5
Results of the ANOVA with between-subject factor group (control vs. acupuncture) and within-subject factor time (Huynh–Feldt adjusted P values)

Instrument	ANOVA (mianserin versus both acupuncture groups)		
	Group	Time	Interaction
CGI item 1	$F_{1,68} = 0.24$ $P = 0.628$	$F_{15,1020} = 8.95$ $P = 0.0001$	$F_{15,1020} = 2.63$ $P = 0.065$
CGI item 2	$F_{1,68} = 1.71$ $P = 0.195$	$F_{15,1020} = 44.60$ $P = 0.0001$	$F_{15,10200} = 3.14$ $P = 0.026$
BRMS (sumscore)	$F_{1,68} = 0.15$ $P = 0.702$	$F_{15,1020} = 21.64$ $P = 0.0001$	$F_{15,1020} = 1.09$ $P = 0.348$
GAS	$F_{1,68} = 1.30$ $P = 0.257$	$F_{15,1020} = 14.20$ $P = 0.0001$	$F_{15,1020} = 3.03$ $P = 0.049$
Bf-S	$F_{1,68} = 0.35$ $P = 0.558$	$F_{15,1020} = 4.21$ $P = 0.005$	$F_{15,1020} = 1.14$ $P = 0.336$

factor group (placebo vs. verum acupuncture) and within-subject factor time did not come out with any statistically significant main effect for the factor group or any significant interaction. Therefore, we could demonstrate an improvement of the depressive psychopathology when acupuncture had been applied, but this effect appeared to be nonspecific.

3.4. Responder analysis

According to GAS scale we defined a low improvement when GAS score at the end of the study was less than 25 points above the baseline value. A medium or high improvement was defined when GAS score at the end was more than 25 points above baseline value. Following this definition we observed a statistically significant difference between the three groups under study ($\chi^2 = 6.75$, df = 2, $P = 0.034$). Comparing placebo and verum acupuncture we could not detect any significant difference in responder rate. However, comparing both verum and placebo acupuncture with control conditions we found a higher responder rate in case of acupuncture ($\chi^2 = 5.01$, df = 1, $P = 0.025$). Table 6 summarizes the responder rate for control, placebo, and verum conditions.

Table 6
Responder analysis according to GAS score

GAS	Control group	Verum acupuncture	Placebo acupuncture
No or low improvement (≤ 25 points)	$n = 23$ 96%	$n = 18$ 82%	$n = 16$ 67%
Medium or high improvement (> 25 points)	$n = 1$ 4%	$n = 4$ 18%	$n = 8$ 33%

4. Discussion

In this single-blind placebo-controlled study we investigated the effectiveness of additionally applied whole body acupuncture in the treatment of severe depression. For this reason three different treatment procedures were selected, having a standardized pharmacological treatment with mianserin in common. The first group experienced verum acupuncture with needling points, which are proposed for the treatment of depressive symptoms (Mann, 1973). In the second group placebo acupuncture was applied with needling points not being regarded as any specific acupuncture locations and not inserted in the recommended depth. In the third group (control) we did not apply any acupuncture technique. The first hypothesis tested could be confirmed: additionally applied acupuncture did improve the course of depression more than pharmacological treatment with mianserin did by itself. The second hypothesis, however, had to be rejected: we could not detect any differences between placebo and verum acupuncture. Thus, our results point to the view that there is no specific effect of needling defined acupuncture points in the treatment of major depression (Wolf et al., 1995).

This outcome did not correspond to a ceiling effect due to highly sufficient pharmacological medication. In each treatment group the patients suffered from a severe major depressive disorder according to DSM-III-R. During the study period of 8 weeks the patients did not experience a full remission, neither in the control group nor in the acupuncture groups. Therefore, the medication dosage chosen did not appear highly potent and verum acupuncture should have shown a measurable improvement if effective. However, patients additionally treated with either verum or placebo acupuncture experienced a statistically significant higher benefit than patients in the control group. There was no difference in mianserin dosage or diazepam comedication between the groups. The responder rate was higher when acupuncture was applied and the differences observed did not depend on different numbers of drop-outs. A more complete analysis revealed a complete rate of the acupuncture groups in the same order as under control conditions. One might discuss whether our placebo condition was really placebo (Patell, 1987; Vincent and Lewith, 1995). It might be the case that the effect of acupuncture does depend on the needling itself and that it is not necessary to needle specific acupuncture locations.

Another reason for the missing effectiveness and superiority of verum acupuncture might be the severity of depression and the operationally defined major depressive episodes according to DSM-III-R criteria, which, of course, were not subject to traditional Chinese proposals in the treatment of mood disorders. It is not excluded that needling of other points would come out with other results. Particularly from the traditional point of view it appears suitable to needle individually selected points for each patient and not performing a standardized acupuncture design as presented here.

The results of our study suggest that the effect of acupuncture is unspecific and might be due to additional attention provided three times a week for nearly half an hour. Patients under acupuncture treatment experienced a calm environment with a high degree of relaxation. Moreover, we cannot exclude that the clinicians performing the acupuncture and necessarily being informed about verum and placebo conditions, intensively cared for in particular the patients receiving placebo acupuncture. This phenomenon might explain why patients under placebo acupuncture improved slightly more than those under verum conditions.

Efficacy and Safety of Auricular Acupuncture for Depression
A Randomized Clinical Trial

Daniel Maurício de Oliveira Rodrigues, PhD; Paulo Rossi Menezes, MD, PhD; Ana Elise Machado Ribeiro Silotto, BSc; Artur Heps, BSc; Nathália Martins Pereira Sanches, MD; Mariana Cabral Schveitzer, PhD; Alexandre Faisal-Cury, MD, PhD

Abstract

IMPORTANCE Depression is a leading cause of disability worldwide, and there is increasing interest in nonpharmacological treatments. Auricular acupuncture (AA) is a simple, low-cost, and well-tolerated option, but further studies are needed to establish its efficacy and safety.

OBJECTIVE To estimate the efficacy and safety of auricular acupuncture as a treatment for depression.

DESIGN, SETTING, AND PARTICIPANTS This randomized clinical trial was conducted at 4 university research centers in Brazil, from March to July 2023. Eligible patients were adults aged 18 to 50 years whose score on the Patient Health Questionnaire–9 (PHQ-9) indicated moderate depression (score 10-14) or moderately severe depression (score 15-19). Exclusion criteria included previous application of AA, risk of suicidal ideation, or severe depression (PHQ-9 score >20). An intent-to-treat analysis and modified intent-to-treat analysis were conducted.

INTERVENTION Participants were randomized into 2 treatment groups, which included specific AA (SA) and nonspecific AA (NSA). Both groups received 12 sessions of AA with semipermanent needles with daily stimulation twice a week over 6 weeks and were followed-up for 3 months. All participants continued with their usual care for ethical reasons. The SA group's treatment protocol consisted of 6 acupuncture points on the auricular pavilion chosen according to the diagnosis of depression by traditional Chinese medicine (Shenmen, subcortex, heart, lung, liver, and kidney). The NSA group's acupuncture points were the external ear, the cheek and face area, and 4 nonspecific points in the helix region unassociated with mental health symptoms. A locator device was used to confirm which areas had neuroreactive points.

MAIN OUTCOMES AND MEASURES The primary outcome was a reduction of at least 50% in the PHQ-9 score (ie, depression recovery) at 3 months. Secondary outcomes included depression recovery at 4 and 6 weeks; depression remission (PHQ-9 score < 5) at 4 weeks, 6 weeks, and 3 months); and adverse events.

RESULTS A total of 304 participants were screened, and 74 participants (62 women [84%]; median [IQR] age, 29 [23-27] years) were included in the intention-to-treat analysis, with 37 participants randomized to each group (SA and NSA). A total of 47 participants (64%) were followed-up through 3 months. The results showed no statistically significant difference in depressive recovery between the groups at 3 months (14 of 24 participants in the SA group [58%] vs 10 of 23 participants in the NSA group [43%]; risk ratio [RR], 1.34; 95% CI, 0.76-2.45; P = .38). The proportions of depression recovery and remission at 4 and 6 weeks based on the PHQ-9 were higher in the SA group (except for depression recovery at 6 weeks) with no statistically significant differences. However, a statistically significant difference was observed in symptom remission at 3 months (11 of 24 participants in the SA

(continued)

Key Points

Question Is auricular acupuncture a safe and effective treatment for depression?

Findings This randomized clinical trial of 74 patients with depression undergoing 6 weeks of auricular acupuncture found no significant differences in adverse event rates between the intervention (specific auricular acupuncture) and control (nonspecific auricular acupuncture) groups, evidencing the intervention's safety. No significant differences were found in depression recovery (50% reduction in Patient Health Questionnaire–9 score from baseline).

Meaning These findings suggest that auricular acupuncture is safe for patients with depression, but additional studies with larger samples and longer interventions are needed for confirmation.

Abstract (continued)

group [46%] vs 3 of 23 participants in the NSA group [13%]; RR, 1.99; 95% CI, 1.16-3.34; *P* = .02) in favor of SA. There were no significant differences in adverse event rates between the groups, evidencing the intervention's safety. Most participants reported mild pain at the needle application site (33 patients [94%] in the SA group vs 32 patients [91%] in the NSA group). Five participants dropped out of the study due to adverse events.

CONCLUSIONS AND RELEVANCE The results of this randomized clinical trial suggest that SA over 6 weeks is safe. Although there was no statistically significant difference between groups for the primary efficacy outcome, patients receiving SA did experience greater symptom remission at 3 months. A larger sample size and longer intervention are needed to further evaluate the efficacy of SA for depression.

TRIAL REGISTRATION ClinicalTrials.gov Identifier: NCT05855421

JAMA Network Open. 2023;6(11):e2345138. doi:10.1001/jamanetworkopen.2023.45138

Introduction

Depression is one of the leading causes of disability worldwide, affecting more than 300 million people (4.4% of the global population).[1] In 2019, depressive disorders represented the highest proportion of disability-adjusted life-years among mental disorders (37.3%).[2] In Brazil, the prevalence depression is among of the highest in the world, affecting 5.8% of the Brazilian population and accounting for 10.3% of years of life lost by Brazilians.[3] However, less than 10% of those affected by the disease receive appropriate treatment.[1,4] Nonadherence to antidepressant treatment is a concern for health care professionals; adherence to antidepressant therapy ranges from 40% to 90% across different studies, with a mean adherence rate of 65%.[5]

Research has shown that Australians and North Americans prefer integrative treatments for depression.[6-8] In this sense, auricular acupuncture (AA), a type of acupuncture in which thin semipermanent needles are inserted into specific points on the auricular pavilion, may be a therapeutic option. AA is easier to implement in clinical settings than body acupuncture owing to its short application time, low technique complexity, relative safety, and daily continuous physiological stimulation.[9]

Several nerves are distributed in the auricular pavilions. The concha area has a rich distribution of the vagus nerve.[10] Anatomical studies have shown that the auricular pavilion is the only place on the human body's surface with a distribution of the afferent vagus nerve.[11] Thus, needle stimulation on the auricular pavilion appears to lead to specific activation in the brain, mainly through the auricular branch of the vagus nerve.[12,13] A systematic review[14] found little evidence of the efficacy of AA for depression. The methodological quality scores showed that most analyzed studies indicated considerable methodological flaws. Additionally, no study in the review[14] used semipermanent needles in the groups. Therefore, this study aims to estimate the efficacy and safety of AA for depression recovery and remission at 4 weeks, 6 weeks, and 3 months.

Methods

Study Design

This randomized clinical trial was approved by the Hospital das Clínicas ethics committee, the University of São Paulo, and the University of Southern Santa Catarina and was monitored by an independent data and safety monitoring board. We followed the Consolidated Standards of Reporting Trials (CONSORT) reporting guideline and the Standards for Reporting Interventions in

Downloaded from jamanetwork.com by guest on 04/28/2026

Clinical Trials of Acupuncture (STRICTA)[15] for the design and reporting of this study. We recruited patients from the community at 4 university research centers in Santa Catarina, Brazil, from March to April 2023. All patients provided written informed consent before participation, and participants did not receive incentives or compensation to be part of the study. The study protocol and statistical analysis plan can be found in Supplement 1.

Participants

The research participants were adults aged 18 to 50 years. Eligible participants were those whose score on the Patient Health Questionnaire–9 (PHQ-9)[16] indicated moderate depression (score of 10-14) or moderately severe depression (score of 15-19). Exclusion criteria included previous application of AA, risk of suicidal ideation, or severe depression (PHQ-9 score ≥20) (eTable 1 in Supplement 2). Demographic characteristics, including gender and race and ethnicity, were collected via self-report on electronic tablets using the REDCap platform. Race and ethnicity categories included Black, White, and multiracial; race and ethnicity were included in this study to align with current research.

Randomization and Blinding

A computer program performed block randomization in a 1:1 ratio, in different block sizes (4, 6, and 8), corresponding to the 2 study groups. The experimental group received specific AA (SA) for depression and usual care, and the control group received nonspecific AA (NSA) and usual care. All participants continued with their usual care for ethical reasons. Participant allocation was concealed and delivered to the acupuncturists in individual opaque sealed envelopes. Participants, evaluators, data managers, and the statistician were blinded to treatment assignment. Neither the study participants nor the investigators had any influence on randomization and allocation concealment, which an independent statistician performed. Participants were informed that there were 2 treatment protocols.

Procedures

The study assessors were trained to approach participants similarly to avoid recruitment biases. The study used a protocol of questions and procedures for all phases: prescreening, screening, data collection, and application of protocols.

Participants with severe depression levels (PHQ score ≥20) or suicidal ideation did not participate in the study and were followed and consulted by a psychiatrist. The sessions of AA application occurred twice weekly, alternating the application on the right and left auricular pavilions, over 6 weeks, totaling 12 sessions, with a duration of 15 minutes each, in reserved rooms. The acupuncturists instructed the participants to stimulate each point manually (de qi stimulation) 3 times a day (morning, afternoon, and evening) for 30 seconds or until the auricular pavilion became red or sensitive to pressure. In this study, the acupuncturists had specific training in the field, with a minimum of 1200 hours in acupuncture and a minimum of 10 years of experience. They received standardized training before the study began.

All participants answered the PHQ-9 questionnaires 4 weeks, 6 weeks, and 3 months after the study initiation and reported adverse events before each AA session (eFigure 1 in Supplement 2). Patients were asked to complete the blinding assessment and treatment efficacy perception assessment and were requested to guess which treatment they received to test the success of blinding after 3 months of the study. More details about AA procedures and outcome assessment can be found in Supplement 1.

SA Treatment

The SA group's treatment consisted of a protocol of acupuncture points chosen according to the diagnosis of depression by traditional Chinese medicine. All SA participants used 6 preestablished points on the auricular pavilion: Shenmen, subcortex, heart, lung, liver, and kidney[17,18] (eFigure 2 and

Downloaded from jamanetwork.com by guest on 04/28/2026

eTable 2 in Supplement 2). The EL11 device (NKL) was used to find the exact location of the points; the device searches on the skin for areas of lower electrical resistance, indicating more neuroreactive points (ie, true acupuncture points).[19] The size of the semipermanent needle (Complementar) used was 0.2 mm wide and 2.5 mm long. The semipermanent needles were inserted to a depth of 2.5 mm.

NSA Treatment

The existing literature acknowledges the difficulty in establishing protocols to be used as a control because of the high responsiveness and innervation of the auricular pavilion (ie, sham needling is not physiologically inert).[19-21] As a control group strategy, our study opted for superficial needling at nonpoints or irrelevant true points, aiming to reach other neural segments. The NSA group points were the external ear, the cheek and face area, and 4 nonspecific points in the helix region (eFigure 3 in Supplement 2), which are points that are not associated with mental health symptoms (eTable 2 in Supplement 2). The EL11 locator device was used to confirm that the sham areas were not neuroreactive points. The size of the needle (Complementar) used in the control group was 0.2 mm wide and 1.0 mm long, aiming for more superficial needling. The semipermanent needles were inserted to a depth of 1.0 mm.

Outcomes

The primary outcome was the proportion of participants who showed improvement of 50% or more in depressive symptoms (ie, depression recovery) between the groups, as assessed by the PHQ-9 at 3 months. Secondary outcomes included the difference in the proportion of participants reaching depression recovery at 4 and 6 weeks; the proportion of participants who achieved a score of less than 5 on the PHQ-9 (indicating depression remission) and differences in depression scores at 4 weeks, 6 weeks, and 3 months; the difference in the proportion of reported adverse events (ie, those arising from the AA technique) and reported adverse effects (ie, the worsening of depression symptoms or the onset of suicidal ideation); and the difference in the proportion of patient blinding to randomization and perception of treatment efficacy (eTable 3 in Supplement 2).

Statistical Analysis

Data analysis in this clinical trial was conducted by an independent hired statistician, blinded to treatment groups. The sample size was designed to detect a 30% difference (experimental group, 60% and control group, 30%) in depression symptom recovery between the 2 groups. A minimum sample of 36 participants per group was estimated, considering the test as 2-tailed, with 80% power and a significance level of $P < .05$. An additional 10% was added, considering segment losses, totaling 40 participants in each group, for 80 participants.

Initially, a baseline comparison between the SA and NSA groups was performed with median and IQR descriptions for continuous variables and frequencies and percentages for categorical variables. Subsequently, intent-to-treat and modified intent-to-treat analyses were conducted to compare the proportions of depression recovery and remission at different time points in the study using Fisher exact test. The effect size for dichotomous variables was calculated as relative risk.

Scores were subjected to a normality test that rejected the normality hypothesis to verify sample normality. Therefore, nonparametric tests were adopted. The reduction of depression scores over time in both groups was evaluated using the median and IQR. The statistical analysis of these data was conducted using the Wilcoxon-Mann-Whitney *U* test.

Cochran *Q* and Friedman analysis of variance tests were also used to verify statistically significant differences in depression scores over time within each group. These tests were followed by post hoc tests to identify significant differences at specific time points. We performed a sensitivity analysis with missing data imputation to evaluate the robustness of the results. Multiple imputation methods were explored, including last observation carried forward, imputation using the generalized estimating equations model, and multiple imputation through the expectation-maximization lag algorithm for categorical variables; the generalized estimating equations model was applied

Downloaded from jamanetwork.com by guest on 04/28/2026

specifically to PHQ-9 depression scores. All analyses were conducted with a significance level of $P < .05$. Relative and absolute frequency were used to assess treatment safety and identify adverse events. The success of blinding and the perception of treatment efficacy were assessed using Fisher exact test. Statistical analyses were performed using R statistical software version 4.1.0 (R Project for Statistical Computing).

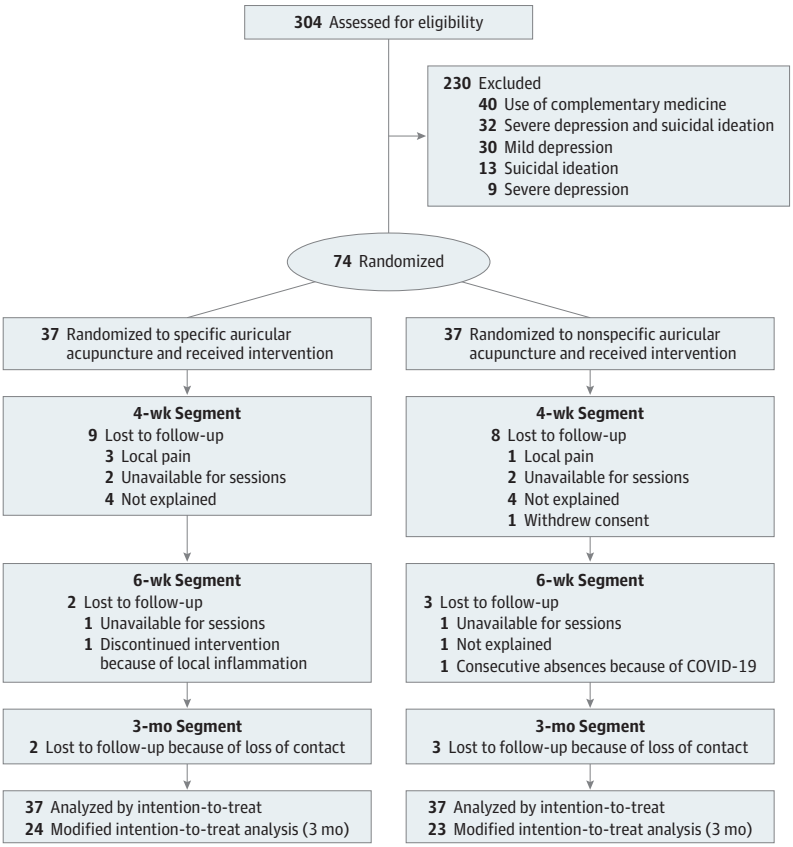
Results

Of the 304 screened volunteers, 230 were excluded for various reasons, resulting in a cohort of 74 participants (62 women [84%]; median [IQR] age, 29 [23-37] years; 5 Black participants [7%]; 61 White participants [82%]; 8 multiracial participants [10%]) comprising the intent-to-treat sample with 37 participants randomized to SA treatment and 37 participants randomized to NSA treatment (**Figure 1**). At 3 months, 27 patients (36%) were lost to follow-up; a total of 47 patients (64%), including 24 patients in the SA group and 23 participants, in the NSA group, comprised the modified intent-to-treat sample. There was no difference between the study groups in the number of patients lost to follow-up (eTable 4 in Supplement 2). We conducted a comparison of baseline depression scores according to the PHQ-9 among the individuals lost to follow-up (eTable 5 in Supplement 2). The groups were similar regarding demographic characteristics, clinical diagnosis, pharmacological treatments, and health characteristics at the study's outset, except for race and ethnicity (**Table 1**).

Primary Outcome

Three months after randomization, 14 of the 24 participants (58%) randomized to the SA group had a reduction of at least 50% in the PHQ-9 score compared with 10 of 23 participants (43%) in the

Figure 1. Flowchart of Screening, Randomization, and Follow-Up



Downloaded from jamanetwork.com by guest on 04/28/2026

NSA group. The result was not statistically significant (risk ratio [RR], 1.34; 95% CI, 0.76-2.45; *P* = .38) (**Table 2**).

Secondary Outcomes

The proportions of patients with depression recovery and remission based on the PHQ-9 at 4 weeks was higher in the SA group, but not at 6 weeks, and there were no statistically significant differences between the groups at 4 or 6 weeks. A statistically significant difference in favor of the SA group was observed in depression remission after 3 months (11 of 24 participants [46%] in the SA group vs 3 of 23 participants in the NSA group [13%]; RR, 1.99; 95% CI, 1.16-3.34; *P* = .02) (Table 2). The median PHQ-9 scores decreased after 4 weeks, 6 weeks, and 3 months in both groups, with no statistically significant differences. Lower scores were observed in the SA group than in the NSA group (eTable 6 in Supplement 2 and **Figure 2**).

The modified intent-to-treat analyses showed the similar results as the intention-to-treat analyses. Intragroup analysis was performed using the Cochran *Q* test, with no statistically significant differences (eTable 7 in Supplement 2). Intragroup analysis was performed using the Friedman analysis of variance test followed by post hoc tests for the differences in PHQ-9 scores at each time

[a] A score of 10 to 14 indicates moderate depression; 15 to 19, moderately severe depression; and 20 to 25, severe depression.

[b] The monthly minimum wage in Brazil is equivalent to $250 in 2023.

Downloaded from jamanetwork.com by guest on 04/28/2026

point compared with baseline, which revealed statistically significant differences in all evaluations, in both groups, at different assessment points (eTable 8 and eFigure 4 in Supplement 2).

Sensitivity Analyses

The sensitivity analyses revealed that there were no statistically significant differences in depression recovery across the visits (eTable 9 in Supplement 2). These analyses confirmed the statistically significant results in favor of the SA group regarding depression remission after 3 months (eTable 10 in Supplement 2). As for PHQ-9 scores, the generalized estimating equations model demonstrated favorable effect sizes of SA, and the visits had a statistically significant effect on the scores (eTable 11 and 12 in Supplement 2).

Safety

Most participants reported mild pain at the needle application site (33 patients [94%] in the SA group vs 32 patients [91%] in the NSA group). One participant had mild local inflammation in 1 of the auricular points and received appropriate treatment. Regarding adverse events, an increase in

Table 2. Primary and Secondary Efficacy Outcomes in the Intention-to-Treat Analysis

Outcomes	Participants, No./Total No. (%)		RR (95% CI)[a]	*P* value[b]
	SA group	NSA group		
Primary outcome, depression recovery at 3 mo vs baseline (n = 47)[c,d]	14/24 (58)	10/23 (43)	1.34 (0.76-2.45)	.38
Secondary outcomes				
Depression recovery at 4 wk vs baseline (n = 57)	12/28 (43)	9/29 (31)	1.28 (0.74-2.14)	.42
Depression recovery at 6 wk vs baseline (n = 51)	10/26 (38)	10/25 (40)	0.96 (0.53-1.65)	>.99
Symptom remission at 4 wk vs baseline (n = 57)[e]	8/28 (28)	5/29 (17)	1.35 (0.72-2.20)	.36
Symptom remission at 6 wk vs baseline (n = 51)	7/26 (27)	5/25 (20)	1.19 (0.61-2.00)	.74
Symptom remission at 3 mo vs baseline (n = 47)	11/24 (46)	3/23 (13)	1.99 (1.16-3.34)	.02

Abbreviations: NSA, nonspecific auricular acupuncture; RR, risk ratio; SA, specific auricular acupuncture.

[a] Effect size was calculated as RR for dichotomous data.

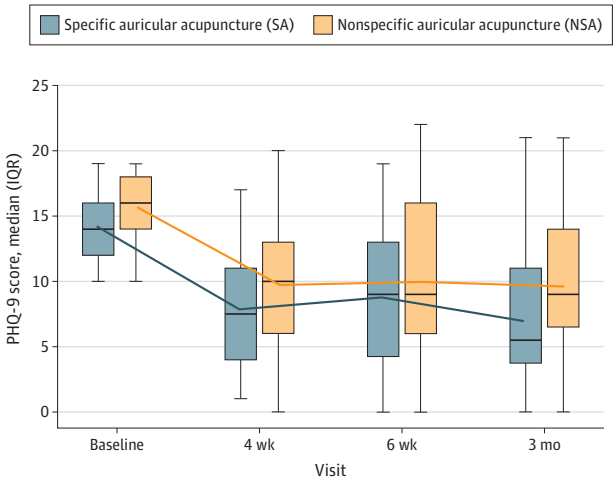
[b] Statistical significance was calculated with Fisher exact test.

[c] The primary outcome (improvement in depression symptoms) was defined as a reduction of 50% or more from baseline Patient Health Questionnaire-9 (PHQ-9) scores. The number of cases and proportions are based on observed data.

[d] Depressive symptoms measured by PHQ-9 scores range from 0 (least) to 27 (greatest) symptom burden.

[e] Participants who achieved a score less than 5 on the PHQ-9, indicating symptom remission.

Figure 2. Median Depression Scores by Intention-to-Treat Analysis



The figure shows the median Patient Health Questionnaire-9 (PHQ-9) scores of patients receiving specific auricular acupuncture (SA) and nonspecific auricular acupuncture (NSA) at baseline, 4 weeks, 6 weeks, and 3 months. A score of 10 to 14 indicates moderate depression; 15 to 19, moderately severe depression; and 20 to 25, severe depression. The lines inside the boxes reflect the medians, with the upper and lower ends of the boxes reflecting the IQRs. The error bars reflect the minimum and maximum values. The line plot reflects means.

Downloaded from jamanetwork.com by guest on 04/28/2026

depression scores was observed during data collection in 3 participants, and 7 individuals responded positively to question 9 of the PHQ-9, which addresses suicidal ideation. These cases were carefully monitored, and the independent data monitoring and safety committee did not consider these events related to the intervention. No statistically significant difference was found between the groups in the proportion of participants with adverse effects (ie, those arising from AA) and adverse events (ie, worsening of depression symptoms or suicidal ideation). Five participants withdrew from the study as a result of adverse effects. No severe adverse events were reported (**Table 3**). The study participants did not change their medications or psychotropic medication dosages throughout the data collection.

Blinding Quality

For results on the success of blinding, see eTable 13 in Supplement 2. No difference was found between groups in the proportion of patients who guessed correctly what kind of AA they had received and their perception of efficacy in symptom relief after the 3 months.

Discussion

The results of this randomized clinical trial showed no difference in depression recovery between the groups at 3 months. However, depression remission at 3 months was significantly higher in the SA group. In addition, no significant differences were observed in the rates of adverse events and adverse effects, and no severe adverse events were recorded, evidencing practice safety. To our knowledge, this is the first randomized clinical trial on the effectiveness of SA using a semipermanent needle with NSA directed at depression as the comparator group. However, previous studies[22-28] using other AA techniques found favorable results in depressive symptoms, but with shorter study duration and different comparators.

Table 3. Adverse Effects and Adverse Events Listed by Treatment Group

Adverse event or adverse effect	Participants, No. (%) (N = 74)	
	SA group (n = 37)	NSA group (n = 37)
Mild and transient adverse effects		
Mild pain	33 (94)	32 (91)
Intense pain	1 (3)	0
Punctate bleeding	3 (9)	2 (6)
Itching in the auricle	11 (31)	14 (40)
Increased appetite	1 (3)	0
Headache	1 (3)	0
Hot flashes	0	1 (3)
Difficulty sleeping	0	2 (6)
Sensitivity to pressure	1 (3)	2 (6)
Facial skin hypersensitivity	0	1 (3)
Moderate adverse effect: local inflammation	1 (3)	0
Moderate adverse events		
Worsening of depressive symptoms (4 wk)	0	0
Worsening of depressive symptoms (6 wk)	0	1 (6)
Worsening of depressive symptoms (3 mo)	1 (3)	1 (6)
Emergence of suicidal ideation (4 wk)	0	2 (6)
Emergence of suicidal ideation (6 wk)	0	2 (6)
Emergence of suicidal ideation (3 mo)	2 (6)	2 (6)
Any severe adverse events and adverse effects	0	0
Discontinuation due to adverse effects		
Local pain	3 (9)	1 (3)
Local inflammation	1 (3)	0

Abbreviations: NSA, nonspecific auricular acupuncture; SA, specific auricular acupuncture.

These preliminary findings are promising and support the use of SA in depression treatment. The rates of recovery (58%) and remission (46%) from depression in the present study are similar to those observed in meta-analyses of pharmacological treatments[29,30] and superior to those for psychotherapy.[31] The 33% difference in symptom remission between the groups (ie, 46% remission in the SA group vs 13% in the NSA group) was clinically meaningful; depression remission is crucial for patients, providing better psychosocial functioning and long-term prognosis, not just symptom improvement.[32]

The absence of statistically significant differences between the groups for depression recovery can be explained. First, the small sample size resulted in insufficient power and may have underestimated true efficacy. Second, considering the economic cost of time and participant adherence, we provided only 12 sessions over 6 weeks in this study. Therefore, adding AA doses by increasing the treatment duration (eg, 16-18 sessions over 8-12 weeks) may be an effective way to streamline the treatment program. Third, the manual stimulation of the semipermanent needle (known as de qi induction) is a factor that affects the efficacy of AA. To maintain the blinding of the study, the NSA group also used this daily stimulation, which may have contributed to an increased effect size of the technique in this group. Fourth, the study's follow-up loss (36%) may have impacted the results. However, adherence to depression treatment remains a relevant and common challenge to overcome in clinical trials. A study by Olfson et al[33] found that 36.4% of patients discontinued antidepressant treatment within the first 30 days. A meta-analysis[34] reported a 36.4% dropout rate for cognitive behavioral therapy. A study[35] on acupuncture in depression treatment observed a dropout rate similar to the present study. This trend of treatment discontinuation seems to be associated with the characteristics of the disease itself (apathy, hopelessness, and lethargy). Regardless of the chosen treatment, patients with depression are likely to discontinue treatment.[36]

First-line therapy for depression is medication, but several factors interfere with treatment access and adherence, such as system barriers and clinical and individual factors.[37] Therefore, it is necessary to offer a wide range of evidence-based therapies to treat depression, aiming at person-centered mental health care.[38] AA may be an option for patients who reject medication or psychotherapy because it has fewer adverse effects than pharmacological treatment. A systematic review[39] of adverse events associated with AA found that most were transient, mildly intense, and tolerable. No severe adverse events were identified in our study, indicating that AA is a safe treatment.

Besides the technique's safety, patients in the SA group had increased rates of symptom remission between 6 weeks and 3 months, which may be associated with the delayed effects of AA treatment.[40] We should underscore that in AA, part of the technique's effect is attributed to stimulating the auricular branch of the vagus nerve, increasing parasympathetic activity while simultaneously decreasing sympathetic nervous system activity.[41,42] This effect may lead to an improvement in depression-related symptoms.[13] A systematic review[43] concluded that trigeminal nerve stimulation and transcutaneous vagus nerve stimulation improve the treatment of specific neuropsychiatric disorders, such as depression.

An additional hypothesis is that AA may reduce serotonin depletion by inhibiting the hyperactive hypothalamic-pituitary-adrenal axis, which would explain the technique's prolonged effect at the 3-month follow-up.[44] Experimental studies confirmed this hypothesis, showing that the antidepressant effect of AA is possibly associated with the normalization of this axis' hyperactivity.[45] Additionally, some studies[10,13]observed that AA can trigger cardioinhibitory effects similar to vagus nerve stimulation. It is essential to highlight that participants in the NSA group may have also experienced temporary inhibition of this axis due to the perception of having received adequate treatment. However, this effect tends to decrease gradually after the end of the treatment sessions.

This study has strengths. First, the research addressed the selection of AA points, providing a solid foundation for future large-scale studies. In addition, the study included a more extended study period and experienced acupuncturists who used semipermanent needles, which are considered

Downloaded from jamanetwork.com by guest on 04/28/2026

more effective than other stimuli. The control group received needling in nonspecific areas, and blinding measures were implemented for assessors, participants, and the statistician.

Limitations

The present study also has limitations. The predominance of women in the sample precluded the detection of possible gender differences in the results. Using self-report instruments to measure the primary outcome may also introduce bias into the results. Other major limitations include the limited sample size and the relatively high loss of participants during the follow-up period. Additionally, an NSA group with positive results indicates the need to investigate better the mechanisms of action and nonspecific outcomes associated with AA.

Conclusions

The results of this randomized clinical trial suggest that SA over 6 weeks is feasible and safe. Although the differences between SA and NSA groups did not reach statistical significance for the primary outcome, SA did produce greater symptom remission at 3 months. A more extensive sample size study, more protracted intervention, and objective evaluation of the results are necessary to further investigate the efficacy of SA for depression.

Hypoglossal Nerve Stimulation for Obstructive Sleep Apnea

Plain Language Summary:

This is a small device placed inside the body for people with certain types of sleep apnea. It is meant to work with the airway and breathing during sleep. The device is one option that may be considered to treat people with this condition.

Staff Analysis Summary:

Significant proposed changes or discussion items:

Recommendation to cover HGNS for adults 21 and older diagnosed with obstructive sleep apnea who meet criteria listed below.

Coverage Question:

Should hypoglossal nerve stimulation be covered for adults with moderate to severe obstructive sleep apnea?

Question source:

Evidence-based guideline subcommittee

Background:

EbGS approved a coverage guidance regarding hypoglossal nerve stimulator devices for obstructive sleep apnea at the 4/16/26 meeting. EbGS previously reviewed this topic on 9/19/24 and voted to table the draft coverage report for 1 year. Staff monitored the release of newly published studies and a newly approved HGNS device prior to bringing the report back to EbGS meeting on 9/11/25 where it was referred for a 30-day comment period and returned the EbGS meeting on 2/5/26 where the approved motion was to post the modified report for an additional 21-day comment period.

The “blue box” wording is shown below:

** Current Dental Terminology © 2025 American Dental Association. All rights reserved

SHOULD HYPOGLOSSAL NERVE STIMULATION BE COVERED FOR ADULTS WITH MODERATE TO SEVERE OBSTRUCTIVE SLEEP APNEA?

We recommend coverage of hypoglossal nerve stimulation (HGNS) for symptomatic adults age 21 and older when all of the following criteria are met:

1) **A polysomnography study is performed within 24 months of first consultation for HGNS implant that shows both**
   a. **Moderate to severe sleep apnea (apnea-hypopnea index (AHI) 15 to 100 events per hour using the 4% oxygen desaturation threshold for hypopneas; AHI4); *AND***
   b. **Predominantly obstructive events (defined as central and mixed apneas less than 25% of the total AHI4); *AND***
2) **Have a body mass index (BMI) 35 kg/m^2 or less; *AND***
3) **Not responsive to continuous positive airway pressure (CPAP) therapy, defined as either of the following (as documented by a sleep specialist):**
   a. **Inability to use CPAP greater than 5 nights per week of at least 4 hours per night; *OR***
   b. **Have a lack of adequate response to CPAP therapy (i.e., AHI4 of greater than 15 despite CPAP usage; *AND***
4) **Drug induced sleep endoscopy (DISE) findings consistent with the absence of concentric collapse at the soft palate level (per FDA labeling); A*ND***
5) **No other anatomical findings that would compromise performance of device (e.g., tonsil size 3 or 4 per standardized tonsillar hypertrophy grading scale); *AND***
6) **Do not have any contraindications to the device.**

Previous HSC/HERC reviews:

No prior review of HGNS.

Current Prioritized List/Coverage status:

DIAGNOSTIC GUIDELINE D8, DIAGNOSTIC TESTING FOR OBSTRUCTIVE SLEEP APNEA (OSA)

For adults over the age of 18 years:

*CPT only copyright 2025 American Medical Association. All rights reserved.
** Current Dental Terminology © 2025 American Dental Association. All rights reserved

Hypoglossal Nerve Stimulation for Obstructive Sleep Apnea

A) For patients with clinical signs and symptoms consistent with obstructive sleep apnea (OSA), a home sleep study is the first-line diagnostic test for most patients, when available.
    1) For portable devices, Type II-III are included on this line. Type IV sleep testing devices must measure three or more channels, one of which is airflow, to be included on this line. Sleep testing devices that are not Type I-IV and measure three or more channels that include actigraphy, oximetry, and peripheral arterial tone, are included on this line.
B) Polysomnography in a sleep lab is indicated as a first-line test for patients with significant cardiorespiratory disease, potential respiratory muscle weakness due to a neuromuscular condition, awake hypoventilation or suspicion of sleep related hypoventilation, chronic opioid medication use, history of stroke or severe insomnia.
C) If a patient has had an inconclusive (or negative) home sleep apnea test and a clinical suspicion for OSA remains, then attended polysomnography is included on this line. Split night diagnostic protocols are required when a diagnosis of OSA is confirmed in the first portion of the night.
D) Repeat sleep studies are covered up to twice a year when one of the following has occurred since the most recent test:
    1) recurrence of OSA symptoms
    2) weight change of more than 10% of body weight
    3) new or worsening health conditions related to OSA
    4) upper airway surgical procedures or initial treatment with oral appliances

For children age of 18 or younger:

A) Obstructive sleep apnea (OSA) must be diagnosed by
    1) nocturnal polysomnography with an AHI >5 episodes/h or AHI >1 episodes/h with history and exam consistent with OSA, OR
    2) nocturnal pulse oximetry with 3 or more SpO2 drops <90% and 3 or more clusters of desaturation events, or
        i) alternatives desaturation (>3%) index >3.5 episodes/h,OR
    3) use of a validated questionnaire (such as the Pediatric Sleep Questionnaire or OSA 18), OR
    4) consultation with a sleep medicine specialist.

*CPT only copyright 2025 American Medical Association. All rights reserved.
** Current Dental Terminology © 2025 American Dental Association. All rights reserved

B) Polysomnography and/or consultation with a sleep medicine specialist to support the diagnosis of OSA and/or to identify perioperative risk is recommended for
   1) high-risk children (i.e., children with cranio-facial abnormalities, neuromuscular disorders, Down syndrome, etc.)
   2) children with equivocal indications for adenotonsillectomy (such as discordance between tonsillar size on physical examination and the reported severity of sleep-disordered breathing), children younger than three years of age

C) Drug-induced sleep endoscopy (CPT *42975) is only covered when ALL of the following criteria are met:
   1) The patient is under 21 years of age; AND
   2) The patient has OSA diagnosed by polysomnography; AND
   3) The patient is being evaluated for upper airway surgery for OSA; AND
   4) The patient has at least one of the following:
      a) A high-risk condition including but not limited to trisomy 21 (Down's syndrome), craniofacial anomalies, hypotonia, or neurological disorder; OR
      b) A known physical airway anomaly.

The development of this guideline note was informed by a HERC coverage guidance. See https://www.oregon.gov/oha/HPA/DSI-HERC/Pages/Evidence-based-Reports.aspx

GUIDELINE NOTE 27, TREATMENT OF SLEEP APNEA

Line 201

For adults over the age of 18 years:

CPAP is covered initially when all of the following conditions are met:

12 week 'trial' period to determine benefit. This period is covered if apnea-hypopnea index (AHI) calculated using the CMS definition of hypopnic episode of at least 4% oxygen desaturation or respiratory disturbance index (RDI) is greater than or equal to 15 events per hour; or if between 5 and 14 events with additional symptoms including one or more of the following:

excessive daytime sleepiness defined as either an Epworth Sleepiness Scale score >10 or daytime sleepiness interfering with ADLs that is not attributable to another modifiable sedating condition (e.g. narcotic dependence), or

documented hypertension, or

ischemic heart disease, or

*CPT only copyright 2025 American Medical Association. All rights reserved.
** Current Dental Terminology © 2025 American Dental Association. All rights reserved

history of stroke
Additionally:
Providers must provide education to patients and caregivers prior to use of CPAP machine to ensure proper use; and
Positive diagnosis through polysomnogram (PSG) or Home Sleep Test (HST).
CPAP coverage subsequent to the initial 12 weeks is based on documented patient tolerance, compliance, and clinical benefit. Compliance (adherence to therapy) is defined as use of CPAP for at least four hours per night on 70% of the nights during a consecutive 30-day period.
Mandibular advancement devices (oral appliances) are covered for those for whom CPAP fails or is contraindicated.
Surgery for sleep apnea in adults is not included on this line (due to lack of evidence of efficacy). Surgical codes are included on this line only for children who meet criteria below
Hypoglossal nerve stimulation for treatment of obstructive sleep apnea is not included on this line due to insufficient evidence of effectiveness and evidence of harm.
For children age of 18 years or younger:

A) Adenotonsillectomy is an appropriate first line treatment for children with OSA. Adenoidectomy without tonsillectomy is only covered when a child with OSA has previously had a tonsillectomy, when tonsillectomy is contraindicated, or when tonsillar hypertrophy is not present. More complex surgical treatments are only included on this line for children with craniofacial anomalies.
B) Intranasal corticosteroids are an option for children with mild OSA in whom adenotonsillectomy is contraindicated or for mild postoperative OSA.
C) CPAP is covered for a 3-month trial for children through age 18 who have
    1) undergone surgery or are not candidates for surgery, AND
    2) have documented residual sleep apnea symptoms (sleep disruption and/or significant desaturations) with residual daytime symptoms (daytime sleepiness or behavior problems)
D) CPAP will be covered for children through age 18 on an ongoing basis if:
    1) There is documentation of improvement in sleep disruption and daytime sleepiness and behavior problems with CPAP use, AND
    2) Annual re-evaluation for CPAP demonstrates ongoing clinical benefit and compliance with use, defined as use of CPAP for at least four hours per night on 70% of the nights in a consecutive 30-day period

The development of this guideline note was informed by a HERC coverage guidance. See https://www.oregon.gov/oha/HPA/DSI-HERC/Pages/Evidence-based-Reports.aspx

*CPT only copyright 2025 American Medical Association. All rights reserved.

HERC staff summary:

The coverage guidance contains criteria that require clarification in order to be implemented:

1) CPAP criteria: "Not responsive to CPAP" is defined as either of the following (as documented by a sleep specialist):
    a. Inability to use CPAP greater than 5 nights per week of at least 4 hours per night; *OR*
    b. Have a lack of adequate response to CPAP therapy (i.e., AHI4 of greater than 15 despite CPAP usage
2) Multiple hypoglossal nerve stimulation devices are FDA approved and may be covered for adults 21 and older with a diagnosis of obstructive sleep apnea with an AHI between 15-100 and a BMI of 35 or less who are not responsive to CPAP therapy.
3) Drug-induced Sleep Endoscopy (DISE): Per FDA labeling, DISE is required prior to placement of an Inspire device, but not Genio.

HERC staff recommendation:

1) Modify Diagnostic Guideline D8 as shown below to address Drug-induced Sleep Endoscopy when required prior to HGNS device placement per FDA labeling
    a) Consider whether to allow DISE for 19-20 year olds according to the adult criteria
2) Modify Guideline Note 27 as shown below

DIAGNOSTIC GUIDELINE D8, DIAGNOSTIC TESTING FOR OBSTRUCTIVE SLEEP APNEA (OSA)

For adults over the age of 18 years:

A) For patients with clinical signs and symptoms consistent with obstructive sleep apnea (OSA), a home sleep study is the first-line diagnostic test for most patients, when available.
    1) For portable devices, Type II-III are included on this line. Type IV sleep testing devices must measure three or more channels, one of which is airflow, to be included on this line. Sleep testing devices that are not Type I-IV and measure three or more channels that include actigraphy, oximetry, and peripheral arterial tone, are included on this line.

** Current Dental Terminology © 2025 American Dental Association. All rights reserved

B) Polysomnography in a sleep lab is indicated as a first-line test for patients with significant cardiorespiratory disease, potential respiratory muscle weakness due to a neuromuscular condition, awake hypoventilation or suspicion of sleep related hypoventilation, chronic opioid medication use, history of stroke or severe insomnia or being evaluated for placement of a hypoglossal nerve stimulator.

C) If a patient has had an inconclusive (or negative) home sleep apnea test and a clinical suspicion for OSA remains, then attended polysomnography is included on this line. Split night diagnostic protocols are required when a diagnosis of OSA is confirmed in the first portion of the night.

D) Repeat sleep studies are covered up to twice a year when one of the following has occurred since the most recent test:
   1) recurrence of OSA symptoms
   2) weight change of more than 10% of body weight
   3) new or worsening health conditions related to OSA
   4) upper airway surgical procedures or initial treatment with oral appliances
   5) an evaluation for placement of hypoglossal nerve stimulator has become necessary

E) Drug-induced sleep endoscopy is covered when the patient is 21 years of age or older and recommended for placement of a hypoglossal nerve stimulator where FDA labeling requires drug-induced sleep endoscopy prior to placement.

For children age of 18 or younger:
Obstructive sleep apnea (OSA) must be diagnosed by
nocturnal polysomnography with an AHI >5 episodes/h or AHI >1 episodes/h with history and exam consistent with OSA, OR
nocturnal pulse oximetry with 3 or more SpO2 drops <90% and 3 or more clusters of desaturation events, or
alternatives desaturation (>3%) index >3.5 episodes/h,OR
use of a validated questionnaire (such as the Pediatric Sleep Questionnaire or OSA 18), OR
consultation with a sleep medicine specialist.
Polysomnography and/or consultation with a sleep medicine specialist to support the diagnosis of OSA and/or to identify perioperative risk is recommended for
high-risk children (i.e., children with cranio-facial abnormalities, neuromuscular disorders, Down syndrome, etc.)

children with equivocal indications for adenotonsillectomy (such as discordance between tonsillar size on physical examination and the reported severity of sleep-disordered breathing), children younger than three years of age

Drug-induced sleep endoscopy (CPT *42975) is only covered when ALL of the following criteria are met:

The patient is under 21 years of age; AND

The patient has OSA diagnosed by polysomnography; AND

The patient is being evaluated for upper airway surgery for OSA; AND

The patient has at least one of the following:

A high-risk condition including but not limited to trisomy 21 (Down's syndrome), craniofacial anomalies, hypotonia, or neurological disorder; OR

A known physical airway anomaly.

The development of this guideline note was informed by a HERC coverage guidance. See https://www.oregon.gov/oha/HPA/DSI-HERC/Pages/Evidence-based-Reports.aspx

GUIDELINE NOTE 27, TREATMENT OF SLEEP APNEA

Line 201

For adults over the age of 18 years:

A) CPAP is covered initially when all of the following conditions are met:
   1) 12 week 'trial' period to determine benefit. This period is covered if apnea-hypopnea index (AHI) calculated using the CMS definition of hypopnic episode of at least 4% oxygen desaturation or respiratory disturbance index (RDI) is greater than or equal to 15 events per hour; or if between 5 and 14 events with additional symptoms including one or more of the following:
      a) excessive daytime sleepiness defined as either an Epworth Sleepiness Scale score >10 or daytime sleepiness interfering with ADLs that is not attributable to another modifiable sedating condition (e.g. narcotic dependence), or
      b) documented hypertension, or
      c) ischemic heart disease, or
      d) history of stroke
   2) Additionally:
      a) Providers must provide education to patients and caregivers prior to use of CPAP machine to ensure proper use; and

HEALTH EVIDENCE REVIEW COMMISSION (HERC) COVERAGE GUIDANCE

HYPOGLOSSAL NERVE STIMULATION FOR OBSTRUCTIVE SLEEP APNEA

DRAFT for May 14, 2026 HERC meeting materials

QUESTION 1

SHOULD HYPOGLOSSAL NERVE STIMULATION BE COVERED FOR ADULTS WITH MODERATE TO SEVERE OBSTRUCTIVE SLEEP APNEA?

We recommend coverage of hypoglossal nerve stimulation (HGNS) for symptomatic adults age 21 and older when all of the following criteria are met:

1) **A polysomnography study is performed within 24 months of first consultation for HGNS implant that shows both**
   a. **Moderate to severe sleep apnea (apnea-hypopnea index (AHI) 15 to 100 events per hour using the 4% oxygen desaturation threshold for hypopneas; AHI4); *AND***
   b. **Predominantly obstructive events (defined as central and mixed apneas less than 25% of the total AHI4); *AND***
2) **Have a body mass index (BMI) 35 kg/m^2 or less; *AND***
3) **Not responsive to continuous positive airway pressure (CPAP) therapy, defined as either of the following (as documented by a sleep specialist):**
   a. **Inability to use CPAP greater than 5 nights per week of at least 4 hours per night; *OR***
   b. **Have a lack of adequate response to CPAP therapy (i.e., AHI4 of greater than 15 despite CPAP usage; *AND***
4) **Drug induced sleep endoscopy (DISE) findings consistent with the absence of concentric collapse at the soft palate level (per FDA labeling); A*ND***
5) **No other anatomical findings that would compromise performance of device (e.g., tonsil size 3 or 4 per standardized tonsillar hypertrophy grading scale); *AND***
6) **Do not have any contraindications to the device.**

Rationale:

We recommend coverage because the improvement in sleep-related quality of life and OSA severity outweighs the risk of the procedure in selected patients. We have added coverage criteria for this treatment consistent with inclusion criteria in the reported studies, additionally informed by certain Medicare criteria and on supplemental data.

RATIONALE FOR DEVELOPMENT OF COVERAGE GUIDANCES AND MULTISECTOR INTERVENTION REPORTS

Coverage guidances are developed to inform coverage recommendations for public and private health plans in Oregon as plan administrators seek to improve patients' experience of care, population health, and the cost-effectiveness of health care. In the era of public and private sector health system transformation, reaching these goals requires a focus on maximizing the benefits and minimizing the harms and costs of health interventions.

The Health Evidence Review Commission (HERC) uses the following principles in selecting topics for its reports to guide public and private payers:

- Represents a significant burden of disease or health problem
- Represents important uncertainty with regard to effectiveness or harms
- Represents important variation or controversy in implementation or practice
- Represents high costs or significant economic impact
- Topic is of high public interest

HERC bases its reports on a review of the best-available research applicable to the intervention(s) in question. For coverage guidances that focus on diagnostic and clinical interventions, evidence is evaluated using an adaptation of the Grading of Recommendations, Assessment, Development, and Evaluations (GRADE) methodology. For more information on coverage guidance methodology, see Appendix A.

Multisector interventions can be effective ways to prevent, treat, or manage disease at a population level. In some cases, HERC has reviewed evidence and identified effective interventions, but has not made formal coverage recommendations when these policies are implemented in settings other than traditional health care delivery systems, as effectiveness could depend on the environment in which the intervention is implemented.

GRADE

HERC develops recommendations by using the concepts of the GRADE approach. GRADE is a transparent and structured process for developing and presenting evidence and for performing the steps involved in developing recommendations. The tables below list the elements that determine the strength of a recommendation. HERC reviews the evidence and assesses each element, which in turn is used to develop the recommendations presented in the coverage guidance box. Estimates of effect are derived from the evidence presented in this document. Assessments of confidence are from published systematic reviews and meta-analyses, where available and judged to be reliable. The level of confidence in the estimate is determined by HERC based on the assessment of 2 independent reviewers from the Center for Evidence-based Policy (Center; see Figure 1).

In some cases, no systematic reviews or meta-analyses encompass the most current literature. In those cases, HERC may describe the additional evidence or alter the assessments of confidence in light of all available information. Such assessments are informed by clinical epidemiologists from the Center. Unless

otherwise noted, statements regarding resource allocation, values and preferences, and other considerations are the assessments of HERC, as informed by the evidence reviewed, public testimony, and subcommittee discussion.

FIGURE 1. GRADE TABLE KEY

OUTCOMES	TABLE KEY				
Confidence in Estimate:	NO DATA ○○○○	VERY LOW ●○○○	LOW ●●○○	MODERATE ●●●○	HIGH ●●●●

GRADE TABLE

GRADE TABLE

HYPOGLOSSAL NERVE STIMULATION FOR ADULTS WITH MODERATE TO SEVERE OBSTRUCTIVE SLEEP APNEA

CRITICAL OUTCOMES

Quality of Life

BENEFIT

Evidence summary

Three studies, which investigated the only FDA-approved hypoglossal nerve stimulation (HGNS) device for adults with moderate to severe obstructive sleep apnea (OSA) who were intolerant to or unable to eliminate OSA with continuous positive airway pressure (CPAP), reported sleep-related quality of life (QoL) outcomes. The studies were 2 randomized controlled trials (RCTs) and 1 cohort study (N = 485). The 2 RCTs enrolled people who had a previous implantation of the HGNS device with a positive response and randomized participants to inactivation of the device or subtherapeutic stimulation. Participants in the cohort study did not begin using HGNS until after enrollment. When reported, there were no significant differences between study groups in terms of baseline sleep-related QoL scores.

Across these studies, groups who received HGNS therapy had better sleep-related QoL compared with controls (i.e., inactive device, subtherapeutic stimulation, no treatment) at follow-up (range, 2 weeks to 6 months), as indicated by significantly higher mean scores on the Functional Outcomes of Sleep Questionnaire (FOSQ). Differences in mean follow-up FOSQ scores between study groups also exceeded the established minimal clinically important difference (MCID; ≥ 1 point).

- EFFECT RCT (2 weeks): 17.0 vs. 14.9 points; $P < .001$
- STAR RCT (1 month): 17.9 vs. 15.0 points; $P < .001$
- ADHERE Comparative Cohort (6 months): 17.1 vs. 12.4 points; $P < .001$

No eligible studies of FDA-approved HGNS devices reported measures of general QoL.

Confidence rating

Low confidence that HGNS improves sleep-related QoL compared with controls.

3 studies (2 RCTs, 1 comparative cohort); N = 485

- Risk of bias concerns: limited methods reporting, selection bias in RCTs, industry funding, and author conflict of interest
- Indirectness: study design heterogeneity; study populations more limited than current FDA indication for HGNS and lack of demographic generalizability to Medicaid
- Other: short follow-up periods relative to intended length of intervention

Device-Related Severe Adverse Events

Evidence summary

Thirteen studies (2 RCTs, 1 comparative cohort study, 3 noncomparative cohort studies, 6 registry studies, and 1 systematic review) investigating the only FDA-approved HGNS device reported on device-related serious adverse events (SAEs). In general, device-related SAEs were infrequently reported in the 13 studies.

Device explants and device revisions were reported most frequently:

GRADE TABLE

HYPOGLOSSAL NERVE STIMULATION FOR ADULTS WITH MODERATE TO SEVERE OBSTRUCTIVE SLEEP APNEA

Revisions and Explants

HARM

- In 3 studies on total device revisions for participants, the rate of device revisions ranged from 0.4% to 6.3% of study participants.
- In 3 studies on total device explants for participants, the rate of device explants ranged from 0.05% to 5.2% of study participants.

Other Device-Related SAEs

HARM

Confidence rating

Studies reported actual harms (i.e., SAEs), but there is moderate (device revisions and explants) and low (other device-related SAEs) confidence of the scope and magnitude of the harms due to:

- Risk of bias concerns: industry funding and author conflict of interest, reporting bias, selection bias, and, for the systematic review, risk of bias methods
- Indirectness: study populations were more limited than current FDA indication for HGNS and lack demographic generalizability to Medicaid (concern for other device-related SAEs, not a concern for device revisions or explants), range of SAEs reported, differences in categorizing outcomes as SAEs versus AEs
- Other: Generally short follow-up periods that limit the ability to consider SAEs that may develop over the course of the intervention

IMPORTANT OUTCOMES

OSA Severity (Polysomnography Outcomes)

BENEFIT

Evidence summary

Five studies, which investigated the only FDA-approved HGNS device for adults with moderate to severe OSA who were intolerant to or unable to eliminate OSA with CPAP, reported OSA severity as measured by polysomnography. The studies included 3 RCTs and 2 cohort studies. The 3 RCTs enrolled people who had a previous implantation of the HGNS device with a positive response and randomized participants to inactivation of the device or subtherapeutic stimulation. Participants in the cohort studies did not begin using HGNS until after enrollment. There were no significant differences in baseline severity between study groups.

Compared with patients with an inactive device, subtherapeutic stimulation, or no treatment (3 RCTs and 1 cohort study; N = 547), patients who received HGNS therapy had significantly lower OSA severity, as indicated by significantly lower apnea-hypopnea index (AHI4) and oxygen desaturation index (ODI4) scores across all follow-up timepoints (range, 2 weeks to 6 months). In 3 studies, the differences in mean follow-up AHI4 and ODI4 scores between study groups exceeded the established MCID (≥ 5 events per hour).

- EFFECT RCT (2 weeks): AHI4, +0.6 vs. +16. (change scores); ODI4, +0.6 vs. +12.7 (change scores); $P < .001$ for both
- STAR RCT (1 month): AHI4, 8.9 vs. 25.8; ODI4, 8.0 vs. 23.0; $P < .001$ for both
- CARDIOSA-12 RCT (10 weeks): AHI4: 18.1 vs. 23.0; ODI4 NR; *P* value NR
- ADHERE Comparative Cohort (6 months): AHI4, 14.7 vs. 26.8; ODI4, 14.1 vs. 25.5; $P < .001$ for both

In the 3 studies that reported mean scores at follow-up, scores in the HGNS groups were generally indicative of mild OSA severity (i.e., ≥ 5 to < 15 events per hour)

whereas scores in the control groups indicated moderate OSA severity (i.e., ≥ 15 to < 30 events per hour).

Compared with patients who received CPAP therapy (i.e., were not CPAP intolerant) (1 cohort study; N = 126), patients who were CPAP intolerant and received HGNS therapy did not exhibit a significant difference in OSA severity, as measured by mean AHI4 at the 12-month follow-up (8.1 vs. 6.6; *P* = .08). However, both study groups had clinically significant AHI4 score reductions from baseline (i.e., ≥ 5 events per hour) and similar proportions of participants had an AHI below the clinical threshold for OSA (i.e., AHI < 5) at follow-up (51% vs. 59%; *P* = .27).

Confidence rating

Low confidence that HGNS reduces OSA severity compared with controls and provides similar benefit to CPAP in people with CPAP intolerance.

5 studies (3 RCTs and 2 cohort studies); N = 673

- Risk of bias concerns: limited methods reporting, selection bias in RCTs, industry funding and author conflict of interest
- Indirectness: study design and comparator heterogeneity; study populations more limited than current FDA indication for HGNS and lack of demographic generalizability to Medicaid
- Other: short follow-up periods relative to intended length of intervention

Daytime Sleepiness

BENEFIT

Evidence summary

Four studies, which investigated the only FDA-approved HGNS device for adults with moderate to severe OSA who were intolerant to or unable to eliminate OSA with CPAP, reported daytime sleepiness outcomes. The studies included 2 RCTs and 2 cohort studies. The 2 RCTs enrolled people who had a previous implantation of the HGNS device with a positive response and randomized participants to inactivation of the device or subtherapeutic stimulation. Participants in the cohort studies did not begin using HGNS until after enrollment. When reported, there were no differences between study groups in terms of baseline daytime sleepiness scores.

Compared with patients with an inactive device, subtherapeutic stimulation, or no treatment (2 RCTs and 1 cohort study; N = 485), groups who received HGNS therapy reported less daytime sleepiness at follow-up, as indicated by significantly lower Epworth Sleepiness Scale (ESS) scores (*P* < .01 for all). The differences in mean follow-up ESS scores between study groups also exceeded the established MCID (≥ 2 points).

- EFFECT RCT (2 weeks): +0.2 vs. +3.5 points (change scores); *P* < .001
- STAR RCT (1 month): 5.6 vs. 10.0 points; *P* = .005
- ADHERE Comparative Cohort (6 months): 7.2 vs. 12.8 points; *P* < .001

In the 2 studies that reported mean scores at follow-up, ESS scores in the HGNS groups were below the excessive sleepiness threshold (i.e., ESS > 10 points), whereas scores in the control groups were at or above the threshold.

Compared with patients who received CPAP therapy (i.e., were not CPAP intolerant) (1 cohort study; N = 126), patients who were CPAP intolerant and received HGNS therapy did not report a significant difference in daytime sleepiness as indicated by

mean ESS scores (7.5 vs. 10.8; $P = .27$). Both groups experienced reductions in ESS scores from baseline that met MCID (≥ 2 points) and scores were generally indicative of normal levels of daytime sleepiness.

Confidence rating

Low confidence that HGNS reduces daytime sleepiness compared with controls and provides similar benefit as CPAP therapy for patients with CPAP intolerance.

4 studies (2 RCTs and 2 cohort studies); N = 611

- Risk of bias concerns: limited methods reporting, selection bias in RCTs, industry funding, and author conflict of interest
- Indirectness: study design heterogeneity; study populations more limited than current FDA indication for HGNS and lack of demographic generalizability to Medicaid
- Other: short follow-up periods relative to intended length of intervention

Major Adverse Cardiac Events

NO DATA

There were no eligible studies that reported MACE outcomes.

Balance of benefits and harms

We have low confidence there is a clinically important improvement in sleep-related quality of life and in apnea severity as measured by AHI4 with HGNS in select patients. The degree of confidence is low because the included studies have a high degree of selection bias and indirectness. Additionally, these RCTs only enrolled people who had a positive initial response to HGNS. We have low to moderate confidence that the full scope and magnitude of harms are described. Overall, these benefits appear to outweigh the reported risk of harms.

Resource allocation

HGNS requires a high level of resource use. Before being eligible for device implantation, patients would need to undergo drug-induced sleep endoscopy (DISE), an invasive procedure requiring anesthesia. The HGNS implantation itself involves surgery, and the follow-up involves an in-lab sleep study. Long-term maintenance of this intervention requires surgical battery replacement every 7–10 years. Patients undergoing HGNS would likely need to continue CPAP therapy if they can tolerate CPAP, resulting in a lack of cost savings from CPAP discontinuation. An economic modeling study did not identify net cost-savings in reductions of OSA complications (stroke, myocardial infarction, or car crashes).

Values and preferences

Many patients who have not adequately responded to first-line OSA therapies would value a second-line treatment that may improve their sleep-related quality of life and reduce their sleep apnea symptoms. Other patients would not value an invasive surgical procedure, especially if it does not reduce their sleep apnea symptoms or eliminate the need for daily CPAP usage.

Other considerations

There are few other available treatments for moderate and severe OSA for patients who cannot tolerate or do not respond sufficiently to CPAP therapy.

Notes. GRADE table elements are described in Appendix A; a corresponding GRADE Evidence Profile for each outcome is in Appendix B.
Abbreviations. AE: adverse event(s); AHI4: Apnea-Hypopnea Index (with 4% blood oxygen desaturation threshold for hypopneas); COI: conflict of interest; CPAP: continuous positive airway pressure; DISE: Drug-induced sleep endoscopy; ESS: Epworth Sleepiness Scale; FDA: US Food and Drug Administration; FOSQ: Functional Outcomes of Sleep Questionnaire; HGNS: hypoglossal nerve stimulation; MACE: major adverse cardiac events; MCID: minimal clinically important difference; ODI4: Oxygen Desaturation Index (with 4% blood oxygen desaturation threshold); OSA: obstructive sleep apnea; QoL: quality of life; RCT: randomized controlled trial; RoB: risk of bias; SAE serious adverse event(s); UAS: upper airway nerve stimulation; US: United States; vs.: versus.

GENIO APPROVAL UPDATE

The FDA approved a new HGNS device, the Nyxoah Genio System 2.1 (Genio System), in August 2025 after the prior coverage guidance update searches were conducted (July 2025).[1] To ensure that coverage guidance evidence was aligned with the current clinical context during deliberation by the Evidence-based Guidelines Subcommittee, and subsequently by HERC, we undertook a targeted update of this coverage guidance that included the following actions:

- Incorporated newly published eligible clinical studies that supported the Genio System FDA approval
- Searched clinical trial registries for the post-approval study of the Genio System as required by the FDA in the approval notice
- Reviewed and compared the FDA labels of all currently approved HGNS devices
- Reviewed included clinical practice guidelines (CPGs) for updated guidance specific to the Genio System
- Reviewed payer policies for changes in HGNS coverage criteria specific to the Genio System

Updated findings are highlighted in call-out boxes at the beginning of each major report section and all results incorporate the new information. This document reflects the most current and updated findings.

Although our updated search resulted in the inclusion of new evidence, the findings ultimately did not alter the original conclusions of this coverage guidance.

2025 UPDATE

Following the presentation of this coverage guidance on September 9, 2024, HERC's Evidence-based Guidelines Subcommittee (EbGS) voted to table this report for 1 year and perform an updated evidence search at that time. In July 2025, we conducted a series of searches and reviews to update this report in advance of the 1-year re-presentation to EbGS (i.e., September 11, 2025):

- Searched clinical databases for eligible studies published after the original coverage guidance search dates (new search range, May 15, 2024–July 1, 2025)
- Searched clinical trial registries for new ongoing studies
- Reviewed the label and recall status of the FDA-approved HGNS device and looked for new FDA approvals
- Reviewed previously included CPGs for updated HGNS recommendations and conducted targeted searches for new relevant CPGs
- Reviewed payer policies for changes in HGNS coverage criteria
- Contacted subject matter experts for information about key industry developments and new important publications

Updated findings are highlighted in call-out boxes at the beginning of each major report section and all results incorporate the new information. This document reflects the most current and updated findings.

Although our updated search resulted in the inclusion of new evidence, the findings ultimately did not alter the original conclusions of this coverage guidance.

BACKGROUND

Genio Approval Update

In the Background section, we reviewed the FDA label for the newly approved Genio System as compared with the previously approved Inspire UAS device, and updated information regarding HGNS device indications, candidate evaluation, and device implantation procedures.

- The Genio System is surgically implanted in the chin and is a leadless, externally powered device that delivers bilateral stimulation of the genioglossus muscle, as compared with Inspire UAS (i.e., the other FDA approved HGNS device), which provides unilateral stimulation.
- The approved Genio System indication criteria largely align with the original approval criteria for the Inspire UAS device (i.e., adults age 22 years and older; confirmed failure or inability to use first-line OSA treatments; AHI 15 to 65; upper BMI warning limit of 32 kg/m^2)
- Compared with Inspire UAS, candidate evaluation for the Genio System does not require DISE

2025 Update

In the Background section, we reviewed the label and recall status for the FDA-approved HGNS device and looked for new FDA approvals between May 2024 and July 2025.

- Inspire UAS remains the only FDA-approved HGNS device and there have been no changes to the indication criteria specified on the label since 2023.
- The class 1 recall of the Inspire IV implantable pulse generator (initiated in June 2024) remains active, but no new injuries or deaths have been reported.
- No new HGNS devices have been approved by the FDA.

Obstructive sleep apnea (OSA) is the most common sleep-related breathing disorder.[2] OSA is caused by recurrent partial or complete collapse of the upper airway, which interferes with the flow of air during sleep.[3] This leads to interrupted sleep, a low oxygen level in the blood, or both.[3] Untreated or undertreated OSA can contribute to poor quality of life, is associated with chronic illnesses such as heart disease, and can cause life-threatening complications.[4-7] OSA is a common condition, affecting an estimated 9% to 38% of the general population.[8,9]

Causes and Consequences of OSA

Anatomy of OSA

The upper airway (i.e., pharynx) is mostly surrounded by soft tissues and is not supported by a bony structure, making it especially vulnerable to collapse.[3] Many factors can contribute to upper airway collapse during sleep, including irregularities in anatomical structures and loss of neuromuscular control.[3]

Symptoms and Complications

Signs and symptoms of OSA may include excessive daytime sleepiness, early morning headaches, and snoring, choking, or gasping during sleep.[10] Due to the frequent interruptions in sleep, excessive daytime

sleepiness is the most common symptom reported by individuals with OSA.[9] Excessive daytime sleepiness from OSA is associated with impaired work performance[11,12] and increased risk of motor vehicle crashes while driving.[13] OSA is also associated with other medical complications including cardiovascular complications such as high blood pressure, congestive heart failure, coronary artery disease, stroke, pulmonary hypertension, atrial fibrillation and other irregular heart rhythms, and sudden cardiac death.[3,6,7,10]

OSA Diagnosis

Diagnostic Testing

Sleep apnea testing is required for a diagnosis of OSA.[10] The American Academy of Sleep Medicine (AASM) recommends testing for OSA in individuals with excessive daytime sleepiness and other clinical features of OSA, such as loud snoring or gasping.[14] Home sleep apnea testing and in-laboratory polysomnography are the most common diagnostic tests for OSA.[2] Home sleep apnea testing typically involves a respiratory effort band around the chest, a nasal cannula with a pressure transducer to measure airflow and snoring, and an oximeter to measure oxygen saturation.[2] In-laboratory polysomnography generally also involves measures of sleep stages and arousals using electroencephalogram (EEG), electrocardiogram results, body position, and leg movements.[9] The diagnosis of OSA depends on the presence of sleep-associated conditions such as fatigue, insomnia, snoring, or breathing interruptions as well as counts of obstructive respiratory events during sleep.[10]

Defining Obstructive Respiratory Events

There are 2 main types of obstructive respiratory events: apneas (complete obstruction) and hypopneas (partial obstruction).[2] An apnea is an event defined as the complete cessation of airflow for 10 seconds or longer.[3] A hypopnea is an event characterized by a partial reduction in airflow.[3]

There is variation in the definition of hypopnea. A common definition of a hypopnea is evidence of a reduction in airflow of 30% or more for 10 seconds or longer accompanied by either an arousal or oxygen desaturation of 3% or more (this definition is abbreviated as AHI3a).[2] A stricter definition of a hypopnea (abbreviated as AHI4) uses an oxygen desaturation threshold of 4% instead of 3% and does not consider arousals.[2]

The Centers for Medicaid & Medicare Services (CMS) uses the AHI4 criteria to define a hypopnea.[15] The decision of which hypopnea definition to use has implications for the prevalence of OSA diagnoses and severity of OSA classification.[16,17] After changes adopted in 2023, the AASM Scoring Manual 3 recommends every accredited sleep center score hypopneas with the AHI3a definition due to evidence that hypopneas with a 3% oxygen desaturation or arousal are associated with health and quality of life deficits.[18] However, the current scoring manual allows sleep centers to also report AHI scores according to the AHI4 criteria for patients insured by a payer that requires it for treatment coverage.[18]

The Apnea-Hypopnea Index and Other Measures of OSA Severity

The apnea-hypopnea index (AHI) is a measure of the total number of apneas and hypopneas per hour of sleep.[2] Advantages of the AHI are that it is fairly objective and reproducible across a standardized context.[3] Generally, severity of OSA is defined by AHI thresholds, with greater than or equal to 5 obstructive events per hour characterized as mild OSA, greater than or equal to 15 events per hour as

moderate OSA, and greater than or equal to 30 events per hour as severe OSA (Table 1; Appendix D, Table D1).[3]

TABLE 1. CLASSIFICATION OF OSA SEVERITY

CLASSIFICATION	AHI SCORE
Mild	≥ 5 and < 15 events per hour
Moderate	≥ 15 and < 30 events per hour
Severe	≥ 30 events per hour

Source. Johnson, 2023.[2]
Abbreviations. AHI: apnea-hypopnea index; OSA: obstructive sleep apnea.

Limitations of AHI as a measure of OSA severity include:

(1) It equates apneas and hypopneas, even though the severity of physiological effects differ[19]

(2) Individual characteristics, such as age, obesity, and cardiopulmonary disease, can be confounding factors that affect the degree of oxygen desaturation[3]

(3) AHI is a continuous measure and the discrete thresholds used to define OSA severity may contribute to misclassification of overall OSA severity when scores are near a threshold[3]

(4) It is unclear whether AHI scores correspond closely to the severity of clinical symptoms of OSA or whether these are useful in predicting morbidity, mortality, or response to treatment[2,3]

Other measures of severity of OSA include the respiratory disturbance index (RDI), the respiratory event index (REI), and the oxygen desaturation index (ODI).[2] The RDI differs from the AHI because it accounts for the number of apneas, hypopneas, and arousals per hour of sleep.[2] The REI is commonly used in home sleep testing and reports the number of apneas and hypopneas per hour of monitoring time, since home sleep tests without EEG cannot account for the total time asleep.[2,20] As such, the REI is sometimes an underestimation of the AHI; in contrast, the RDI is often higher than the AHI because it accounts for arousals separately.[20] The oxygen desaturation index (ODI) counts the number of oxygen desaturations (typically either the AHI3a ≥ 3% standard or the AHI4 ≥ 4% standard) per hour of sleep time or monitoring time.[21]

Patient-Reported Measures of OSA Severity

Beyond measures based on sleep apnea, hypopnea, and desaturation testing, several patient-reported assessments help evaluate the severity of OSA, including the response to therapy. These instruments are the Epworth Sleepiness Scale (ESS), which measures daytime sleepiness, and the Functional Outcomes of Sleep Questionnaire (FOSQ), which measures sleep-related quality of life (QoL) impairments (Appendix D, Table D1).[9,22]

OSA Treatment

The aim of OSA treatment is to reduce AHI score, improve symptoms, and increase patient quality of life.[23] Complete remission of OSA is rare and lifelong treatment is usually necessary, with the exception of sustained weight loss.[9,23] Common criteria for measuring treatment success for OSA surgeries is referred

to as the Sher criteria, a compound measure defined as a greater than or equal to 50% reduction in baseline AHI and a postoperative AHI of less than 20 events per hour.[24]

Continuous positive airway pressure (CPAP) therapy is considered the standard first-line therapy for most adults with OSA.[23] CPAP devices work by creating a constant flow of air through a mask to support breathing.[3] The positive air pressure generated by the CPAP device helps to maintain an open airway during sleep.[3]

Hypoglossal Nerve Stimulation for OSA

Hypoglossal nerve stimulation (HGNS), a form of upper airway nerve stimulation (UAS), is a second-line treatment option for individuals with moderate or severe OSA who are intolerant to or unable to eliminate OSA with CPAP.[25,26]

How Does HGNS Work?

In OSA, the genioglossus—an extrinsic muscle of the tongue that helps stabilize the upper airway during sleep—tends to lose its muscle tone causing the tongue to fall backward and obstruct the upper airway.[7,27] HGNS therapy is intended to open and stiffen the upper airway.[25,26] It works primarily by monitoring a person's breathing and sending an electrical impulse to the hypoglossal nerve at the start of a breath, stimulating the genioglossus to move the tongue forward and open the airway.[28]

HGNS Devices and Indications

There are currently 2 FDA-approved HGNS devices:

- The Inspire UAS system, approved in May 2014, uses a stimulation lead implanted in the neck around a single branch of the hypoglossal nerve, and a respiratory sensing lead and pulse generator implanted in the chest wall.[25,29,30] The Inspire pulse generator batteries must be surgically replaced at an estimated interval of 7–10 years.[31] The manufacturer precautions advise considering that battery replacements may require serial reimplantation over an individual's lifetime, with the potential for future surgical complications.[31]
- The Genio System, approved in August 2025, is a leadless, externally powered device that is implanted in the chin over the genioglossus muscle targeting bilateral branches of the hypoglossal nerve.[1,32] The implanted stimulator unit is powered by a rechargeable external activation chip that is snapped onto a single-use disposable adhesive patch placed on the skin underneath a patient's chin each night.[33]

FDA indication criteria for HGNS therapy have evolved over time and vary by device (Table 2).

TABLE 2. KEY INDICATION CRITERIA FOR FDA-APPROVED HGNS DEVICES IN ADULTS WITH OBSTRUCTIVE SLEEP APNEA

	ORIGINAL INSPIRE APPROVAL (2014)[34]	SUPPLEMENTAL INSPIRE APPROVAL (2020)[34]	SUPPLEMENTAL INSPIRE APPROVAL (2023)[30,35]	ORIGINAL GENIO APPROVAL (2025)[1]
AGE	≥ 22 years	≥ 18 years	No change[a]	≥ 22 years
AHI	≥ 20 and ≤ 65 events/hour	≥ 15 and ≤ 65 events/hour	≥ 15 and ≤ 100 events/hour	≥ 15 and ≤ 65 events/hour

BMI WARNING THRESHOLD	32 kg/m^2	No change	40 kg/m^2	32 kg/m^2
PLACE IN THERAPY	Second-line ▪ Confirmed intolerance[b] or insufficient response[c] to CPAP therapy	No change	No change	Second-line ▪ Confirmed intolerance[b] or insufficient response[c] to all first-line therapies[d]
OTHER	Does not have complete concentric collapse as confirmed by DISE	No change	No change	DISE may be used to optimize therapy settings

Notes. a A 2023 supplemental expanded the Inspire indication to include children with Down syndrome (ages 13–18 years) who meet certain developmental and physiological criteria. b Unable or unwilling to use intervention more than 5 nights per week for at least 4 hours per night. c AHI greater than 15 despite confirmed intervention. d First-line therapies include lifestyle modifications, CPAP therapy, oral appliances, and pharmacotherapy.
Abbreviations. AHI: apnea-hypopnea index; BMI: body mass index; CPAP: continuous positive airway pressure; DISE: drug-induced sleep endoscopy; FDA: US Food and Drug Administration; HGNS: hypoglossal nerve stimulation.

Other HGNS devices with different configurations are under investigation, such as the aura6000 system by LivaNova (previously ImThera).[32,36]

Candidate Evaluation and Device Implantation

Potential candidates for HGNS who are intolerant or nonresponsive to CPAP therapy and meet age and BMI criteria may first be referred for drug-induced sleep endoscopy (DISE).[25,26,33] With DISE, the upper airway is evaluated endoscopically to assess for palate collapse and tongue position during light sedation to mimic sleep.[25,26] Individuals with complete concentric collapse at the level of the soft palate are generally not considered good candidates for HGNS.[33,35]

HGNS devices are typically implanted during an outpatient procedure performed under general anesthesia in an operating room.[25,30,33] Once implanted, the HGNS device is not activated until the system components are fully healed in place, approximately a month after implantation.[1,25,33] Following activation by a clinician, the patient is able to turn the device on and off during the night or adjust the strength of the stimulus using a remotely controlled device or a mobile phone app.[1,25,33] Patients usually return for a follow-up in-lab polysomnography for titration of the device settings by a clinician to maximize sleep quality and individual comfort.[1,26,33]

HGNS Device Recalls

On June 17, 2024, the FDA announced a recall of 32 devices of the Model 3028 Inspire UAS system implantable pulse generator due to a manufacturing defect.[37] This defect can lead to complications such as stimulation below normal levels, early depletion of the battery, inappropriate or inconsistent stimulation effect, painful stimulation, or perceived shocking sensation, and death.[37] This recall was designated as the most serious type by the FDA.[37] There are no open device recalls for the Genio System.

Access and Equity

Although clinicians of many specialties can play a role in identifying and referring patients for diagnostic testing for OSA, the AASM recommends that follow-up be under the supervision of a physician trained in sleep medicine.[14] However, there is an anticipated national shortage of sleep medicine specialists in the US.[38] This shortage is especially pronounced in federally designated Health Professions Shortage Areas, which may contribute to sleep health disparities for individuals with lower socioeconomic status and those from racial and ethnic minority groups.[39]

Differences and Disparities in OSA Prevalence and Diagnosis

The prevalence of OSA varies by sex, with men having higher rates of OSA than women.[10] When excluding mild OSA, US-specific estimates indicate approximately 13% of men and 6% of women have moderate or severe OSA.[40] However, the prevalence of OSA also increases in menopausal and pregnant people due to changes in hormone levels.[41]

Furthermore, the prevalence and severity at diagnosis of OSA may vary by race and ethnicity although the precise relationship is unclear. Some studies suggest that African American young adults experience a higher prevalence of OSA than White young adults, independent of body weight.[42] Other studies reveal a racial disparity in higher OSA prevalence for African American children, though evidence of a disparity is less robust for middle-aged populations.[43] At the time of diagnosis, OSA tends to be more severe among African American individuals compared with White individuals.[44,45] Another study found that South Asian individuals with severe obesity had higher prevalence and severity of OSA than White Europeans with severe obesity.[46] However, other study evidence indicates that rates of OSA are similar or lower among Asian individuals and Asian Americans compared with White individuals.[43]

Disparities in Treatment Coverage and Availability

For HGNS therapy specifically, evidence on insurance-related disparities was limited. Some evidence suggests that individuals with Medicare coverage, compared with privately insured individuals, had shorter waiting periods and fewer insurance-related delays in receiving HGNS, though individuals with private insurance received HGNS therapy at a younger average age.[47]

According to an Inspire Medical Systems, Inc. database, there are currently 18 clinicians at 10 practices listed as Inspire UAS system-trained providers in Oregon (as of August 2025) available for individuals who have been diagnosed with OSA and had difficulty using CPAP.[48] Eight practices (14 providers) are located between Portland and Salem in the Willamette Valley and 2 practices (4 providers) are located in Central Oregon, specifically in Bend. Compared with our initial review of the directory in August 2024, the Portland and Salem areas added 2 clinicians at 2 new practices, there were no changes in provider availability in Bend, and the single provider and practice formerly listed in Southern Oregon, specifically in Medford, was no longer listed.[48] Per personal communications with Inspire Medical Systems, Inc., (August 2024), clinicians must opt in to be listed in the database and, therefore, this database is likely not inclusive of all clinicians in Oregon trained on implantation of the Inspire UAS system.[48]

METHODS

Genio Approval Update

We reviewed the FDA approval packet and labeling materials for studies of the Genio System published since the prior update. We also searched clinical trial registries for new ongoing studies and reviewed policy landscape materials for Genio-related updates to cover the gap in time between the 2025 update searches and the posting of this updated coverage guidance (July 2025–January 2026).

2025 Update

We used the review methods described below to conduct this coverage guidance update. All searches and reviews were repeated to cover the gap in time between the original coverage guidance searches and this update (May 15, 2024–July 1, 2025).

The following section summarizes the overall scope of the evidence review, including Key Questions (KQs) and Contextual Questions (CQs), inclusion and exclusion criteria, and a brief overview of the methods used to conduct the review. Additional information regarding methods can be found in Appendix C.

Key Questions

KQ1. What is the effectiveness of hypoglossal nerve stimulation versus nonsurgical treatments for OSA in adults?

KQ2. What are the harms of hypoglossal nerve stimulation for OSA?

KQ3. How does the effectiveness and harms of these interventions vary by:

- a. Intervention characteristics
- b. Patient characteristics
  - i. Severity of OSA
  - ii. Race, ethnicity, culture, or language
  - iii. Gender or sex
  - iv. Age
  - v. Comorbidities
  - vi. Response to prior interventions

Contextual Questions

CQ1. What is the evidence for effectiveness of hypoglossal nerve stimulation for OSA on outcomes (e.g., all-cause mortality, major adverse cardiac events, motor vehicle crashes) from systematic reviews that include observational and nonrandomized studies?

CQ2. What is the comparative effectiveness of hypoglossal nerve stimulation for OSA from randomized controlled trials?

CQ3. What is the of hypoglossal nerve stimulation for OSA?

Study Eligibility Criteria

Table 3 summarizes the criteria used to inform study selection for the KQ evidence review. See Appendix C for more detailed selection criteria.

TABLE 3. EVIDENCE REVIEW CRITERIA OVERVIEW

CATEGORY	INCLUDED	EXCLUDED
POPULATION	■ Adults with moderate to severe OSA	■ Children and adolescents (i.e., aged < 18 years) with OSA ■ Adults with mild OSA ■ Adults with central sleep apnea
INTERVENTIONS	■ Upper airway nerve stimulation devices (i.e., hypoglossal nerve stimulation [HGNS])	■ Nonsurgically implantable nerve stimulation (e.g., transcutaneous electrical stimulation, Neuromuscular electrical stimulation
COMPARATORS	■ Nonsurgical OSA interventions (including noninvasive PAP therapy) ■ No treatment ■ Subtherapeutic stimulation (sometimes called "sham stimulation") or an inactive device	■ Other surgical airway interventions, including other HGNS devices ■ Intensive weight loss interventions
OUTCOMES	**Critical** ■ Device-related serious adverse events ■ Quality of life **Important** ■ Change in OSA severity (as measured by specific polysomnography indices: AHI, RDI, REI, or ODI) ■ Daytime sleepiness ■ Major adverse cardiac events	**Considered by HERC but not selected for review:** ■ All-cause mortality ■ Change in A1c ■ Remission of hypertension or diabetes ■ Fatigue-related injury ■ Other polysomnography outcomes ■ General harms
STUDY DESIGNS	**KQ1 (effectiveness)** ■ RCTs of any size ■ Comparative prospective cohort studies (N > 100) **KQ2 (harms)** ■ RCTs and prospective cohort studies (as defined above) ■ Systematic reviews including nonrandomized studies ■ Single-arm prospective NRS (N > 100) ■ Registry studies	■ Studies conducted in non-very-high-HDI countries ■ Individual retrospective cohort studies (including, cross-sectional studies, case series, or case reports)

Note. See Appendix C for complete inclusion and exclusion criteria. See Appendix D, Table D1 for information regarding outcome scale interpretation.
Abbreviations. A1c: glycated hemoglobin; AHI: apnea-hypopnea index; HDI: Human Development Index; HGNS: hypoglossal nerve stimulation; KQ: key question; ODI: oxygen desaturation index; OSA: obstructive sleep apnea; RDI: respiratory disturbance index; REI; respiratory event index.

Methods Overview

To answer the KQs, we searched multiple clinical evidence databases (e.g., Ovid MEDLINE, Cochrane CENTRAL) for published randomized controlled trials (RCTs), prospective nonrandomized studies (NRS), systematic reviews (SRs) of NRS, and registry studies, evaluating the effectiveness and harms of HGNS therapy for adults with moderate to severe OSA. We performed an updated database search 1 year after our initial search at the direction of the Evidence-based Guidelines Subcommittee.

In addition to the eligibility criteria described in Table 3, primary studies had to be available in English, include device implantation or follow-up of at least 12 weeks for RCTs and 6 months for NRS and registry studies, be conducted in very-high Human Development Index (HDI) countries,[49] and be published in 2000 or later (2014 for SRs).

- Notably, other forms of upper airway stimulation under investigation for OSA were excluded from this review: transcutaneous electrical nerve stimulation (TENS) devices are not FDA-approved for OSA and eXciteOSA, a neuromuscular electrical stimulation device, is only approved for adults with mild OSA.[50]
- To account for event overlap in studies analyzing datasets from the same clinical registry (e.g., FDA's Manufacturer and User Facility Device Experience [MAUDE]), we reported outcomes from the study with the most comprehensive dataset when overlap was identified.
- We included device-related adverse events when defined as "severe" or "serious" by study authors. In instances where the severity of adverse events was not explicitly defined, we applied FDA definitions of serious adverse events, which include: death, life-threatening events, inpatient hospitalization or prolongation of an existing hospitalization, persistent or significant incapacity or substantial disruption of the ability to conduct normal life functions, or congenital abnormalities and birth defects.[51]

Two reviewers independently examined abstracts and full-text articles for inclusion and assessed the risk of bias of included studies. Disagreements were primarily resolved through consensus and were referred to a third reviewer when consensus could not be achieved. We assessed the overall strength of evidence using the Grading of Recommendations, Assessment, Development and Evaluations (GRADE) method, the results of which are presented in the previously described GRADE table.

We identified evidence for CQs by using results of the KQ database searches, auditing reference lists of relevant SRs, and performing targeted searches of relevant English-language sources as needed. Evidence regarding the CQs is summarized by question following the KQ review.

For the Policy Landscape section, we conducted targeted searches in Ovid MEDLINE, websites of relevant professional societies and guideline groups, and DuckDuckGo to identify relevant CPGs published since 2014 and key payer policies regarding HGNS for adults with moderate to severe OSA. Two reviewers independently assessed the quality of the included CPGs; disagreements were primarily resolved through consensus and were referred to a third reviewer when consensus could not be achieved. Relevant position statements and consensus documents from professional societies were also included for contextual purposes and were considered to have high risk of bias.

EVIDENCE REVIEW

Genio Approval Update

In the Evidence Review section, we reported on new studies of the Genio System published since the prior update. We also reported information on CQs and ongoing studies where relevant.

Key Questions

- We identified 1 new study of the Genio System that reported eligible HGNS-related serious adverse events outcomes (KQ2), but findings from this study did not change our certainty of evidence rating (i.e., GRADE) for the magnitude and range of harms.
- We did not identify any studies of the Genio System that reported eligible HGNS effectiveness outcomes (KQ1) or subgroup analyses of differential effectiveness or harms (KQ3).

Contextual Questions

- We did not identify any new eligible studies of the Genio System that reported key endpoints from systematic reviews (CQ1), comparative effectiveness of HGNS versus other surgical interventions for OSA (CQ2), or cost effectiveness of HGNS (CQ3).

Ongoing Studies

- 1 previously identified ongoing study of the Genio System published primary results, but this study has an ongoing open-label extension phase.
- We identified 1 new ongoing prospective nonrandomized post-approval study, which was mandated by the FDA for ongoing approval of the Genio System.

2025 Update

In the Evidence Review section, we searched clinical databases for new eligible studies addressing the key and contextual questions published between May 15, 2024, and July 1, 2025. We also searched clinical trial registries for new ongoing studies.

Key Questions

- We identified 3 new studies of HGNS-related serious adverse events (KQ2), but findings from these studies did not change our certainty of evidence rating (i.e., GRADE) for the magnitude and range of harms.
- We did not identify any new eligible studies reporting HGNS effectiveness (KQ1) or differential effectiveness or harms (KQ3).

Contextual Questions

- We did not identify any new eligible studies reporting key endpoints from systematic reviews (CQ1), comparative effectiveness of HGNS versus other surgical interventions for OSA (CQ2), or cost effectiveness of HGNS (CQ3).

Ongoing Studies

- We determined that none of the ongoing studies identified in the original coverage guidance were published during the update period.
- We did not identify any new eligible ongoing studies.

Key Question Review

The following results section organizes findings on the effectiveness and harms of HGNS in adults with moderate to severe OSA by outcomes:

- Quality of life (QoL)
- Device-related serious adverse events (SAE)
- OSA severity as measured by key polysomnography indices
- Daytime sleepiness
- Major adverse cardiac events (MACE)

Within each section, results are summarized by FDA-approval status of the HGNS devices.

We initially screened 476 records for eligibility and identified 17 studies[52-68] (reported in 20 publications[52-71]) on HGNS for moderate to severe OSA in adults, with publication dates ranging from 2014 to 2024 (Table 4).

- Our updated database search in July 2025 generated an additional 120 records for screening; 3 new studies met inclusion criteria (Table 3; Appendix D, Figure D1, Tables D2, D3, D4).[72-74] While the updated database search resulted in inclusion of newly published studies, the findings of these studies did not alter the GRADE ratings.

- The Genio approval update, conducted in January 2026, resulted in inclusion of 1 new study, reported in 2 publications (Table 3; Appendix D, Figure D1, Tables D2, D3, D4).[75,76] However, the findings of this study did not alter the GRADE ratings.

Six studies reported effectiveness outcomes (KQ1; none of which were identified in the updated database search or as part of the Genio approval update),[53,55,59-61,66] 19 studies reported harms outcomes (KQ2; 3 were identified in the updated database search; 1 was included in the Genio approval update),[52,54-58,60-68,72-75] and none of the studies reported effectiveness and harms of HGNS by patient or intervention characteristics (KQ3).

Four of the studies were RCTs,[53,55,60,61] along with 5 nonrandomized cohort studies (1 identified in the Genio approval update),[54,59,66,67,75] 6 registry studies (2 of which were identified in the updated database search),[56,57,64,65,72,74] and 6 SRs (1 of which was identified in the updated database search).[52,58,62,63,68,73] Within these categories of study design, significant variability exists. For example, 2 of the RCTs are crossover trials with a withdrawal design in which all participants had the HGNS device activated and are randomized to either active stimulation or subtherapeutic stimulation (i.e., low-level stimulation to deceive the participant).[60,61] Two RCTs are noncrossover withdrawal trials,[53,55] in which participants who previously had an HGNS device activated were randomized to keep the device on or turn the device off. One of the noncrossover withdrawal RCTs[53] is part of an included noncomparative cohort study reported in a separate publication.[54] Additionally, within the nonrandomized cohort studies, 2 are comparative[59,66] and 3 are noncomparative (i.e., single-arm cohort study with no comparison group).[54,67,75]

None of the included studies are low risk of bias (RoB). Specifically:

- The RCTs were rated as having moderate[61] or high RoB[53,55,60]
- The nonrandomized cohort studies were rated as having high RoB[54,59,66,67,75]
- The registry studies were all rated as having high RoB[56,57,64,65]
- The SRs were rated as having a moderate[52,62,63,68,73] or high RoB[58]

The 9 included RCTs and nonrandomized cohort studies ranged from 2 weeks to 5 years of follow-up with total sample sizes ranging from 46 to 1,849 (Appendix D, Table D2).[53-55,59-61,66,67,75] Of the 6 registry studies,[56,57,64,65,72,74] 4 reported data (with some notable data duplication) from the FDA MAUDE database,[64,65,72,74] 1 reported data from the TriNetX Research Network,[57] and 1 reported data from a post-market surveillance database (Appendix D, Table D2).[56] Data on event reports, participants, or devices was collected from 2000 to 2023, and sample sizes ranged from 132 to 20,881 (Appendix D, Table D2).[56,57,64,65,72,74] The 6 SRs, with publication dates from 2015 to 2024, included primary studies from 1997 to 2023 (Appendix D, Table D4).[52,58,62,63,68,73] There was some overlap of primary studies across the SRs.

The majority of the primary studies (n = 13 RCTs, cohort studies, and registry studies) included a US population,[53-57,61,64-67,72,74,75] with 2 other primary studies conducted in Germany[59,60] (Appendix D, Table D2). Study populations in the RCTs and nonrandomized cohort studies overwhelmingly consisted of White males between the ages of 50–70 years (Appendix D, Table D2).[53-55,59-61,66,67,75] Comorbidities and concomitant medication use were reported infrequently in these studies (Appendix D, Table D3).[53-55,59-61,66,67]

With the exception of 1 RCT,[55] 1 cohort study,[75] and 5 SRs,[58,62,63,68,73] the FDA-approved Inspire UAS system was the only HGNS device of interest in the included publications. Other HGNS devices evaluated in the 1 RCT[55] and 5 SRs[58,62,63,68,73] were the aura6000 system (not FDA approved), the Genio System (newly FDA approved),[75] and the discontinued Apnex Medical HGNS system (not FDA approved).[77] In half of the RCTs and cohort studies,[53-55,59-61,66,67] the HGNS device was implanted prior to study enrollment,[53,60,61,67] while in the other half, the HGNS device was implanted after enrollment.[54,55,59,66,75] HGNS was compared against an inactive device in 2 RCTs[53,55] and subtherapeutic stimulation in 2 included RCTs.[60,61] In the 2 comparative nonrandomized cohort studies,[59,66] individuals who were CPAP intolerant had HGNS implanted and then were compared with individuals who tolerated CPAP (and continued to use it).[59] In the other study, individuals who were intolerant to CPAP and implanted with an HGNS device were compared with individuals who were intolerant to CPAP but not implanted with an HGNS device due to insurance coverage denial.[66]

All of the RCTs and nonrandomized cohort studies considered select adults with moderate to severe OSA eligible for study participation.[53-55,59-61,66,67,75] When considering mean baseline AHI, 6 of these studies enrolled participants with severe OSA (mean baseline AHI range of 32.0 to 37.9 events per hour).[54,55,59,61,66,67] The remaining 2 studies (both RCTs) randomized participants with mild OSA.[53,60] However, these 2 RCTs contained cohorts with an HGNS device implanted before randomization occurred and had mean baseline AHI data prior to implantation indicative of severe OSA.[53,60] Additionally, all of the studies eligible for effectiveness data (KQ1) and those that reported on OSA severity outcomes indicated the use of the Centers for Medicaid & Medicare Services (CMS)'s more stringent AHI4 criteria.[15,53,55,59-61,66]

When considering the FDA criteria for implantation of the Inspire UAS system, the majority of the primary studies[53-57,59-61,64-67] did not report eligibility criteria (BMI scores, AHI scores, and age), or in the case of the registry studies, search dates, that would allow for the current FDA indication for the Inspire UAS system, which was expanded in 2023 (Appendix D, Table D5). Only 2 identified studies allowed for the possibility of participants who met the expanded FDA criteria: 1 of the MAUDE registry trials, which searched for reports of adverse events through December 2023 and the ADHERE trial, an ongoing nonrandomized cohort study with interim publications that had evidence for the FDA to expand implantation criteria (final results have not yet been published).[30,67,74]

Notes. a Or registry. b Evaluated as a events/hr and reported as in mean (SD). Indicates mean baseline AHI at study initiation for entire study cohort unless otherwise specified. c For studies reporting on OSA severity outcomes that meet eligibility for KQ1. d Missing baseline characteristics for this study were extrapolated from FDA criteria for implantation of the Inspire UAS given the US population. e This study includes non-FDA-approved device(s) and is not included in GRADE. f Primary comparative follow-up is 4 months. g Primary comparative follow-up is ~1 month. h Sample size after propensity matching. N = 227 total. i As of March 2020. The most recent publication contains N = 2,755 participants as this is an ongoing trial that has not yet published final results.
Abbreviations. AHI: apnea-hypopnea index; AHI4: evidence of a reduction in airflow of 30% or more for 10 seconds or longer accompanied by either an arousal or oxygen desaturation of 4% or more; CPAP: continuous positive airway pressure; CQ: contextual question; FDA: US Food and Drug Administration; GRADE: Grading of Recommendations, Assessment, Development, and Evaluations; HGNS: hypoglossal nerve stimulator; KQ: key question; MAUDE: Manufacturer and User Facility Device Experience; MMA: maxillomandibular advancement; NA: not applicable; NCT: national clinical trial; NR: not reported; NRS: nonrandomized study; OSA: obstructive sleep apnea; QoL: quality of life; RCT: randomized controlled trial; ROB: risk of bias; SAEs: serious adverse events; SRs: systematic reviews: UAS: upper airway stimulation.

Quality of Life

Four high-RoB studies, including 3 RCTs[53,55,60] and 1 comparative cohort study,[66] assessed QoL outcomes (Table 5).

- All studies reported sleep-related QoL using the validated Functional Outcomes of Sleep Questionnaire (FOSQ), which measures the amount of sleep-related impairment individuals experience in 5 domains of daily living: activity levels, vigilance, intimacy and sexual relationships, productivity, and social outcomes).[78] The FOSQ has a possible score range of 5–20 points, with scores of 18 points or greater indicating normal sleep-related QoL, while a change of 1 or more points between assessments is considered to be clinically meaningful.[78,79]

- One study[55] of a non-FDA-approved device additionally reported general QoL outcomes as measured by the validated EuroQoL-5D visual analogue scale (EQ-5D VAS). The EQ-5D VAS has a possible score range of 0–100, with higher scores indicating higher self-rated overall health, but no minimum clinically important difference has yet been established for this scale.[80]

Table 5 summarizes QoL outcomes at the longest comparative follow-up timepoint and full outcome details are available in Appendix D, Table D6. For a detailed description of reported QoL scales see Appendix D, Table D1.

TABLE 5. QOL OUTCOMES AT LONGEST COMPARATIVE FOLLOW-UP

Notes. See Appendix D, Table D6 for complete QoL outcomes data. a Crossover trial. b Withdrawal RCT. c This study investigated a non-FDA-approved device and is not included in GRADE.
Abbreviations. HGNS: hypoglossal nerve stimulation; MCID: minimal clinically important difference; MD: mean difference; mo(s): month(s); QOL: quality of life; RCT: randomized controlled trial; wk: week.

Sleep-Related QoL

Three studies that reported sleep-related QoL, including 2 RCTs[53,60] and 1 cohort study,[66] investigated the FDA-approved Inspire UAS system (Table 5). Across these studies, HGNS groups had significantly higher mean FOSQ scores, indicating better sleep-related QoL, compared with nonsurgical control groups at final study follow-up ($P < .01$ for all).[53,60,66] Follow-up FOSQ scores in the HGNS groups were indicative of mild sleep-related QoL impairment (score range, 17.0–17.9 points) whereas scores in the control groups

indicated moderate impairment (score range, 12.4–15.0 points); differences in mean scores between study groups exceeded the established MCID (i.e., ≥ 1 point change in FOSQ score).[53,60,66]

- Control group participants in the 2 withdrawal RCTs[53,60] additionally exhibited statistically and clinically significant short-term reductions in sleep qualty after their Inspire UAS system devices were inactivated or adjusted to deliver subtherapeutic stimulation levels at baseline as compared with the groups who received continuous active HGNS therapy ($P < .001$ for both; Table 5).
- In the cohort study,[66] participants who received HGNS had significantly higher mean FOSQ10 (short-form) scores at 6 months compared with the no-treatment controls who did not receive HGNS due to insurance coverage denial (17.1 vs. 12.4 points; $P < .001$).[66] The FOSQ10 uses the same scoring scale as the long-form version and has been shown to have a high degree of interrater reliability.[78]

One withdrawal RCT (THN3)[55] investigated sleep-related QoL outcomes for the aura6000, a non-FDA-approved HGNS device (Table 5). As compared with the other RCTS, participants in this study were implanted with an HGNS device *after* enrollment and baseline assessment and participants were randomized after healing and device adjustment was complete.[55] At the primary 4-month follow-up, the active HGNS group reported significantly greater improvements in sleep-related QoL from baseline compared with the inactive device group (FOSQ: MD, 4.7 points [95% CI, 0.9 to 8.6]).[55] The mean difference in FOSQ between the groups also exceeded the threshold for clinical significance (i.e., ≥ 1 point change).[55,79]

General QoL

The THN3 trial,[55] which investigated the non-FDA-approved aura6000 HGNS device, was the only study that reported a general patient-reported QoL measure (Table 5). At the primary 4-month follow-up, the active HGNS group reported significantly greater improvement in general health status from baseline compared with the inactive device group (EQ-5D visual analogue scale: MD, 1.5 points [95% CI, 0.3 to 2.6]).[55] Although the mean difference in EQ-5D change between the groups was statistically significant, we were unable to assess whether the changes were clinically significant as there is no widely accepted EQ-5D MCID.

Device-Related Serious Adverse Events

Nineteen studies (in 21 publications), including 3 RCTs,[55,60,61] 1 comparative cohort study,[66] 3 noncomparative cohort studies (in 5 publications; 1 that was identified during the Genio approval update),[54,67,69,71,75,76] 6 registry studies (2 of which were identified in the updated database search),[56,57,64,65,72,74] and 6 SRs (1 of which was identified in the updated database search),[52,58,62,63,68,73] assessed device-related serious adverse events (SAEs) in adults with moderate to severe OSA. Thirteen of the studies were rated as having high risk of bias[54-58,60,64-67,72,74,75] and 6 as moderate risk of bias[52,61-63,68,73] due to concerns regarding conflicts of interest, selection bias, reporting bias and, for the SRs, methods and insufficient integration of risk of bias in study conclusions. Thirteen studies reported only on FDA-approved HGNS devices (i.e., Inspire UAS system, Genio System),[52,54,56,57,60,61,64-67,72,74,75] 5 SRs also included non-FDA-approved devices (i.e., aura6000, Apnex Medical HGNS system),[58,62,63,68,73] and 1 RCT (THN3) only evaluated a non-FDA-approved device (i.e., aura6000).[55]

In general, device-related SAEs were infrequently reported in the publications eligible for KQ2 (harms).[52,54-58,60-67,69,71-75] Device explants (n = 12 studies)[54-57,63,65,67,69,71-74] and device revisions (n = 12

studies)[52,54-57,64,66,67,69,71-73] were the most frequently reported device-related SAEs; however, rates of these events were low:

- In the 4 studies that reported on total device revisions for participants using the Inspire UAS system, the rate of device revisions ranged from 0.4% to 6.3% of study participants.[54,57,66,71,75]
- In the 4 studies that reported on total device explants for participants using the Inspire UAS system, the rate of device explants ranged from 0.05% to 5.2% of study participants.[54,57,67,69,71,75]
- The most frequently reported reasons for device revisions were discomfort (including pain)[54,64,66,68,71-73] or technical issues with the device.[54,56,64,68,71,73,75] The most frequently reported reason for device explant was infection.[54,56,65,68,71-74] However, not all studies reported on reasons for device explants or revisions.

Beyond device explants and device revisions, study authors reported infections,[57,67,69] pneumothorax,[57,67,69,72,74] and total SAEs[54,62,64,67,69,75] in at least 2 of the eligible studies (Appendix D, Table D7). Additional device-related SAEs include: stroke,[60] pleural effusion on the day of surgery,[57] treatment related SAEs,[55] serious device-related AEs,[52] hematomas,[67,69,75] obstructive events,[67,69] bleeding from the nose after intubation,[75] temporary hypoglossal nerve paralysis,[75] device extrusion,[75] anesthesia-related intraoperative arrest,[67,69] one death (cause unknown),[61] inability to implant the device on the right side (a separate procedure was conducted on the left side),[67,69] external device malfunction,[58] and internal device malfunction.[58,75] In one study, it was unclear if serious complications arose from the external and internal device malfunctions as this was not reported.[58] Study authors also have broadly reported "other" SAEs.[54,67,69,71,75]

There was significant heterogeneity in study design and categorization of SAEs across the included studies. For example, device explants and device revisions were reported as a combined outcome[55] and separately.[64] Additionally, some device-related SAEs were reported both separately and as justification for revisions or explants. For example, infection was reported as a distinct outcome in 2 studies,[57,67,69] as a reason for device explant in 2 studies,[56,65] and as a reason for device revision in 1 study.[64] Different units of analysis (i.e., participants, reports, devices, events) also were used to report rates of SAEs.

Inspire UAS Pulse Generator Class 1 Recall

In June 2024, the FDA issued a class 1 recall (the most serious recall type) for the Inspire IV implantable pulse generator, citing a manufacturer defect. This recall includes 32 devices of the Model 3028 and may require revision surgery to correct. At the time of writing this report (including during the updated database search), no injuries or death related to this recall were reported by the FDA.[37] Therefore, it is unlikely that the included studies reflect SAEs that may have occurred due to this manufacturing defect. Such SAEs may be reported in future studies, if these occur.

OSA Severity

Six studies, including 4 RCTs[53,55,60,61] and 2 comparative cohort studies,[59,66] assessed OSA severity outcomes as measured by select polysomnography indices, specifically AHI, RDI, REI, and ODI (Table 6).

Five studies were assessed as having high RoB[53,55,59,60,66] and 1 was moderate.[61]

- All 6 studies reported some measure of AHI (i.e., the frequency of apneas and hypopneas per hour of sleep); all studies[53,55,59-61,66] used the AHI4 criteria to define hypopneas (i.e., airflow reductions of ≥ 30% for at least 10 seconds with an oxygen desaturation of ≥ 4% or greater).
- Four studies[53,55,60,66] additionally reported some measure of ODI (i.e., the frequency of clinically significant oxygen desaturations per hour of sleep) and used the ODI4 criteria to define clinically significant events (i.e., desaturations ≥ 4% lasting for at least 10 seconds).
- AHI and ODI use a 3-category OSA severity grading system of mild (≥ 5 to < 15), moderate (≥ 15 to < 30), and severe (≥ 30); individuals with scores less than 5 are not considered to have OSA.[79]
- A change of 5 or more events per hour between assessments is considered clinically meaningful for AHI and ODI measures.[79]
- No studies reported RDI or REI outcomes.

Table 6 summarizes OSA severity outcomes at the longest comparative follow-up timepoint and full outcome details are available in Appendix D, Table D8. For a detailed description of OSA severity polysomnography measures, see Appendix D, Table D1.

TABLE 6. OSA SEVERITY AT LONGEST COMPARATIVE FOLLOW-UP

Notes. See Appendix D, Table D8 for complete OSA severity outcomes data. [a] Crossover RCT. [b] Withdrawal RCT. [c] This study investigated a non-FDA-approved device and is not included in GRADE. [d] The *P*- values for means were not reported in study text and were ascertained through personal email communication with the THN3 trial authors on August 2, 2024.
Abbreviations. AHI: apnea-hypopnea index; CFB: change from baseline; CPAP: continuous positive airway pressure; HGNS: hypoglossal nerve stimulation; MCID: minimal clinically important difference; MD: mean difference; mo: month; NR: not reported; ODI: oxygen desaturation index; OSA: obstructive sleep apnea; RCT: randomized controlled trial; RR: relative risk; wk: week.

AHI outcomes

Five studies that reported AHI4 outcomes, including 3 RCTs and 2 cohort studies, investigated the FDA-approved Inspire UAS system (Table 6). In the 4 studies with inactive comparators (i.e., subtherapeutic stimulation,[60,61] inactive device,[53] no treatment[66]), HGNS groups had significantly lower OSA severity compared with controls across all follow-up timepoints (range, 2 weeks to 6 months) as evidenced by statistically significant between-group differences in mean AHI4 scores[53,61,66] and changes from baseline indicating comparatively lower AHI scores in treatment groups[53,60,66] (Table 6).

- Among the studies that reported mean AHI, HGNS groups in the STAR RCT and ADHERE comparative cohort study had follow-up scores indicating mild OSA severity compared with moderate severity in the control group[53,66]; both study groups in the CARDIOSA-12 trial had

moderate-severity AHI4 scores (Table 6).[61] No study groups had a follow-up AHI4 score below the clinical threshold for OSA (i.e., < 5 events per hour).

- Control group participants in the EFFECT and STAR withdrawal RCTs exhibited clinically significant increases in AHI4 (i.e., ≥ 5 events per hour[79]) after their HGNS devices were inactivated or adjusted to deliver subtherapeutic stimulation levels at baseline, and also as compared within the groups who received continuous HGNS therapy ($P < .001$ for both; Table 6).[53,60] However, the between-group difference in mean AHI4 in the CARDIOSA-12 trial (–4.9 events per hour) was just below the threshold for clinical significance.[61]
- In the EFFECT RCT, participants in the HGNS group were significantly more likely to achieve AHI4 scores indicating mild OSA severity (i.e., < 15 events per hour) at 1-week pre-crossover assesssment period compared with subtherapeutic stimulation controls (73.3% vs. 29.5%; $P < .001$).[60] HGNS group participants also appeared to be more likely to have AHI4 scores below 10 and 5 events per hour, but tests of significance were not reported (Appendix D, Table D8).

In the 12-month cohort study (N = 126) that compared HGNS as a second-line OSA therapy in patients with CPAP intolerance and CPAP therapy as a first-line therapy in treatment-naïve patients,[59] there was no significant difference between groups in terms of change in AHI4 from baseline ($P = .08$), although both groups experienced a clinically significant reduction in AHI4, suggesting both therapies similarly improved OSA severity (Table 6).

- There were also no significant between-group differences in the rate of participants achieving AHI4 scores indicating mild OSA severity (< 15 events per hour) or scores below the clinical threshold for OSA (< 5 events per hour); however, the proportion of participants achieving these AHI4 thresholds was high in both groups (> 80% and > 50%, respectively).[59]

One study, the THN3 trial[55] (N = 138), reported AHI4 findings for a non-FDA-approved HGNS device (aura6000). At the primary 4-month follow-up, participants in the HGNS group had significantly lower mean AHI4 scores compared with the inactive device controls ($P < .002$), but scores in the HGNS group were still indicative of moderate OSA versus severe OSA in the control group (Table 6).[55]

- In accord with lower mean scores, the HGNS group was significantly more likely to have achieved the study-defined AHI4 treatment response threshold (i.e., ≥ 50% reduction and < 20 events per hour) compared with the inactive device group (52.3% vs. 19.6%; $P < .001$).[55]

ODI outcomes

Three studies (2 RCTs[53,60] and 1 cohort study[66]) that reported ODI outcomes investigated the Inspire UAS system. Across these studies, HGNS groups exhibited significantly lower OSA severity compared with controls across all follow-up timepoints (range, 2 weeks to 6 months) as evidenced by statistically significant between-group differences in mean ODI4 scores[54,66] and changes from baseline indicating comparatively lower ODI4 scores in treatment groups[53,60] ($P < .001$ for all; Table 6).

- In the single study that reported mean ODI4 at final follow-up,[66] participants in the HGNS group had mean scores indicating mild OSA at 6 months whereas participants in the no-treatment control group had scores indicating moderate OSA (Table 6). No study groups had a follow-up ODI4 score below the clinical threshold for OSA (< 5 events per hour[79]).
- Control group participants in the EFFECT and STAR withdrawal RCTs exhibited clinically significant increases in ODI4 (≥ 5 events per hour) after their HGNS devices were inactivated or

adjusted to deliver subtherapeutic stimulation levels at baseline as compared with in the groups who received continuous HGNS therapy ($P < .001$ for both; Table 6).[53,60]

One study, the THN3 trial,[55] reported ODI4 findings for a non-FDA-approved HGNS device (aura6000). At the primary 4-month follow-up, participants in the HGNS group had significantly lower mean ODI4 scores compared with the inactive device controls ($P < .002$), but scores in the HGNS group were still indicative of moderate OSA, versus severe in the control group (Table 6).[55]

- The HGNS group was significantly more likely to have achieved an ODI4 score reduction of 25% or more at 4 months compared with the inactive device group (62.5% vs. 41.3%; $P = .02$).[55]

RDI Outcomes

No studies reported RDI outcomes.

REI Outcomes

No studies reported REI outcomes.

Daytime Sleepiness

Five high-RoB studies, including 3 RCTs[53,55,60] and 2 comparative cohort studies,[59,66] assessed daytime sleepiness outcomes. All studies used the Epworth Sleepiness Scale (ESS), a validated self-report instrument that evaluates an individual's likelihood of falling asleep during 8 common daytime activities, to measure differences between groups.[81] The ESS has a possible score range of 0 to 24 points, with scores greater than 10 points indicating excessive daytime sleepiness; a change of 2 or more points between assessments is considered to be clinically meaningful.[79,81] Table 7 summarizes daytime sleepiness outcomes at the longest comparative follow-up timepoint, and full outcome details are available in Appendix D, Table D9. For a detailed description of the ESS see Appendix D, Table D1.

Abbreviations. CPAP: continuous positive airway pressure; HGNS: hypoglossal nerve stimulation; MCID: minimal clinically important difference; MD: mean difference; mo: month; NR: not reported; RCT: randomized controlled trial; RR: relative risk; wk: week.

Four studies that reported daytime sleepiness outcomes, including 2 RCTs[53,60] and 2 cohort studies,[59,66] investigated the FDA-approved Inspire UAS system. In 3 studies with inactive comparators (i.e., subtherapeutic stimulation[60] inactive device,[53] no treatment[66]), HGNS groups reported significantly less daytime sleepiness compared with controls across all follow-up timepoints (range, 2 weeks to 6 months) as indicated by significantly lower mean ESS scores or changes from baseline indicating comparatively lower scores ($P < .01$). Mean ESS scores in the HGNS groups were below the excessive sleepiness threshold (> 10 points[81]) whereas mean scores in the inactive comparator groups were at or above the threshold (Table 7).[53,60,66]

In 1 cohort study (N = 126) with an active comparator (CPAP therapy),[59] there was no significant difference in mean ESS scores at 12 months (7.5 vs. 10.8 points; $P = .27$). Although both study groups reported a clinically significant reduction in ESS scores (≥ 2 points),[81] the HGNS group reported a significantly greater improvement in subjective daytime sleepiness compared with the CPAP group ($P = .04$; Table 7).[59] Notably, only the HGNS group experienced a clinically and statistically significant change in daytime sleepiness from baseline ($P < .001$).[59]

One study, the THN3 trial[55] (N = 138), reported AHI findings for a non-FDA-approved HGNS device (aura6000). At the primary 4-month follow-up, participants in the HGNS group reported a statistically and clinically greater reduction in ESS compared with controls (MD, –3.3 [95% CI, –4.8 to –1.9])[55]; however, mean scores (baseline or follow-up) were not reported so the effect of the aura6000 on daytime sleepiness remains unclear.

Major Adverse Cardiac Events

No eligible studies reported comparative MACE outcomes.

Review Summary and Limitations

There is a reasonable evidence base from multiple RCTs and comparative prospective cohort studies regarding the effectiveness of HGNS devices for the treatment of moderate to severe OSA in adults and a substantial evidence base regarding associated device-related harms from SRs, large registry studies, and

other prospective nonrandomized studies. In the following summaries, low levels of confidence indicate that if new information from additional studies were published, our understanding of the evidence would likely change. Moderate levels of confidence indicate that it is unlikely, yet possible, that data from new studies would change our understanding of the evidence.

Evidence Summary

We identified 21 eligible studies (17 from our initial search, 3 from our updated database search in 2025, and 1 from the 2026 Genio approval update) that assessed the effectiveness and harms of HGNS devices in adults with moderate to severe OSA. Of these, 15 studies had evidence regarding FDA-approved HGNS devices and were included in the GRADE confidence ratings. The other 6 studies also assessed HGNS devices that have not yet been approved by the FDA and were excluded from GRADE. While the Genio approval update resulted in the inclusion of 1 additional study reporting on harms, the findings of this study did not alter the conclusions of this coverage guidance.

Effectiveness

Five studies (3 RCTs and 2 comparative cohort studies) investigated the effectiveness of the Inspire UAS system as compared with nonsurgical control groups in adults with moderate to severe OSA. All 3 RCTs compared HGNS with controls (either subtherapeutic stimulation or an inactive device) in participants who were implanted with an HGNS device and demonstrated a clinical response before enrollment. Participants in the cohort studies did not begin HGNS therapy until after enrollment. One cohort study compared HGNS with no treatment among a group of people who met the clinical criteria for HGNS, and 1 cohort study compared HGNS therapy among participants with CPAP intolerance versus a CPAP therapy among participants who were responsive to first-line CPAP therapy.

We have low confidence that HGNS therapy:

- **Improves sleep-related QoL compared with inactive controls**. This assessment was based on consistent findings of statistically and clinically higher scores on validated QoL scales in HGNS groups compared with controls (2 RCTs and 1 cohort study; N = 485).
- **Improves OSA severity compared with inactive controls and has similar benefit to CPAP therapy.** This assessment was based on consistent findings of statistically and clinically lower AHI4 and ODI4 scores from polysomnography in HGNS groups compared with controls (3 RCTs and 1 cohort study; N = 547), and no difference in mean scores between participants treated with second-line HGNS therapy versus first-line CPAP therapy (1 cohort study; N = 126).
- **Improves daytime sleepiness compared with inactive controls and has similar benefit to CPAP therapy.** This assessment was based on consistent findings of statistically and clinically lower scores on the validated ESS scale in HGNS groups compared with controls (2 RCTs and 1 cohort study; N = 485), and no difference in mean scores between participants treated with second-line HGNS therapy versus first-line CPAP therapy (1 cohort study; N = 126).
- The low-confidence ratings for these outcomes were due primarily to risk of bias concerns (e.g., limited methods reporting, selection bias, conflicts of interest) and indirectness from heterogeneity in study design and assessment timepoints, as well as limited generalizability due to more restrictive study enrollment criteria relative to the current indication for FDA-approved HGNS devices.

No eligible studies reported:

- General or overall measures of QoL
- Comparative MACE outcomes

Harms

Thirteen studies (2 RCTs, 4 cohort studies, 6 registry studies, and 1 SR) reported device-related SAEs for FDA-approved HGNS devices.

- We have **moderate confidence of the scope and magnitude of device revisions and explants** and **low confidence of the scope and magnitude of other device-related SAEs** in individuals with moderate to severe OSA who are treated with HGNS.
- These ratings are based upon generally low rates of reported device-related SAEs and availability of large sample sizes. However, there are concerns with risk of bias for the studies reporting these outcomes, specifically reporting bias and conflicts of interest. While we have some increased confidence in the scope and magnitude of device explants and revisions based on the available evidence, we are less confident in the scope and magnitude of other device-related SAEs, given additional concerns regarding generalizability to a Medicaid population.

Review Limitations

Although our evidence reviews are conducted using rigorous and systematic methods, we often encounter limitations in the literature or in the review design that are important to acknowledge. Below we describe limitations that broadly affected our GRADE ratings.

- **Discrepancy between enrolled study populations and current HGNS eligibility criteria:** As of 2023, FDA eligibility criteria for HGNS therapy with the Inspire UAS devices includes adults with AHI scores up to 100 events per hour and a BMI warning for patients with BMIs greater than 40 kg/m^2.[30] However, studies that assessed efficacy outcomes had lower AHI and BMI enrollment thresholds that more closely aligned with the initial 2014 Inspire UAS system FDA indication (AHI > 15 to ≤ 65 events per hour) and the lower BMI warning (BMI greater than 32) (Appendix D, Table D5).[30] Moreover, no eligible efficacy studies reported relevant subgroup analyses by AHI or BMI and current evidence for HGNS performance among participants with higher OSA severity scores, and higher BMI is limited to uncontrolled, nonrandomized studies.
- **Substantial industry-related conflicts of interest:** All primary studies received industry funding and many study authors reported receiving financial disbursements or study support from HGNS manufacturers, which may have increased the risk of publication bias. A 2021 retrospective analysis demonstrated a significant relationship between author conflict of interest, specifically with Inspire Medical Systems, Inc., and published position on HGNS.[82] The analysis demonstrated that 80% of authors with an Inspire Medical Systems, Inc., conflict of interest published articles with favorable views on HGNS, whereas only 10% of authors with an Inspire Medical Systems, Inc., conflict of interest published articles with neutral views on HGNS ($P < .004$).[82]
- **Highly selected study populations:** Study populations in the RCTs were limited to participants who received an HGNS device and demonstrated either tolerability or a positive treatment response before randomization. In multiple studies, participants were required to demonstrate a 50% or greater reduction in baseline AHI and have AHI below 20 events per hour before enrollment, generally exceeding the established threshold for clinically meaningful change in AHI

(≥ 5 events per hour). The substantial selection bias likely present in these studies may have resulted in larger effect sizes than would be experienced in clinical settings.

- **Study design and reporting heterogeneity:** There was substantial heterogeneity in the studies, including heterogeneity in study design and reported device-related SAEs specific to the studies eligible for harms evaluation. Important design variations included HGNS implantation timing differences for study participants (pre- or post-enrollment), RCT types (e.g., crossover studies, withdrawal), and length of follow-up with limited consistency between studies (follow-up range: 2 weeks to 12 months). These study design variations limited our ability to make direct outcome comparisons and the heterogeneity in reported device-related SAEs limited our ability to understand the scope and magnitude of this outcome.
- **Lack of long-term follow-up:** FDA-approved HGNS devices are intended to last for almost a decade, with component replacements potentially occurring throughout a patient's lifetime; yet, there was a lack of long-term comparative data for efficacy outcomes (≤ 12 months). However, 5-year results from the uncontrolled STAR NRS cohort study suggest the effectiveness of the Inspire UAS system observed in comparative studies, including the related STAR RCT, may be durable.[71] In this study, significant beneficial treatment effects were observed for OSA severity (AHI4 rate), sleep-related QoL (FOSQ scores), and daytime sleepiness (ESS scores) among trial participants at 12 months compared with baseline.[71] When assessed at the 5-year follow-up, the magnitude of these treatment effects persisted.[71] Additionally, an analysis adjusted for losses to follow-up found most participants (66%) continued to meet the composite AHI4 treatment response criteria at 5 years (i.e., reduction of ≥ 50% to below 20 events per hour) and maintain normal FOSQ and ESS scores (67% and 78%, respectively).[71] Long-term, open-label assessments of participants implanted with the Genio System are ongoing.[83]

Contextual Questions

We identified 2 studies that informed the contextual questions, both of which were identified in our initial database search.[68,84]

- **2025 update:** We did not identify any new evidence to inform the contextual questions in our updated database search
- **Genio approval update:** We did not identify any new evidence to inform the contextual questions during the Genio approval update.

CQ1. Key Clinical Endpoints From SRs of HGNS

We reviewed published literature and identified 1 SR, including 17 studies (1 RCT and 16 nonrandomized studies) of all available HGNS devices with data on 1,962 participants, that evaluated key clinical endpoints for OSA (all-cause mortality).[68] This SR was assessed as having a moderate risk of bias due to potential industry-related COI and limited statistical methods reporting. Among patients receiving HGNS therapy, 7 deaths were reported over a mean follow-up duration of 17.5 months (SD, 16.9), resulting in a weighted all-cause mortality rate of 0.01% (95% CI, 0.0 to 0.2).[68] Deaths were attributed to cancer (n = 3), cardiac events (n = 3), and homicide (n= 1), and none were related to HGNS therapy.[68] Importantly, follow-up durations were 5 years or less, a short time period to assess OSA-related mortality, and none of the studies were specifically powered to detect this outcome.

We did not identify SRs reporting any other OSA-relevant clinical endpoints, such as fatigue-related injuries (e.g., motor vehicle crashes), blood pressure control or use of antihypertensive medication, or rates of major adverse cardiac events.

CQ2. Comparative Effectiveness of HGNS Versus Other OSA Surgeries

We did not identify any RCTs comparing the effectiveness of HGNS with other OSA surgeries.

CQ3. Cost and Cost-Effectiveness of HGNS

We prepared this section in anticipation of the implementation of Senate Bill 1508 of the 2024 Oregon legislative session, effective January 1, 2025.[85] As such, we did not consider or extract any outcomes based on quality adjusted life years (QALY) and only extracted other cost measures anticipated to be compliant with the new law.[85] We reviewed published literature and identified 1 study that estimated such measures.[84]

In that study, the investigators developed a US-based model to estimate the costs and outcomes of the Inspire UAS system, as compared with no treatment, in individuals with OSA.[84] For costs, the study estimated the incremental costs of HGNS versus no treatment from a health care payer perspective.[84] This considered the costs of HGNS implantation, device and battery replacement every 11 years, and annual office visits.[84] For outcomes, the study looked at 3 key clinical endpoints: risk of myocardial infarction (heart attack), risk of stroke, and risk of motor vehicle collisions.[84] As available RCTs and comparative cohort studies on HGNS do not directly study or report the effect of HGNS on these outcomes, estimates of the effects of HGNS versus no treatment for the model were informed by observational and other related studies.[84] The study examined both costs and outcomes at a 10-year and a lifetime time horizon.[84] Both costs and outcomes were discounted at 3% per year.[84]

The only available measure for extraction was the estimated cost per outcome averted with HGNS.[84] The study did not report a full net cost analysis.[84] We extracted estimated cost per myocardial infarction averted, cost per stroke averted, and cost per motor vehicle collision averted. We adjusted the results from 2013 United States Dollars (USD) reported by the study to June 2024 USD, using the Consumer Price Index Inflation Calculator from the US Department of Labor, Bureau of Labor Statistics.[86] Table 8 shows the cost per outcome for the 3 identified outcomes at both time horizons.

TABLE 8. ESTIMATED COST PER OUTCOME AVERTED FROM A COST-EFFECTIVENESS STUDY OF HGNS

OUTCOME	ABSOLUTE RISK REDUCTION FOR HGNS VS. NO TREATMENT (A)	INCREMENTAL COST OF HGNS (B)	ESTIMATED COST PER OUTCOME AVERTED (B/A)
10-YEAR TIME HORIZON			
Myocardial infarction	0.050	$33,741	$674,820
Stroke	0.017	$33,741	$1,984,765
Motor vehicle collisions	0.313	$33,741	$107,799

LIFETIME TIME HORIZON			
Myocardial infarction	0.092	$58,602	$636,978
Stroke	0.009	$58,602	$6,511,333
Motor vehicle collisions	0.663	$58,602	$88,389

Notes. Outcome rates and costs are extracted from Pietzsch, et al.,[84] and inflation-adjusted to June 2024 USD using the Consumer Price Index.[86]
Abbreviations. HGNS: hypoglossal nerve stimulator.

This study has several limitations, as reported by the study investigators.[84] First, model inputs represent best estimates from observational and other related studies, as opposed to direct results from RCTs and comparative cohort studies of HGNS.[84] For example, the estimates of reduction in cardiovascular risk were taken from an observational study examining the association between AHI and cardiovascular risk.[84] This approach inherently assumes that reducing AHI through HGNS treatment will causally reduce cardiovascular risk, which has not been directly demonstrated. Second, by definition, model-based studies project outcomes using a simplified form of the disease process.[84] Third, a key model assumption is that long-term results can be estimated from short-term study findings.[84] Another related key assumption is that adherence remains high through an individual's lifetime (86% in the base case analysis).[84] Fourth, the study estimated outcomes based on the STAR study,[54] which may not be generalizable to the broader Medicaid-insured population potentially eligible to receive HGNS.[84] Finally, estimates of the cost of HGNS implantation were derived from clinical practice experience at the time (i.e., the percentage implanted in the outpatient versus inpatient setting) and would likely change if practice patterns changed.[84]

Ongoing Studies

We identified ongoing studies with searches of the ClinicalTrials.gov registry conducted in May 2024. Results of the ongoing studies search are summarized below. See Appendix D, Table D10 for individual study characteristics.

- **2025 update:** We evaluated all previously identified ongoing studies during our database search update in July 2025 and repeated our search for new ongoing studies. Of the 7 identified ongoing studies, none had been published and no new eligible ongoing studies were identified.
- **Genio approval update:** 1 previously identified ongoing study of the Genio System published primary 12-month study results in November 2025 (i.e., the DREAM study[75]); however, the long-term extension phase of this study is still ongoing with an estimated study completion date of February 2028. We additionally identified 1 new ongoing prospective nonrandomized post-approval study (i.e., BREATHE), which was mandated by the FDA for ongoing approval of the Genio System.

There are currently 8 ongoing studies of upper airway nerve stimulation for adults with moderate or severe OSA that are likely to meet the scoped inclusion criteria for this review, including:

- 1 RCT[87]
- 2 registry studies[88,89]
- 5 prospective nonrandomized studies (NRS), including 1 from the Genio approval update[83,90-93]

The ongoing RCT we identified is the OSPREY trial, a multicenter crossover RCT conducted in the US with a total study duration of 13 months and a primary completion date of October 2023.[87] This study enrolled

150 participants with moderate to severe OSA and a BMI of 35 kg/m^2 or less.[87] All participants are implanted with the aura6000 system; the HGNS group will receive active stimulation from months 1 through 7, whereas devices in the control group will be inactivated until outcomes are assessed at 7 months, at which point the crossover phase of the trial begins.[87] No published results of this trial are yet available.

Among the 7 remaining NRS, estimated primary completion dates range from September 2022 to April 2034 and planned study durations range from 12 months to 5 years.[83,88-93] Excluding the registry studies,[88,89] estimated study enrollments range from 110 to 229 participants.[83,87,90-93] The location of these studies are as follows (with some taking place in more than 1 country):

- 5 studies in the US[87,88,90-93]
- 4 in European countries (Belgium, France, Switzerland, Germany, or the Netherlands)[83,88-90]
- 1 in Australia[90]

Four of the ongoing NRS investigate the Genio System[83,90,92,93] and the other 3 studies, including the 2 registry studies, investigate the Inspire UAS system.[88,89,91] All 5 of the prospective NRS[83,90-93] and 1 of the registry studies[89] are noncomparative cohorts with pre-post comparison from baseline outcomes. The remaining registry has a control group of patients who were denied insurance coverage for the Inspire UAS system.[88]

While all ongoing NRS focus on adults with moderate to severe OSA, 5 studies specify an AHI threshold (e.g., 15 to 65 events/hour)[83,89,91-93] and 2 did not,[88,90] with 1 of these referring only to a likely diagnosis of moderate to severe OSA.[90] Four of the ongoing NRS specify BMI in the enrollment criteria,[83,89,92,93] with 3 studies including participants with a BMI of 32 kg/m^2 or less,[89,92,93] while the other has participants with a BMI of 35 kg/m^2 or less.[83] Notably, these inclusion criteria differ from 2023 changes to the FDA-approved indication and BMI warning for the Inspire UAS system.[30] While the Inspire UAS system is currently indicated only for individuals who do not have complete concentric collapse at the soft palate level,[30] 1 ongoing NRS of the Genio system is studying individuals with OSA who do have complete concentric collapse of the soft palate.[92]

All 8 identified ongoing studies include OSA severity (as measured by polysomnography) as an outcome of interest, though none look at major adverse cardiovascular events.[83,87-93] Four ongoing studies include quality of life outcomes,[83,87-89] 5 had procedure- or device-related severe adverse events,[83,87,90,91,93] and 5 looked at daytime sleepiness as represented by the ESS.[87-89,91,93]

POLICY LANDSCAPE

Genio Approval Update

Clinical Practice Guidelines

- We did not identify changes to HGNS recommendations related to the Genio System approval in any of the guidelines included in the original coverage guidance.

Payer Coverage Policies

- 1 payer policy released an update that newly acknowledges the Genio System approval (i.e., Regence), but HGNS coverage criteria did not change.
- We identified changes in HGNS coverage criteria in 3 payer policies reviewed in the original coverage guidance (Cigna, Moda, and Regence).

2025 Update

In the Policy Landscape section, we searched for new or updated HGNS-related recommendations in relevant CPGs and reviewed the previously included payer policies for changes in HGNS coverage.

Clinical Practice Guidelines

- We did not identify changes to HGNS recommendations in any of the guidelines included in the original coverage guidance.
- We did not identify any new eligible CPGs with HGNS-related recommendations.

Payer Coverage Policies

- We did not identify changes in HGNS coverage status or coverage criteria in any of the 6 payer policies reviewed in the original coverage guidance (i.e., Medicare, Washington Medicaid, Aetna, Cigna, Moda, Regence).

In the following section, we summarize evidence-based clinical guildelines about HGNS for OSA from professional societies and governmental health agencies and report on payer policies from select public and private organizations.

In this section, we summarize clinical guidelines from professional societies and public and private payer policies with guidance on HGNS as a treatment for moderate to severe OSA. Table 9 presents a high-level summary of HGNS recommendations and coverage (candidate selection) criteria.

- **2025 update:** All references cited in the following sections refer to the most current version as identified in our updated database search in July 2025. Of note, while some guidelines (Department of Veterans Affairs and the Department of Defense and German Sleep Society)[94,95] and payer policies (Aetna and Moda) were updated since conducting our initial search, HGNS-specific recommendations did not change.
- **Genio approval update:** We did not identify any Genio-specific changes to clinical practice recommendations or payer policy coverage criteria. To date, only 1 payer policy has released an update that explicitly acknowledges the Genio System (i.e., Regence).[96]

TABLE 9. CLINICAL RECOMMENDATIONS AND PAYER COVERAGE CRITERIA FOR HGNS

	CLINICAL GUIDELINES				PAYER POLICIES[a]				
	VA/DoD[97]	GSS[98]	ERS[99]	NICE[100]	Medicare LCD[101]	Aetna[102]	Cigna[103]	Moda[104]	Regence[96]

DISE to Evaluate for Concentric Collapse		✓			✓	✓	✓	✓	✓

Table Key. A check indicates the criterion is endorsed. Blank cells indicate the HGNS recommendation or HGNS candidate selection criteria is not applicable. A blank indicates specific criterion was not mentioned or specific criteria falls into a different category (for age, AHI, or BMI demographic).

Notes. a Washington Medicaid was not included in this table because the most relevant identified Health Technology Assessment (HTA) from Washington State Health Care Authority did not include any information on HGNS therapy. b The ERS recommendation specified AHI <50 events per hour (with no lower limit indicated). c The GSS recommendation specified < class I obesity [BMI < 34.9 kg/m2].

Abbreviations. AHI: apnea hypopnea index; BMI: body mass index; DISE: drug-induced sleep endoscopy; ERS: European Respiratory Society; GSS: German Sleep Society; HGNS: hypoglossal nerve stimulation; LCD: local coverage determination; NICE: National Institute for Health and Care Excellence; PAP: positive airway pressure; VA/DoD: Department of Veterans Affairs and the Department of Defense.

Evidence-Based Recommendations

We identified 4 clinical guidelines with HGNS-specific recommendations from the following organizations:

- Department of Veterans Affairs and the Department of Defense (VA/DoD)[97]
- German Sleep Society (GSS)[98]
- European Respiratory Society (ERS)[99]
- National Institute for Health and Care Excellence (NICE)[100]

As indicated in Table 9, there were 2 guidelines (VA/DoD[97] and GSS[98]) that endorsed HGNS as a second-line treatment, 1 guideline (ERS[99]) included a conditional recommendation against HGNS, and 1 guideline (NICE[100]) indicated HGNS should only be used with special arrangements (in the UK). Table 9 also details 3 of the 4 guidelines used for HGNS candidate selection criteria (age, AHI range, BMI range, documentation of PAP failure or intolerance, and DISE findings).[97-99]

In addition, we identified 2 position statements and 1 position paper with HGNS-specific recommendations.[105-107] The position paper and 1 of the position statements endorsed HGNS as a second-line treatment for OSA.[105,107] The position paper used HGNS candidate selection criteria (including AHI and BMI ranges),[107] but the 2 position statements did not.

We also identified 1 review with consensus recommendations on perioperative care of patients with OSA undergoing upper airway surgery, including HGNS.[108] Not within the scope of the identified review, recommendations for HGNS candidate selection were *not* specified.[108]

Clinical Guidelines With HGNS-Specific Recommendations

For this report, we assessed the methodological quality of the 4 identified clinical guidelines, which were from 4 distinct professional organizations[97-100]:

- A guideline from the VA/DoD had good methodological quality.[97]
- A guideline from the GSS had poor methodological quality.[98] A meaningful issue was lack of clarity regarding potential connections between recommendations given and the lengthy list of references; there were no in-text citations.[98] Related to this, a comprehensive discussion on the methods used to formulate recommendations was absent from the English language version of the guidelines.[98]
- Guidelines from the ERS had fair methodolgical quality; concerns were author conflicts of interest.[99]
- Guidelines from the NICE had fair methodolgical quality; concerns were lack of clarity regarding methods used for formulating recommendations.[100]

Department of Veterans Affairs and the Department of Defense (VA/DoD)

2019 guidelines from the VA/DoD included 12 recommendations on treatment and management of OSA.[97] One of the 12 workgroup recommendations on treatment and management of OSA was *select* patients who cannot adhere to PAP should be evaluated for surgical treatment with HGNS.[97] Using the GRADE system, the strength of the recommendation was graded by the VA/DoD workgroup as *weak*, consistent with a suggestion to *offer* (but not necessarily recommend) HGNS as an option.[97] In addition,

the 1 OSA recommendation pertaining to HGNS indicated the following HGNS candidate selection criteria[97]:

- AHI 15 to 65 events per hour
- BMI < 32 kg/m^2

German Sleep Society (GSS)

2017 GSS guidelines on sleep-related breathing disorders in adults had recommendations on non-pap therapies including HGNS and other surgeries.[98] The 1 recommendation on HGNS indicated use only in the case of CPAP intolerance or ineffectiveness and when DISE findings are consistent with no concentric obstruction.[98] Furthermore, the GSS recommended that HGNS should be used only in patients meeting both of the following criteria[98]:

- AHI 15 to 50 events per hour
- < class I obesity (BMI < 34.9 kg/m^2)

National Institute for Health and Care Excellence (NICE)

2017 NICE interventional procedures guidance on HGNS indicated that evidence on the safety and efficacy of HGNS for moderate to severe OSA was limited in quantity and quality.[100] Guidance indicated HGNS should be used only with special arrangements for clinical governance, consent, and audit or research.[100] The committee noted that DISE had been used for study participant screening in HGNS clinical trials; however, the committee emphasized DISE is not commonly used in the UK.[100] AHI and BMI candidate selection criteria were *not* given by the NICE.[100]

European Respiratory Society (ERS)

2021 ERS clinical guidelines on non-CPAP therapies for OSA were developed via systematic review.[99] One of the PICOs focused on whether HGNS during sleep should be used or if *no treatment* should be used in patients with OSA.[99] The task force conditionally recommended against the intervention based on what was assessed as *very low* quality of evidence (using GRADE).[99] Compared with *no treatment*, HGNS can be considered as a salvage treatment for patients meeting both of the following HGNS candidate selection criteria[99]:

- AHI < 50 events per hour
- BMI < 32 kg/m^2

Additionally, the ERS indicated the conditional recommendation *against* HGNS was based on limited evidence from 3 RCTs that had strict participant selection criteria (~10% of those screened participated in the 3 studies).[99]

Recently, experts from World Sleep Society's International Sleep Medicine Guidelines Committee and Sleep and Breathing Task Force reviewed the 2021 ERS guidelines for relevance and applicability to the global practice of sleep medicine.[109] In early 2024, the World Sleep Society task force published an endorsement of the ERS guidelines, specifically including the conditional recommendation *against* HGNS.[109]

Position Statements and Position Papers That Included Information on HGNS Surgery

American Academy of Otolaryngology-Head and Neck Surgery (AAO-HNS)

In 2019, the AAO-HNS revised an HGNS position statement first submitted for review in 2014. The entirety of the current statement is as follows[105]:

- "The American Academy of Otolaryngology-Head and Neck Surgery considers upper airway stimulation (UAS) via the hypoglossal nerve for the treatment of adult obstructive sleep apnea syndrome to be a safe and effective second-line treatment of moderate to severe obstructive sleep apnea in patients who are intolerant or unable to achieve benefit with positive pressure therapy."

Australasian Sleep Association (ASA)

In 2020, the ASA published a position statement on surgical management of OSA.[106] The authors noted although HGNS is commercially available internationally, at the time the statement was published, HGNS remained in clinical trial phase only in Australasia.[106] No criteria were shared pertaining to HGNS candidate selection (such as PAP failure or intolerance, DISE findings, AHI range, or BMI range).[106]

German Society of Oto-Rhino-Laryngology

In 2021, the German Society of Oto-Rhino-Laryngology published a 6-page position paper on HGNS for OSA.[107] After PAP therapy, HGNS is considered recommended as a second-line treatment.[107] DISE assessment for concentric collapse is required and the authors noted that "profound expertise" is needed to perform and evaluate a DISE.[107] In Germany, HGNS can be considered in patients meeting both of the following criteria[107]:

- AHI 15 to 65 events per hour
- BMI < 35 kg/m^2

Recommendations on Perioperative Care of Patients With OSA Undergoing Upper Airway Surgery

A 2019 review with consensus recommendations on perioperative care of patients with OSA undergoing upper airway surgery had recommendations and statements specific to a variety of procedures, including HGNS.[108] Authors were experts from the US and Europe.[108]

Two consensus recommendations specific to HGNS were as follows[108]:

- HGNS surgery can be performed in a daycare or clinical setting, depending on the clinical judgment of the surgeon and/or anesthesiologist. (Quality of evidence was considered very low and strength of the recommendation was considered strong according to the GRADE system.)
- In most cases, patients undergoing HGNS surgery should not have prolonged postoperative monitoring. (Quality of evidence was considered very low and strength of the recommendation was considered strong.)

Given these recommendations were focused on perioperative care, no recommendations were provided for HGNS candidate selection.[108]

Payer Coverage Policies

We identified 5 policies related to coverage of HGNS from Aetna, Cigna, Moda, Regence, and the Medicare local coverage determination (LCD).[96,101-104] The 5 payers cover HGNS for *select* adult patients with OSA.[96,101-104] All payers require that patients be previously insufficiently treated with CPAP and that DISE findings are consistent with absence of complete concentric collapse at the soft palate level.[96,101-104]

Additional coverage criteria include but are not limited to varying AHI ranges and BMI ranges.[96,101-104] As noted previously in this report, FDA-approved indications for use of the Inspire UAS system were expanded in June 2023 to include a higher upper limit for AHI and a higher upper limit of the warning for BMI.[34] This was based on the FDA's analysis of data from the ADHERE registry through 2022 (Appendix D, Table D11).[110] For AHI, the FDA compared 1,483 people with an AHI ≤ 65 with 57 people with an AHI of greater than 65 to 100. FDA did not find any significant difference in key outcomes: final AHI, AHI responder, final ESS, and change in ESS and determined the safety profile to be "similar."[110] For BMI, the analysis compared 1,218 people with a BMI ≤ 32 kg/m^2 with 279 people with a BMI of greater than 32 to 40 kg/m^2.[110] The FDA also did not identify a significant difference key outcomes: final AHI, change in AHI, AHI responder, AHI nonresponder, final ESS, change in ESS, and also determined the safety profile to be "similar."[110] See Table 9 for a concise visual summary of commonalities and differences in payer policy criteria, including AHI and BMI.

We also identified a 2012 Health Technology Assessment (HTA) from Washington State Health Care Authority on sleep apnea diagnosis and treatment that did *not* include any information on HGNS therapy, which is likely related to FDA approval after completion of the Washington HTA.[111]

Medicare

We identified 1 coverage determination document for Medicare with information about HGNS.[101] This LCD (L38312), shown in Table 9, covers Oregon and was revised with an effective date of March 2020.[101] Beneficiaries diagnosed with moderate to severe OSA are potential candidates for HGNS if *ALL* of the following criteria are met[101]:

- Beneficiary is 22 years of age or older
- BMI is less than 35 kg/m2
- A polysomnography study is performed within 24 months of first consultation for HGNS implant
- Beneficiary has predominantly obstructive events (defined as central and mixed apneas less than 25% of the total AHI)
- AHI is 15 to 65 events per hour
- Beneficiary has documentation demonstrating CPAP failure (defined as AHI greater than 15 despite CPAP usage) or CPAP intolerance (defined as less than 4 hours per night, 5 nights per week, or the CPAP has been returned) including shared decision making that the patient was intolerant of CPAP despite consultation with a sleep expert
- Absence of complete concentric collapse at the soft palate level as seen on a DISE procedure
- No other anatomical findings that would compromise performance of device (e.g., tonsil size 3 or 4 per standardized tonsillar hypertrophy grading scale)

HGNS is considered NOT medically reasonable and necessary when ANY of the following contraindications are present [101]:

- Beneficiaries who have central and mixed apneas that make up more than 25% of the total AHI
- Beneficiaries who have an implantable device and could experience unintended interaction with the HGNS implant system
- BMI equal to or greater than 35
- Neuromuscular disease
- Hypoglossal-nerve palsy
- Severe restrictive or obstructive pulmonary disease

- Moderate to severe pulmonary arterial hypertension
- Severe valvular heart disease
- New York Heart Association class III or IV heart failure
- Recent myocardial infarction or severe cardiac arrhythmias (within the past 6 months)
- Persistent uncontrolled hypertension despite medication use
- An active, serious mental illness that reduces the ability to carry out activities of daily living (ADLs) and would interfere with the patient's ability to operate the HNS and report problems to the attending provider
- Coexisting nonrespiratory sleep disorders that would confound functional sleep assessment
- Beneficiaries who are or who plan to become pregnant
- Beneficiaries who require magnetic resonance imaging (MRI) with model 3024
- Beneficiaries who require MRI with model 3028, and can undergo MRI on the head and extremities if certain conditions and precautions are met
- Beneficiaries who are unable or do not have the necessary assistance to operate the sleep remote
- Beneficiaries with any condition or procedure that has compromised neurological control of the upper airway

The coverage guidance includes the following caveats[101]:

- DISE: Due to documented inconsistency in determining if complete concentric collapse is present, the inserting provider shall be certified by the FDA-approved manufacturer's second opinion service of validation by video clip submissions of at least 80% agreement in at least 15 consecutive studies. Inserting providers shall have documentation to submit to this contractor if necessary.
- Provider qualifications: HGNS for the treatment of OSA must be ordered and furnished by qualified personnel. Insertion of the device must be performed by a qualified physician (MD or DO) who is a board-certified or a board-eligible otolaryngologist having completed a residency and/or fellowship program and maintains ongoing certification in otolaryngology.

The coverage policy did not provide specific rationale for coverage more restrictive than the FDA approval criteria.[101]

Private Payers (Aetna, Cigna, Moda, Regence)

Among 4 private payers (Aetna, Cigna, Moda, and Regence), coverage criteria for HGNS have commonalities and differences. As indicated above in Table 9, commonalities include these requirements[96,102-104]:

- Documentation of PAP failure or intolerance
- Polysomnography (sleep study), including AHI results, within the previous 2 years
- DISE findings consistent with the absence of concentric collapse at the soft palate level
- Also detailed above in Table 9, AHI and BMI differences in coverage criteria are nuanced. The most recent policies align with (or more closely align with) the June 2023 expanded FDA indication and BMI warning[30] for use of the Inspire UAS system.

Coverage guidance is prepared by the Health Evidence Review Commission (HERC), HERC staff, and subcommittee members. The evidence summary is prepared by the Center for Evidence-based Policy at Oregon Health & Science University (Center). This document is intended to guide public and private purchasers in Oregon in making informed decisions about health care services.

The Center is not engaged in rendering any clinical, legal, business, or other professional advice. The statements in this document do not represent official policy positions of the Center. Researchers involved in preparing this document have no affiliations or financial involvement that conflict with material presented in this document.

Suggested citation: Durbin S, Bachhuber M, Cooper C, Ryan JJ, Young E, King V. *Coverage guidance: hypoglossal nerve stimulation for obstructive sleep apnea*. Portland, OR: Center for Evidence-based Policy, Oregon Health & Science University; 2026.

The authors would also like to acknowledge Firozeh Darabi, Emma Kenagy, Jacqui Krawetz, Jami Hoffman, and Heather McConnell from the Center for Evidence-based Policy as well as our subject matter experts, Louis Libby, MD and Derek J. Lam, MD, MPH, for their contributions to this work.

APPENDIX A. GRADE TABLE ELEMENT DESCRIPTIONS

TABLE A1. GRADE TABLE ELEMENTS

ELEMENT	DESCRIPTION
Balance of benefits and harms	The larger the difference between the desirable and undesirable effects, the higher the likelihood that a strong recommendation is warranted. An estimate that is not statistically significant or has a confidence interval crossing a predetermined clinical decision threshold will be downgraded.
Quality of evidence	The higher the quality of evidence, the higher the likelihood that a strong recommendation is warranted.
Resource allocation	The higher the costs of an intervention—that is, the greater the resources consumed in the absence of likely cost offsets—the lower the likelihood that a strong recommendation is warranted.
Values and preferences	The more values and preferences vary, or the greater the uncertainty in values and preferences, the higher the likelihood that a weak recommendation is warranted.
Other considerations	Other considerations include issues about the implementation and operationalization of the technology or intervention in health systems and practices within Oregon.

Abbreviation. GRADE: Grading of Recommendations, Assessment, Development, and Evaluations approach.

Confidence in Estimate Rating Across Studies for the Intervention and Outcome

Assessment of confidence in estimate includes factors such as risk of bias, precision, directness, consistency, and publication bias.

High: The subcommittee is very confident that the true effect lies close to that of the estimate of the effect. Typical sets of studies are randomized controlled trials (RCTs) with few or no limitations, and the estimate of effect is likely stable.

Moderate: The subcommittee is moderately confident in the estimate of effect: The true effect is likely to be close to the estimate of the effect, but there is a possibility that it is substantially different. Typical sets of studies are RCTs with some limitations or well-performed nonrandomized studies with additional strengths that guard against potential bias and have large estimates of effects.

Low: The subcommittee's confidence in the estimate of effect is limited: The true effect may be substantially different from the estimate of the effect. Typical sets of studies are RCTs with serious limitations or nonrandomized studies without special strengths.

Very low: The subcommittee has very little confidence in the estimate of effect: The true effect is likely to be substantially different from the estimate of effect. Typical sets of studies are nonrandomized studies with serious limitations or inconsistent results across studies.

DEVICE-RELATED SAE						
13 studies (2 RCTs; 4 cohort studies; 6 registry studies; 1 SR)	**Serious** Downgraded 1 level ■ 10 studies rated high RoB; 2 studies rated moderate RoB ■ Industry funding and author COI ■ Reporting bias ■ Selection bias ■ Specific to the included systematic reviews, concerns over the transparency of methods used for risk of bias and integration of risk of bias evaluations into the synthesis	**Not serious** ■ Generally low rates of SAEs ■ Reasonably consistent rates of SAEs that could be compared (rates of participants with device explants or revisions)	**Not serious (device revisions and explants)** **Serious (other device-related SAEs)** Downgraded 1 level ■ Population mismatch [other device-related SAEs, not area of concern for device revisions or explants]: 1) mismatch with current FDA indication [i.e., more limited by age, AHI, and BMI] 2) Participants mostly white and male (limited applicability to Medicaid) ■ Variety of different outcomes reported under this broad category ■ Differences in classification of outcomes as an SAE or AE across the studies	**Not serious** ■ Few events are reported; studies have generally large sample sizes	■ Limited long-term data (the STAR NRS, at 5 years, is the longest available timepoint)	Moderate [device revisions and explants] ●●●○ **Low** (other device-related SAEs) ●●○○

NO. OF STUDIES SAMPLE SIZE	RISK OF BIAS	INCONSISTENCY	INDIRECTNESS	IMPRECISION	OTHER FACTORS	LEVEL OF CONFIDENCE
OSA SEVERITY (POLYSOMNOGRAPHY INDICES)						
5 studies (3 RCTs and 2 cohort studies) N = 673	**Serious** Downgraded 1 level ■ All studies rated as high RoB ■ Industry funding and author COI ■ Limited randomization and blinding information in RCTS ■ No control for confounding and in cohort study ■ Selection bias in RCTs ■ Data in crossover RCTs analyzed for combined periods (subject to possible unit-of-analysis error)	**Not serious** ■ Consistent direction and magnitude of effect, QOL severity measures, and timepoints across studies with inactive comparators (i.e., significantly lower OSA severity with HGNS) ■ No difference findings in study comparing HGNS and CPAP does not conflict with inactive comparator findings - both active conditions were significantly and clinically effective	**Serious** Downgraded 1 level ■ Differences between studies in terms of comparators and assessment timepoints ■ Study population concerns: 1) mismatch with current FDA indication [i.e., more limited by age, AHI, and BMI] 2) Participants mostly white and male (limited applicability to Medicaid)	**Not serious** ■ Some wider confidence intervals, but reasonable samples sizes ■ Studies were sufficiently powered to detect differences in AHI and ODI	■ Limited long-term data (12 months is longest follow-up) to assess an ongoing intervention	**Low** ●●○○

NO. OF STUDIES SAMPLE SIZE	RISK OF BIAS	INCONSISTENCY	INDIRECTNESS	IMPRECISION	OTHER FACTORS	LEVEL OF CONFIDENCE
DAYTIME SLEEPINESS						
4 studies (2 RCTs and 2 cohort studies) N = 611	**Serious** Downgraded 1 level ■ All studies rated as high RoB ■ Industry funding and author COI ■ Limited randomization and blinding information in RCTS ■ No control for confounding and in cohort study ■ Selection bias in RCTs ■ Data in crossover RCTs analyzed for combined periods (subject to possible unit-of-analysis error)	**Not serious** ■ Consistent direction and magnitude of effect across studies with inactive comparators (i.e., significantly lower daytime sleepiness with HGNS) ■ No difference findings in ESS means in study comparing HGNS and CPAP does not conflict with inactive comparator findings—values in both study groups indicated normal daytime sleepiness at 12 months	**Serious** Downgraded 1 level ■ Differences in assessment timepoints between studies ■ Study population concerns: 1) mismatch with current FDA indication [i.e., more limited by age, AHI, and BMI] 2) Participants mostly white and male (limited applicability to Medicaid)	**Not serious** ■ Some wider confidence intervals, but reasonable samples sizes ■ Studies were sufficiently powered to detect differences in ESS scores	■ Limited long-term data (12 months is longest follow-up) to assess an ongoing intervention	**Low** ●●○○
MAJOR ADVERSE CARDIAC EVENTS						
No eligible studies						

Notes. [a] These are all from the MAUDE database so there may be overlap in the number of reports.
Abbreviations. AHI: apnea-hypopnea index; BMI: body mass index; COI: conflict of interest; ESS: Epworth Sleepiness Scale; FDA: US Food and Drug Administration; HGNS: hypoglossal nerve stimulation; MAUDE: Manufacturer and User Facility Device Experience Database; NRS: nonrandomized study; OSA: obstructive sleep apnea; QoL: quality of life; RCT: randomized controlled trial; RoB: risk of bias; SAE: serious adverse event; SR: systematic review.

APPENDIX C. METHODS

Scope Statement

Populations

Adults aged 18 years and older with moderate to severe OSA (generally defined as having an AHI ≥ 15 events per hour)

Interventions

Upper airway nerve stimulation

- Hypoglossal nerve stimulation

Comparators

- No treatment
- Usual care (i.e., patient education)
- Sham surgery (i.e., placebo)
- Nonsurgical interventions for OSA
    - Noninvasive positive airway pressure therapy (i.e., CPAP, BiPAP)
    - Pharmacotherapy
    - Mandibular advancement devices

Outcomes

Critical:

- Procedure- or device-related serious adverse events
- Overall and sleep-related quality of life (as measured by validated assessment scales)

Important:

- Improvement in OSA severity as measured by polysomnography indices (i.e., apnea-hypopnea index, respiratory disturbance index, respiratory event index, oxygen desaturation index)
- Daytime sleepiness (as measured by validated assessment scales)
- Major adverse cardiac events

Considered, but not selected for GRADE table: All-cause mortality, change in A1c, remission of hypertension, fatigue-related accidents, other polysomnography-related outcomes

Study Designs*

Effectiveness:

- RCTs of any size
- Prospective comparative cohort studies (N > 100)

Harms:

- RCTs (as defined above)
- Prospective comparative cohort studies (as defined above)
- Systematic reviews (including any study design)
- Prospective single-arm cohort studies (N > 100)

- Registry studies (i.e., retrospective studies of data collected from a named centralized database with multisite inputs)

*Studies only eligible if conducted in the US or very-high Human Development Index (HDI) nations.

Follow-up

RCTS: 12 weeks or greater (including device implantation)
Cohort and registry studies: 6 months or greater

Publication Date

Primary studies: 2000 or later

Systematic reviews: 2014 or later

Key Questions

KQ1. What is the effectiveness of hypoglossal nerve stimulation versus nonsurgical treatments for OSA in adults?
KQ2. What are the harms of hypoglossal nerve stimulation for OSA?
KQ3. How does the effectiveness and harms of these interventions vary by:
  a. Intervention characteristics
  b. Patient characteristics
    i. Severity of OSA
    ii. Race, ethnicity, culture, or language
    iii. Gender or sex
    iv. Age
    v. Comorbidities
    vi. Response to prior interventions

Contextual Questions

CQ1. What is the evidence for effectiveness of hypoglossal nerve stimulation for OSA on outcomes (e.g., all-cause mortality, major adverse cardiac events, motor vehicle crashes) from systematic reviews that include observational and nonrandomized studies?
CQ2. What is the comparative effectiveness of hypoglossal nerve stimulation for OSA from randomized controlled trials?
CQ3. What is the cost-effectiveness of hypoglossal nerve stimulation for OSA?

Key Question Search Strategy

We searched bibliographic databases to identify randomized controlled trials (RCTs), systematic reviews (with and without meta-analyses), cohort studies, and clinical practice guidelines including the terms *obstructive sleep apnea, sleep disordered breathing, hypoglossal nerve, HGNS,* and *nerve stimulation*. We limited records retrieved to those studies focused on human subjects and published in the English language after 2000. No additional search limits were applied. Systematic reviews were used for reference list searching and not as evidence sources. Initial database searches were conducted on May 22, 2024. Updated database searches were conducted on July 1, 2025.

Ongoing Studies Search Strategy

We searched Clinical Trials.gov in May 2024 and again in July 2025 for ongoing studies using the following search strategy:

- **Condition/Disease:** Obstructive Sleep Apnea \(OSA\) OR Sleep Apnea, Obstructive OR Sleep Apnea OR Sleep Disordered Breathing
- **Intervention/treatment:** Hypoglossal Nerve Stimulation (HGNS) OR Upper Airway Stimulation (UAS) OR Inspire® Upper Airway Stimulation \(UAS\) System
- **Status:** Not yet recruiting, Recruiting, Active, not recruiting, Completed, Enrolling by invitation, Unknown status studies
- **Age groups:** Adult (18–64), Older adult (65+)
- **Study type:** Interventional, Observational studies
- **Primary completion:** on or after 01/01/2020

Policy Landscape Methods

For the Policy Landscape section, we conducted targeted searches in Ovid MEDLINE, websites of relevant professional societies and guideline groups, UpToDate, and DuckDuckGo to identify relevant clinical practice guideline and key payer policies. Two reviewers independently assessed the quality of the included CPGs; disagreements were resolved through consensus or by a third reviewer.

We limited searches for CPGs to those issued by professional societies in the US or other very-high Human Development Index countries published since 2014. We conducted a search for relevant clinical practice guidelines using MEDLINE and the following sources:

- American Academy of Otolaryngology-Head and Neck Surgery (AAO-HNS)
- American Academy of Sleep Medicine (AASM)
- American College of Surgeons (ACS)
- American College of Physicians (ACP)
- American Medical Association
- Canadian Agency for Drugs and Technologies in Health (CADTH)
- Centers for Disease Control and Prevention (CDC)
- European Respiratory Society
- Health Quality Ontario
- The International Sleep Surgery Society (ISSS)
- National Institute for Health and Care Excellence (NICE)
- Scottish Intercollegiate Guidelines Network (SIGN)
- United States Preventive Services Task Force (USPSTF)
- Veterans Administration/Department of Defense (VA/DoD) Clinical Practice Guidelines

We additionally sought payer coverage policies from select public and commercial payers, including:

- Medicare
- Washington State Medicaid
- Aetna
- Cigna
- Moda
- Regence BlueCross BlueShield of Oregon

Risk of Bias of Included Studies

We assessed the risk of bias of the included systematic reviews, RCTs, cohort studies, and CPGs using standard instruments developed and adapted by the Center that are modifications of instruments used by several renowned, respected organizations.[112-115] Two experienced researchers independently rated all included studies. In cases in which there was disagreement about the risk of bias of a study, a third rater resolved the disagreement.

Systematic Reviews

If a meta-analysis or network meta-analysis was conducted, the risk of bias of the analyses was considered in the overall rating for the systematic review. In brief, low-risk-of-bias systematic reviews include a clearly focused question, a literature search sufficiently rigorous to identify all relevant studies,

criteria used to assess study quality and select studies for inclusion (e.g., randomized controlled trials), and assessment of similarities between studies to determine whether combining them is appropriate for evidence synthesis. Moderate-risk-of-bias systematic reviews have incomplete information about methods that might mask important limitations or a meaningful conflict of interest. High-risk-of-bias systematic reviews have clear flaws that could introduce significant bias.

Randomized Controlled Trials

Low-risk-of-bias randomized controlled trials include a clear description of the population, setting, intervention, and comparison groups; a random and concealed allocation of patients to study groups; low dropout rates; and intention-to-treat analyses. Low-risk-of-bias randomized controlled trials also have low potential for bias from conflicts of interest and funding source(s). Moderate-risk-of-bias randomized controlled trials have incomplete information about methods that might mask important limitations or a meaningful conflict of interest. High-risk-of-bias randomized controlled trials have clear flaws that could introduce significant bias.

Cohort Studies

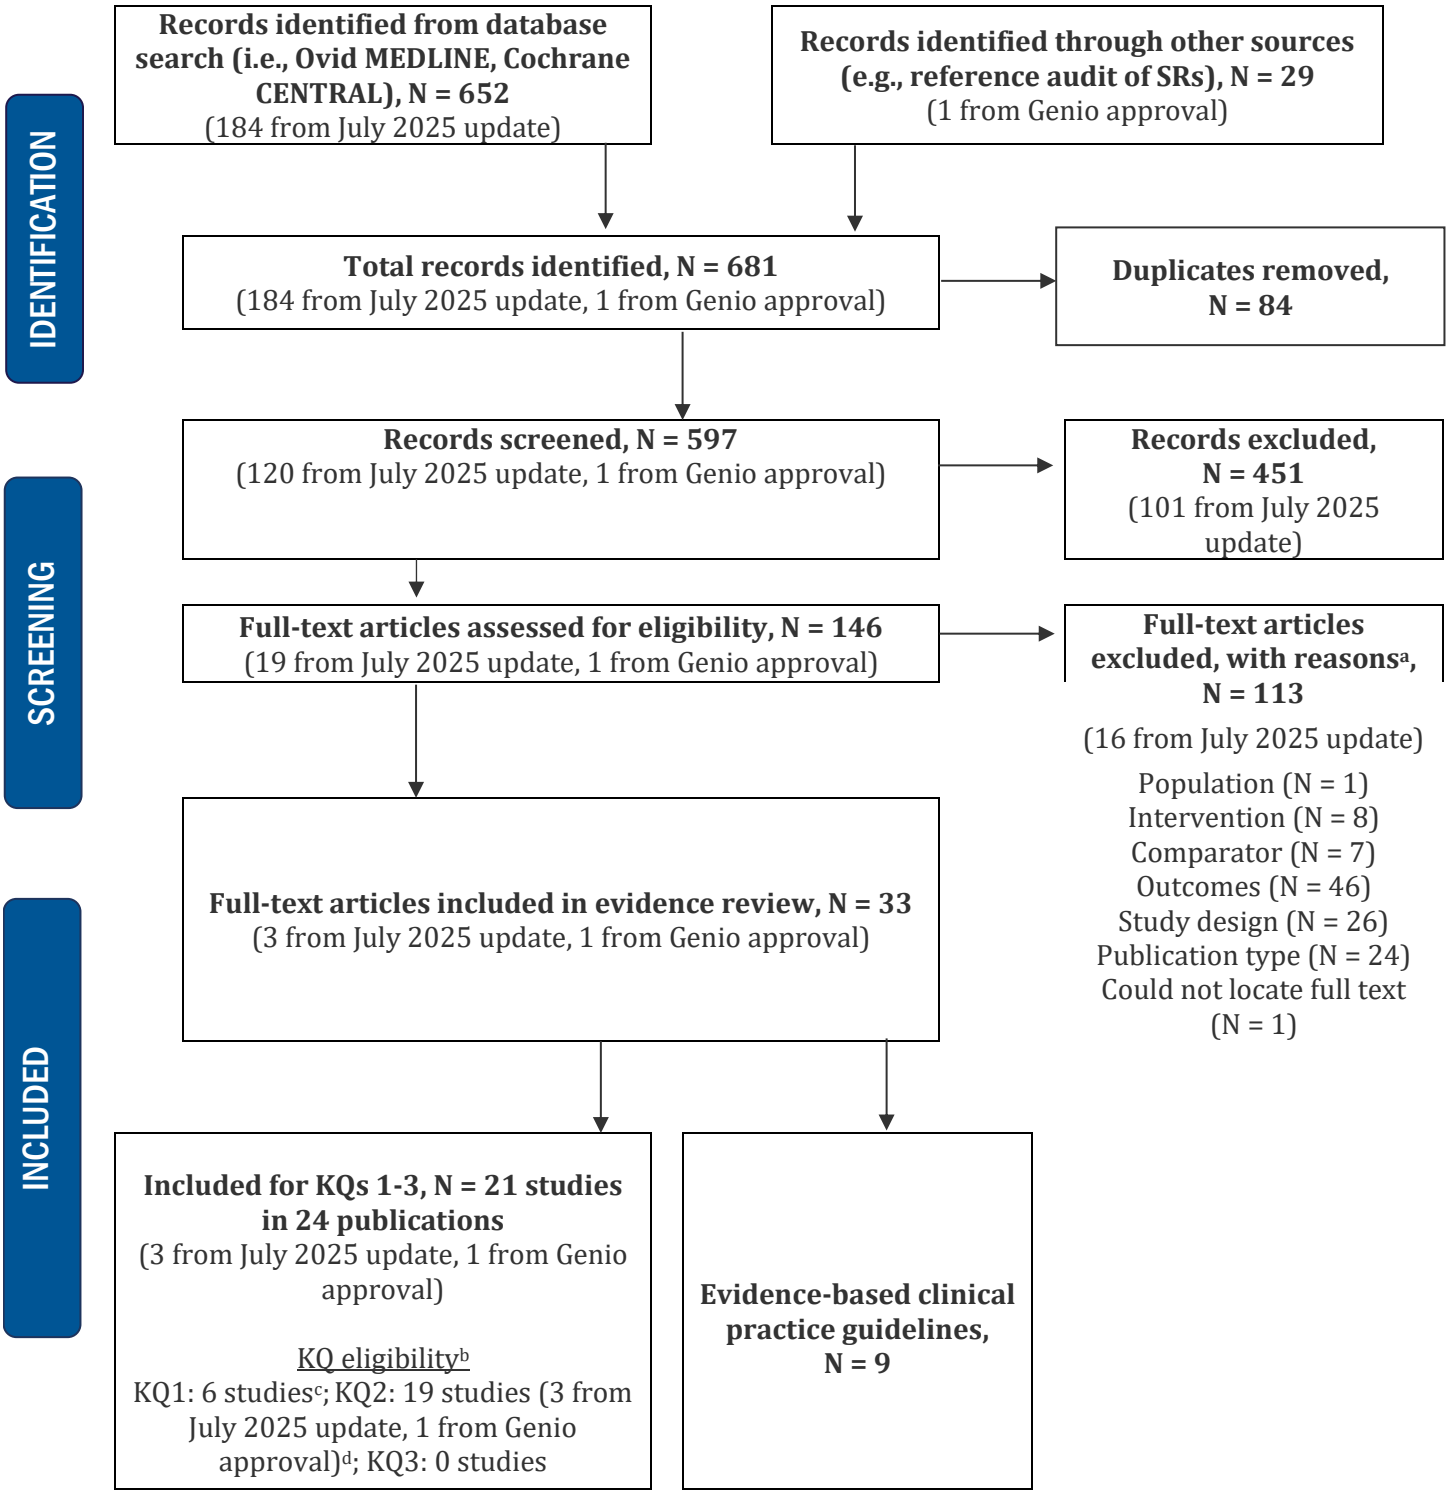
Low-risk-of-bias cohort studies include a sample that is representative of the source population, have low loss to follow-up, and measure and consider relevant confounding factors. Low-risk-of-bias cohort studies also list their funding source(s) and have a low potential of bias from conflicts of interest. Moderate-risk-of-bias cohort studies might not have measured all relevant confounding factors or adjusted for them in statistical analyses, have loss to follow-up that could bias findings, consist of a sample that is not representative of the source population, or have potential conflicts of interest that are not addressed. High-risk-of-bias cohort studies have a clear, high risk of bias that would affect findings.

Clinical Practice Guidelines

We assessed the methodological quality of the guidelines using an instrument adapted from the Appraisal of Guidelines Research and Evaluation (AGREE) Collaboration.[115-117] Each rater assigned the study a rating of good, fair, or poor based on its adherence to recommended methods and potential for biases. A good-quality guideline fulfills all or most of the criteria outlined in the instrument. A fair-quality guideline fulfills some of the criteria, and its unfulfilled criteria are not likely to alter the recommendations. A poor-quality guideline met few or none of the criteria.

APPENDIX D. ADDITIONAL FIGURE AND EVIDENCE TABLES

FIGURE D1. STUDY FLOW DIAGRAM



Notes. This diagram contains all references identified and reviewed in the initial search (May 2024) and the bridge search (July 2025). [a] No studies were excluded for study duration, study setting, publication date, or lack of availability in English. [b] There is overlap in the studies with data available for KQ1 and KQ2. [c] Five of these studies were eligible for GRADE as these evaluated the only currently FDA-approved device, Inspire UAS. [d] Twelve of these studies were eligible for GRADE as these evaluated the only currently FDA-approved device, Inspire UAS.
Abbreviations. FDA: US Food and Drug Administration; GRADE: Grading of Recommendations, Assessment, Development, and Evaluations; KQ: key question; SRs: systematic reviews.

TABLE D1. OUTCOME MEASURES AND MINIMAL CLINICALLY IMPORTANT DIFFERENCES (MCIDS)

MEASUREMENT SCALE	ABBREVIATION	MEASURE	SCORE RANGE	SCORE INTERPRETATION	MCIDS
VALIDATED PATIENT-REPORTED OUTCOME SCALES					
Epworth Sleepiness Scale[81]	ESS	Daytime sleepiness	0–24 points	Higher scores indicate increased daytime sleepiness	■ ± 2 or 3 points
Functional Outcomes of Sleep Questionnaire[118]	FOSQ (long form) FOSQ10 (short form)	Functional status	5–20 points	Higher scores indicate improvement in functional status	■ ± 1 point
EuroQol-5d: Visual Acuity Scale[80]	EQ-5D VAS	Generic measure of health	0–100 points	Higher scores indicate higher self-rated overall health	Variability exists for this outcome measure.[119]
POLYSOMNOGRAPHY MEASURES					
Apnea-Hypopnea Index[118,120]	AHI	OSA severity	0–no upper limit	Higher scores indicate greater OSA severity	■ ± 5 events per hour ■ ± 10%
Oxygen Desaturation Index[118]	ODI	OSA severity	0–no upper limit	Higher scores indicate greater OSA severity	■ ± 5 events per hour
Respiratory Disturbance Index[118]	RDI	OSA severity	0–no upper limit	Higher scores indicate greater OSA severity	■ ±10%

Notes. The respiratory event index (REI) was not included in this table as it was not identified in any of the evidence eligible for inclusion in this report. The REI reports the number of apneas and hypopneas per hour of monitoring time and is commonly used in home sleep testing.
Abbreviations. MCIDs: minimal clinically important differences; OSA: obstructive sleep apnea.

TABLE D4. ADDITIONAL STUDY CHARACTERISTICS: SYSTEMATIC REVIEWS

AUTHOR, YEAR	REVIEW OBJECTIVE	PUBLICATION DATE RANGE	STUDY INCLUSION CRITERIA	STUDY EXCLUSION CRITERIA	TOTAL INCLUDED STUDIES STUDY DESIGNS	TOTAL PARTICIPANTS
Certal, 2015[63,a] Moderate	Systematically review the evidence regarding the key clinical questions of efficacy and safety of HGNS in the treatment of OSA	2010 to 2014	■ Studies with a primary objective of evaluating the efficacy of HGNS to treat OSA in adults ■ Studies that provided quantitative outcomes pre- and post-implantation of a HGNS device for AHI, ODI, and ESS	■ Studies that didn't include quantitative outcomes pre- and post-implantation of a HGNS device for AHI, ODI, and ESS ■ Studies focused on pediatric populations ■ Studies with less than 2 participants were excluded from the meta-analysis	N = 6 studies ■ Case report ■ Prospective case series	200 participants
Chu, 2024[73,a] Moderate	Explore reasons for HGNS device explantation and associated complications	2014 to 2023	■ Case series, case reports, cohort studies ■ Studies on HGNS for OSA on implantation and explantation ■ Adults ■ English only	■ Commentaries, meta-analyses, systematic reviews, book chapters, conference abstracts, study protocols, animal studies, letters to the editor ■ Non-English papers	N = 14 studies ■ Case report ■ Case series ■ Prospective cohort studies ■ Retrospective cohort studies	1,040 participants

AUTHOR, YEAR	REVIEW OBJECTIVE	PUBLICATION DATE RANGE	STUDY INCLUSION CRITERIA	STUDY EXCLUSION CRITERIA	TOTAL INCLUDED STUDIES STUDY DESIGNS	TOTAL PARTICIPANTS
Costantino, 2020[62,a] Moderate	Quantify long-term clinical outcomes for HGNS with a larger patient cohort through a systematic review and meta-analysis	2011 to 2018	■ Studies including adults with OSA ■ Studies on HGNS ■ Pre (baseline) and post-implantation data on AHI, ODI, ESS (at minimum) ■ Prospective studies ■ No language, publication date, follow-up, or publication status restrictions ■ Articles had to be published in a peer-reviewed journal	■ Animal study ■ Intervention other than HGNS ■ Children ■ Retrospective design ■ Insufficient data ■ Redundant cohort ■ Unrelated study ■ Non-original study	N = 12 studies ■ Prospective cohort studies	350 participants
Kompelli, 2019[58,a] High	Meta-analyze objective and subjective outcomes and side effects of HGNS for OSA	2001 to 2018	■ Studies with the primary objective of assessing HGNS to treat sleep apnea in adults	■ Case reports, review articles, and nonhuman studies ■ Articles without primary endpoints of AHI, ODI, and ESS	N = 16 studies ■ NR	NR
Wollny, 2024[68,a] Moderate	Synthesize the best-available information on HGNS safety and AEs for OSA	2012 to 2023	■ Studies with at least 10 participants ■ Studies published between 2000 to 2023 ■ Studies written in English	■ Case reports, review articles, editorials, abstracts ■ Nonhuman and in vitro studies ■ Pediatric populations	N = 17 studies ■ Cohort studies ■ RCTs	1,962 participants

AUTHOR, YEAR	REVIEW OBJECTIVE	PUBLICATION DATE RANGE	STUDY INCLUSION CRITERIA	STUDY EXCLUSION CRITERIA	TOTAL INCLUDED STUDIES STUDY DESIGNS	TOTAL PARTICIPANTS
			■ Studies with a follow-up at least 6 months post implant ■ Studies that reported on adverse events and complications related to HGNS	■ Language other than English		
Zhou, 2022[52] Moderate	Evaluate and compare the efficacy of MMA and HGNS for moderate-to-severe OSA through the assessment of AHI and ESS as well as assess postoperative complications	1997 to 2021 (all studies) 2012 to 2021 (HGNS studies only)	■ Studies on adult patients with moderate-to-severe OSA who underwent MMA or HGNS ■ Studies that reported pre- and post-operative PSG data ■ Studies with a follow-up ≥ 6 months ■ Study designs: RCTS, quasi-experimental studies, and cohort studies ■ English language	■ Sample size < 10 patients ■ Patients who underwent other adjunctive surgical procedures at the time of MMA or HGNS ■ Preliminary studies in which the findings had been nested in other studies with larger sample size and/or longer follow-up	N = 30 (studies on MMA or HGNS) ■ Prospective cohort studies ■ Retrospective cohort studies	N = 1,029 (in the 9 studies on HGNS)

Note. [a] This study includes non-FDA-approved device(s) and is not included in GRADE.
Abbreviations. AEs: adverse events; AHI: apnea hypopnea index; ESS: Epworth Sleepiness Scale; FDA: US Food and Drug Administration; GRADE: Grading of Recommendations, Assessment, Development, and Evaluations; HGNS: hypoglossal nerve stimulation; MMA: maxillomandibular advancement; NR: not reported; ODI: oxygen desaturation index; OSA: obstructive sleep apnea; PSG: polysomnogram; RCT: randomized controlled trial.

TABLE D5. CLINICAL RESEARCH POPULATION OVERLAP WITH KEY FDA CRITERIA AND WARNINGS FOR HGNS

	Woodson, 2014[51]	Mehra, 2020[64]	Heiser, 2021[58]	Heiser, 2023[57]	Dedhia, 2024[59]
	STAR RCT	ADHERE Comparative	EFFECT		CARDIOSA-12
STUDY PARTICIPANT SELECTION CRITERIA RELEVANT TO INSPIRE UAS SYSTEM FDA LABELS					
AHI, events per hour (pre-implant)					
15–65 (FDA Inspire UAS 2014 and Genio System 2025 approval)	✓[a]	✓	✓[b]	✓	✓[b]
15–100 (FDA Inspire UAS 2023 expansion)					
Upper limit of BMI warning (kg/m^2)					
32 (FDA Inspire UAS 2014 and Genio System 2025 approval)	✓	✓[c]	✓[b]	✓[d]	✓[b]
40 (FDA Inspire UAS 2023 expansion)					
PAP Failure or Intolerance	✓	✓	✓	✓	✓
DISE Findings Consistent with Absence of Concentric Collapse	✓	✓	✓	✓	✓

Table Key. A check indicates the criterion was used as part of research participant selection criteria. Blank cells indicate the criterion did not apply to the study or falls into a different category (for AHI and BMI demographics).

Notes. [a] AHI enrollment criteria for the STAR study was 20–50 events per hour. [b] No upper AHI or BMI limits were defined for participants in the EFFECT and CARDIOSA-12 trials; however, participants were implanted with the Inspire UAS system in community settings before enrollment and were subject to the pre-2023 FDA criteria. [c] No defined BMI enrollment criteria, but mean baseline BMI was < 32. [d] BMI enrollment threshold ≤ 35, but mean baseline BMI was < 32.

Abbreviations. AHI: apnea hypopnea index; BMI: body mass index; DISE: drug-induced sleep endoscopy; FDA: United States Food and Drug Administration; HGNS: hypoglossal nerve stimulation; PAP: positive airway pressure.

TABLE D6. QUALITY OF LIFE OUTCOMES

STUDY INFO	STUDY DESIGN	TIME POINT	MEASURE	HGNS		CONTROL		BETWEEN-GROUP ESTIMATE	*P* VALUE
				N	MEAN (SD)	N	MEAN (SD)		
FUNCTIONAL OUTCOMES OF SLEEP QUESTIONNAIRE (FOSQ)[a]									
Heiser, 2021[60] EFFECT N = 89 High RoB	Crossover RCT ■ Inspire UAS ■ Subtherapeutic stimulation	2 wk	Mean	86	17.0 (3.2)	86	14.9 (3.6)	NR	*P* < .001
			CFB	86	+0.2 (95% CI, −0.5 to 0.9)	86	−1.9 (95% CI, −2.6 to −1.2)	MD, 2.1 (95% CI, 1.4 to 2.8)	*P* < .001
Mehra, 2020[66] ADHERE Comp. N = 350 High RoB	Cohort study ■ Inspire UAS ■ No therapy	6 mo	Mean	221	17.1 (3.2)	75	12.4 (3.7)	NR	*P* < .001
Schwartz, 2023[55] THN3 N = 138 High RoB	RCT ■ aura6000 ■ Inactive device	4 mo	CFB	92	+5.3 (13.4)	46	+0.6 (8.4)	MD, 4.7 (95% CI, 0.9 to 8.6)	NR
Woodson, 2014[53] STAR RCT N = 46 High RoB	RCT ■ Inspire UAS ■ Inactive device	1 mo	Mean	23	17.9 (2.9)	23	15.0 (4.0)	MD, 2.9 (95% CI, 0.8 to 5.0)	*P* = .008
			CFB	23	0.0 (1.0)	23	−2.3 (3.0)	MD, −2.3 (95% CI, −3.8 to −0.9)	*P* = .001
EUROQOL 5D VISUAL ANALOGUE SCALE (EQ-5D VAS)[b]									
Schwartz, 2023[55] THN3 N = 138 High RoB	RCT ■ aura6000 ■ Inactive device	4 mo	CFB	92	+2.5 (3.0)	46	+1.1 (3.2)	MD, 1.5 (95% CI, 0.3 to 2.6)	NR

Notes. [a] FOSQ score range, 5–20 points; higher scores are better; MCID ≥ 1 point.[78,79] [b] EQ-5D VAS score range, 0–100 points; higher scores are better; MCID not established.
Abbreviations. CFB: change from baseline; CI: confidence interval; HGNS: hypoglossal nerve stimulation; MCID: minimal clinically important difference; MD: mean difference; mo; month; NR: not reported; RCT: randomized controlled trial; RoB: risk of bias; SD: standard deviation; UAS: upper airway stimulation, wk: week.

TABLE D7. REPORTED DEVICE-RELATED SERIOUS ADVERSE EVENTS IN ≥2 ELIGIBLE STUDIES

AUTHOR, YEAR STUDY OR REGISTRY NAME HGNS DEVICE	STUDY DESIGN	TIMEPOINT	DEVICE-RELATED SAEs FOR HGNS[a]
DEVICE REVISIONS			
Schwartz, 2023[55,b,c] THN3 aura6000	RCT	12 mos	▪ 10 events ▪ 9 out of 138 participants (6.5%) **Revision reasons NR**
Mehra, 2020[66] ADHERE comparative Inspire UAS	Comparative cohort	6 mos	▪ 2 events ▪ 1 out of 230 participants (0.4%) **Reported revision reasons:** uncomfortable stimulation lead position
Boon, 2018[67,69] ADHERE Inspire UAS	Noncomparative cohort	12 mos	▪ 13 out of 1,849 participants (0.7%) (sensor lead revision)[d] ▪ 12 out of 1,849 participants (0.7%) (stimulation lead revision)[d] ▪ 2 out of 1,849 participants (0.1%) (IPG pocket revision)[d] ▪ 3 out of 1,849 participants (0.2%) (system revision, 2 or more components)[d] **Revision reasons NR**
Strollo, 2014[54,71] STAR NRS Inspire UAS	Noncomparative cohort	5 yrs	▪ 9 events ▪ 8 out of 126 participants (6.3%) **Reported revision reasons:** resolution of discomfort, unfavorable tongue placement, to improve response, insulation failure, and stimulation lead cut
Woodson, 2025[75] DREAM Genio System	Noncomparative cohort	12 mos	▪ 2 out of 115 participants (1.7%) **Reported revision reasons:** device malfunction resulting in replacement

AUTHOR, YEAR STUDY OR REGISTRY NAME HGNS DEVICE	STUDY DESIGN	TIMEPOINT	DEVICE-RELATED SAEs FOR HGNS[a]
Chu, 2024[73,b,c,e] Apnex Medical HGNS Inspire UAS NR	SR	NR	■ 13 out of 1,040 participants (1.3%) ■ **Reported revision reasons:** device malfunction, infection, device migration, discomfort, improper placement, ineffective device, post-implantation complications, need for MRI, traction, elective removal, nerve palsy, poor cosmesis, mixed tongue activity, unrelated systematic septic arthritis, overstimulation, need for unrelated surgery
Zhou, 2022[52e] Inspire UAS	SR	NA	■ In 4 out of 5 studies reporting on patient complications there were 50 serious device-related AEs that required surgical repositioning or replacement of the neurostimulator or implanted leads **Reported revision reasons:** serious device-related AEs
Wollny, 2024[68,c,e] Inspire UAS Apnex HGNS System aura6000 Genio System	SR	NR	■ Pooled rate: 0.08% (95% CI, 0.0 to 0.2%) **Reported revision reasons:** hematoma or seroma, scar corrections, or repositioning of device components due to discomfort or technical dysfunction
Commesso, 2025[72,f, g] MAUDE database Inspire UAS	Registry	NR	■ 7 out of 12 reports on adverse events related to whole respiratory lead migration (58.3%) ■ **Reported revision reasons:** pain, pneumothorax, lump, dehiscence, dyspnea
Bestourous, 2020[64,f,g] MAUDE database Inspire UAS	Registry	NR	■ 83 out of 196 adverse events (42.3%) **Reported revision reasons:** pain, allergic reaction, infection, hematoma/seroma, neck swelling, neuropraxia, overstimulation, muscle tethering/traction, device expulsion through skin, postoperative complications, IPG, sensing lead, stimulation lead, device placement

AUTHOR, YEAR STUDY OR REGISTRY NAME HGNS DEVICE	STUDY DESIGN	TIMEPOINT	DEVICE-RELATED SAEs FOR HGNS[a]
Lorenz, 2023[57] TriNetX Research Network Inspire UAS	Registry	NR	■ 25 out of 1,813 participants (1.4%)[h] **Revision reasons NR**
Morocco, 2024[56] Post market surveillance data Inspire UAS	Registry	12 mos	■ 322 out of 20,881 devices (1.5%) **Reported revision reasons:** surgical correction, device correction, device defect, twiddler syndrome, cardioversion, other causes
		12 mos to 3 yrs	■ 207 out of 5,820 devices (3.6%) **Reported revision reasons:** surgical correction, device defect, device correction, twiddler syndrome, cardioversion, other indications
DEVICE EXPLANTS			
Schwartz, 2023[55,b,c] THN3 aura6000	RCT	12 mos	■ 10 events ■ 9 out of 138 participants (6.5%) **Explant reasons NR**
Boon, 2018[67,69] ADHERE Inspire UAS	Noncomparative cohort	12 mos	■ 1 out of 1,849 participants (0.05%)[c] **Explant reasons NR (elective explant)**
Strollo, 2014[54,71] STAR NRS Inspire UAS	Noncomparative cohort	5 yrs	■ 3 events ■ 3 out of 126 participants (2.4%) **Reported explant reasons:** implantable pulse generator removal in a nonresponder, system removal in a nonresponder, nonelective removal in a nonresponder due to septic arthritis

AUTHOR, YEAR STUDY OR REGISTRY NAME HGNS DEVICE	STUDY DESIGN	TIMEPOINT	DEVICE-RELATED SAEs FOR HGNS[a]
Woodson, 2025[75] DREAM Genio System	Noncomparative cohort	12 mos	■ 3 out of 115 participants with an SAE-related explant (2.6%) ■ 3 out of 115 participants with a non-SAE-related explant (2.6%) ■ 6 out of 115 participants with any device explant (5.2%) **Reported explant reasons:** failure of hypoglossal nerve activation due to postoperative device migration (scar tissue prevented reimplantation), device extrusion during a dental procedure, device malfunction, loss of stimulation due to undetermined cause
Certal, 2014[63, c] Apnex HGNS System aura6000 Inspire UAS	SR	NA	■ 9 out of 200 participants (4.5%) **Reported explant reasons:** serious-device related AEs
Chu, 2024[73,b,c,e] Apnex Medical HGNS Inspire UAS NR	SR	NR	■ 13 out of 1,040 participants (1.3%) ■ **Reported explant reasons:** device malfunction, infection, device migration, discomfort, improper placement, ineffective device, post-implantation complications, need for MRI, traction, elective removal, nerve palsy, poor cosmesis, mixed tongue activity, unrelated systematic septic arthritis, overstimulation, need for unrelated surgery
Wollny, 2024[68,c,e] Inspire UAS Apnex HGNS System aura6000 Genio System	SR	12 mos (median)	■ System survival probability: 0.99 (95% CI, 0.98 to 0.99)
		5 yrs (maximum)	■ System survival probability: 0.98 (95% CI, 0.98 to 0.99) **Reported explant reasons**: most common reasons were infection in the implant area and patient request for various reasons
Bellamkonda, 2021[65,f,g] MAUDE database Inspire UAS	Registry	5 yrs	■ 17 out of 134 reports (12.7%) **Reported explant reasons:** infection, vocal cord weakness, CN VII palsy, hematoma, twiddler's syndrome, lead erosion, lead wire protrusion from wound

AUTHOR, YEAR STUDY OR REGISTRY NAME HGNS DEVICE	STUDY DESIGN	TIMEPOINT	DEVICE-RELATED SAEs FOR HGNS[a]
Bentan and Nord, 2024[74,g] MAUDE database Inspire UAS	Registry	NR	■ 253 out of 1,025 procedure-related adverse events (24.7%) ■ 85 out of 287 device-related adverse events (29.6%) ■ **Reported explant reasons:** pain, infection, hematoma or seroma, edema or swelling, neuropraxia, pneumothorax, allergic reaction, stimulation discomfort, lead tethering or traction, device erosion or skin extrusion, device migration, twiddler syndrome
Commesso, 2025[72,f,g] MAUDE database Inspire UAS	Registry	NR	■ 3 out of 12 reports on adverse events related to whole respiratory lead migration (25%) ■ **Reported explant reasons:** malfunction, infection, dehiscence, pain, pneumothorax
Lorenz, 2023[57] TriNetX Research Network Inspire UAS	Registry	NR	■ 22 out of 1,813 participants (1.2%) **Explant reasons NR**
Morocco, 2024[56] Post market surveillance data Inspire UAS	Registry	12 mos	■ 151 out of 20,881 devices (0.7%) **Reported explant reasons:** infection, elective removal, lack of symptom relief, inadequate effectiveness, pain, discomfort, MRI, twiddler syndrome, other reasons or indications
		12 mos to 3 yrs	■ 156 out of 5,820 devices (2.7%) **Reported explant reasons:** no symptom relief, pain, removal due to MRI, infection, twiddler syndrome, other reasons or indications

AUTHOR, YEAR STUDY OR REGISTRY NAME HGNS DEVICE	STUDY DESIGN	TIMEPOINT	DEVICE-RELATED SAEs FOR HGNS[a]
Woodson, 2025[75] DREAM Genio System	Noncomparative cohort	12 mos	■ 11 events ■ 8 device- or procedure-related events ■ 10 out of 115 participants (8.7%)
Constantino, 2020[62,c] Apnex HGNS System aura6000 Inspire UAS	SR	NA	■ 14 events ■ 12 out of 195 participants (6.2%)
Bestourous, 2020[64,f,g] MAUDE database Inspire UAS	Registry	NR	■ 1 out of 146 patient-related adverse events (0.7%)

Notes. [a] This is referring to the intervention group (active HGNS) unless otherwise specified. [b] These are reported as combined device explants, revisions, and replacements in the study publication so are reported in both sections of this table. [c] This study includes non-FDA-approved device(s) and is therefore not included in GRADE. [d] Reported as a follow-up period SAE. [e] This SR includes primary studies that have also been included in this review, due to this there is some suspected overlap in the data. [f] This study is only collecting reports on AEs for the FDA-approved HGNS device, the Inspire UAS system. [g] There is likely overlap across all the MAUDE data. [h] Reported as combined "revision/replacement" in the study publication. [i] Reported as an intraoperative SAE. [j] It is unclear if any of these events were serious. [k] Unclear if all events are treatment related.

Abbreviations. APPENDIX E. APPLICABLE CODES

TABLE E1. APPLICABLE CODES FOR HYPOGLOSSAL NERVE STIMULATION

CODE	DESCRIPTION
ICD-10-CM CODES	
G47.33	Obstructive sleep apnea (adult) (pediatric)
CPT CODES	
64568	Incision for implantation of cranial nerve (e.g.: vagus nerve) neurostimulator electrode array and pulse generator
64582	Open implantation of hypoglossal nerve neurostimulator array, pulse generator and distal respiratory sensor electrode or electrode array.
64583	Revision or replacement of hypoglossal nerve neurostimulator array and distal respiratory sensor electrode or electrode array, including connection to existing pulse generator.
64584	Removal of hypoglossal nerve neurostimulator array, pulse generator, and distal respiratory sensor electrode or electrode array.
0466T	Insertion of chest wall respiratory sensor electrode or electrode array, including connection to pulse generator (list separately in addition to code for primary procedure)
0467T	Revision or replacement of chest wall respiratory sensor electrode or electrode array, including connection to existing pulse generator
0468T	Removal of chest wall respiratory sensor electrode or electrode array
HCPCS CODES	
	None reported

Abbreviations. CPT: Current Procedural Terminology; HCPCS: Healthcare Common Procedure Coding System; ICD-10-CM: International Classification of Diseases, Tenth Revision, Clinical Modification.

A1	I glanced at your coverage criteria and my only suggestion is to avoid re-defining the criteria that constitutes successful usage of a CPAP. The industries well established language of 4-Hours per night, 70% of nights in a 30-day period should be used instead of the current language in your proposed policy. Although your proposed language ; "Inability to use CPAP greater than 5 nights per week of at least 4 hours per night;" seems like a simplistic way of saying something similar it isn't the same. The databases relied upon to measure PAP adherence are designed around the 70% usage language, not a 5-day (71%) usage. The industry appreciates consistency. Please consider.	Thank you for your comment. The criteria in the coverage recommendation align with those in the FDA approval letter for Inspire UAS and the Genio system. These criteria are also used by the Medicare LCD (L38310) that covers Oregon.[1] For Inspire UAS (from FDA approval dated June 8, 2023), the threshold for "inability to use PAP" is defined as "greater than 5 nights per week of usage; usage defined as greater than 4 hours of use per night)" For the Genio system, the same definition is provided in the FDA approval letter dated August 8, 2025.
B1	I am writing in support of coverage for the Inspire hypoglossal nerve stimulator (HGNS) for treatment of moderate-severe obstructive sleep apnea (OSA) in patients who cannot tolerate positive pressure therapy. I am a head and neck surgeon who primarily treats patients with OSA, both with soft tissue reconstructive procedures as well as with implantation of the Inspire HGNS device.	Thank you for your comment and for your involvement in caring for OHP members.

ID/#	Comment	Disposition
B2	Inspire HGNS therapy has demonstrated efficacy for management of moderate-severe OSA in 2 separate clinical cohort studies. The STAR trial (first published in 2014 with 5 year follow up outcomes published in 2018) demonstrated a significant reduction in AHI and improvement in subjective measures via the Epworth Sleepiness Score with hypoglossal nerve stimulator therapy. The original patient cohort in the STAR trial included those with pre-treatment AHI between 15-65 and BMI 32 or less. Given the encouraging results from therapy in this population, the patient cohort was subsequently expanded to include AHI 15-100 and BMI 40 or less with the ADHERE study. These data demonstrated sustained efficacy of therapy with expanded AHI and BMI parameters with no statistical differences in response to therapy between patients who satisfied the original criteria (AHI 15-65, BMI < 32) compared to those in the expanded criteria group (AHI 65-100, BMI 32-40). The findings from the ADHERE study allowed for expanded FDA approval for Inspire HGNS therapy to include patients with a BMI 40 or less and AHI 15-100.	Thank you for providing this additional information. The referenced study by Thaler et al., was a retrospective registry study of 1,017 individuals who received the Inspire UAS from October 2016 to February 2019. The mean BMI of study participants was 29.3 kg/m^2. Investigators found that a lower BMI was a predictor of success, and that "[e]ach unit decrease of BMI is associated with 8.5% increased odds of having a more favorable [apnea-hypopnea index] response." In the discussion, the authors noted that, "[a]lthough surgical success has been reported at higher BMIs, the BMI cutoff of 32 by STAR criteria remains a useful guide for surgical decision-making until there are better preoperative assessment tools available to screen out those patients who would not succeed with UAS therapy." The FDA has since expanded the Inspire UAS approval to increase the upper limit BMI warning to 40 kg/m^2; however, the comparative prospective cohort studies and randomized trials we identified that reported on efficacy did not include subgroup analyses by BMI. Further, the mean baseline BMI of participants ranged from 27.3 kg/m^2 to 30.6 kg/m^2. In other words, we did not find comparative prospective cohort study or randomized trial evidence to support similar efficacy of the Inspire UAS at higher BMIs. Consequently, the initial HERC staff recommendation was

ID/#	Comment	Disposition
		coverage up to a BMI of 32 kg/m^2. The Coverage Guidance has been updated to include additional information on this topic.
B3	While there are differences between insurance company coverage for the device, the vast majority have now expanded their approval criteria at least up to 35, if not all the way to 40. The Centers for Medicare/Medicaid Services (CMS) currently uses the BMI criteria up to 35 in their approval for the device in patients covered by Medicare.	In the Coverage Guidance, we found that the upper limit of BMI for coverage was 32 kg/m^2 for Cigna and Moda, 35 kg/m^2 for Medicare (LCD 38312 which covers Oregon) and Regence, and 40 kg/m^2 for Aetna. In response to this comment, we performed another search on March 16, 2026, and found several policy changes: the upper limit of BMI changed to 40 kg/m^2 for Cigna,[2] Moda,[3] and Regence,[4] with the Medicare LCD (35 kg/m^2) and Aetna (40 kg/m^2) policy remaining unchanged. We will provide the subcommittee with this information for their discussion. The Coverage Guidance has been updated to reflect current payer policies.
B4	I encourage the review team to consider coverage of the Inspire HGNS device for treatment of patients with moderate-severe OSA (AHI 15-100) and at least BMI of 35 or less, in line with current standard set by CMS and many other commercial insurance providers (Aetna, Regents Blue Cross, United Healthcare, Cigna, and Providence).	We thank you for your comment and will provide it to the subcommittee for discussion.

Section 9.0

HERC

Reproductive Health Equity Act (RHEA) – 2026 Review

Plain Language Summary:

Every 2 years the Health Evidence Review Commission reviews clinical practice recommendations related to providing preventive care and ensures that these services remain covered per Oregon law.

Staff Analysis Summary:

No significant change to current coverage or statute are recommended.

Background:

House Bill 3391 was passed in 2017 to ensure coverage of reproductive health services in Oregon. It requires health plan coverage (including commercial plans and coverage for those who would be eligible for Medicaid but for their immigration status) for screening and other services without a deductible, coinsurance, copayment, or any other cost-sharing requirement.

ORS 414.694 states:

> The Health Evidence Review Commission shall review the coverage described in ORS 743A.067 (2) and, no later than November 1 of each even-numbered year, report to the interim committees of the Legislative Assembly related to health any recommended changes to the coverage described in ORS 743A.067 (2) based upon the latest clinical research.

Previous HSC/HERC reviews:

Previous HERC reviews were completed in 2018, 2020, 2022 and 2024.

Current HERC review:

HERC staff reviewed relevant evidence-based clinical guidelines which are new since January 1, 2024. These included review of US Preventive Service Task Force (USPSTF) A and B recommendations, as well as the Health Resources and Services Administration (HRSA) Women's Preventive Services Guidelines.

HERC staff recommendation:

HERC staff have reviewed the statute and do not recommend any changes because existing statute generally meets the reproductive health needs of Oregonians.

To further reinforce its commitment to providing updated and inclusive reproductive health and preventive services, the legislature could consider the following minor changes:

1) Update the date referencing USPSTF and HRSA to January 1, 2026.
2) Clarify that listed preventive services should be covered in accordance with national evidence-based standards (i.e., USPSTF, HRSA), when applicable.

See attached draft report.

Dear Legislative Leaders,

This report was approved by the Health Evidence Review Commission (HERC), in fulfillment of ORS 414.694, which requires HERC to report to the interim committees related to recommended changes to the coverage described in ORS 743A.067. HERC does not recommend any changes to this statute because existing law supports coverage of the relevant health services.

Rationale

ORS 743A.067, enacted under House Bill 3391 (2017), includes a list of preventive reproductive health and other services to be provided without cost sharing to people insured under state-regulated health plans. This statute lists a comprehensive set of reproductive and reproduction-related health services, including services related to pregnancy, family planning, prevention of intimate partner violence, and prevention of sexually transmitted infections. In addition, it includes "Any additional preventive services for women that must be covered without cost sharing under 42 U.S.C. 300gg-13, as identified by the United States Preventive Services Task Force or the Health Resources and Services Administration of the United States Department of Health and Human Services as of January 1, 2017." A separate law (ORS 743A.262) also references the services required to be covered in 42 U.S.C. 300gg-13 as of January 1, 2023, and requires that they be covered by state-regulated health plans without cost sharing except as allowed by federal law.

In addition, ORS 414.432 (House Bill 3391) created a program covering the services listed in ORS 743A.067(2) for individuals who can become pregnant and who would otherwise be eligible for medical assistance if not for federal law excluding certain immigrants from medical assistance programs (8 U.S.C. 1611 and 1612).

Before November 1 of each even numbered year, ORS 414.694 requires the Health Evidence Review Commission (HERC) to report to the legislature on recommended changes to the coverage listed in ORS 743A.067(2).

After review of statute and recent federal guidance, the most important preventive services for women are currently required to be covered by Oregon state-regulated insurance plans without cost sharing by ORS 743A.067(2) and ORS 743A.262. Thus, HERC recommends no changes to statute.
