[1] Test section locations will be finalized after final engineering design and the construction contractors have been selected for the project.

[2] Beginning and end mileposts were extrapolated from environmental alignment sheets. Mileposts were not calculated from engineering stationing and may not provide a direct correlation between milepost and engineering stationing. "R" represents a revised milepost location based on the incorporation of reroutes into the proposed route.

[3] Section length reflects actual footage calculated directly from engineering stationing.

[4] Section volumes were calculated using section length directly from engineering stationing.

[5] Estimated discharge volume – based on previous test section volume. Water will be cascaded between test sections, where practical, to fill each section to minimize test water requirements.

[6] Jurisdiction corresponds with each test section's beginning MP except Test Section 72 where jurisdiction is provided for both the beginning and ending MPs.

[1] Small brush or trees may be cleared by a rubber-tired rotary or flail motor (brush hog) or by hand with machetes/chainsaws. No soil disturbance will occur. A rubber-tired or track hoe will be utilized to lay the discharge line and to remove the saturated hay bales or filter bags upon completion of hydrostatic discharge.

[2] These volumes are included in Table 3.1.3.3-6; they are NOT additional volumes. Estimated discharge volume – based on previous test section volume. Water will be cascaded between test sections, where practical, to fill each section to minimize test water requirements.

Permission to discharge the hydrostatic test water would be applied for concurrently with the request for coverage under the ODEQ General Stormwater Discharge Permit and permitted through a separate letter of approval. Hydrostatic test water would be discharged into upland areas at a rate to prevent scour, erosion, and sediment migration to sensitive resources such as wetlands and waterbodies (see Pacific Connector's ECRP in appendix F). Discharge rates would range from several hundred gallons per minute to several thousand gallons per minute, depending on the length of the test section, profile, topography, vegetation cover, and soil type, and as reviewed by the contractor and the EI.

The hydrostatic testing discharge would be conducted utilizing discharge structures that dissipate velocity of the discharge and filter out any potentially present dirt, grit, or oxidation that would be present collectively as total dissolved solids. The discharge structure is placed in an upland location that is topographically appropriate to allow the flow to "pool" and discharge uniformly through the structure to promote infiltration of the discharge water. Flow rates to the discharge structure can be controlled by controlling the discharge valve to ensure the discharged flows do not flow above the carrying capacity of the structure(s). Additionally, as shown in the ECRP (see attachment C to appendix F, Drawing 3430.34-X-0012) water discharge can be controlled by discharging into a central tank and then pumping to multiple discharge structures concurrently or successively (one then the other) to control discharge rates/volumes to promote infiltration, minimize overland flow and to prevent overland flow to waterbodies (for more detail see the Hydrostatic Testing Plan in appendix U). Pacific Connector's EIs would be responsible for monitoring discharge activities and making appropriate adjustments to facilitate proper infiltration through the discharge structures.

The hydrostatic discharge would be filtered on uptake and again upon discharge, and this filtering would prevent the transport of seeds or vegetative matter through the hydrostatic testing process. Where possible, Pacific Connector would release water within the same basin from which it was withdrawn. However, cascading water from one test section to another to minimize water withdrawal requirements may make it impractical to release water within the same basin where the water was withdrawn. Where water is withdrawn from surface waters, pump screening would meet both NMFS and ODFW screening criteria, which would minimize the potential of invasive species transmission from the hydrostatic testing process. Prior to water withdrawal, Pacific Connector would also review U.S. Geological Survey (USGS) biological research division data to determine where known locations of invasive species and pathogen infestation exist along the pipeline project area and at proposed water source locations (see Appendix U).

Hydrostatic test water would be discharged at a rate to prevent scour, erosion, and sediment migration to sensitive resources such as wetlands and waterbodies. When discharged, the test water would be released into a dewatering device such as a straw bale structure or sediment bag to minimize possible peak flow effects by dissipating the energy of the test water flow, filter the test water to avoid sedimentation, and by allowing release of the test water as sheet flow back into the ground (see appendix U, attachment A, Drawing 3430.34-X-0012 and Drawing 3430.34-X-0013). The discharge would occur to an appropriately sized discharge structure based on the expected quantity of water to be discharged. Hydrostatic test water would be released in upland areas through a discharge structure prior to entering the ground at least 150 feet from wetlands and waterbodies. The hydrotest water would not be allowed to discharge directly to wetlands or waterbodies. Pacific Connector would ensure, as stated in the FERC staff's Procedures (VII.D.2), that discharge into state-designated exceptional value waters, waterbodies that provide habitat for federally listed threatened or endangered species, or waterbodies designated as public water supplies would not occur unless appropriate federal, state, and local permitting agencies grant written permission.

Generally, water quality of discharged water from hydrostatic testing is similar to the quality of water when filled, especially test water discharged from new pipes (Tallon et al., 1992). Tallon et al. (1992) recognized that "concentrations of constituents found in the discharge waters did not significantly change from those observed in the fill waters. Exceptions to this observation include oil and grease." But, the excess oil and grease reported was only from one of the three pipelines studied. If not for that one sample, there would not have been a significant change in oil and grease between fill and discharge water, consistent with the other constituents analyzed. Tallon et al. (1992) further explain, "as would be expected, existing pipelines were reported to have higher constituent levels than new pipelines." In any case, hydrostatic test water would not be discharged into aquatic environments. Tallon's discharge water analysis was from hydrostatic testing of pipelines that had been in service from 34 to 43 years, not for water discharged from newly constructed pipelines.

Pacific Connector has data from a 2006 pipeline construction project in Washington that installed a new 36-inch-diameter natural gas pipe. The results of the hydrostatic discharge test from this project are more comparable to the expected discharge quality that would occur from testing of the Pacific Connector pipeline. The 2006 project discharged 17,034,047 gallons of test water from multiple discharge points over a 4-month period. The 2006 project was under a state permit that had a permit discharge limitation for oil and grease at 10 mg/L (ppm). This is identical to the NPDES discharge limits issued by ODEQ for discharges to waters of the United States and state of Oregon. The 2006 project discharge water was analyzed for oil and grease as total petroleum hydrocarbons (TPH) in the range of diesel or oil organic compounds using methods NWTPH-D and NWTPH-Dx, again the same methodology recognized by ODEQ. The 2006 project analyzed only the discharge water, not the source water, so it would be assumed that the source water oil and grease levels are “Non Detect.”

For the 2006 project in Washington, almost all of the discharged hydrostatic test water (99.99 percent) contained levels of oil and grease below the permit limit. To break out concentrations of oil and grease from testing new pipe installations, the following data analysis is provided.

- 9,494,054 gallons (56 percent) of the test water discharged by the 2006 project was reported to have oil and grease at “Non Detect” levels or no greater than the source water;
- 4,459,460 gallons (26 percent) of test water discharge contained reported oil and grease at levels above “Non Detect” but less than 1 ppm for either range;
- 3,076,033 gallons (18 percent) of test water discharge contained reported oil and grease at levels above 1ppm but less than 3 ppm for either range;
- 1,200 gallons (0.01 percent) of test water exceeded the oil and grease permit limit of 10 ppm (discharge reported at 21ppm diesel range/11 ppm oil range organic compounds, the source of which was identified to be a greased fitting on the discharge valve controller that extended into the water flow).

Considering that water is essentially a non-compressible material, temperature increases from pressurization during hydrostatic testing is negligible. During the hydrostatic testing phase of the project, the pipeline is buried, except for a small area (approximately 200 feet) immediately at the hydrostatic test header location and is not exposed to potential solar heating. Therefore, the test water is at ground temperature and the potential to increase water temperatures during hydrostatic testing is inconsequential.

It is projected that pipeline construction would be completed in late summer to early fall of the pipeline construction season, which would also minimize potential adverse impacts to terrestrial and aquatic ecosystems. The pipeline must be tested immediately following completion of construction so that any failures could be repaired and retested while the construction phase is still active. Intentionally delaying hydrostatic testing until late fall or winter would result in unnecessarily extending the entire construction duration of the project, extending the length the construction contractor remains on site, continued right-of-way and access disturbance, as well as delaying final cleanup and restoration of the right-of-way. Winter testing would be particularly problematic in that much of the right-of-way would be under snow and in wet/muddy condition.

Dust and Fire Control Water

During pipeline construction, Pacific Connector would need to obtain water for dust and fire control purposes. Control of construction-generated fugitive dust may be necessary during dry periods, such as the summer. The EI would direct dust control efforts to places deemed necessary, including residential areas and other locations along the pipeline route where dust is considered a safety or public nuisance, including access roads. Typically, water trucks would fill up with water at designated sources, and spray selected areas along the construction right-of-way and access roads, to keep dust down. The water trucks would spray only enough water to control dust or reach an optimum soil moisture content, and not enough to create a problem with water runoff, erosion, and sedimentation.

Additionally, Pacific Connector has indicated it may utilize a synthetic product such as Dustlock®, in addition to water, for dust control. Dustlock® is a naturally occurring by-product of the vegetable oil refining process. Dustlock® penetrates into the bed of the material and bonds to make a barrier that is naturally biodegradable, ensuring that the surrounding ground and water are not contaminated, and minimizing any potential effects to fish and wildlife. While there are no known health risks by the use of Dustlock® to fish and wildlife resources, Pacific Connector would not use Dustlock® within riparian areas.

Cleanup and Permanent Erosion Control Devices

*Cleanup*

Pacific Connector would make every effort to complete final cleanup of an area within 20 days after backfilling the trench. Final cleanup would include final grading and installation of permanent erosion control structures. In no case would Pacific Connector delay final cleanup beyond the end of the next recommended seeding season. During final cleanup, Pacific Connector would remove all construction debris and grade disturbed areas to approximate preconstruction grade to the extent practicable. During final cleanup and initial restoration, fences, gates, drainage ditches, culverts, and other structures that may have been temporarily removed or damaged during construction would be permanently repaired, returned to their preconstruction condition, or replaced. All drain tiles crossed by the pipeline would be checked, and if damaged, they would be repaired before backfilling. All areas disturbed by construction activities would be re-graded during restoration, with contours matching the surrounding landscape, and pre-construction natural drainage patterns re-established. Pacific Connector would install erosion control fabric (such as jute or excelsior) to stabilize streambanks during restoration.

However, if it appears that construction may continue into the winter because of unforeseen delays and cleanup and reseeding is delayed until the spring, Pacific Connector would implement the winterization plan (see attachment E to the ECRP in appendix F). This plan describes the procedures that would be implemented to minimize potential impacts associated with delayed cleanup (i.e., temporary erosion controls procedures, topsoil stabilization, reseeding, etc.).

*Permanent Erosion Control Devices*

Pacific Connector would install permanent erosion control devices or BMPs consistent with the requirements of Section V.B. of the FERC staff's Plan and as described in the pipeline project-specific ECRP provided in appendix F. These BMPs would consist predominantly of trench breakers, slope breakers or waterbars, and revegetation measures to permanently stabilize disturbed areas. Pacific Connector would utilize the spacing for these structures as specified in FERC staff's Plan (Section V.B.1.b, and V.B.2.b) or as recommended by the BLM, USFS, or NRCS. Because the recommendations from these agencies varied, Pacific Connector developed specifications that are consistent across the pipeline project based on slope and soil characteristics, and that utilize the agency recommendations as much as practical.

Revegetation

As required by the FERC staff's Plan, Pacific Connector consulted with the NRCS, the BLM, and the USFS regarding specific seeding dates and recommended seed mixtures for the pipeline project area. The recommendations have been incorporated into the pipeline project-specific ECRP (see appendix F). The ECRP describes the procedures that would be implemented to minimize erosion and enhance revegetation success for the entire pipeline project. The ECRP describes the procedures that would be utilized to minimize the spread of noxious weeds as a result of pipeline project construction. The ECRP describes the silvicultural prescriptions that would be implemented in areas that are outside the permanent easement.

All areas disturbed by construction, including the construction right-of-way, TEWAs, UCSAs, and contractor yards as necessary, would be restored and revegetated in accordance with Pacific Connector's ECRP. Prior to seeding, the disturbed areas would be prepared as a seedbed approximately 3 to 4 inches deep using appropriate equipment, as necessary in certain areas, as determined by the EI. This could include chisel plowing or disking. In most areas, typical regrading and contouring during restoration would create a suitable rough, yet firm, seedbed, conducive to capturing seeds and retaining soil moisture. In residential and cropland areas, additional cleanup activities prior to the preparation of a proper seedbed may include rock removal.

Pacific Connector would work with individual landowners in agricultural areas to determine how the right-of-way would be restored where the pipeline would cross croplands. Usually, in agricultural areas, the landowner determines whether or not Pacific Connector would be responsible for seeding. In some situations, the owner of agricultural land may do the final restoration and seeding and Pacific Connector would compensate the landowner for those efforts.

In residential areas, Pacific Connector would restore disturbed lawns, ornamental shrubs, gardens, and other landscape features in accordance with their agreement with the landowner. The restoration work in residential areas would be done by a contractor familiar with local horticultural or landscape practices, or Pacific Connector may choose to compensate a landowner to restore their property.

Based on Oregon State University Extension Service recommendations for fertilization rates for nitrogen fertilizer on new pasture seedlings, Pacific Connector intends to use a standard fertilization rate of 200 pounds per acre bulk triple-16 fertilizer on disturbed areas to be seeded. The NRCS did not recommend the addition of lime or other soil pH modifiers. Fertilizer would not be used in wetlands, unless required by the land-managing agencies, and would not be applied within 100 feet of streams. The fertilizer would be stored outside of riparian reserves and away from streams, and would not be applied during heavy rains or high wind conditions. It could be either broadcast, or incorporated in the slurry for hydroseeding.

Prior to construction, Pacific Connector would submit a Request for Service (RFS) to native seed vendors and growers to provide the necessary quantity of native seed that would be required for pipeline project restoration and erosion control. In the RFS, Pacific Connector would provide the estimated quantity of native grass seed required by species and by ecozone according to the Seed Mixtures specified in Tables 10.9-1, 10.9-2 and 10.9-3 of the ECRP (see appendix F). Pacific Connector has had discussions with various local native seed vendors in Oregon during the prefiling process regarding availability of native seed and ability to provide/produce the necessary quantity of seed for the pipeline project. Pacific Connector contacted Heritage Seedlings, Inc. Oregon Wholesale Seed Company, Pacific NW Natives, and Callahan Seed, among others. These vendors indicated that they could provide the various native seed species required for the pipeline project over the 2-year collection/growing season that would occur between the beginning of construction and restoration. Further, the Native Seed Network (http://www.nativeseednetwork.org/index) provides a useful tool to search for available native seed and seed vendors.

Pacific Connector also visited the J. Herbert Stone Nursery, at the direction of the USFS and BLM, because the nursery produces native seed for these agencies' projects and for fire restoration. Under a cooperative agreement the nursery could produce seed for the pipeline project. The nursery also stores surplus native seed for the various agencies and this surplus seed could also be available through agreements with the agencies based their need.

It is expected that seeding would be timed to begin in August and could extend into the winter months at lower elevations. Seeding may be done by broadcast methods, drilling, or hydroseeding. Broadcast seeding, using a mechanical broadcaster seeder, is the preferred method of seeding on steep slopes. After broadcast, the seedbed would be dragged by chains or other appropriate harrows to cover the seeds thinly with soil. Hydroseeding would be done in accessible upland areas. Hydroseeding equipment would include tanks, pumps, nozzles, and other devices for mixing the seed hydraulically with wood fiber mulch and tackifier. A built-in agitator would keep the seed, mulch, tackifier, and water mixed together homogeneously until pumped from the tank. A drill seeder pulled by a tractor may be used in gently sloping areas.

The seed mixtures were determined in consultations with the land-managing agencies and the NRCS. The seed mixtures on BLM land were developed based on BLM Instruction Memo-2001-014, which specifies the use of native species, if possible. During right-of-way easement negotiations, private landowners may select their own seed mixtures other than those proposed for elsewhere along the pipeline route. The seed mixture seeding rates are based on Pure Live Seed. The seed mixture should be free of noxious weeds.

Mulch would be applied on slopes were necessary to stabilize the right-of-way after seeding. Mulch would consist of native wood chips, wood fiber mulch mixed with the hydroseed, bonded fiber matrix to be used on slopes steeper than 40 percent grade (greater than 2.5 to 1), and certified weed-free straw.

Waterbody Crossings

The Pacific Connector pipeline would affect 400 waterbodies. Of the 400 waterbodies that would be affected, 101 are perennial, 164 are intermittent, 128 are ditches, 6 are stock ponds, and 1 is an estuary (Coos Bay). Waterbodies would be crossed in accordance with the FERC staff's Procedures and applicable permits from other agencies. It is expected that the intermittent waterbodies and the ditches would be dry during construction. Excluding the ditches, the table in appendix M lists the waterbodies affected by the Pacific Connector pipeline and provides the proposed crossing method for each, the rationale for the proposed method, whether federally listed species are present, the ODFW-recommended in-water work window, and whether a crossing bridge is required.

The list of waterbodies crossed by the pipeline is based on field investigations that were conducted during 2006 and 2008; review of USGS topographic maps; review of GIS data from the Oregon/Washington Hydrography Framework Partnership (August 29, 2005) published by the BLM in Oregon providing geographic hydrology information; and review of recent low level and high resolution aerial photography (2012) and LiDAR data developed for the pipeline project during 2006. Pacific Connector would cross waterbodies using conventional crossing techniques within the ODFW suggested in-water construction windows.

Pacific Connector plans to cross intermittent flowing streams, and irrigation canals and ditches when they are dry, using standard upland, cross-country pipeline construction methods. If water is flowing at the time of the crossing, a dry crossing method would be used (i.e., flume or dam-and-pump, see below). The standard depth of cover would be 5 feet below intermittent flowing streams and ditches.

Pacific Connector proposes to use an HDD to go under three rivers (Coos River, Rogue River, and Klamath River) and a Direct Pipe to go under the first crossing of the South Umpqua River. Three waterbodies (Kentuck Slough, Catching Slough, and the Medford Canal) would be bored under. The crossing of Coos Bay would be a wet open cut. The second crossing of the South Umpqua River would be done using a diverted open cut. All other waterbodies would be crossed with dry open cut methods.

Forty-five streams crossed or adjacent to the pipeline route are known to support anadromous salmon and/or steelhead, and 33 streams are assumed to support anadromous salmon and/or steelhead. There are 48 streams crossed or adjacent to the pipeline route that are known to support resident fish, and 69 that are assumed to support resident fish. In all, there are 116 waterbodies known or assumed to be fish-bearing and one estuarine waterbody that is fish-bearing. Of that total, EFH species and habitat have been documented in 40 waterbodies and are assumed to be present in 36 more (see appendix M).

Pipeline crossings of perennial waterbodies would be made nearly perpendicular to the axis of the waterbody channel, where feasible. The pipeline route would avoid paralleling a waterbody within 15 feet or less, where feasible. Where possible, Pacific Connector has located TEWAs so that they are no closer than 50 feet from waterbody boundaries. However, where topographic conditions or other constraints prevent the 50-foot waterbody setback, these areas have been noted and described in appendix H. Consistent with Section V. B. 2. a. of the FERC staff's Procedures, where the uplands adjacent to a waterbody consist of actively cultivated or rotated cropland or other disturbed land, the TEWAs have been located adjacent to the waterbody.

Pacific Connector, in a response to comments from NMFS during ESA Subgroup meetings of the Interagency Task Force, has agreed to a 150-foot set back from streams for refueling activities under the pipeline project SPCCP. Relative to construction rights-of-way and TEWAs, the location, size and spacing of TEWAs have been established for construction of the pipeline facilities factoring in safety, topography, and pipeline construction progressions using the FERC staff's Wetland and Waterbody Procedures allowance of a 50-foot setback from waterbodies. The TEWA placement nearer to the waterbody than 50 feet is due to the use of these areas by contractors to ensure that all of the waterbody crossing limitations (within the necked down right-of-way) can be performed. To further limit the placement of TEWAs would result in increasing risk of failure of the construction right-of-way to serve for safe and environmentally-sound construction. The conservation and control measures (e.g., BMPs) are specifically designed to minimize potential impacts to waterbodies associated with construction of a linear facility that crosses the waterbodies. Pacific Connector continues to recognize the need for a variance procedure for overnight "parking" and/or fueling of equipment where necessary as a variance from this setback. The required BMPs and approval of the EI for any such variance is delineated in the project SPCCP. Pacific Connector agrees that on BLM and NFS lands, the authorized BLM or USFS representative would be informed of the EI's determination. The representative can evaluate the situation and the decision of the EI.

The proposed pipeline would cross numerous irrigation canals and ditches in agricultural fields in Klamath County. Some of the irrigation canals and ditches in this area are part of Reclamation's Klamath Project. Reclamation would require that the pipeline be installed at least 3 feet below the bed of facilities over which it has jurisdiction. To minimize agricultural impacts and to schedule the crossings of the majority of the canals and ditches when they are dry and not in use, Pacific Connector is proposing to install its pipeline through the Klamath Basin between about MPs 188 and 228, during the winter. This would correspond with the ODFW recommended crossing window for the Lost River. The winter construction schedule would also minimize the crossing of high groundwater areas in the Klamath Basin, which are caused from irrigation and canal leakage or drainage. Reclamation would require that irrigation canals and ditches under its jurisdiction be crossed between October 15 and March 15, outside of the irrigation season.

Pacific Connector would work with Reclamation, the appropriate irrigation districts, and individual landowners to develop site-specific procedures to minimize disruption of irrigation canals and ditches during construction. If these features are in use at the time of construction, Pacific Connector would utilize a dry crossing technique, such as fluming, boring, or dam-and-pump methods to prevent disruption of downstream flows and to minimize any downstream impacts. Pacific Connector would maintain water flow in all crop irrigation systems, unless shutoff is coordinated with affected landowners. Pacific Connector would negotiate with the landowners at these locations to minimize impacts to their agricultural operations and would compensate the landowners for any crop loss/damage resulting from pipeline construction.

*Major Waterbodies*

Major waterbodies as defined by the FERC are those greater than 100 feet wide. Pacific Connector has completed geotechnical studies at these waterbodies to determine feasible crossing methods. Pacific Connector has prepared detailed, site-specific construction drawings with construction details for each of these waterbody crossings that identify the areas that would be disturbed by the proposed construction method including the areas necessary to fabricate the pipeline for the crossing, stage equipment, store spoil, and construct the crossing (see appendix W). Sediment control structures at these crossings are shown in the site-specific construction drawings. During development of the crossing methods, Pacific Connector consulted with all appropriate federal and state agencies. The crossing methods are described below.

*Coos Bay and Haynes Inlet*

A wet open-cut crossing construction technique would be used to cross approximately 2.4 miles of Coos Bay and Haynes Inlet, a tidal waterbody that has substantial flows and fluctuating water levels. A construction plan for the Coos Bay estuary crossing is provided in appendix D.

Construction in Coos Bay would use several different pipeline installation methods. A Shallow Water Lay Barge would be used to install the pipeline in water between 0 feet to 20 feet deep. The pipeline would be installed at shore approaches using open-cut trench methods, with shore based equipment where possible. From the barge a combination of the conventional S-lay method and "pipe push" method would be used. To make certain that the pipe is buried at least 5 feet deep, a pre-lay trench would be dug.

*Coos River, Rogue River, and Klamath River*

Pacific Connector is proposing to use the HDD method for the crossing of the Coos River (MP 11.13R), the Rogue River (MP 122.65), and the Klamath River (MP 199.38). Pacific Connector plans to HDD the Coos, Rogue, and Klamath River crossings during the first year of pipeline construction (Project Year Two or BA Year 3 – see figures 3.2-1 and 3.2-3) to allow sufficient time to pursue permits for an alternative crossing location or method in the unlikely event the proposed HDDs are unsuccessful. The alternate crossing method or a HDD at an alternate location would then be completed during the second year of pipeline construction (Project Year Three or BA Year 4 – see figures 3.2-1 and 3.2-3) during mainline construction and would be constructed within the ODFW-recommended in-water work window to protect aquatic species. appendix E provides HDD crossing plans for each river as well as a Drilling Fluid Contingency Plan and a Failure Mode Plan.

The HDD method involves boring under a feature and pulling the pipeline into place through the borehole that has been reamed to accommodate the diameter of the pipeline. This procedure involves three main phases, pilot hole drilling, subsequent reaming passes, and pipe pullback. HDD typically is used for the crossing of major waterbodies (greater than 100 feet wide).

<u>Pilot Hole</u>

The pilot hole establishes the ultimate position of the installed pipeline. For this operation, an initial hole is drilled from the entry point to the exit point on the opposite side of the crossing. The head of the pilot drill string contains a pivot joint to provide directional control of the drill string. By altering or steering the drill head, the operator can control the direction as the drill progresses. Thus, the pilot hole can be directed downward at an angle until the proper depth is achieved, then turned and directed horizontally for the required distance, and finally angled upward to the surface. Tracking and steering of the HDD drill head is generally guided using a two-wire system. The system consists of two insulated wires (approximately 0.25-inch in diameter) that are laid on the ground and are charged with an electrical current. A magnetometer accelerometer probe located behind the drill bit detects the electric current to triangulate the drill bit for steering.

As the pilot drill string is advanced, additional sections of drill pipe are added at the drill rig located at the entry point. High-pressure jetting of drilling fluid at the drill head and, in harder soil formations, rotation of the drill bit, facilitates advancement of the drill string. The drilling fluid (mud) is typically a non-toxic bentonite clay mixed with freshwater to make a slurry. Once the pilot hole exits in an acceptable location, the reaming operation is initiated.

*Reaming*

During the reaming phase, a reaming head is attached to the drill pipe and pulled back through the pilot hole to enlarge it. Several reaming passes may be made with incrementally larger reaming heads to enlarge the hole to approximately 1.5 times the diameter of the pipeline. Various reaming heads can be utilized, depending on the substrate encountered. High-pressure drilling fluid is jetted through the reaming head to float out drill cuttings and debris, to cool the drilling head, and to provide a cake wall to stabilize the hole. Once the drill hole is enlarged to the proper diameter, the pipe is pulled back through the reamed hole.

*Pullback*

The last step to complete a successful installation is the pullback of the pre-fabricated product pipe into the enlarged hole. The pullback process is the most critical step of the HDD process. A reinforced pullhead is welded to the leading end of the product pipe and to a swivel connected to the end of the drill pipe. The swivel is placed between the drill rig and the product pipe to reduce torsion and prevent rotation from being passed to the product pipe

During pullback, the pull section is supported with a combination of roller stands and/or product pipe handling equipment to direct the product pipe into the hole at the correct angle, reduce tension during pullback, and prevent the product pipe from being damaged. After the product pipe is in place, the installed crossing is hydrostatically tested, pigged (optional), and tie-in welds on each side of the crossing are completed.

*South Umpqua River – MP 71.30*

Pacific Connector is proposing a Direct Pipe (DP) crossing of the South Umpqua River at MP 71.30 during the first year of pipeline construction (Project Year Two or BA Year 3 – see figures 3.2-1 and 3.2-3) to allow sufficient time to pursue permits for an alternative crossing location or method in the unlikely event the proposed DP is unsuccessful. The alternate crossing method or crossing at an alternate location would then be completed during the second year of pipeline construction (Project Year Three or BA Year 4 – see figures 3.2-1 and 3.2-3) and would be constructed within the ODFW-recommended in-water work window to protect aquatic species. DP is a trenchless construction method to install pipelines beneath rivers, highways, railroads, levees, wetlands and other features that require special attention to environmental and logistical concerns. DP is, in its simplest definition, a combination of the traditional microtunneling process and HDD. DPs are completed using an articulated, steerable microtunnel boring machine (MTBM) mounted on the leading end of the product pipe or casing which is jacked into position using a pipe thrusting machine mounted at or near the ground surface (see appendix E).

Internal instrumentation is typically used to survey the progress of the MTBM so that its location can be compared to the design requirements. A gyroscope mounted within the MTBM locates the orientation and a precision manometer is used to locate the elevation of the MTBM.

The MTBM exerts continuous and controllable pressure at the excavation face and is capable of excavating a wide variety of soils under significant groundwater pressures. Soil and rock are excavated by the cutting head and removed through pressurized slurry pipes to the launching pit at a rate that is balanced with the advance rate of the machine, as the MTBM and pipe are jacked through the formation. A pipe thrusting machine located in or near the launching pit provides the necessary force to advance the product pipe and provide the face pressure required for excavation. The product pipe is typically pre-fabricated in a continuous section or in smaller sections, typically 300 to 500 feet. The smaller sections are welded to the back of subsequent sections after each section is advanced.

Friction between the pipe and surrounding soil can create significant resistance during DP installation. To reduce the frictional resistance, over cutting is employed to create a small annular space between the pipe and external soil. The over cut is typically on the order of 1 to 2 inches. The use of bentonite slurry helps reduce the frictional resistance between the pipe and soil as well as reducing the risk of collapse of the annulus around the pipe. Bentonite lubrication is typically added from the launch seal and from a specialized lubrication ring located behind the MTBM and in front of the jacking pipe.

Following completion of the tunneling process, the MTBM is retrieved from the receiving pit. If the DP-installed pipe is to be used as casing, after completion of the grouting the product pipe may be installed within the casing using centralizers or resting on the bottom of the casing if the product pipe is concrete coated. After the product pipe is installed and tested, the interior annular space between the casing and product pipes may be filled with cement grout.

*South Umpqua River – MP 94.73*

The second crossing of the South Umpqua River at MP 94.73 is planned for the ODFW recommended in-water work window between July 1 and August 31 during the first year of pipeline construction (Project Year Two or BA Year 3 – see figures 3.2-1 and 3.2-3). The South Umpqua River channel at MP 94.73 is sufficiently flat, wide, and shallow to divert all of the river flow to one side or bank of the river while work is proceeding in the dry on the opposite bank. Typically in August water levels at the crossing have been sufficiently low that a diverted open-cut crossing method could easily have been utilized at this crossing location.

This crossing method would require TEWAs to be located in the river and would require equipment to work in the river to place the diversion structures or dams to divert the river flow from one side of the river and then to the other. The diversion could be constructed using imported riprap, concrete jersey barriers, water bladder portadams, and/or sand bags to divert the river's flow temporarily away from the work area in order to minimize contact between stream flow and the excavation and backfill activities. This would require Pacific Connector to place equipment within the stream to install, maintain, and ultimately remove the diversion structures. The crossing would take a minimum of 14 days to complete including 3 to 4 days of in-stream work to install, rearrange, and remove the diversion structures. Some turbidity would result during in-stream activities and when the water is diverted to the backfilled areas.

The diverted open-cut crossing method at this location would require an in-stream tie-in, but it would be made in the dry behind the diversion structure. During the crossing, initial trenching would first occur on the dry side of the river; however, depending on the water levels during the season, it may be necessary to install a diversion to push or divert the flow to at least the middle of the river. Once the construction right-of-way has been isolated by the diversions and/or sediment control devices, trenching would proceed to approximately the middle of the river. Trench spoil would be stored within the stream channel behind the diversion or sediment control structures to ensure that sedimentation from saturated materials does not flow back into the river. After the trench has been completed, a section of pipe would be placed in the trench. Trench boxes or another marker form would be placed at the end of the pipe section in the middle of the riverbed for the tie-in. The trench would be backfilled and the streambed restored to the original contour configuration, except for the immediate area around the tie-in.

The diversion structure would then be removed and rearranged to divert the flow temporarily to the other side or dry side of the river in order to minimize contact between stream flow and the excavation and backfill activities. This would again require Pacific Connector to place equipment within the stream in order to rearrange the diversion structures. Once the diversion structures have been properly reconfigured and extended beyond the tie-in location and the river flow diverted to the opposite side of the river, excavation for the other section of pipe would begin. Trenching would proceed across the river bed to the tie-in point in the middle of the river where it would be uncovered. Once the excavation is complete, the second pipe section would be carried in and tied-into the first section. After the tie-in has been made, the streambed would be restored to its original contours and configuration and the diversions structures would be removed. Streambanks would be reestablished and stabilized.

During the diverted open cut, multiple discharge pumps would be required to keep the tie-in area dry while the welds are being made and to control any flow seepage in the work areas. The discharge from this activity would occur to a straw bale discharge structure located in an upland area as far away from the river as possible to prevent any silt-laden water from flowing into the river.

*Kentuck Slough (MP 6.28R), Catching Slough (MP 11.11), and Medford Aqueduct (MP 133.38)*

Conventional bores of waterbodies are proposed at Kentuck Slough (MP 6.28R), Catching Slough (MP 11.11), and the Medford Aqueduct (MP 133.38). The specific type of bore (i.e., jack and bore, slick bore, hammer, etc.) that would be utilized would be determined during the design phase of the pipeline project and depends on construction characteristics, the type of soils present, and the contractor's familiarity with the method. The hammer is typically utilized in difficult soils containing consolidated rock, and the slick bore is used in soils with fewer frictional characteristics. Although each type of bore is somewhat different, the requirements and risks associated with each are similar. In all cases, the bore must be completed along a straight pathway requiring excavation of a bore pit on either side of the crossing (called launching and receiving pits). The depth of the bore pits must be several feet deeper than the bottom of the pipeline and can be quite deep when accounting for the depth of the feature to be crossed and the depth of cover between the bottom of the feature (e.g. stream bed) and the top of the pipeline. Welders and other laborers must work within the confined space of the bore pit; and the presence of water can be problematic.

During a standard boring operation, the spoil material is passed into the bore pit. Trackhoes then remove this spoil from the bore pit. Pipe is welded up and eventually pulled through the bore hole. Each section of the pipe is joined using full-penetration welding procedures and 100 percent of the welds are inspected using non-destructive testing procedures (x-ray) to form a continuous pipeline segment. This is a difficult operation, requiring the welders to work in the confined space of the bore pit. Because conventional boring does not limit water migrating into the bore, an important factor in the design of launching and receiving pits is groundwater control.

Dewatering systems using deep wells or well points are frequently used. Trench boxes or sheet piling are often used to support the pit walls and to cut off groundwater inflows.

*Minor and Intermediate Waterbodies*

If water is present in the streambed at the time of construction, Pacific Connector would utilize a dry-ditch crossing method (flume or dam-and-pump) to cross all minor and intermediate waterbodies consistent with the requirements of Section V.B.6 of the FERC staff's Procedures. Fluming and dam-and-pump procedures that would be utilized to cross these waterbodies are provided in appendix K.

<u>*Storage of Hazardous Materials*</u>

Hazardous materials, chemicals, fuels, and lubricating oils would be stored in upland areas at least 150 feet from waterbodies and wetlands or in accordance with FERC's Procedures (see appendices C and L). Restricted areas for storage of these materials would be clearly marked in the field. Concrete coating, refueling, and equipment maintenance activities would be conducted according to FERC's Procedures. Concrete trucks would not be washed on the right-of-way. All hazardous materials would be handled in accordance with the SPCCP (see appendix L). If any unanticipated spill occurs during construction, Pacific Connector would implement the procedures outlined in the SPCCP.

<u>*Temporary Bridges*</u>

If water is present in any streambeds at the time of construction, Pacific Connector would utilize temporary construction bridges during all phases of construction to cross these waterbodies. Equipment bridges would not be installed on intermittent waterbodies, which are dry at the time of construction. However, if a storm occurs that results in water in the streambed of the otherwise intermittent waterbody, no equipment would cross the waterbody until the streambed dries up or until a bridge is installed. Although FERC's Procedures (see Section V. B. 5. a.) allow clearing equipment and equipment necessary for installation of the temporary bridges to cross waterbodies prior to bridge installation, Pacific Connector would not allow clearing equipment to cross waterbodies prior to bridge placement. Where feasible, Pacific Connector's contractors would attempt to lift, span, and set the bridges from the streambanks. However, where it is not feasible to install or safely set the temporary bridges from the streambanks, only the equipment necessary to install the bridge or temporary support pier would cross the waterbody.

The temporary equipment bridges would be constructed to maintain unrestricted flow and to prevent soil from entering the waterbody. Soil would not be used to stabilize equipment bridges. Bridges would be designed according to the FERC staff's Procedures (Section V.B.5.B) and would be maintained to withstand and pass the highest flow expected to occur while the bridge is in place. The highest flow expected would be determined during the season of construction and would take into account an evaluation of regional climate and physical conditions as well as existing historical streamflow data and peak discharge statistics from nearby USGS gauging stations.

Where feasible, bridges would be designed to span the entire ordinary high water mark (OHWM) of the waterbody. If it is not possible to span the OHWM with a bridge, a temporary culvert or pier may be required. These culverts/piers would be installed to minimize flow restrictions that may deflect stream flow to banks to prevent streambank erosion or scour.

The ECRP (appendix F - see Drawing 3430.34-X-0010) provides additional details for temporary bridges. These structures would meet the requirements attached to permits or approvals issued by the COE, ODSL, ODEQ, and ODFW for this project. To allow for the delivery of materials and equipment up and down the construction right-of-way, it may be necessary to install some bridges outside the ODFW recommended in-water construction windows.

Temporary bridges would be set during clearing operations in the first year of pipeline construction (Project Year Two or BA Years 2 and 3 – see figures 3.2-1 and 3.2-3) as well as during mainline construction the following year. The temporary bridges set during clearing operations would be temporarily removed after clearing is complete and would not be left in place across a waterbody over the winter. During mainline construction in the second year of pipeline construction (Project Year Three or BA Years 3 and 4 – see figures 3.2-1 and 3.2-3), the temporary bridges would be reset and would be removed as soon as possible after permanent seeding. If there would be more than one month between final cleanup and the beginning of permanent seeding and reasonable alternate access to the right-of-way is available, equipment bridges would be removed as soon as possible after final cleanup as required by the FERC staff's Procedures (Section V. B. 5. f.).

Sediment barriers would be installed immediately after initial disturbance of the waterbody or adjacent upland as shown on Drawings 3430.34-X-0005 and 3430.34-X-0007 in the pipeline project-specific ECRP (see appendix F). Sediment barriers would be properly maintained throughout construction and reinstalled as necessary (such as after backfilling of the trench) until replaced by permanent erosion controls or restoration of adjacent upland areas is complete.

All waterbodies supporting fisheries would be backfilled with material removed from the trench with the upper 1-foot of the trench backfilled with clean gravel or native cobbles. The bottom and banks would be returned to preconstruction contours; banks would be stabilized; and temporary sediment barriers would be installed before returning flow to the waterbody channel.

Pacific Connector requested a modification from Section V.C.1. of the FERC's Procedures in fish-bearing streams that do not have gravel, cobble, or other rock substrates (see appendix H). This modification was requested because many of the streams to be crossed by the pipeline are remote and are located in steep valley or ravine bottoms; therefore, hauling rock to these steams is impractical especially where these streams do not have these substrate characteristics.

#### 3.1.4.4 Operations, Maintenance, and Monitoring – Pacific Connector Pipeline

Pacific Connector would test, operate, and maintain the proposed pipeline facilities in accordance with DOT regulations provided in 49 CFR Part 192, Transportation of Natural and Other Gas by Pipeline: Minimum Federal Safety Standards, FERC's guidance at 18 CFR 380.15, and maintenance provisions of the FERC staff's Plan and Procedures. The pipeline right-of-way would be clearly marked where it crosses public roads, waterbodies, fenced property lines, and other locations as necessary. Table 3.1.4.4-1 lists the habitat types affected by operation of the pipeline facilities.

TABLE 3.1.4.4-1

**Summary of Operation-Related Disturbance to Habitat by the Proposed Pacific Connector Pipeline (acres a/)**

| General Vegetation Type | Mapped Vegetation Category Type | Forest Stand by Age | Pipeline Facilities | | | | | | | Aboveground Facilities | | | | | | | | | | | | | | | | | | Total Operation Impacts by Habitat Type |

[1] Acres disturbed were evaluated using GIS; footprints for each component (aboveground facilities, permanent easement, and 30-foot maintenance corridor) were overlaid on the digitized vegetation coverage.

[2] The "Late Successional and Old-Growth" category (L-O) describes those forest areas with a majority of trees over 80 years of age. Forests with stands greater than 175 years are considered to have old-growth characteristics.

[3] The "Mid-Seral" category (M-S) describes those forest areas with a majority of trees over 40 years of age but less than 80 years of age.

[4] The "Grass-shrub-sapling or Regenerating Young Forest" category (C-R) describes those forest areas that are either clear-cut (tree age 0-5 years) or regenerating (tree age 5 to 40 years).

[5] CT = Communications tower

[6] Subtotal by Habitat Type includes the 30-foot maintenance corridor, permanent access roads, and only aboveground facilities with a meter station or compressor station (mainline block valves located within the 30-foot maintenance corridor).

General: If percentages were less than 1/100ths, they were not included in the table.

-Columns and rows do not necessarily sum correctly due to rounding.

Acres of impacts to non-vegetated areas are included within this table for consistency in values reported within this Resource Report.

The pipeline would be inspected regularly by aerial patrols or on-the-ground personnel to observe general right-of-way conditions and to identify any indications of soil erosion that may expose the pipe, stressed vegetation that may indicate a leak in the line, damage to erosion control structures, unauthorized encroachment onto the right-of-way, and other conditions that could present a safety hazard or require preventive maintenance or repairs. All inspections would be in accordance with DOT standards. Generally, repair of erosion control structures, drain tiles, and the need for additional fill may be required in the first year or two following construction in areas where the trench may have settled. Areas susceptible to damage from large storm events would be inspected and repaired as appropriate depending on the nature of damage. Waterbody crossings would be inspected periodically. Any areas of concern (AOCs) that are brought to the attention of the pipeline operator would be assessed and repaired as necessary. A supply of replacement pipe, leak clamps, sleeves, and related materials would be stored at local district offices for use during repair activities.

Vegetation maintenance would be a required periodic use of the federal or private lands crossed by the pipeline, and would be covered in lease agreements for each individual affected property. No herbicides would be used to control vegetation (i.e., brush and trees) on the permanent pipeline easement unless approved or required by the landowner. Herbicides would not be used in or within 100 feet of a waterbody's mean high water mark. Vegetation at aboveground facilities would be periodically maintained using mowing, cutting, trimming, and herbicides (selectively). Vegetation within the permanent easement would be periodically maintained by mowing, cutting, and trimming (either by mechanical or hand methods). In upland areas, the permanent easement would be maintained in a condition where trees or shrubs greater than 6 feet tall would be controlled (cut or trimmed) within 15 feet either side of the centerline (for a total of 30 cleared feet). Maintenance activities are expected to occur approximately every 3 to 5 years depending on the growth rate of vegetation. During maintenance, vegetation would be cut/trimmed in 4- to 6-foot lengths and scattered across the permanent easement to naturally decompose, discourage OHV traffic, and benefit wildlife habitat. Occasionally where site conditions allow, chipping of this material may also occur. Pacific Connector believes that the slash materials generated and scattered across the permanent easement during maintenance activities would not exceed the fuel loading specifications discussed above. To facilitate periodic corrosion and leak surveys, a corridor not exceeding 10 feet in width centered on the pipeline may be maintained annually in a herbaceous state, if required.

In forested and shrub wetland areas, vegetation maintenance would be as described above except trees and shrubs would be selectively removed as necessary to minimize equipment operating within the wetland. Where the pipeline crosses a waterbody, vegetation maintenance would be limited to allow a riparian strip at least 25 feet wide, measured from the waterbody's OHWM, to permanently revegetate with native species, with the exception of maintenance required to maintain vegetation no greater than 6 feet tall within 15 feet of the centerline of the pipe.

On federal lands where riparian reserves are affected, a 100-foot riparian strip (or less if the pre-construction riparian vegetation did not extend to 100 feet) would be planted perpendicular to the waterbody on both sides of the waterbody. However, to facilitate periodic pipeline corrosion/leak surveys, a corridor centered on the pipeline and up to 10 feet wide would be maintained in an herbaceous state in this riparian strip with no vegetation greater than 6 feet in height. Herbicides would not be used in or within 100 feet of a waterbody's mean high water mark. Herbicides would only be used on NFS lands if needed to control invasive species, in accordance with each National Forest's management plans.

In addition to DOT-required surveys, Pacific Connector would monitor the pipeline system using a supervisory control and data acquisition (SCADA) system. SCADA systems are used to monitor and control facilities or equipment in industries such as telecommunications, water and waste control, energy, oil and gas refining, and transportation. A SCADA system gathers information; transfers the information back to a control center; carries out necessary analysis and control; and displays the information in a logical and organized fashion 24 hours a day, 7 days per week. The control center for the Pacific Connector pipeline would be provided by Williams Pacific Operator and would be located in Salt Lake City, Utah.

If noxious weed infestation occurs on the permanent easement, selective use of herbicides would be used to control these species. All use of herbicides at aboveground facilities or on the permanent easement would be in accordance with federal, state, and local regulations and land managing agency requirements as well as landowner approval and would be consistent with FERC's Plan and Procedures. The Noxious Weed Control Plan, provided in the ECRP in Appendix F provides additional details regarding noxious weed control on the permanent easement.

Generally, repair of erosion control structures and the need for additional fill may be required in the first year or two following construction in areas where the trench may have settled or any other areas disturbed by construction activities. Depending on the location of the trench settlement or AOC, minor repairs of waterbars or drain tiles may be necessary because the settlement could affect the drainage or proper function of these features and regrading and/or addition of fill material may be necessary. Erosion control structures and the need for additional fill would be assessed by operations personnel along the right-of-way during routine inspections. Areas susceptible to damage from large storm events would be inspected and repaired as appropriate depending on the nature of damage. All areas disturbed by construction activities would be restored and monitored and appropriate repairs would be made as necessary. A supply of emergency replacement pipe, leak repair clamps, sleeves, and related materials would be stored at the local district office for repair activities.

Waterbody crossings would be inspected periodically by Pacific Connector's operations personnel. Operation and maintenance activities, including aerial inspection of the pipeline, would be conducted only within the permanent easement. Aerial inspections would be conducted by helicopter and/or small fixed-wing aircraft to examine the pipeline right-of-way once per year during the life of the pipeline.

**Cathodic Protection System**

The pipeline would be protected from external corrosion using a low voltage impressed current electrical system, referred to as a cathodic protection (CP) system, which would be installed about one year following construction, to allow for collection of post-construction data of electroconductivity soil potentials, which is required before the CP system can be designed and installed. This system would input a low-voltage electrical charge into the pipeline underground. Permitting for the CP system is not applied for in the FERC Certificate application because the system design would be conducted after the pipeline is installed. The CP system cannot be designed properly until the ground is settled and there is good soil contact with the new pipe following pipeline construction. Pacific Connector would consult with federal, state, and local agencies regarding permitting of the CP system following pipeline construction. Pacific Connector anticipates that it would need to install approximately 12 rectifiers for the CP system at separate locations along the 232-mile length of the pipeline, typically spaced about 15 to 20 miles apart and generally located near existing access roads and existing power distribution lines. The exact locations of the rectifiers is not known at this time because the system would be designed after the pipeline is completed. If a vertical deep well anode bed were to be installed, it would require a trunk-mounted drill rig to drill a 10-inch diameter well 300 feet deep. A horizontal anode bed would require the use of a standard backhoe for installation within an area approximately 300 feet long, 2 feet wide, and 5 feet deep. Approximately 2 acres of ground surface would be disturbed during the installation of the CP system.

Pacific Connector intends to install the CP system in full compliance with any seasonal restriction or daily timing restriction for any federally listed avian species should any of the CP sites be located within an area (e.g., MAMU stand or NSO Core area). To the extent that the CP system design allows flexibility of placement of sites, all specified avoidance and minimization efforts would be followed to locate CP sites outside of such areas. CP sites are typically installed in the operational right-of-way or immediately adjacent in the construction right-of-way, so it is not expected that additional timber removal would be required. Systems are usually designed to utilize existing permanent access roads, so crossing of streams or waterbodies by temporary bridging is not anticipated. CP sites would not be installed in riparian zones.

**Maintenance and New Operational Facilities**

In Docket No. CP13-492-000, Pacific Connector also applied for a blanket certificate under Part 157, subpart F of the Commission's regulations and requested issuance of a blanket certificate under Subpart G of Part 284, respectively. According to the FERC's regulations at 18 CFR Part 380.4, these requests for blanket authorities are categorically excluded from environmental review. The currently unknown and unspecified future actions that may take place under the blanket certificate issued under Part 157 that may result in ground disturbance or changes in operational air or noise emissions, reported to the Commission by the applicants as prior notices or annual reports, would be subject to individual environmental reviews in accordance with Part 157.206 of the FERC regulations.

Pacific Connector would be able to replace facilities and build new minor facilities under the blanket certificate programs. The regulations covering operational activities that could result in new and additional construction disturbance are found at 18 CFR Part 2, Part 157 and Part 380. The regulatory framework is outlined below:

**2.55(a) Auxiliary Installations**

A project classified as a 2.55(a) project represents installation of auxiliary installations to existing facilities. Examples of such installations are valves, drips, pig launchers/receivers, yard and station piping, CP systems, gas cleaning cooling and dehydration equipment, residual refining equipment, water pumping treatment and cooling equipment, electrical and communication equipment, and buildings. Such auxiliary facilities are virtually always placed within the footprint of the existing right-of-way or construction disturbance area. Although no specific FERC reporting requirements apply to this type of project, alternate reporting requirements may be dictated by other approvals (i.e. wetlands, stormwater, etc.).

**2.55(b) Like-Kind Replacement Project (with ground disturbance)**

Projects classified as 2.55(b) are reportable projects to FERC in annual reporting documents. However, the project is required to consist of like-kind replacement (e.g., replacement of one or more pipe joints) such that all work is limited to the easement or previously disturbed construction right-of-way. Should the project scope change, requiring additional workspace or operational right-of-way, the classification of the project and its subsequent reporting requirements change to a Blanket Authorization activity or may require the filing of an Application pursuant to section 7(c) of the NGA.

**Automatic Blanket Authorization 157.208(a)**

Construction, acquisition, operation, replacement, and miscellaneous rearrangement of eligible facilities. Projects may be classified as blanket certificate projects pursuant to section 157.208 under the automatic authorization provisions. For such projects, the following reporting requirements are necessary prior to any construction activity. For environmental compliance, informal consultation must be initiated and completed with the FWS relative to any issues pursuant to the ESA and with NMFS pursuant to the ESA and MSA. Other federal clearances must also be obtained. The pipeline operator is formally the non-federal designee to conduct the informal consultation with the agencies on behalf of FERC. Such projects may involve construction outside of the original project's construction disturbance area, but they may not commence until the applicable federal resource agencies concur that the projects would not likely adversely affect a listed species or its critical habitat or adversely affect EFH in the case of MSA. Additionally, the total project cost must be below the dollar amount limit in 157.208(d). If the project exceeds this cost; it is elevated to a Prior Notice Project.

**Blanket Certificate Project – Prior Notice 157.208(b)**

Projects classified as construction, acquisition, operation, replacement, and miscellaneous rearrangement of eligible facilities with prior notice to FERC. The pipeline operator is formally the non-federal designee to conduct the informal consultation with the agencies on behalf of FERC. Such projects may involve construction outside of the original project's construction disturbance area, but they may not commence until the federal resource agencies concur that the project would not likely adversely affect a listed species or its critical habitat or adversely affect EFH in the case of MSA. Prior Notice projects require the preparation of a notice application to FERC and require Commission approval prior to commencing. Approval occurs at the end of a 10-day notice period and 60-day comment period if not protested.

#### 3.1.4.5 NonJurisdictional Facilities and Interrelated Activities

In addition to the facilities discussed, the Pacific Connector pipeline project would require construction of facilities that do not fall under the FERC's jurisdiction. Although these facilities are not regulated by the FERC, they are related to the Project and their potential environmental impacts are considered in this BA and EFH Assessment.

Utility Connections

Electrical power and phone service would also be required for each of Pacific Connector's proposed meter and compressor stations. Installation of the utility connections is not regulated by the FERC. These actions may be regulated by the counties or the state or Oregon.

Because the compressor station and the meter stations would either be installed adjacent to the proposed South Dunes Power Plant or adjacent to existing roads and utility service, no additional disturbance beyond what is evaluated for construction of the compressor station and the meter stations themselves would result from the utility connections.

### 3.1.4.6 Future Plans and Abandonment – Pacific Connector Pipeline

At this time, Pacific Connector has no foreseeable plans for future expansion or modifications of the facilities. Expansion or modification activities are authorized under the regulatory framework for operations and maintenance of the pipeline that is granted by the FERC Certificate.

**Expansion Projects Requiring an Application Pursuant to Section 7(c) of the NGA and Compliance with Part 380 NEPA Regulations**

The pipeline operator cannot proceed with any expansion project without filing a new application for a Certificate for Public Convenience and Necessity pursuant to Section 7(c) of the NGA. All applications must include the environmental data required under 18 CFR Part 380.12. In accordance with Part 380.13, the applicant must assist the FERC with compliance with the ESA, by entering into informal consultations with the FWS and NMFS. If the project could affect listed species, the applicant must conduct appropriate surveys and produce a draft BA. The FERC would consider an expansion to be a new undertaking and, if necessary, would enter into separate formal consultations with the Services.

**Abandonment of Facilities**

The pipeline operator has no plans for abandonment of the proposed facilities and at such time abandonment is necessary, the operator would be required to file an application with the FERC to abandon any of the facilities. Abandonment or deactivation of facilities would comply with Williams Pacific Gas Operator's Operations and Maintenance Manual and DOT 49 CFR 192.727 Abandonment or Deactivation of Facilities. The pipeline would be abandoned in place, where necessary, and would be disconnected from all sources and supplies of gas, purged of gas and have the ends sealed. Regarding aboveground facilities, when service is permanently discontinued to a customer, one of the following would be completed:

- The valve that is closed to prevent flow of gas would be fitted with a locking device or other means to prevent gas flow;
- a mechanical device or fitting would be installed to prevent the flow of gas in the service line or meter assembly; or
- physical disconnection of the customer piping from the gas supply source and sealing the pipe ends.

Typically, Pacific Connector would attempt to maintain abandonment and deactivation procedures within the existing right-of-way. There may be circumstances that require Williams Pacific Gas Operator to work outside of the existing right of way in limited areas in order to complete necessary excavations to seal or cap the pipe ends, e.g. block valve removal may require a 50 x 50 foot extra workspace. Prior to conducting any abandonment activities, Pacific Connector would apply for permits/authorizations with all applicable federal, state and local agencies to ensure compliance with all policies and regulations.

In order to abandon facilities, a company must file an application with the FERC under section 7(b) of the NGA. Again, as with an expansion, this application would be considered a new, separate undertaking. The applicant would assist the FERC in complying with the ESA by having informal consultations with the Services about its proposed action. If the abandonment activities have the potential to adversely affect a federally listed species, the FERC would initiate formal consultations with the Services.

## 3.2 SCHEDULE

Prior to the FERC providing written permission to begin construction, Jordan Cove and Pacific Connector must each have received all authorizations required by federal law.

Some of the actions that must be completed prior to construction include:

- The FERC must complete formal consultations under the ESA with the FWS and NMFS.
- The FERC must complete the process required under the Advisory Council on Historic Preservation's (ACHP's) regulations (36 CFR 800) for complying with section 106 of the National Historic Preservation Act (NHPA).
- The BLM must issue a Right-of-Way Grant for the pipeline over federal lands, with the concurrence of the USFS and Reclamation;
- The applicants must obtain other necessary federal and federally-delegated permits and authorizations, including permits from the COE under the RHA and CWA, permits from the ODEQ under the CWA and CAA, and a consistency determination from the ODLCD under the Coastal Zone Management Act (CZMA); and
- Jordan Cove must satisfy the conditions of the Coast Guard WSR.

At this time it is unknown when all necessary state and federal permits and approvals would be obtained. Therefore, the project schedule below discusses construction in terms of calendar years and Project Years without strict calendar dates. Project Years begin in the 4$^{th}$ quarter (October); "BA Years" are calendar years (see figure 3.2-1).

In general, construction of the proposed LNG terminal and the pipeline would take about 3.5 years. The first year of construction would be for the beginning of work at Jordan Cove's LNG terminal. The construction of the pipeline would actually begin during the second year of LNG terminal construction. Therefore, the first and second year of pipeline construction would actually correspond to Project Years Two and Three.

### 3.2.1 Jordan Cove LNG Terminal and Marine Facilities

Construction of Jordan Cove's LNG terminal and the marine components (access channel and slip) is expected to take approximately 42 months as shown on the general schedule for the major Project construction activities in figure 3.2-2. During Project Year One, Jordan Cove would conduct the following activities:

- Mobilize;
- Begin final engineering design;
- Prepare site;
- Start cut and fill activities;
- Excavate upland portion of the slip and haul soils to power plant site;
- Excavate dredge pocket behind berm, and begin to hydraulically convey dredged materials to power plant site;
- Conduct dredging of access channel in the bay during the first in-water work window;
- Start installation of piles in the portion of the slip behind the berm; and
- Start foundations for LNG storage tanks.

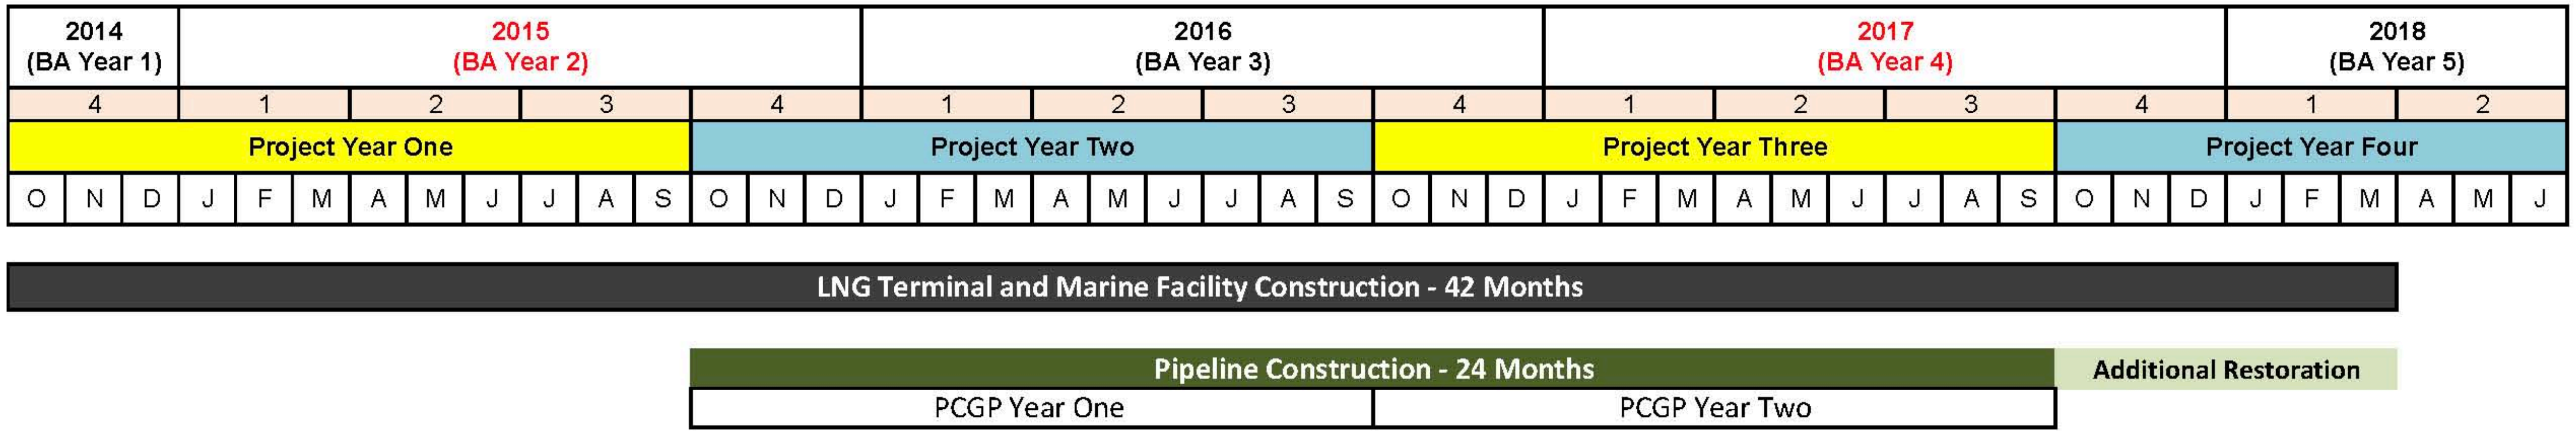

**Figure 3.2-1.** Project Schedule for LNG Terminal and Marine Facilities and Pacific Connector Pipeline

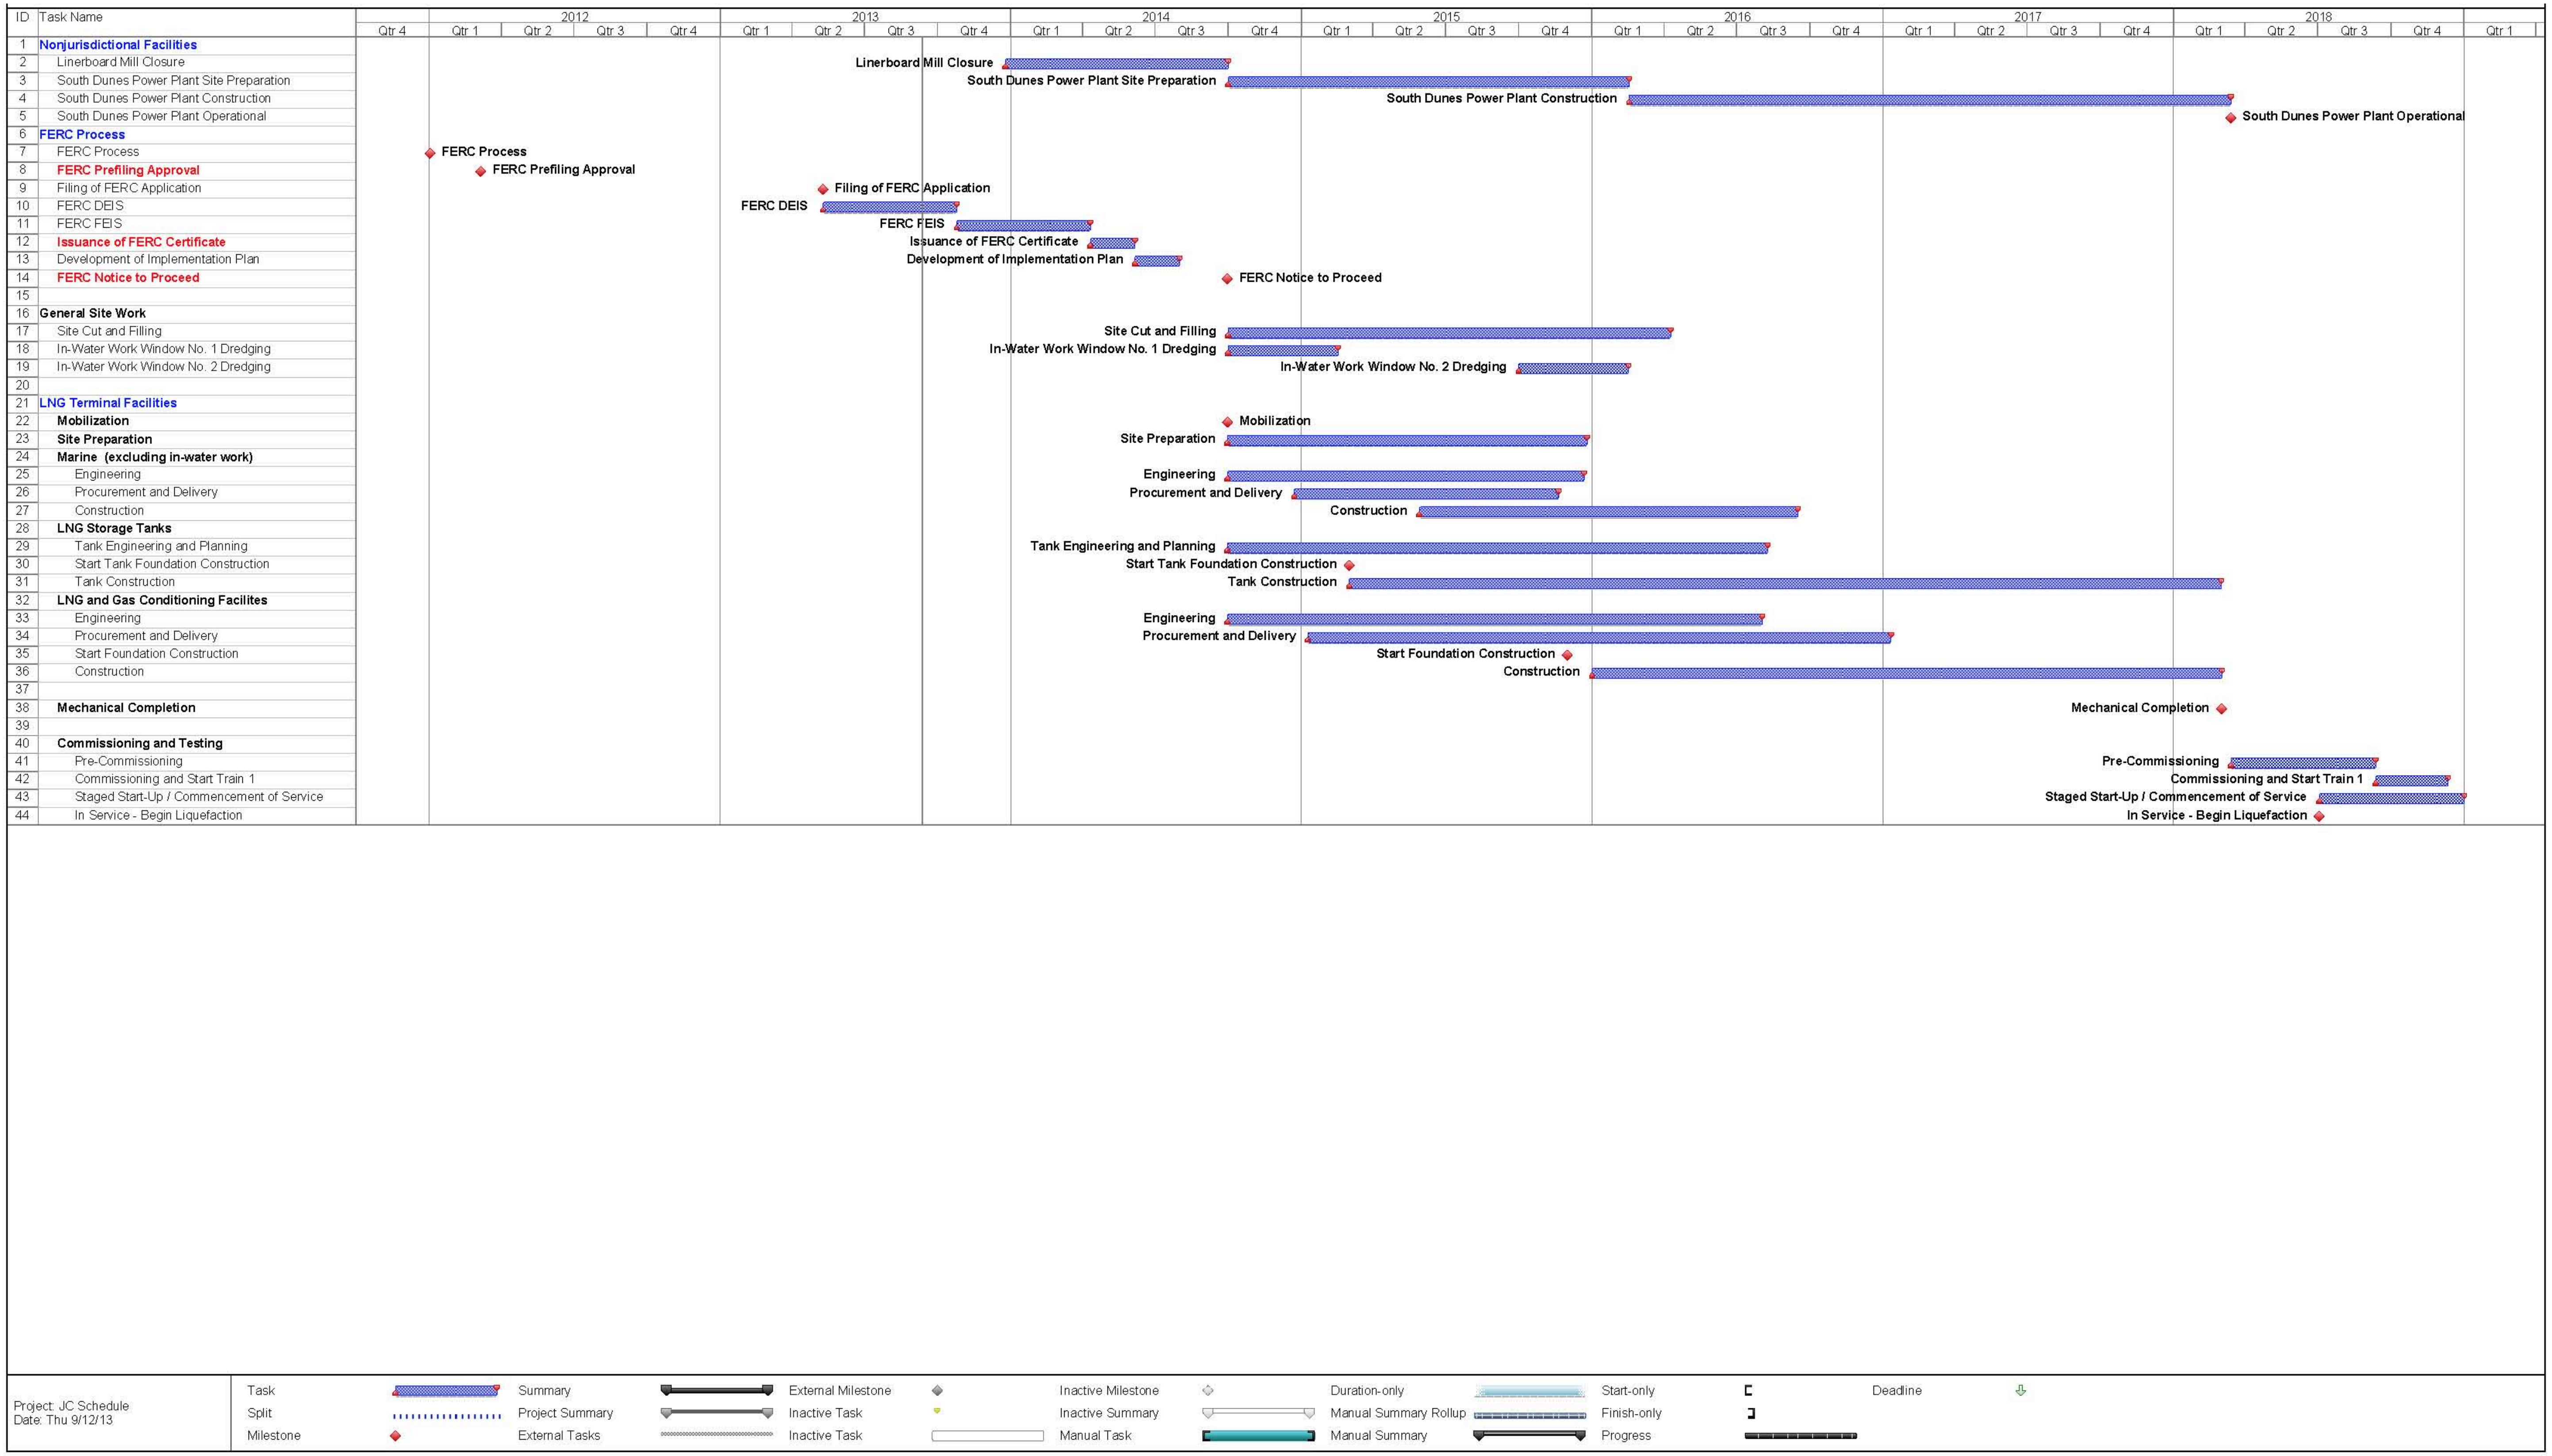

**Figure 3.2-2.** Schedule for LNG Terminal and Marine Facilities

During Project Year Two, the following activities would be conducted:

- Complete excavation of dredge pocket behind the berm, and hydraulically transport materials to power plant site;
- Complete installation of piles in the portion of the slip behind the berm;
- Construction of the LNG berth facilities;
- Complete final engineering design;
- Start foundation construction in liquefaction area;
- Start mechanical installations;
- Conduct additional dredging in the bay during the second in-water work window;
- Continue construction of the LNG storage tanks.

During Project Year Three, the following activities would be conducted:

- Complete structural foundations;
- Complete erecting buildings;
- Start electrical installations;
- Complete the berth and LNG loading facilities;
- Complete construction of LNG storage tanks;
- Continue construction of liquefaction facilities and gas processing.

During Project Year Four, the following activities would be conducted:

- Complete LNG storage tank construction;
- Commission and start Train 1;
- Staged Start-up and Commencement of Service; and
- Begin liquefaction.

All construction within Coos Bay would occur during the allowable in-water work window recommended by the ODFW (October 1 through February 15).

### 3.2.2 Pacific Connector Pipeline Facilities

Pacific Connector anticipates starting construction on the Pacific Connector pipeline in Project Year Two and continuing through Project Year Three. Restoration of construction disturbance is expected to begin in the fall of Project Year Three and be completed by the end of the winter season in the early part of Project Year Four when forest, wetland, and riparian revegetation – trees and shrubs – would be planted. Depending on site-specific conditions, it may be necessary to continue restoration and revegetation through spring of Project Year Four.

During the first year of pipeline construction (Project Year Two or BA Year 3), Pacific Connector plans to conduct the HDDs at the Coos, Rogue and Klamath Rivers and the Direct Pipe method at the first South Umpqua River crossing to allow sufficient time to pursue permits for alternate crossing locations or methods in the unlikely event the proposed HDDs/DP are unsuccessful. An alternate crossing method or an HDD at an alternate location would then be completed in the second year of pipeline construction (Project Year Three or BA Year 4) during mainline construction, if the original HDD/DP could not be completed in Project Year Two. Also in Project Year Two, Pacific Connector plans to clear forest along the pipeline route to minimize overall construction workspace requirements. Additionally, Pacific Connector anticipates starting pipeline construction in Project Year Two for: 1) the Coos Bay water route segment (MPs 1.7R to 4.1R) to allow pipeline installation to occur during the recommended in-water work period established by ODFW; 2) portions of the Klamath Basin (MPs 188 to 228) to minimize agriculture impacts and to allow the crossing of most irrigation canals when they are dry; 3) areas identified during biological surveys to have MAMU presence or occupied stands and/or NSO activity to minimize disturbance to those federally-listed species, except where identified in sections 4.3.3 and 4.3.4 of this BA; and 4) some areas of severe slopes.

Pacific Connector intends to construct the pipeline using five geographic spreads as previously mentioned. The construction spreads would include all timber clearing, construction, and restoration activities within a specific milepost range along the pipeline. The location of each construction spread is provided in table 3.2.2-1.

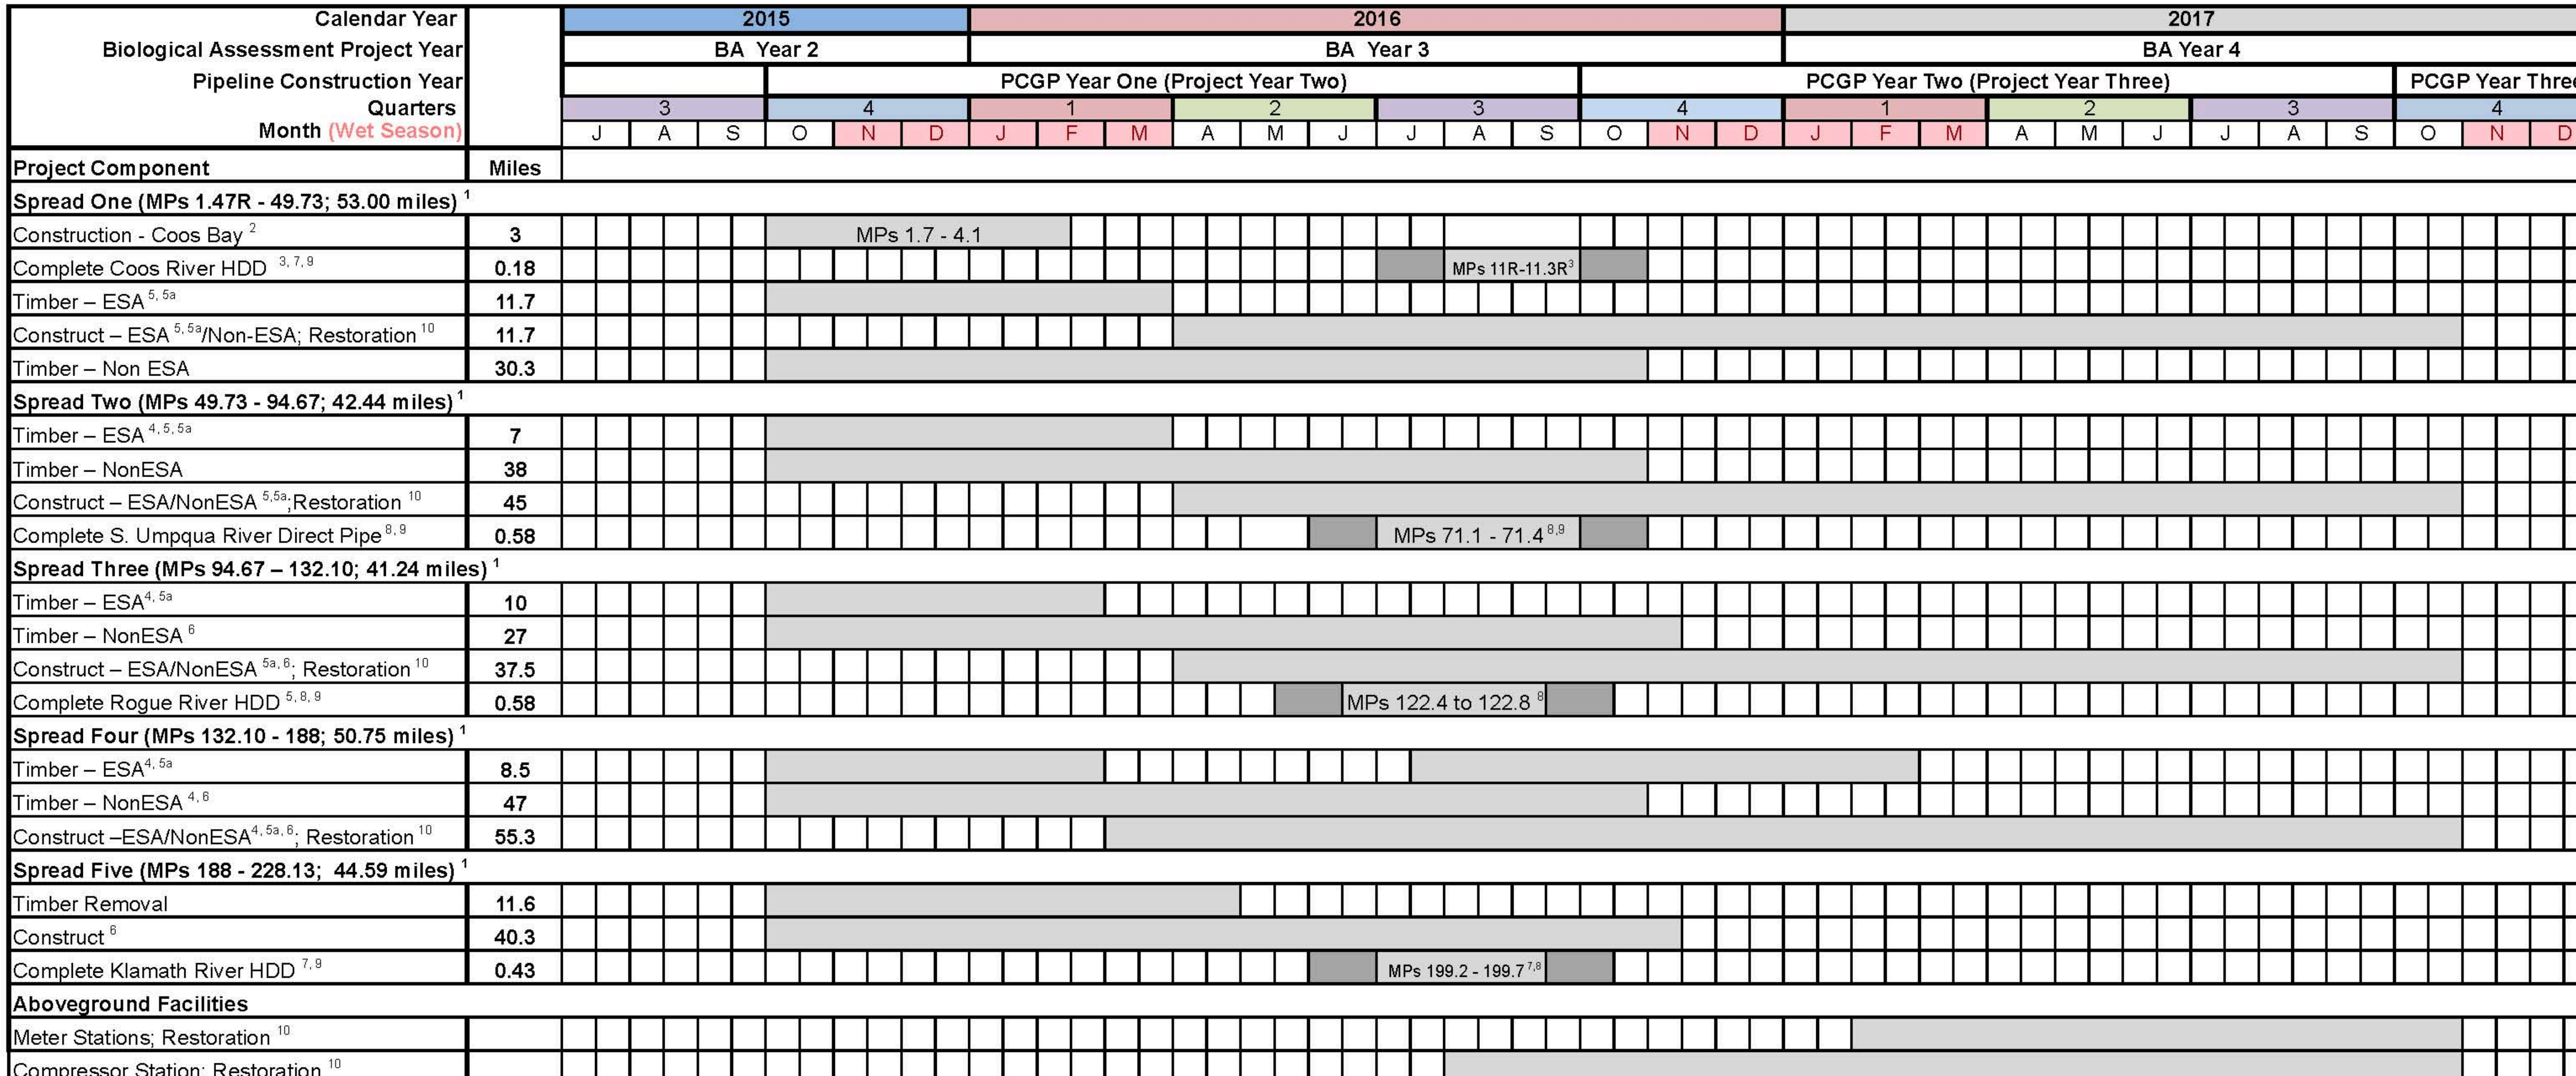
TABLE 3.2.2-1

**Pacific Connector Pipeline Construction Spread Locations**

| Spread | Milepost Range [1] | Length (miles) a/ |
|---|---|---|
| 1 | 1.47R to 49.73 | 53.00 |
| 2 | 49.73 to 94.67 | 42.44 |
| 3 | 94.67 to 132.10 | 41.24 |
| 4 | 132.10 to 188.00 | 50.75 |
| 5 | 188.00 to 228.13 | 44.59 |

a/ Mileposts remain the same (through the use of equations), although reroutes have been incorporated into the alignment and the actual spread lengths have been adjusted.

A schedule has been developed for each spread for Project Years Two, Three, and Four (PCGP Years One and Two), taking into consideration seasonal construction constraints (timing windows) stipulated to protect biological resources (NSO, MAMU, in-stream construction/fisheries, and big game wintering habitats). The schedule allows for reasonable time requirements to remove timber and construct the Pacific Connector pipeline to reduce potential environmental impacts and construction safety risks associated with winter construction. If stipulated timing windows for two or more resources conflict with each other or cannot be considered for environmental and safety reasons, efforts have been taken to reduce the seasonal constraints near the ends of recommended in-stream construction windows (ODFW 2000a) and/or NSO and MAMU breeding seasons. Except where noted below, construction across waterbodies would occur within the ODFW-recommended in-stream construction timing windows, although the majority of bridges, where required, would be installed prior to and removed after the in-stream timing window. General timing of activities for each of the five construction spreads is discussed below and shown schematically in figure 3.2-3. A more comprehensive Project description specific to each listed species is included below in section 4.0 of this BA.



[1] Because of the various reroutes incorporated into the Proposed Project alignment and the incorporation of engineering station equations, milepost ranges cannot be subtracted to calculate the spread length.

[2] Construction within ODFW-recommended in-water work window (October 1 through February 15).

[3] ODFW-recommended in-water work window is from October 1 through February 15. Because of the extensive wetland location on the south side of the Coos River, Pacific Connector has scheduled the HDD during the dry season outside the in-water work window between August 1 and September 30 to minimize surface impacts within the saturated floodplain wetland.

[4] This segment of pipeline may require helicopter use for timber removal and pipeline construction.

[5] Timber clearing is scheduled to be completed between 9/16 and 3/31 within 300 feet of marbled murrelet (MAMU) stands; construction within 0.25 mile of MAMU stands is scheduled to adhere to daily timing restrictions (DTRs) from April 1 through August 5.

[5a] Timber clearing is scheduled to be completed between 10/1 and 2/28 within 0.25 mile of northern spotted owl (NSO) nests; construction within 0.25 mile of NSO nests is scheduled not to occur between March 1 and July 15.

[6] Within designated big game range, timber removal and construction is scheduled to be conducted between May 1 through November 15.

[7] ODFW-recommended in-water construction window is July 1 through January 31; construction would precede the window by 1 to 2 weeks based on ODFW input.

[8] Construction is aligned, to the extent feasible based on drilling requirements and interagency discussions, with the ODFW-recommended fish windows, which are July 1 through August 31 for the South Umpqua River and June 15 through August 31 for the Rogue River.

[9] For all HDDs and Direct Pipe, upland rig-up and preparation can occur outside the fish window (dark shaded area). Actual drilling under waterbody is denoted by lighter shading. Frac-out risk is highest during initial drilling period; the risk becomes lower as drilling operations proceed and is lowest during pipe pullback. The schedules presented anticipate a reasonable drilling schedule (shown in lighter gray) without major delays due to potential issues such as stuck drill or reaming tools or pipe installation problems. If such issues create delay, the HDD duration, actual drilling, and pipe installation, as denoted by the lighter gray duration periods in the schedule, could extend into the darker gray durations at the end of the HDD/DP or beyond.

[10] Restoration is expected to begin in the fall of Year Two and be completed by the end of the winter season the following year when the forest, wetland, and riparian plantings would be completed.

**Figure 3.2-3.** General Construction Schedule for the Pacific Connector Pipeline

#### 3.2.2.1 Construction Spread One (MPs 1.47R to 49.73)

Pacific Connector considered the following biological concerns when determining the schedule for construction of Spread One:

- Coos Bay/Haynes Inlet crossing October 1 to February 15 (ODFW work window);
- Coos River HDD August 1 to September 30 (ODFW work window is October 1 to February 15, but crossing is scheduled during dry portion of the year due to the extensive wetland on the south side of the river);
- All other perennial/intermittent waterbody crossings July 1 to September 15 (ODFW work window);
- Possible bald eagle nest near MPs 4.4 to 4.9 - Pacific Connector would not construct within 0.25 mile of the nest if it is occupied during the breeding season between January 1 and August 31.
- Timber removal October 1 through February 28 [0.25 mile from NSO nests]/March 31 [300 feet from MAMU stands] – Project Year Two and Year Three.

#### 3.2.2.2 Construction Spread Two (MPs 49.73 to 94.67)

Pacific Connector considered the following biological concerns when determining the schedule for construction of Spread Two:

- South Umpqua River (MP 71.3) Direct Pipe crossing July 1 to September 30 (ODFW work window is July 1 to August 31);
- All other perennial/intermittent waterbody crossings July 1 to September 15 (ODFW work window);
- Timber removal October 1 through February 28 [0.25 mile from NSO nests]/March 31 [300 feet from MAMU stands] – Project Year Two and Year Three.

#### 3.2.2.3 Construction Spread Three (MPs 94.67 to 132.10)

Pacific Connector considered the following biological concerns when determining the schedule for construction of Spread Three:

- South Umpqua River (MP 94.7) Diverted Open Cut crossing July 1 to August 31 (ODFW work window);
- Rogue River HDD June 15 to September 15 (ODFW work window is June 15 to August 31);
- Perennial/intermittent waterbody crossings between MPs 94.85 and 110.98 July 1 to September 15 (ODFW work window);
- All other perennial/intermittent waterbody crossings June 15 to September 15 (ODFW work window);
- Timber removal October 1 through February 28 [0.25 mile from NSO nests] – Project Year Two and Year Three;
- A 1.5-mile-recommended no disturbance buffer from February 1 through August 31 of a known and productive peregrine falcon nest located on Umpqua National Forest.
- Timber removal and construction within designated big game range May 1 to November 15 unless within a 0.25 mile of an NSO activity center.

#### 3.2.2.4 Construction Spread Four (MPs 132.10 to 188.00)

Pacific Connector considered the following biological concerns when determining the schedule for construction of Spread Four:

- Perennial/intermittent waterbody crossings between MPs 132.10 and 166.21 June 15 to September 15 (ODFW work window);
- Perennial/intermittent waterbody crossings between MPs 166.21 and 177.76 August 1 to September 30 (ODFW work window);
- All other perennial/intermittent waterbody crossings July 1 to January 31 (ODFW work window);
- Timber removal October 1 through February 28 [0.25 mile from NSO nests] – Project Year Two and Year Three;
- Timber removal and construction within designated big game range May 1 to November 15 unless within a 0.25 mile of an NSO activity center.

#### 3.2.2.5 Construction Spread Five (MPs 188.00 to 228.13)

Pacific Connector considered the following biological concerns when determining the schedule for construction of Spread Five:

- Klamath River HDD July 15 to September 15 (ODFW work window is July 15 to January 31);
- Perennial/intermittent waterbody crossings between MPs 188.0 and 199.38 July 1 to January 31 (ODFW work window);
- Bureau of Reclamation features October 15 to March 15;
- Irrigation canals/ditches during the winter/non-irrigation season;
- All other perennial/intermittent waterbody crossings July 1 to March 31 (ODFW work window);
- Timber removal and construction within designated big game range May 1 to November 15.

## 3.3 PROPOSED CONSERVATION MEASURES

### 3.3.1 Proposed Conservation Plan

The applicants have developed a program of conservation measures for the Project that they believe would mitigate adverse impacts to proposed or listed species and their habitats, including proposed or designated critical habitats. Each of the applicants' proposed conservation measures has been categorized into one of five "mitigation" applications, described by the CEQ (43 FR 55990 §1508.20, 1978):

1. Avoiding the impact altogether by not taking a certain action or parts of an action;
2. Minimizing impacts by limiting the degree or magnitude of the action and its implementation;
3. Rectifying the impact by repairing, rehabilitating, or restoring the affected environment;
4. Reducing or eliminating the impact over time by preservation and maintenance operations during the life of the action; or

5. Compensating for the impact by replacing or providing substitute resources or environments.

The goal of the proposed conservation measures is to compensate for unavoidable impacts to listed species and their habitats, intended to improve the status of the species within the context of their listing or proposal for listing under the ESA. The Proponents recognize that two factors will be key to achieving that goal – the same factors that FWS and NMFS would consider when evaluating conservation efforts in decisions whether or not to list species under ESA (FWS and NMFS, 2003). Those two factors include 1) some level of certainty that the conservation measure (or effort) will be implemented, and 2) some level of certainty that the conservation measure (or effort) will be effective.

In general, mitigation or conservation efforts (measures) that avoid impact to proposed and/or listed species and critical habitats have been developed by all Proponents during project design. Measures that minimize impact will be primarily applied on-site at the time of project construction while conservation measures that rectify impact by repair, rehabilitation, or restoration and those that involve impact reduction (by preservation and/or maintenance) are planned for implementation immediately after construction and final site preparation prior to restoration being completed. Compensatory mitigation will be implemented after approval and/or initiation of the project.

The effectiveness of individual conservation measures in improving the status of listed species will be difficult to predict. However, many of the conservation measures can be classified as "best management practices" that have been published by FERC in its *Upland Erosion Control, Revegetation, and Maintenance Plan* and *Wetland and Waterbody Construction and Mitigation Procedures* and are the current standards applied by the natural gas pipeline industry. FERC's BMPs have been subject to the public scoping process with extensive review by the pipeline industry, knowledgeable public, and state and federal regulators nationwide. Reference to a specific section in FERC's Plan and/or Procedures is made in the following sections when relevant to an individual conservation measure.

Other agencies with jurisdictions affected by the Project (BLM and Forest Service) also have BMPs within their respective land management plans that have been promulgated to conserve the natural resources under their authority. However, those agencies' BMPs, by necessity, are more general than FERC's BMPs because they apply to a wide variety of actions, not specifically to pipeline construction.

The Mitigation Policy developed by FWS (1981) specifically excluded any application to listed threatened or endangered species or their critical habitats. Nonetheless, FWS specifically stated that the most desirable sequence of mitigation begins with avoidance, with minimization as the next preferred, then followed by restoration and reduction of impact, and finally compensation. Considering compensatory mitigation in *Guidance for the Establishment, Use, and Operation of Conservation Banks*, FWS (2003a) emphasized that "off-site conservation banks may be the only mitigation option when on-site conservation measures are not practicable for a project or when the use of the bank is environmentally preferable to on-site measures" (FWS, 2003, page 1).

ODFW (2005a) has likewise prioritized impact mitigation actions in the following order: 1) avoid the impact, 2) minimize the impact, 3) repair, rehabilitate or restore the affected area, and 4) replace or provide comparable habitats.

### 3.3.1.1 Avoiding Impact

In CEQ's definition of mitigation by avoidance, an impact does not occur because the action or parts of the action do not occur. Implied in that definition is some knowledge about the action that otherwise would have occurred and analysis of effects to the potentially impacted resource. No such analyses have been conducted for the instances where impacts have been avoided by one or more Project components.

No federally listed species were identified in the upland portions of Jordan Cove's proposed LNG terminal. However, there are federally-listed fish species in Coos Bay that may be affected by proposed dredging for the access channel and slip, and by LNG carrier cooling water and discharges of ballast water. Those acquatic species, impacts, and mitigation are discussed elsewhere in this BA.

Jordan Cove would avoid direct impacts on western snowy plovers and their designated critical habitat since all material excavated and dredged from the slip will be placed at the South Dunes Power Plant site which is not utilized for nesting by snowy plovers. Since all the material to be excavated and dredged from the slip can be used in the development of the South Dunes Power Plant site, other disposal or placement alternatives were dismissed as not being environmentally preferable because use of those sites had the potential for adverse impacts on snowy plover habitat on the North Spit.

Similarly, Pacific Connector would avoid direct impacts on some federally listed species by how it designed the route for its pipeline at specific locations (see Appendix V). Some of the locations are listed below:

- MP 11.13R – HDD under the Coos River avoids direct impacts on Coho salmon;
- MPs 29.8 to 30.1 – route avoids MAMU habitat and an occupied stands;
- MPs 51.5 to 52.1 – route avoids MAMU stands;
- MPs 57.8 to 57.9 – route avoids population of Kincaide's lupine;
- MPs 110.2 to 110.4 – route avoids NSO nest patches;
- MP 122.6 – HDD under the Rogue River avoids direct impacts on Coho salmon;
- MPs 161.2 to 161.4 – route avoids NSO nest patch;
- MPs 195.4 to 196.5 – route avoids population of Applegate milk vetch; and
- MP 199.4 – HDD under Klamath River avoids direct impacts on Lost River and shortnose suckers.

Pacific Connector would be able to avoid impacts on specific populations and critical habitat for vernal pool fairy shrimp, large-flowered woolly meadowfoam, and Cook's lomatium within the Burril Lumber and Medford Industrial Park proposed contractor/pipe storage yards (Jackson County) by not using portions of those yards which contain individuals or habitat.

### 3.3.1.2 Minimizing Impact

In CEQ's definition of mitigation by minimization, impact occurs, but effects (magnitude of impacts) are limited by different means, including 1) design of the proposed action and its components, and 2) application of specific conservation measures (including BMPs) during implementation of the proposed action that minimize impact. Many of the conservation measures associated with the proposed Project that would reduce impacts on federally listed species can be classified as BMPs. These BMPs have been incorporated into Jordan Cove's Plan and Procedures and Pacific Connector's ECRP. The project-specific applicant-prepared plans and procedures and ECRP are based upon the FERC staff's Plan and Procedures, which are the current standards applied by the natural gas pipeline industry. The FERC staff's Plan and Procedures have been subject to public scrutiny for many years, including extensive review by state and federal resource agencies and/or regulators nationwide. Reference to a specific section in the FERC staff's Plan and/or Procedures is made in the following sections when relevant to an individual conservation measure.

Other agencies with jurisdictions affected by the Project (BLM, USFS, and Reclamation) also have BMPs within their respective land management plans that have been promulgated to conserve the natural resources under their authority. However, those agencies' BMPs, by necessity, are more general than the FERC staff's Plan and Procedures because they apply to a wide variety of actions, not specifically to pipeline construction.

Jordan Cove has also developed a plan to reduce the chance for LNG carriers to collide with federally listed marine mammals and sea turtles within the EEZ. Jordan Cove would request all LNG carriers calling on the LNG terminal to reduce speeds to 10 knots or less within 30 nautical miles of the entrance to Coos Bay during the whale migratory period. During the 96-hour pre-notification process to be followed by all LNG carriers calling on the terminal, Jordan Cove would check with the NMFS for information on the migratory patterns of whales within the route of the LNG carrier and would inform the ship's master of the patterns reported by NMFS. Jordan Cove would request that all LNG carrier operators consult current whale sighting information prior to calling on the LNG terminal and be aware of the reported locations of whales and plan their operations accordingly. LNG carriers would be requested to route around and maintain a 100-yard distance from the whales observed and to avoid crossing in front of the whales and maintain a parallel route, if possible.

Jordan Cove would provide a ship strike avoidance measures package to shippers exporting LNG cargo from the Jordan Cove LNG terminal. This package would include the measures proposed by NMFS for avoidance of marine mammals to further reduce the likelihood of adverse effects on these species. Some of the suggested measures include the following:

- Provide training to LNG carrier crews, including the use of a reference guide such as the Marine Mammals of the Pacific Northwest, including Oregon, Washington, British Columbia and South Alaska by Pieter Folkens. This is a pamphlet that would be provided to LNG carriers calling on the terminal and would be included as part of the terminal use agreement to the shippers.
- Provide a copy of the NMFS CD-rom-based training program entitled A Prudent Mariner's Guide to Right Whale Protection as part of a ship strike avoidance measures package to all LNG carriers calling on the terminal. While this CD-rom-based training program is specific to right whales, NMFS has stated that the guidance and avoidance measures are also applicable to fin, humpback, and sperm whales.
- Require LNG carrier crews to maintain a watch for marine mammals and slow the ship to 10 knots or less to avoid striking protected species.

- When whales are sighted, maintain a distance of 90 meters (or 100 yards) or greater from the whale.
- Attempt to maintain a parallel course to the animal and avoid excessive speed or abrupt changes in direction until the animal has left the area.
- Reduce ship speed to 10 knots or less when pods or large assemblages of cetaceans are observed near an underway ship.
- When whales are sighted in a ship's path or in proximity to a moving ship, reduce speed to 10 knots or less or shift the engine to neutral until whales are clear of the area or path of the ship.

LNG carrier crews would be asked to report sightings of any injured or dead protected species immediately, regardless of whether the injury or death is caused by the ship. If the injury or death is caused by collision with the ship, appropriate regulatory agencies (FERC or NMFS) would be notified within 24 hours of the incident. Information to be provided would include the date and location (latitude/longitude) of the strike, the ship name, the species or a description of the animal, if possible.

LNG carrier masters would be requested to provide reports of sightings of marine mammal while in the EEZ action area and to provide the report upon docking at the LNG terminal. This reporting request would be included in the Ship Strike Avoidance Measures Package provided to each LNG carrier calling on the terminal and compliance with the measures and the reporting would be included in all terminal service agreements with shippers.

Conservation measures that have been proposed to minimize impacts during construction and operation are provided in table 2A in Appendix N for the marine facilities, in table 2B in Appendix N for the Jordan Cove LNG Terminal, and in table 2C in appendix N for the Pacific Connector pipeline. The diverse array of conservation measures provided in those tables has been organized along several hierarchal categories that have been formulated to provide for focus and evaluation of how each measure would contribute to minimizing impact. First, project locations have been included where each measure is most likely to be applied. In all but a few instances, locations are broadly identified (for example, waterbodies crossed or the construction right-of-way along the Pacific Connector pipeline route) because measures are likely to be applied in all or most of those locations.

In each of the three tables in Appendix N, multiple conservation measures may apply to the same resource. Resources have also been broadly identified by relevance to proposed and listed species and their habitats overall, not just proposed or designated critical habitats. As examples, "water quality" and "soils" are resources relevant to aquatic and terrestrial species in very broad terms, whereas the resource identified as "EFH-pelagic, groundfish, salmon, other fish and invertebrate species" is specific to those species within the Coos Bay estuary while "EFH-freshwater salmon, fisheries and aquatic resources" applies to species in fresh waterbodies affected by pipeline construction.

In many instances, while multiple conservation measures apply to the same general location and same general resource, specific conservation measures are likely to minimize impact to the resource differently, depending on how the impact potentially affects the resource. To account for the different ways that conservation measures are likely to minimize impact, impact pathways have been schematically described to further categorize the potential utility of each measure. To illustrate, Jordan Cove (table 2A in Appendix N) has proposed to install all piles while the slip is isolated from the bay. That measure virtually eliminates impact along the following schematic pathway in which arrows indicate likely cause-and-effect relationship: "acoustic shock → physiological damage, displacement from habitat → mortality of fish and other aquatic species." That conservation measure and pathway apply to the "EFH-pelagic, groundfish, salmon, other fish and invertebrate species" resource.

Jordan Cove would reduce impacts on western snowy plovers through implementation of 1) BMPs and 2) education and outreach programs. During construction of the LNG terminal, the facility would be kept clear of debris and food wastes that could attract snowy plover predators. Covered, animal-proof receptacles would be provided in eating and break areas, parking lots, and at appropriate locations around the construction site. The site would be policed on a daily basis during construction to remove any food or other debris left by workers.

Jordan Cove would train all construction and operations staff on the need for snowy plover conservation; current snowy plover regulations and recreational use restrictions; and the importance of conservation measures, including: litter control, avoidance of nesting and foraging areas, keeping pets on-leash, and remaining on established roads and trails. The training program would be developed based on guidance provided in Appendix K of the 2007 Plover Recovery Plan, or would be contracted for through state/local agencies or organizations (such as the Oregon Coast Aquarium, National Park Service, Western Snowy Plover Working Team, or Oregon Coast Community College) who may have pre-existing plover education and outreach programs. Prior to implementation, the training program would be submitted for comment to members of the Western Snowy Plover Working Team.

The training would be administered concurrently with safety training provided to all staff at the beginning of their employment. Environmental training would also be provided to operational personnel, to ensure that all personnel are aware of and comply with the management tools in place to affect the recovery and maintenance of the snowy plover population on the North Spit. Printed educational materials would be posted at the proposed facilities for the life of the LNG terminal. The types of educational materials may vary, but could include posters, table tents, maps, brochures, or fact sheets. Numerous sources for existing educational materials are provided in Appendix K of the Plover Recovery Plan (FWS, 2007c).

Some examples of conservation measures for Pacific Connector's pipeline include modifications incorporated into the proposed route that would reduce impacts on some federally listed species. In general, these route or TEWA modifications reduced the amount of old growth forest that would need to be cleared at specific locations, thus reducing impacts on species that inhabit that forest. In some cases, the proposed pipeline route or TEWA was moved to locations where the forest was previously harvested, or the pipeline was co-located with an existing right-of-way. Places where the pipeline route was modified or TEWAs changed to reduce impacts are detailed in Appendix V:

Pacific Connector can also reduce impacts on federally listed species through the timing and duration of construction activities. For example, all waterbodies would be crossed during the ODFW recommended in-water work windows, thus minimizing impacts on federally listed fish species. Similarly, impacts on MAMU can be minimized if tree clearing activities within

MAMU nesting habitats are conducted between September 16 and March 31, outside of the MAMU critical breeding period that lasts from April 1 through August 5.

#### 3.3.1.3 Restoration and Monitoring

CEQ distinguished between mitigation of impact by repairing, rehabilitating, or restoring the affected environment (restoration), and reducing or eliminating the impact over time by preservation and maintenance operations during the life of the action (reduction). In practice, these two approaches are often combined or the distinction between the two approaches becomes blurred.

Restoration of the affected environment is a key element of the FERC staff's Procedures for affected waterbodies (Section V.C.1-8) and wetlands (Section VI.C.1-7). The FERC staff's Procedures also require monitoring for restoration success (Section VI.D.3 and 4) as follows:

- Monitor and record the success of wetland revegetation annually for the first 3 years after construction or until wetland revegetation is successful. At the end of 3 years after construction, file a report with the Secretary identifying the status of the wetland revegetation efforts. Include the percent cover achieved and problem areas (weed invasion issues, poor revegetation, etc.). Continue to file a report annually until wetland revegetation is successful.
- Wetland revegetation shall be considered successful if the cover of herbaceous and/or woody species is at least 80 percent of the type, density, and distribution of the vegetation in adjacent wetland areas that were not disturbed by construction. If revegetation is not successful at the end of 3 years, develop and implement (in consultation with a professional wetland ecologist) a remedial revegetation plan to actively revegetate the wetland. Continue revegetation efforts until wetland revegetation is successful.

Likewise, Section VII in the FERC staff's Plan specifies the following monitoring requirements (Section VII.A):

1. Conduct follow-up inspections of all disturbed areas after the first and second growing seasons to determine the success of revegetation.
2. Revegetation in non-agricultural areas shall be considered successful if upon visual survey the density and cover of non-nuisance vegetation are similar in density and cover to adjacent undisturbed lands. In agricultural area, revegetation shall be considered successful if crop yields are similar to adjacent undisturbed portions of the same field.
3. Continue revegetation efforts until revegetation is successful.
4. Monitor and correct problems with drainage and irrigation systems resulting from pipeline construction in active agricultural areas until restoration is successful.
5. Restoration shall be considered successful if the right-of-way surface condition is similar to adjacent undisturbed lands, construction debris is removed (unless requested otherwise by the landowner or land managing agency), revegetation is successful, and proper drainage has been restored.

Reporting requirements (the FERC staff's Plan Section VII.B) include:

1. The project sponsor shall maintain records that identify by milepost:

    a. method of application, application rate, and type of fertilizer, pH modifying agent, seed, and mulch used;
    b. acreage treated;
    c. dates of backfilling and seeding;
    d. names of landowners requesting special seeding treatment and a description of the follow-up actions; and
    e. any problem areas and how they were addressed.
2. The project sponsor shall file with the Secretary quarterly activity reports documenting problems, including those identified by the landowner, and corrective actions taken for at least 2 years following construction.

These FERC requirements form the basis for Project monitoring and response to less-than-satisfactory restoration progress.

Conservation measures that have been proposed to rectify, repair, and rehabilitate the affected environment or reduce and eliminate impacts after construction are provided in table 3A in Appendix N for the Jordan Cove Terminal and Marine Facilities and in table 3C in Appendix N for the Pacific Connector pipeline. Conservation measures provided in those tables have been organized by the same hierarchal categories that were described above for tables 2A, 2B, and 2C in Appendix N. As before, Project locations have been included where each measure is most likely to be applied. Also, resources have also been broadly identified by relevance to proposed and listed species and their habitats overall. And, impact pathways have been schematically described to further categorize the potential utility of each measure as they were in tables 2A, 2B, and 2C in Appendix N.

During operation of its proposed LNG terminal, Jordan Cove would conduct the following monitoring activities to reduce impacts on western snowy plovers. The facility and grounds would be regularly inspected to assure that no garbage is allowed to accumulate. Structures associated with the LNG terminal and the LNG loading berth would be monitored to discourage use by avian predator species. Frequent inspections would ensure that nests are not being constructed and all nests found would be removed immediately. It is anticipated that there would be sufficient inspections and other activities mandated by safety and security requirements to keep the structures nest free. However, in the unlikely event that a nest becomes established and it is not discovered until young birds are present, the disposition of the nest would be handled in accordance with the provisions of the Migratory Bird Treaty Act.

In the event that a clearly demonstrable and sustained decrease in snowy plover productivity is detected by the ongoing ORNHIC monitoring, Jordan Cove would coordinate with ORNHIC, BLM, OPRD, Wildlife Services, ODFW, FWS and other interested parties to identify adaptive management strategies, as appropriate, to help reverse any such trend.

In the case of the Kincaid's lupine, a federally listed plant, as part of its conservation measures, Pacific Connector has recommended the translocation and replanting of individuals that cannot be avoided during pipeline construction. Pacific Connector proposes that locations for these species be monitored for three years following replanting, to check for germination and successful establishment of the plantings. Pacific Connector has suggested that monitoring should be conducted by a third-party botanical contractor with appropriate credentials to perform the monitoring. Monitoring reports would be provided to FWS, NMFS, FERC and other relevant agencies that request copies of the reports.

### 3.3.2 Compensatory Mitigation Program

Impacts and effects that cannot be otherwise mitigated would be primarily addressed through the applicants' Compensatory Mitigation Plan (CMP) (see Appendix O). The overarching goal of the CMP is to compensate for unavoidable impacts to listed species and their habitats through substitute habitat and/or habitat stewardship.

The applicants have developed this BA in informal consultation and cooperation with FWS and the applicants remain committed to continue working cooperatively with FERC and FWS to refine the mitigation proposal associated with the BA. The CMP is considered a working document that would be revised throughout the ESA consultation process. The following sections are summaries of the compensatory mitigation proposed for each of the Project components.

#### 3.3.2.1 LNG Terminal Components

There are no threatened or endangered species that would be directly affected by the construction of the upland portion of the slip or by construction or operation of the LNG terminal. Operation of the slip (berthing and unloading of LNG carriers) could have some potential direct effects on marine ESA species that make their way into the slip over time. Transit of the LNG carriers could result in potential effects to marine organisms and marine mammals, birds, and reptiles through accidental contact with the ships.

There are potential indirect effects associated with the conversion or removal of upland habitat, placement of dredged materials, and offsite construction worker effects that would be minimized by management practices and oversight of construction activities and personnel. Compensatory mitigation is proposed for those species, such as the snowy plover, where management practices alone may not be sufficient to avoid potentially adverse effects (see section 4.3.3.3 of this BA).

The natural habitats that would be affected most heavily by the construction of the slip and access channel are open-water habitat, and dune forest, with lesser impacts to shoreline habitat. The relatively natural habitat that would be affected most by construction of the upland portions of Jordan Cove's terminal is dune forest, with lesser impacts to grasslands and herbaceous associations. The mitigation strategy that has been proposed for the upland habitat affected by the slip and LNG terminal involves the restoration/enhancement of approximately 48 additional acres in the proposed mitigation area for intertidal habitat.

The approximately 37 acres of upland ODFW Habitat Category 4 affected by the construction of the slip would be converted to approximately 37 acres of open water Habitat Category 5 following construction. The 3.9 acres of the intertidal unvegetated sand-mud flat (Habitat Category 4), the 4.2 acres of intertidal algal flat (Habitat Category 4), and 2.48 acres of eelgrass (Habitat Category 3) affected by the construction of the slip would be mitigated by Jordan Cove (see Attachment 9 to Appendix O).

To mitigate for loss of intertidal unvegetated sand-mud flats and algal flat, Jordan Cove proposes to create new wetlands at a former golf course adjacent the south bank of Kentuck Slough.

Approximately 35 acres disturbed by the construction and operation of the golf course would be restored to a mud-flat condition by re-establishing tidal connections with Kentuck Inlet. This would be accomplished through the removal of tidegates and dikes.

Restoration effort at the Kentuck Slough mitigation site would result in some impacts; however, they would be temporary short term impacts as they would be limited in scope and would only exist during the actual restoration process. Potential impacts include a temporary reduction in water quality due to an increase in sedimentation during dike/tidegate removal, temporary disturbances to adjacent wildlife, and a temporary impact to vegetation removed during restoration activities. As the site is currently utilized as a golf course, these impacts would be less than significant.

To mitigate for impacts on eelgrass, Jordan Cove proposes to create new eelgrass habitat at a shallow unvegetated island approximately 900 feet southwest of the Coos-Bay North Bend Airport runway. This site is adjacent to a successful eelgrass restoration site owned by the State of Oregon and managed by the ODSL. The 2-acre eelgrass mitigation site would be dredged/excavated to the appropriate elevation and then revegetated with eelgrass during summer months (the optimal time for eelgrass transplantation). The proposed success criteria for this eelgrass mitigation site would be the successful establishment of new eelgrass habitat. The COE, NMFS, and EPA have expressed concern regarding the mitigation ratio proposed.

Another element of the CMP for the JCE & PCGP Project is having the applicants fund various projects that would generally benefit species. Jordan Cove reviewed a list of mitigation measures provided by the FWS, BLM, USFS, and ODFW through the Sediment Placement subgroup of the Interagency Task Force and agreed to provide funding as enumerated below. The funding would be provided to the entity as defined by the agencies and it would be the responsibility of the particular entity to administer the funding. Jordan Cove is also requesting that the funding of these conservation measures be used in part to contribute to other habitat mitigation requirements imposed by the ODFW.

Year 1 (when construction begins) – provide $60,000 for:

- fencing (~$30,000)
- signage
- application of shell hash
- tree removal
- one year of maintenance – $10,000

Years 2 and 3 – provide $30,000 (each year) for:

- annual maintenance – $10,000
- beach grass elimination grant (minimum of $10,000)
- shell hash

Years 4 to 2020 – provide $10,000 for:

- annual maintenance

Jordan Cove would fund one additional entry-level wildlife services position dedicated to snowy plover predator monitoring and control during the 42-month construction period.  This staff member would be employed by Oregon Wildlife Services, which is administered by the U.S. Department of Agriculture and Animal and Plant Health Inspection Services.  The specific duties of this additional staff member would be determined by Wildlife Services based on Coos Bay North Spit management needs, but would concentrate on predator management.  This additional position would allow Wildlife Services to better evaluate predator densities and more quickly and effectively respond in the unlikely event that predator pressure on the CBNS increases during Project construction.

#### 3.3.2.2 Pacific Connector Pipeline Component

Appendix O provides Pacific Connector's draft compensatory mitigation plan for effects to ESA species and/or critical habitat as well as Pacific Connector's proposed compensatory mitigation for in-stream and riparian habitat modifications.

# 4.0 SPECIES ACCOUNTS, CRITICAL HABITAT, PROJECT EFFECTS, AND DETERMINATIONS OF EFFECT

This section describes the current status of the species and critical habitat (if applicable) analyzed in this BA. Information provided includes descriptions of species' range and/or critical habitat that may be affected by construction, operation, and maintenance activities of the LNG terminal, Port component, and pipeline and any information relevant to a species' current status.

As applicable, the *Endangered Species Consultation Handbook* (FWS and NMFS, 1998) was used for guidance to analyze the potential Project effects to plant and animal species listed under ESA, their proposed or designated critical habitats, and their recovery. Information on listed species' distributions, habitat requirements, and potential occurrence in the Project area and vicinity was gathered from many sources including 1) published scientific literature; 2) agencies' published and unpublished reports including proposed and final actions published by FWS and NMFS in the Federal Register; 3) agencies' unpublished raw and/or compiled data; 4) agencies' geo-spatial databases, which document species observations; 5) on-site surveys for species and habitats; and 6) personal communications with agency personnel knowledgeable about species ecological status in the Project area and vicinity.

## 4.1 INTRODUCTION

The following subsections describe how the species accounts, critical habitat, project effects, and determinations of effect were developed or determined for the species addressed in this section. Also included are rationales used to exclude four species that are listed or proposed for listing under ESA from consideration in this BA, based on the stepped procedure outlined in Section 4.1.1 which would conclude in a **no effect** determination for the species.

### 4.1.1 Determination of Effects

The FWS (1998) utilized a four-step dichotomous key to make one of the following determinations under the ESA: **No effect**, **Likely to adversely affect**, or **Not likely to adversely affect**. The key was used for evaluating bull trout, but is sufficiently general and rigorous to be used, with modification, to evaluate Project effects on the other listed species considered in this BA.

1) Is the proposed/listed species and/or proposed/designated critical habitat present in the Project area?

   NO - **No effect**.
   YES - Go to step 2.

2) Will the proposed action have any affect whatsoever on the species; designated or proposed critical habitat; seasonally or permanently occupied habitat; or unoccupied habitat necessary for the species' survival? (Any affect whatsoever includes small effects, effects that are unlikely to occur, and beneficial effects)

   NO - **No effect.**
   YES - May affect; Go to step 3.

3) Does the proposed action have potential to result in "take" of any proposed/listed species? ("Take" is defined as "to harass, harm, pursue, hunt, shoot, wound, trap,

capture, collect, or attempt to engage in any such conduct." "Harm" is further defined as "significant habitat modification or degradation that results in death or injury to listed species by significantly impairing behavioral patterns such as breeding, feeding, or sheltering", and "harass" as "actions that create the likelihood of injury to listed species to such an extent as to significantly disrupt normal behavior patterns which include, but are not limited to, breeding, feeding, or sheltering".)

NO - Go to step 4
YES - **Likely to adversely affect**.

4) Does the proposed action have potential to cause an adverse effect to any proposed/listed species' habitats, such as: adverse effects to critical habitat constituent elements or segments; impairing the suitability of seasonally or permanently occupied habitat; or impairing or degrading unoccupied habitat necessary for the survival of the species locally?

NO - **Not likely to adversely affect.**
YES - **Likely to adversely affect** (including adverse effects to critical habitat).

### 4.1.2 Determinations of No Effect

There are four species, listed or proposed for listing that occur within Oregon but would not be affected by the Proposed Action. Those species include the Canada lynx - Contiguous U.S. Distinct Population Segment, North American wolverine - proposed for listing, bull trout - Klamath River Distinct Population Segment, and yellow-billed cuckoo - Western Distinct Population Segment, proposed for listing. Brief synopses of the rationales to exclude the species from consideration in this BA are provided below.

Canada lynx. When FWS (2000a) listed Canada lynx as threatened in a final rule, Oregon was included in the species' range based on 12 verified lynx records (see McKelvey et al., 1999) in the state during the previous 100 years. The records (in museum collections) were from the 1800s and early 1900s including one in the U.S. National Museum from the east side of the Cascade Range at Fort Klamath (pre-1900) in Klamath County (Verts and Carraway, 1998). Recent lynx documented in the state were from Wallowa County (1964), Benton County (1974), and Harney County (1993), all in atypical habitats suggesting animals were dispersing from Canadian population centers (Verts and Carraway, 1998; McKelvey et al., 1999). Currently, northeast Oregon/southeast Washington is recognized as a peripheral area in the lynx recovery plan (FWS, 2005a) which could, sustain short-term survival during lynx dispersal. There appears to be an extremely remote chance of a lynx dispersing into southwest Oregon but that is not foreseeable during the construction of the Proposed Action and Canada lynx are not considered in this BA.

North American wolverine. The FWS (2013a) proposed listing the North American wolverine subspecies (*Gulo gulo luscus*) under the ESA. Wolverines in the Sierra Nevada and North Cascades Range are separated by an area in southern Oregon and northern California where there are no historic records of the species. The distribution of wolverines in this area is probably of two disjunct populations, separated for 2000 years prior to the extirpation of the Sierra Nevada population (FWS, 2013a). Currently, there is a small population in the Northern Cascades, sustained by colonizing individuals from Canada. The California wolverine subspecies (*Gulo gulo luteus*) was an Oregon state-threatened species although the subspecies designation is in question (Stone, 2007). One male wolverine recently immigrated to the Sierra Nevada and apparently still survives (FWS, 2013a). Wolverines were thought to have been extirpated in Oregon but since 1965 wolverines have been found in Linn County, on Steens Mountain in Harney County, in Wheeler County, in Hood County, in the Wallowa Mountains of northeastern Oregon (Grant County), and in 2011 one was confirmed in Wallowa County (ODFW, 2011a). The proposed listing under ESA includes wolverines in northeastern Oregon (FWS, 2013a). Due to their large home ranges and habitat preferences, a wolverine may occur in the project area, but none are expected in the foreseeable future. There have been no verified historical or recent records of the species occurring in the PCGP Project vicinity (ORBIC, 2012; Stone, 2007; Verts and Carraway, 1998), and the species would not be affected by the Proposed Action.

Bull trout. Bull trout in the Klamath River DPS inhabit seven isolated stream areas in the Klamath River Basin (FWS, 1998a). Critical habitat for bull trout in the coterminous United States includes Critical Haitat Unit 9, Klamath River Basin. Unit 9 inlcudes three subunits: Upper Klamath Lake, Sycan River, and upper Sprague River subunit (FWS, 2010a). The Upper Klamath Lake subunit is within the Long Lake Valley-Upper Klamath Lake fifth field watershed which is not crossed by the PCGP Project. Agency Lake is the only waterbody in Unit 9 with hydrologic connectivity to the Klamath River (within the Lake Ewauna-Klamath River fifth field watershed); connectivity is through Agency Straits, Upper Klamath Lake, and Link River. As of 2010, Agency Lake was not occupied by bull trout (FWS, 2010b) and no bull trout are present in the PCGP project area. Neither the species nor potentially occupied habitat would be affected by the Proposed Action.

Yellow-billed cuckoo. FWS (2013c) proposed listing the yellow-billed cuckoo, western DPS that nests west of the Continental Divide, for listing as threatened under ESA. In Oregon, the western DPS included birds that nested along the Willammette River and Columbia River although the last confirmed nesting records are from the 1940s and the birds dissappeard in Oregon by 1945 (Wiggins, 2005). Although ORBIC (2013) includes Klamath County within the range of yellow-billed cuckoo, surveys conducted during 1988 in Klamath County did not find any cuckoos (FWS, 2013c). There are recent records (1990 to 2009) from Deschutes, Malheur, and Harney counties (FWS, 2013c). Yellow-billed cuckoos are considered a riparian obligate species and are usually found in large tracts of cottonwood/willow habitats with dense sub-canopies, but may also be found in urban areas with tall trees (FWS, 2007c). No suitable habitats are present within the project area and the species would not be affected by the Proposed Action.

#### 4.1.2.1 Format

There are 30 species listed as threatened or endangered under the ESA and 1 species proposed for listing, totaling 31 species considered in this section. Included are 7 marine mammals, 5 birds, 5 herpetofauna (4 reptiles and 1 amphibian), 6 fish, 1 invertebrate, and 7 plants. This section was organized to address similar information and environmental analyses consistently among the diversity of organisms that could be affected by the proposed action. The following five sections are included for each species:

1. Species Account and Critical Habitat in which the current status under the ESA is identified, past threats that lead to listing and current threats to continued existence, recovery plan components if available, abbreviated species' life history, population estimates and/or trends, and critical habitat that has been designated or proposed;

2. Environmental Baseline in which the species analysis area (portions of the Project action area where species are affected by the proposed action) relevant to each species is described, as well as the species' presence within the action area, species' habitat within the action area, and species' critical habitat present within the action area are described and evaluated;
3. Effects by the Proposed Action in which direct and indirect effects to the species and critical habitats are evaluated in each action area component;
4. Conservation Measures that have been proposed by the applicants in addition to those defined in Section 3.3; and
5. Determination of Effects in which the action agency evaluates how the proposed action would affect the species and critical habitat.

### 4.1.3 Action Area

The action area includes all areas that would be affected directly or indirectly by the proposed action and not just the immediate area involved in the action. Because the proposed action potentially can affect such a variety of species inhabiting diverse habitats within marine, estuarine, riverine, and various terrestrial locations, there are multiple components of the action area that have been defined as species' analysis areas, the areas where individual or groups of listed species are affected by the proposed action. Species' analysis areas are described in detail in each species' environmental baselines. For some species there may be more than one analysis area if the listed species utilizes multiple habitats in diverse locations. Analysis areas and associated species include:

- The EEZ analysis area, which applies to all listed marine mammals), some birds (short-tailed albatross, MAMU), green sturgeon, eulachon, and listed sea turtles;
- The gray wolf analysis area only applies to a solitary gray wolf, OR-7, that has an area of known activity in Jackson, Klamath, and Douglas counties.
- The estuarine analysis area, which applies MAMU, green sturgeon, eulachon, and coho salmon (Oregon Coast ESU);
- The LNG terminal analysis area, which applies to western snowy plovers and streaked horned larks;
- Terrestrial nesting analysis area, which applies only to MAMU;
- Provincial analysis area, which applies only to NSO;
- Several riverine analysis areas that are in specific geographic locations each in the respective ranges of coho salmon in the Oregon Coast ESU and in the SO/NCC ESU, listed suckers, and Oregon spotted frogs; and
- Botanical analysis areas that include vernal pool-associated species (fairy shrimp and two listed plants) and other listed plant species.

## 4.2 MAMMALS

### 4.2.1 Blue Whale

#### 4.2.1.1 Species Account and Critical Habitat

**Status**

The blue whale was listed as endangered throughout its range under the Endangered Species Conservation Act on December 2, 1970 (FWS, 1970) and has been listed under the ESA since its implementation in 1973. Blue whales off the U.S. West Coast are in the Eastern North Pacific stock. Blue whales are classified as depleted throughout its range under the Marine Mammal Protection Act (MMPA) of 1972. Depleted stocks are managed to not fall below their optimum sustainable population levels.

**Threats**

Hunting (whaling) played a large role in the decrease of the blue whale population (Sears and Perrin, 2009). At least 9,500 blue whales were taken by commercial whalers in the North Pacific Ocean from 1910-1965 and at least 11,000 were taken in the North Atlantic from the 1890s-1960s (NOAA Fisheries, 2013a).

There is an ongoing threat of ship strikes to blue whales. Between 2007 and 2011 there were 10 blue whales killed or injured by vessel strikes along the Pacific west coast, 9 of them off the California coast and one off the Oregon coast (Carretta et al., 2013a). Five of the deaths occurred in 2007, the highest number recorded for any year. . Injured whales do not always strand or if they do, they do not always have obvious signs of trauma. Consequently, additional mortality from ship strikes probably goes unreported (Carretta et al., 2013b). Anthropogenic noise is a habitat concern, identified by NMFS (Reeves et al., 1998) as a factor influencing the distribution of blue whales. Noise from ships and boats may interfere and mask cetacean communication, finding prey, avoiding predators, and possibly navigation (Würsig and Richardson, 2009).

Hybridization between blue whales and fin whales has been documented, and may decrease the fitness of the blue and fin whales that hybridize (Berube and Aguilar, 1998). Entanglement with commercial fishing gear remains a threat to blue whales and some whales swim off while still entangled in fishing gear, so the number and extent of injury and death from entanglement is not fully known (Reeves et al., 1998).

Blue whale food sources may be damaged and they may gain new stressors with certain climate-changing processes such as global warming. The impacts from climate change could affect everything from phytoplankton to organisms at higher trophic levels. Stressors from metabolic demands with warmer oceans may impact the health of animals. Shifts of marine populations either towards the poles or in the ocean depths they use are expected (Fogarty and Powell, 2002). Increased stratification from an increased temperature, and/or increased freshwater inputs may affect nutrient exchange and primary production. There may be reductions in the available nutrient levels and possible changes in the timing and intensity of phytoplankton blooms. There may also be reductions of upwelling and downwelling, thereby limiting the nutrient availability to marine life in specific stratified levels of the ocean. Changes in the California Current have reduced the zooplankton populations, primarily as a result of increased water temperatures, which led to intensified stratification and a lowering of mixing and nutrient regeneration in the water column (Fogarty and Powell, 2002).

**Species Recovery**

A recovery plan was drafted in July 1998 for the blue whale. The goals of the recovery plan (NMFS 1998a) are to downlist and delist the species. The stepdown outline to achieve the goal includes the following steps:

- Determine stock structure of blue whale populations occurring in U.S. waters and elsewhere.
- Estimate the size and monitor trends in abundance of blue whale populations.
- Identify and protect habitat essential to the survival and recovery of blue whale populations.
- Reduce or eliminate human-caused injury and mortality of blue whales.
- Minimize detrimental effects of directed vessel interactions with blue whales.
- Maximize efforts to acquire scientific information from dead, stranded, and entangled blue whales.
- Coordinate state, federal, and international efforts to implement recovery actions for blue whales.
- Establish criteria for deciding whether to delist or downlist blue whales.

**Life History, Habitat Requirements, and Distribution**

Blue whales, the largest mammals on earth, are baleen whales known to occur in oceans worldwide. Three separate populations of blue whale are recognized today: Northern Atlantic, Northern Pacific, and Southern Hemisphere. Blue whales are migratory animals known to feed in northern waters during spring and summer. Southern migrations towards subtropical winter breeding grounds begin in the fall (Carretta et al., 2013b). Blue whales inhabit the Gulf of California and offshore waters of Central America during late fall to spring. They migrate north along the west coast of North America durng April and May. Many blue whales occur off the California coast although some migrate to Canadian waters while other groups disperse north to the Gulf of Alaska or west toward the Aleutian Islands (Sears and Perrin, 2009).

The blue whale inhabits and feeds in both coastal and pelagic environments and, as a result, is frequently found on the continental shelf and far offshore in deep waters. They prey mainly on two krill (euphausiid) species, *Euphausia pacifica* and *Thysanoessa spinifera* (Reeves et al., 1998a). *E. pacifica* is an offshore euphausiid that is smaller than the more neritic euphausiid *T. spinifera*. Recent studies have shown a shift in the distribution of blue whales closer to the coast of California due to a shift in feeding more on *T. spinifera* (Reeves et al., 1998a). Blue whales typically travel alone or in pairs, and sometimes they can be found in loose aggregations in better feeding areas. They generally dive between 5 and 20 minutes and between 150 and 200 meters deep, although shallow dives are frequent (Shirihai and Jarrett, 2006).

Blue whales are thought to reach sexual maturity between 5 and 15 years of age. Females are thought to produce young every other year during the winter season in warmer waters (NMFS 1998a). The gestation period for blue whales is between 10 and 12 months, and the calves are weaned between 6 and 8 months. Not much is known about longevity and natural mortality of blue whales, but the lifespan is estimated at up to 90 years (Shirihai and Jarrett 2006). Ice entrapment is not a known factor of natural mortality for the Pacific population of blue whales, but there has been documentation of killer whale attacks on this population (NMFS 1998a).

**Population Status**

Blue whales along the mainland Pacific Coast are part of the Eastern Northern Pacific stock. The best estimate of the Eastern Northern Pacific blue whale population is 1,647 whales, based on mark-recapture estimates (Calambokidis, 2013, cited in Carretta et al., 2013b). The minimum population is estimated at 1,551 whales (Carretta et al., 2013b). The potential biological removal, is the maximum number of animals killed (not including natural deaths), that would still allow for the population to achieve its optimum sustainable population (Barlow et al., 1995). The overall potential biological removal for this blue whale population is 9.3 whales per year, but because this population spends one-quarter of its time in United States waters, the potential biological removal for blue whales is 2.3 whales per year in U.S. waters (Carretta et al., 2013b). The abundance of blue whales off of the West Coast, from Baja California to Washington, has not increased over the past two decades (Carretta et al., 2013b).

**Critical Habitat**

Critical habitat for this species has not been designated.

#### 4.2.1.2 Environmental Baseline

**Analysis Area**

The analysis area applicable to blue whales is the EEZ, extending 200 nautical miles (nmi) offshore from the Coos Bay Head (figure 4.2-1) and within the EEZ from San Diego, California, to Cape Flattery, Washington. Under the 1982 United Nations Convention on the Law of the Sea (LOS Convention), the United States has limited sovereign rights within the EEZ (U.S. Commission on Ocean Policy, 2004) and all analyses of effects by the proposed action are confined to the U.S. Pacific coast EEZ. Within the EEZ analysis area, effects to blue whales would be associated with LNG carriers inbound and outbound from the LNG terminal. To date, sources of LNG that would be shipped from the LNG terminal have not been identified. Potential markets for exported LNG, including Hawaii and the Cook Inlet region of Alaska, have been identified (see Resource Report 1, JCEP LNG Terminal Project). However, the main global LNG markets are currently in Korea and Japan (International Gas Union, 2012).

Alternatively, JCEP has retained the capability within the LNG Terminal design to add import and regasification facilities if market conditions were to change in the future (see Resource Report 1, JCEP LNG Terminal Project). Consequently, destinations and/or sources of LNG are not foreseeable and have been assumed in order to conduct the analyses of direct, indirect, and cumulative effects on blue whales and other species within the EEZ analysis area.

For reasons described in detail below, LNG carriers transiting to LNG destination ports near the equator are assumed to traverse the EEZ perpendicular to the coast. Other LNG carriers bound to or passing Central and South America are expected to parallel the coast from California to Coos Bay and are assumed to follow a north-south course 50 nmi offshore.

**Species Presence**

While exact dates vary each year, long-term acoustic data offshore from Oregon indicates that blue whales are present, at least on a seasonal basis, from late July until January when they migrate to southern waters (Stafford et al., 1999). As they migrate north along the west coast of North America, blue whale call intensities off the Oregon coast peak during October and steadily diminish through January (Burtenshaw et al., 2004). The blue whales off the Oregon coast were typically found farther from shore than where they were found in California where they fed closer to the coast. However, based on records spanning a 72-year period from 1930 to 2002, blue whales are the least frequent of five balaenopterid species found stranded on Oregon and Washington coasts; only one female had been reported stranded in Washington (Norman et al., 2004).

Line-transect ship surveys conducted off the coasts of California, Oregon, and Washington in summer and fall of 1991, 1993, 1996, 2001, 2005, and 2008 (Barlow and Forney, 2007; Forney, 2007; Barlow, 2010) have been used to estimate populations within the California and Oregon-Washington strata and to estimate populations for specific stocks. During each of those years (only California waters were surveyed in 1991 and 1993), line-transect locations were pre-determined to survey for pelagic cetaceans within approximately 300 nmi of the West Coast.

The mean density estimates for species in the California stratum are computed as the Mean Population Estimate divided by the area in the surveyed stratum, 819,470 $km^2$ (Barlow, 2010) which is assumed to be the same in all of the years surveyed. The mean density of blue whales in the California stratum is 0.157 whale per 100 $km^2$ or 0.046 whale per 100 $nmi^2$. Similarly, mean population estimates for species in the Oregon-Washington stratum are the geometric means of population estimates derived from surveys conducted in 1996, 2001, 2005 (data from Barlow and Forney, 2007; Forney, 2007) and 2008 (data from Barlow, 2010). The mean density of blue whales in the Oregon-Washington stratum is 0.030 whales per 100 $km^2$ or 0.009 whale per 100 $nmi^2$.

The mean encounter rate (number observed per linear distance of transect) for each cetacean species is the geometric mean of the number of animals counted along line transects in the California stratum during each survey year (1991 through 2008, see above) divided by total transect length in the stratum for each survey year (data from Barlow and Forney, 2007; Forney, 2007; Barlow, 2010). If no individuals were sighted in one or more years, the arithmetic mean was used. The mean encounter rate for blue whales in the California stratum is 0.2125 whale per 100 km or 0.1147 whale per 100 nmi of ship transect. Likewise, the mean encounter rate (number observed per linear distance) for cetaceans observed in the Oregon-Washington stratum is the geometric mean of the number of animals counted along line transects during each survey year (1996 through 2008, see above) divided by total transect length in the stratum for each survey year (data from Barlow and Forney, 2007; Forney, 2007; Barlow, 2010). The mean encounter rate for blue whales in the Oregon-Washington stratum is 0.0870 whale per 100 km or 0.0470 whale per 100 nmi of ship transect.

### Habitat

The U.S. West Coast is one of the most important feeding areas during summer and fall; blue whales migrate to highly productive areas south in winter off Baja California and the Gulf of California (Carretta et al., 2013b). They are found in coastal waters but are generally more offshore than other whales. Blue whales are occasionally heard or seen off Oregon; as primary production blooms (phytoplankton) and associated euphausiid biomass increase, advancing along the west coast from south to north, aggregations of blue whales move through Oregon offshore waters between October and January en route to foraging areas off the coast of Vancouver Island (Burtenshaw et al., 2004). It is estimated that blue whales spend approximately 75 percent of their time outside the 200 nmi wide EEZ (Carretta et al., 2013b). However, this stock of blue whales may occur within the EEZ analysis area.

### Critical Habitat

Critical habitat for this species has not been designated.

### 4.2.1.3 Effects by the Proposed Action

#### Direct and Indirect Effects

Direct effects of the proposed action include injury and/or mortality due to ship strikes, adverse effects from vessel underwater noise, and potential adverse effects from an accidental ship release of LNG and fire at sea. Spills and/or released LNG could indirectly affect blue whales by impacting forage species. These effects are addressed below.

<u>Ship Strikes by LNG Carriers</u>

There is an ongoing threat of ship strikes to large cetaceans, causing mortality or serious injury. From available accounts (Laist et al., 2001; Jensen and Silber, 2003; Douglas et al., 2008; Carretta et al., 2013a), cetaceans collide with ships fairly infrequently. The rate of ship-strikes to blue whales and other large cetaceans is assumed to be the product of ship traffic and the cetacean population density within the EEZ. From 2007 to 2011 ship strikes of blue whales averaged 1.8 death or injury per year in California and 0.2 death or injury per year off the Oregon-Washington coast (Carretta et al., 2013a). Those estimates are undoubtedly minimal since many ship strikes with cetaceans are unknown and unreported.

**Ship Traffic**. A considerable amount of shipping traffic currently occurs within the EEZ analysis area. Along the coastal portion from Coos Bay north to the Columbia River, vessel traffic averaged 3,694 transits annually (see table 4.2.1-1), while from Coos Bay south to Humboldt Bay (California) vessel traffic averaged 3,658 transits per year, based on data compiled during 1998-1999 (Pacific States/British Columbia Oil Spill Task Force, 2002).

**Table 4.2.1-1**

[1] Distances between ports from Appendix B, Coast Pilot 7 (NOAA, 2008)
[2] Annual Coastal Ship Transits from Appendix D, Pacific States/British Columbia Oil Spill Task Force (2002)

Ships traveling to and from the southern hemisphere would most likely parallel the coastline, transiting the EEZ from San Diego north to Coos Bay. In 1999, the estimated total coastal vessel traffic within California, Oregon, and Washington is more than 5 million ship-miles per year, of which more than 3 million ship-miles occur within California waters annually (see table 4.2.1-1). LNG carriers would transit 887 nmi between San Diego and Coos Bay and 90 ships per year (180 annual transits) would generate an additional 159,660 ship-miles per year (assuming that all LNG carriers would return to ports of origin along the West Coast). Potential shipment of LNG to Cook Inlet, Alaska (see Resource Report 1, JCEP LNG Terminal Project) would require transit of 393 nmi within the EEZ between Coos Bay and Cape Flattery; 90 ships per year (180 annual transits) would generate an additional 70,740 ship-miles per year within that segment en route to Alaska.

There is no single authority defining shipping lanes along the Pacific Coast. Typical West Coast vessel traffic patterns reported by Pacific States/British Columbia Oil Spill Task Force (2002) include the following:

- Tank ships operated by Western States Petroleum Association (WSPA) members that carry crude oil transit at distances of ≥50 nmi off the U.S. West Coast except when they enter port or enter a traffic separation scheme around a port;
- Crude oil and refined petroleum tankers not operated by WSPA members may or may not transit closer to shore;
- In general, tank barges hauling crude oil and refined petroleum transit ≥25 nmi offshore except when they enter port or enter a traffic separation scheme around a port;
- Dry cargo and bulk carriers vary from 3 to 30 nmi or more during offshore transits, and avoidance of heavy weather is a factor during all vessel transits; and
- In general, preferred offshore tracks are 25 nmi in northern waters and 30 nmi along southern tracks; seldom are north or south transits outside of the EEZ (Pacific States/British Columbia Oil Spill Task Force, 2002).

From these vessel traffic patterns, which are mostly voluntary, LNG carriers transiting to and from the south or north would be expected to parallel the West Coast a distance of 50 nmi offshore, entirely within the EEZ.

Recent information indicates that ship traffic to U.S. West Coast ports was increasing between 2002 and 2007 but deviated from the established trajectory in 2008, at the onset of the global financial crisis (see figure 4.2-2). Data from the U.S. Department of Transportation, Maritime Administration (MARAD, 2013) through 2011 indicates a progressive return to the pre-2008 trend which had been increasing by constant amount of 435 vessels per year between 2002 and 2007. Based on that observed constant amount of annual increase, the pre-2008 trend predicts 21,530 vessel calls to West Coast ports in 2018 (with 95% prediction intervals ranging from 17,360 to 25,710 vessel calls), the year the JCEP and PCGP projects are expected to be in service. The annual percent change in vessel calls, however, would be 2.1 percent in 2018, lower than the percent change in 2007 which is 2.7 percent, based on the regression model in figure 4.2-2 (note: the annual percent change in vessel calls is a negative exponential function if there is a constant increase in the number of vessels each year).

Applying the yearly percent change in Total Annual Vessel Calls at all West Coast ports based on the regression model in figure 4.2-2 to the total ship-miles along the West Coast beginning in 1999 (5,049,298 ship-miles in table 4.2.1-1), there would be an estimated 8,199,320 ship-miles along the West Coast, expected in 2018.

Similarly, the data from MARAD (2013) were used to estimate ship-miles along the California Coast and along the Oregon-Washington Coast in 2018 from the data in table 4.2.1-1 from 1999 provided by Pacific States/British Columbia Oil Spill Task Force (2002).

- From 2002 to 2007, total vessel calls to California ports increased by a constant number of 251 vessel calls per year (regression model y = 250.74x – 492,585, $r^2$ = 0.78, P=0.019). There were 3,041,597 ship-miles in 1999 within California waters (see table 4.2.1-1); 4,717,894 ship-miles are expected in 2018.
- From 2002 to 2007, total vessel calls to Oregon-Washington ports increased by a constant number of 185 vessel calls per year (regression model y = 184.6x – 364,401, $r^2$ = 0.56, P=0.086). There were 2,007,701 ship-miles in 1999 within Oregon-Washington waters (see table 4.2.1-1); 3,533,752 ship-miles are expected in 2018.

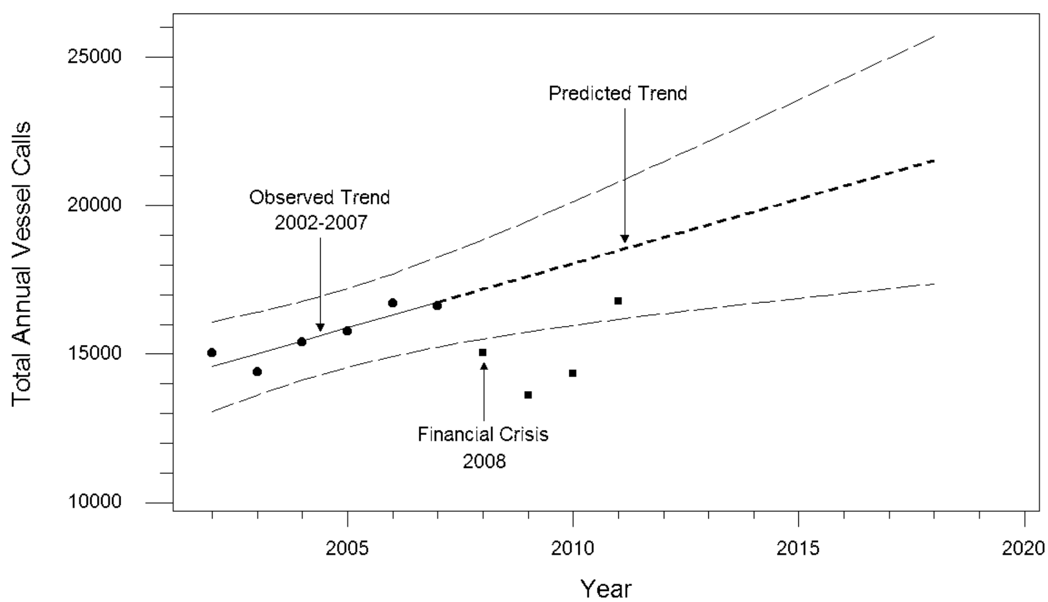

**Figure 4.2-2**
**Total Annual Vessel Calls at All U.S. West Coast Ports from 2002 to 2011. The Observed Increasing Trend from 2002 to 2007 (solid line) is Significant ($r^2$ = 0.81, P=0.015). The Predicted Trend (heavy dashed line) and 95% Prediction Intervals (light dashed lines) through 2018 are Based on the 2002-2007 Observed Trend (y = 435.3 x – 856,986). (Source: MARAD, 2013).**

According to Lloyd's (2013), over 80 percent of global LNG carrier imports are to the Far East, 5.9 percent are to Southern Europe, 5.8 percent are to South America (Atlantic Coast), 5.1 percent are to Northern Europe, and 3.0 percent are to the Indian Subcontenent. LNG carriers from and to the Far East and Indian ports are assumed to traverse the EEZ perpendicularly - east and west - as they depart and approach Coos Bay because most existing shipping traffic between Asia and the United States West Coast travels a "Great Circle route." Similarly, LNG carriers supplying fuel to Hawaii (see Resource Report 1, JCEP LNG Terminal Project) would likely traverse the EEZ perpendicularly. Ships traveling Great Circle routes are usually not considered components of north-south coastal shipping traffic (Pacific States/British Columbia Oil Spill Task Force, 2002).

The Project is designed to accommodate 90 LNG tankers a year. If all LNG tankers approach the Jordan Cove terminal by perpendicular transits through the EEZ, they will contribute 36,000 ship miles annually to vessel traffic in the Oregon-Washington stratum in 2018. If all LNG tankers approach the terminal by parallel transits along the California coast, they will contribute 137,160 ship-miles annually to vessel traffic within the California stratum in 2018. Observed and predicted vessel traffic within both strata in 1999, 2007, 2008, and 2018 are provided in table 4.2.1-2, including the addition of project-related LNG tanker traffic in 2018. During the life of the project, there may be years of mixed LNG tanker traffic, some transiting the EEZ perpendicular and other traffic paralleling the coast but such variability can not be estimated.

**Table 4.2.1-2**
**Estimates of Vessel Traffic, Blue Whale Encounter Rates, Relative Ship-Strike Risk, and Estimates of Blue Whales Struck per Year (with Percent Change from the Previous Estimate) in the California and Oregon-Washington Strata of the Project Activity Area**

[4] Assume 90 LNG tankers with perpendicular transits through West Coast EEZ in Oregon-Washington stratum (36,000 ship-miles per year) or parallel transits through EEZ in California stratum (137,160 ship-miles per year).
[5] Estimates of Whales Struck derived from data reported by Carretta et al., 2013a for ship-strikes in the California and Oregon-Washington EEZ strata.

**Ship-Strike Risk**. An index of relative ship-strike risk within an explicitly defined gridded study area was described by Williams and O'Hara (2009). They multiplied whale density estimates at each grid point by the nearest value of shipping intensity using regular-interval ship locations on the grid from agencies' remote monitoring of shipping in Canadian waters. Regrettably, no such fine-scale data for whales or ships are available within the West Coast EEZ activity area but the approach by Williams and O'Hara (2009) was adapted to the coarse-scale analysis area and two strata by using mean whale encounter rates, described above for blue whales, and shipping intensity as indicated by the total annual ship-miles derived from vessel transits along the West Coast (see table 4.2.1-2) in the California and Oregon-Washington strata.

The encounter rate for blue whales in both EEZ strata combined is significantly ( $P< 0.01$) related to the species' density, based on data collected during surveys conducted in 1996, 2001, 2005 (data from Barlow and Forney, 2007; Forney, 2007) and 2008 (data from Barlow, 2010), shown in figure 4.2-3. The relationship supports predictions, below, that future encounter rates (eg, in 2018) would be expected to increase as the blue whale population increases.

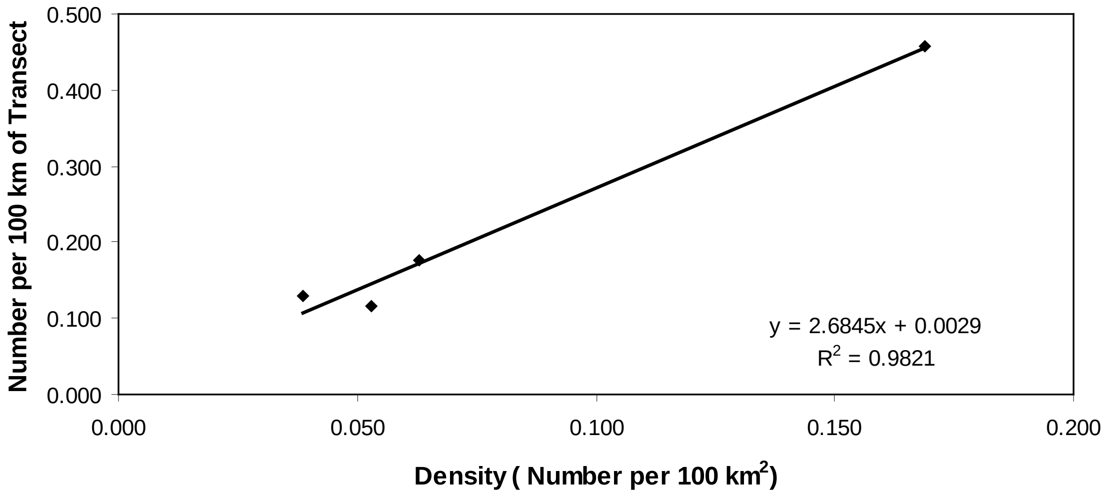

**Figure 4.2-3**

**Relationship of Ship-Transect Encounter Rate with Blue Whales (Number per 100 km) to Blue Whale Density (Number per $km^2$ ) in the California and Oregon-Washington EEZ Strata, Combined. Data were Collected in 1996, 2001, 2005, and 2008. The Relationship is Significant ($P < 0.01$)**

Relative ship-strike risks during 2008 and 2018 (see table 4.2.1-2) are the products of cetacean species' encounter rates and total ship miles expected in each stratum during the two years. The encounter rate for blue whales in 2008 was discussed in Section 4.2.1.2, above. An estimate of the encounter rate in 2018 (beginning of the project operation) is directly proportional to blue whale population and density in that year.. The logistic equation for exponential population growth in discrete generations or time periods, is $N_{t+1} = N_t + r_{max} N_t ((K – N_t)/K)$ where $N_{t+1}$ is the number of animals in the next generation or year, $N_t$ is the number of animals in the current generation or year, $R_{MAX}$ or $r_{max}$ is the maximum value of the per capita growth rate for a species and K is the environmental carrying capacity for the species. If $N_t$ is very small relative to K, as it is for many marine mammal species that are slowly recovering from past overharvesting (Carretta et al., 2013a), the term $((K - N_t)/ K)$ is nearly equal to K/K or 1 and the population is expected to grow exponentially. If exponential growth is assumed, the population size ($N_t$) at time = t is $N_t = N_0 e^{r t}$ where $N_0$ = the initial population size at t = 0 and r is assumed to be $R_{MAX}$. NMFS established default values for $R_{MAX} = 0.04$ if stock-specific measured values were unavailable (Barlow et al., 1995; Wade, 1998).

This approach was used with the default value for $R_{MAX}$ to estimate blue whale encounter rates (as indices of population) in 2018, given the encounter rates of blue whales within the California and Oregon-Washington strata in 2008. In 2008, the blue whale encounter rate in the California stratum was 0.115 whale per 100 nmi and 0.047 whale per 100 nmi in the Oregon-Washington stratum. Based on assumed population growth between 2008 and 2018, the blue whale encounter rate in California in 2018 is estimated at 0.171 whale per 100 nmi and 0.070 whale per 100 nmi in the Oregon-Washington stratum, an increase of 49 percent from the 2008 encounter rates (see table 4.2.1-2).

In 2008, the relative ship-strike risk in the Califonia stratum would be 0.115 whale per 100 nmi multiplied by 3,316,554 ship-miles = 3,806. In 2018, the assumed growth of the blue whale population increases the encounter rate proportionately to 0.171 whale per 100 nmi. Between 2008 and 2018 ship traffic is also be expected to increase to 4,717,894 ship-miles. The relative ship-strike risk in 2018 would be 8,077 which is 112.2 percent of the 2008 encounter rate (table 4.2.1-2). If all 90 LNG tanker transits occur in the California stratum, the total expeced vessel traffic would be 4,855,054 ship miles in 2018 and the ship-strike risk would increase to 8,311, an estimated increase of 2.9 percent. Similar calculations woud apply to the blue whale population growth, encounter rate, relative ship-strike risk in the Oregon-Washington stratum, provided in table 4.2.1-2.

**Estimated Ship-Strikes to Blue Whales**. Data provided by Carretta et al. (2013a) indicated 9 blue whales were struck in the California EEZ between 2007 and 2011 (1.8 whales per year) and 1 blue whale was struck in the Oregon-Washington EEZ during the same period (0.20 whale per year). Jensen and Silber (2003) reported 0.31 blue whale struck per year between 1987 and 2002 along the U.S. Pacific Coast. Using recent ship-strike data from Carretta et al. (2013a), the increased ship-strike risk in 2018 is assumed to increase the annual rate of blue whales struck proportionately in the California stratum to 3.820 per year and to 0.420 per year in the Oregon-Washington stratum (Table 4.2.1-2). The additional project-related LNG tanker traffic would increase the annual rate in California to 3.931 whales per year, an increase of 0.111 ship-strike per year (one injury or death in 9 years) and would increase the annual rate in Oregon-Washington waters to 0.424 whale per year, and increase of 0.004 ship-strike per year (one injury or death in 250 years). Ship-strikes to blue whales by project-related LNG tankers are more likely in California than in the Oregon-Washington EEZ stratum but in both areas, death or injury of blue whales is insignificant and discountable.

<u>Underwater Noise</u>

All vessels produce noise; propeller cavitation produces most of the broadband noise with dominant tones derived from the propeller blade rate. Propellers creat more noise if damaged, if operating asynchronously, or operating without nozzles. Engines and auxiliary machinery can also radiate noise during operation which is related to ship size (larger ships are noisier than small ones), speed (noise increases with ship speed), and mode of operation (ships underway with full loads, towing or pushing loads, are noisier than unladen ships) (Greene and Moore, 1995). In general, rorquals including blue, fin and minke whales move away, abruptly change direction, or dive to avoid close approach by vessels. When whales are exposed to low-level sounds from distant or stationary vessels, they appear to ignore the sounds. Baleen whales will interrupt normal behavior and swim away from strong or rapidly changing vessel noise, especially if a vessel is headed directly toward the whale (Richardson, 1995). However, radiated ship noise of oncoming ships may not be immediately detected by whales near the surface due to bow null-effect acoustic shadow zones (Allen et al., 2012). Because of acoustic shadow zones, whales may not hear approaching ships to allow time for their avoidance response even though whale auditory ranges overlaps with peak intensities of ship noise.

Steam turbine power has been replaced by dual fuel diesel electric (DFDE) power plants adapted to utilizing LNG gas boil-off and diesel fuel to power electric drives in many recently constructed LNG vessels. The DFDE propulsion system is more fuel efficient with less engine noise and vibration (Gilmore et al., 2005). Whether or not lower noise-producing propulsion systems will cause increased ship-strikes with marine mammals is unknown.

Ambient noise in the Northeast Pacific Ocean has increased in nearshore and deep ocean environments over the past several decades. Comparisons of ambient noise from the 1990s with noise measurements take during the 1960s indicate ambient noise increased by about 10 dB (Andrew et al., 2002). Recently measured ambient noise are only slightly increasing, decreasing, or showing no trend (Andrew et al., 2011). Low frequency noise especially, generated by commercial vessel traffic, has been estimated at 10 to 12 dB higher in the early 2000s compared to the 1960s (McDonald et al., 2006). In addition to ships, ambient ocean noise is a product of wind, precipitation, wave noise, and sounds generated by cetaceans and fish (McDonald et al., 2008). The low frequencies generated by ships overlap sounds generated by large baleen whales, including the fin whale (Würsig and Richardson, 2009).

Noise from ships and boats may interfere and mask cetacean communication, finding prey, avoiding predators, and possibly navigation (Würsig and Richardson, 2009). Exposure of dolphins to intense underwater noise caused significant increases in neural-immune parameters with higher levels of norepinephrine, epinephrine, and dopamine levels, but with decreased aldosterone and monocytes after exposure compared to before exposure (Romano et al., 2004). Anthropogenic noise and vessel disturbance may affect blue whales but there is little evidence available to describe or quantify the impacts of these threats on the species. While anthropogenic noise may threaten other cetaceans, little is known about whether, or how, vessel noise affects blue whales (NOAA Fisheries, 2013a). One blue whale that had been calling prior to nearby passage of a merchant ship continued to call during the passage even though the ship noise at the whale's position exceeded the ambient sound level by as much as 26 dB (McDonald et al., 1995). Vessel disturbance (like whale-watching boats) may affect blue whales, but there is no direct evidence to demonstrate that persistent close approaches by vessels such as tour boats has a negative effect on them.

Noise can cause hearing loss in cetaceans which may be temporary (abbreviated TTS for temporary threshold shift or permanent (abbreviated PTS for permanent threshold shift). Repeated TTS may lead to PTS in which sensory hair cells in the inner ear are destroyed with damage to the cochlea (Nordmann et al., 2000).

NOAA Fisheries is developing comprehensive guidance on sound characteristics likely to cause injury and behavioral disruption based on known causes of TTS. At the present, NOAA has provided interim guidance for thresholds of received sound pressure levels from broad band sounds that may cause behavioral disturbance and injury to marine mammals which are conservative until formal guidance as been developed. The conservative thresholds are applied in MMPA permits and Endangered Species Act Section 7 consultations for marine mammals to evaluate the potential for sound effects. The criterion levels specified in table 4.2.1-3 are specific to the levels of harassment permitted under the MMPA.

**Table 4.2.1-3**
**NOAA Fisheries Current In-water Acoustic Thresholds**

| Criterion | Criterion Definition | Threshold [1] |
|---|---|---|
| Level A | PTS (injury) conservatively based on TTS | 190 $dB_{rms}$ for pinnipeds<br>180 $dB_{rms}$ for cetaceans |
| Level B | Behavioral disruption for impulsive noise (e.g., impact pile driving) | 160 $dB_{rms}$ |
| Level B | Behavioral disruption for non-pulse noise (e.g., vibratory pile driving, drilling) | 120 $dB_{rms}$ [2] |
| [1] All decibels referenced to 1 micro Pascal (re: 1uPa). Note all thresholds are based off root mean square (rms) levels.<br>[2] The 120 dB threshold may be slightly adjusted if background noise levels are at or above this level.<br>Source:NOAA Fisheries, 2013b. | | |

Southall (2004) provided the following descriptions of impulsive noise and non-pulse noise, based on characteristics at the noise source:

- **Single Pulse:** Single sound of short duration, fast rise time generated by a single explosion, single airgun, watergun, or sparker pulse, single ping of certain sonars/depth sounders.
- **Single Non-Pulse:** Single sound of long duration, slow rise time generated by a single vessel pass, drilling event, aircraft overflight, single ping of certain sonars.
- **Multiple Pulse:** Multiple sounds each of short duration, fast rise time generated by airguns, some sonar/depth sounder systems, waterguns, sparkers, pile driving, serial explosions.
- **Multiple Non-Pulse:** Multiple sounds of long duration, slow rise time generated by multiple vessel/aircraft passes, certain sonar systems, tomography sources.

In the following analysis, noises generated by LNG tankers transiting the West Coast EEZ activity area are assumed to be single non-pulse sources during each transit and would be expected to cause behavioral disruption, including masking detection of important sounds (intraspecific communication, prey and/or predator detection, eminent ship-strike), for species within distances at which tanker noise attenuates to 120 dB or more. However, occurrences of single pulse sounds by LNG tankers cannot be completely ruled out (depth or echo sounders, single or serial explosions).

A review of LNG carriers in service during 2013 (Colton, 2013; MarineTraffic, 2013) revealed there are 267 vessels with capacities of 148,000 $m^3$ or less, the current size limit for LNG carriers utilizing the Jordan Cove terminal (although the LNG carrier berth was designed to accommodate LNG carriers up to 217,000 $m^3$). Hatch et al. (2008) determined underwater noise levels from various commercial ships while transiting the Stillwagen Bank National Marine Sanctuary off the Massachusetts coast. Estimates of sound levels from one ship, an LNG Taker (the Berge Everett also known as the BW Suez Everett) built in 2003 with 138,028 $m^3$ capacity (93,844 gross tonnage), are used here to estimate exposure of marine mammals to project-related shipping noise. The reported noise levels from that tanker serves as the standard for the following analysis of noise effects on blue whales within the West Coast EEZ analysis area.

The LNG tanker in the Hatch et al. (2008) study produced sound levels (with 1 standard error) of 182 ± 2 dB re: 1 µPa @ 1 meter that attenuated to 160 dB at 35 ± 11 meters and to 120 dB at 16,185 ± 5,359 meters (Hatch et al., 2008). Using those attenuation distances, one LNG tanker transit across the length of the California EEZ stratum for 762 nmi would produce sound levels of ≥160 dB within an area 15.6 ± 4.9 nmi$^2$ and would produce sound levels ≥120 dB but <160 dB within an area 7,175.9 ± 2,376.3 nmi$^2$. Likewise, one LNG tanker transit across the width of the Oregon-Washington EEZ stratum for 200 nmi would produce sound levels of ≥160 dB within an area 4.1 ± 2.6 nmi$^2$ and would produce sound levels ≥120 dB but <160 dB within an area 1,883.4 ± 1,247.4 nmi$^2$.

Based on population growth between 2008 and 2018 described above for blue whale encounter rates, the predicted density of blue whales is 0.068 whale per 100 nmi$^2$ in the California stratum in 2018 and is 0.013 whale per 100 nmi$^2$ in the Oregon-Washington stratum in 2018. Assuming an LNG tanker transit distance of 762 nmi within the California stratum, the number of blue whales within range of noise levels of 160 dB produced by a single LNG tanker transit through the stratum would be equal to the density (0.068 whale per 100 nmi$^2$) multiplied by the total area of noise effects (15.6 nmi$^2$), equal to 0.01 whale affected.

The number of blue whales within range of noise levels of 120 dB (radius of 16,185 m or 4.72 nmi) produced by a single LNG tanker transit through the stratum would be equal to the density (0.068 whale per 100 nmi$^2$) multiplied by the total area of noise effects (7,176 nmi$^2$), equal to 5 whales (an estimate between 2 and 8 whales based on the density within distances of ± 2 standard deviations of LNG noise attenuating to 120 dB, from Hatch et al., 2008) affected by noise levels that could cause behavioral disruptions (see table 4.2.1-3).

Similar calculations have been done for blue whales in the Oregon-Washington stratum. Assuming an LNG tanker transit distance of 200 nmi across the Oregon-Washing stratum, the number of blue whales within range of noise levels of 160 dB produced by a single LNG tanker transit through the stratum would be equal to the density (0.013 whale per 100 nmi$^2$) multiplied by the total area of noise effects (4.08 nmi$^2$), equal to <0.001 whale affected. The number of blue whales within range of noise levels of 120 dB produced by a single LNG tanker transit through the stratum would be equal to the density (0.013 whale per 100 nmi$^2$) multiplied by the total area of noise effects 1,883 nmi$^2$), equal to 0.244 whale affected by noise levels that could cause behavioral disruptions (see table 4.2.1-3).

Existing commercial vessels within the West Coast EEZ analysis area produce underwater noise levels that are comparable or exceed noise from the LNG tanker described by Hatch et al. (2008). Noise generated by various types of commercial ships (container ships, crude oil tankers, product tankers, bulk carriers, and others) were recently evaluated by McKenna et al. (2012). Underwater noise levels varied by ship type and also by vessel length, gross tonnage, vessel speed, and to some extent, vessel age (older vessels tended to be louder than newer vessels). For example, a 54,000 Gross Ton (GT) container ship generated the highest acoustic source level of 188 dB re: 1 µPa @ 1 meter while a 26,000 GT chemical tanker had the lowest at 177 dB re: 1 µPa @ 1 meter (McKenna et al., 2012). Noise levels from the vessels examined in that study are assumed to be typical of ship noise in the California and Oregon-Washington EEZ strata and would produce radiated noise levels through the two strata that would exceed the threshold for Level B single non-pulse noise of 120 $dB_{rms}$ (see table 4.2.1-3, above). With the existing levels of background shipping noise and the expected increase in shipping traffic by 2018, effects by project LNG tanker-related noise on blue whales are possible in the in California EEZ stratum but the noise would be commensurate with existing noise levels and would not be expected to cause injury.

Two tractor tugs would guide the LNG tanker from a point approximately 5 nmi offshore the entrance to Coos Bay and to the JCEP LNG terminal. Noise produced by tugs would attenuate to 160 dB at 11 ± 4 meters (upper end) and to 120 dB at 4,992 ± 1,599 meters (upper end) (Hatch et al., 2008). Unlike LNG tankers, project-related tug traffic would only occur in the Oregon-Washington stratum. LNG ship noise and noise from tugs would exceed the ambient noise levels within the West Coast EEZ activity area assuming those range from 64 dB to 72 dB re 1 µPa2 (at 62 Hz, similar to the ocean noise 7 nmi west of San Diego reported by McDonald et al., 2008) but would not cause behavioral disruptions to blue whales.

<u>Releases and Fire at Sea</u>

The density of LNG is approximately 42 percent of sea water density so LNG accidentally released from a tanker would float on the water, spreading sideways while exposing the LNG fuel to air over an increasing surface area (Fay, 2003). The density of liquid LNG is 450 $kg/m^3$ and the density of LNG vapor is 1.74 $kg/m^3$ (Luketa et al., 2008), both of which are denser than air (density ≈ 1.2 $kg/m^3$ for dry air at sea level and at 20°C) and would remain at the ocean surface until it evaborated. Spreading of an LNG pool over water would be influenced by the following factors (Hightower et al., 2004):

1. The spreading speed of the leading edge of the LNG pool.
2. The variable thickness of the LNG pool as it spreads.
3. Friction between the LNG pool and water.
4. The evaporation rate of LNG on water.

The evaporation rate over water would be dependent on the thickness of the LNG pool (increasing evaporation rate with increasing thickness) and the surface turbulence intensity of the water (increasing evaporation rate with increasing turbulence) (Morse and Kytomaa, 2010). At the water-vapor LNG pool interface, the cryogenically cooled LNG would begin to vaporize but, because of its relatively high density, the plume would remain at or close to the surface interface; methane is an asphyxiant but with low toxicity, at least to humans (Hightower et al., 2004). If a marine mammal surfaced to breathe at the LNG pool location, it could suffer from oxygen deficiency and potential physiological effects, which have been described for humans - ranging from impaired thinking to loss of consciousness with decreasing oxygen concentrations (Table 39 in Hightower et al., 2004) - but not for marine mammals. Because the estimated densities of marine mammals are generally low within the California and Oregon-Washington strata of EEZ, the chance of an animal becoming asphyxiated by contact with a pool of LNG would extremely remote (see discussion about potential thermal injury, below).

If the vapor from an LNG spill were to come in contact with an ignition source, the resulting fire would burn back to the spill source and could affect species at the water surface within some distance with the fire. Sandia National Laboratories modeled LNG spills from a standard LNG vessel (with capacity of 125,000 to 140,000 $m^3$) over water and potential injury to humans due to ignition of the fuel (Hightower et al., 2004). Thermal effects from a fire would vary, depending on the size of the LNG pool released. If one LNG tank is accidentally breached, due to collision with another ship, grounding, or ramming, the potential spill of LNG could form a pool with diameter of 685 feet.[1] Ignition could cause a fire to burn for 20 minutes with severe thermal

[1] Intentional releases due to terrorism, maliciousness, or other human acts could cause more LNG to be released than accidental releases and provide a simultaneous ignition source (Hightower et al., 2004).

injuries extending to 820 feet away from the center of the pool (based on an exposure of 10 minutes and thermal flux of 37.5 $kW/m^2$) and second-degree skin burns on exposed skin (human) to a distance of 2,572 feet (based on an exposure of 10 minutes and thermal flux of 5 $kW/m^2$) from the center of the burning pool of LNG (see Table 41 in Hightower et al., 2004). Surfacing cetaceans within those distances would be assumed to experience severe burns or mild burns, based on similar thermal fluxes effects on humans although exposures for 10 minutes or more would be unlikely.

Expected densities of blue whales in the California EEZ stratum during 2018 would be 0.068 whale per 100 $nmi^2$ and 0.013 whale per 100 $nmi^2$ in the Oregon-Washington EEZ stratum, the same densities that were used in the analysis of effects due to ship noise, above. Based on the model of accidental LNG release and fire described above (from Hightower et al., 2004), a circular pool of released LNG with diameter of 685 feet would cover an area of 0.010 $nmi^2$. An ensuing fire would cause severe thermal injuries over an area of 0.057 $nmi^2$ and the area where fire could cause second degree burns would extend to an area of 0.563 $nmi^2$. Considerably fewer than one blue whale would be expected to be present within any of those areas in either of the two EEZ strata during 2018 and injuries to blue whales due to LNG release and fire would be insignificant and discountable.

LNG carriers have been operating commercially since 1959. Since then there have been more than 38,000 LNG carrier voyages, covering more than 60 million miles and transporting a total of 1.5 billion cubic meters of LNG. Currently, approximately 352 LNG carriers safely transport more than 51,975,000 million cubic meters of LNG annually to ports around the world (Lloyd's, 2013). There have been approximately 11 reportable incidents between 1979 and 2006, worldwide. Because LNG has not been transported to the Pacific Northwest, no data are available. However, due to the double hulls of LNG carriers, none of the incidents that have occurred with LNG carriers have resulted in the loss of LNG cargo or other significant petroleum-based spills.

**Cumulative Effects**

FWS and NMFS describe cumulative effects (50 CFR § 402.02) as the result of future actions by state or private entities, not involving federal actions, but reasonably certain to occur in the action area considered in this BA. Future federal actions that are unrelated to the proposed action are not considered here because they require separate consultation pursuant to section 7 of the ESA.

Analysis of direct and indirect effects to blue whales focused on death or injury due to ship strikes. Future incidence of ship strikes to whales is assumed to be related to the whale population size and volume of vessel traffic within the EEZ analysis area. Available information indicates that ship calls to the Port of Coos Bay have been declining since 2002. Most calls to the Port have been by dry bulk vessels (most or all were wood-chip carriers) with occasional calls by general cargo vessels. In 2002, there were 60 vessel calls but only 25 vessel calls in 2011 (see figure 4.2-4). The observed declining linear trend in annual vessel traffic is significant ($r^2 = 0.836$, $P < 0.001$) and the regression analysis model ($y = 7385 – 3.66 x$) was used to predict numbers of vessel calls to Coos Bay in the future. When the LNG terminal is expected to begin operation in 2018, no vessels are forecast with a 95 percent prediction interval between 0 and 17.6 vessels (see figure 4.2-4).

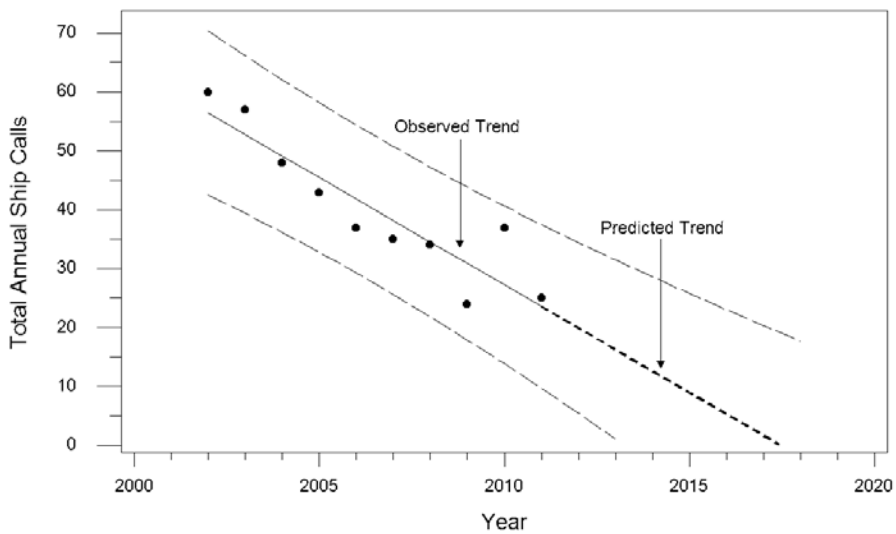

**Figure 4.2-4**
**Annual Calls to Coos Bay by All Vessel Types, 2002-2011 and Predictions (with 95 percent prediction intervals) through 2018, given the Observed Trend (y = 7385 – 3.66 x; $r^2$ = 0.836, P<0.001). Source: MARAD, 2013**

Releases of diesel fuel and/or gasoline are possible in the foreseeable future. According to annual reports published by the Pacific States/British Columbia Oil Spill Task Force, ODEQ reported 34 spills from fishing vessels or other harbor craft in 2002, 38 spills in 2003, and 7 spills from fishing vessels, plus spills from 27 other vessel types in 2004. Those relatively consistent incidences apparently increased in 2005 with 18 spills from fishing vessels, 20 from recreational vessels, and 27 spills by other vessel types. By contrast in 2006, there were 3 spills from fishing vessels, 6 spills from recreational vessels, and only 6 spills from other vessel types. Though not known, it appears that the background rate of spills off the Oregon coast (incidence of spills in proportion to total vessel operation) by fishing vessels, recreation vessels, and other vessel types is generally low and expected to continue at low frequencies in the foreseeable future.

The foreseeable cumulative effect of 90 LNG carriers per year with anticipated dry bulk vessel traffic in 2017 would be less than effects based on past or present levels of vessel traffic calls to the Port of Coos Bay. Consequently, cumulative effects to blue whales would likely be less than the estimate of direct effects discussed in the previous sections. Those effects were judged to be insignificant and discountable.

The volume of annual vessel transits within the EEZ of California, Oregon, and Washington is related to numbers of vessel calls to ports in those states. Total annual calls for all vessels at ports in California, Oregon, and Washington (MARAD, 2013) were plotted above in figure 4.2-2 for 2002 through 2011. Unlike the trend analyzed for Coos Bay (see figure 4.2-4) the observed linear trend in annual vessel traffic (port calls) along the U.S. West Coast was significantly increasing at a rate of 2.1 percent per year between 2002 and 2007. The increasing trend was interrupted by the global economic crisis in 2008 but data through 2011 indicate a return to the established increasing trend prior to 2008. The pre-2008 trend predicts 21,530 vessel calls to West Coast ports in 2018 (with 95% prediction intervals ranging from 17,360 to 25,710 vessel calls), the year the JCEP and PCGP projects are expected to be in service. Even with such uncertainty generated by available data, there is a reasonably foreseeable increasing trend, albeit imprecise, for vessel traffic volume in the future, by 2018, although unforeseen global events such as future economic crises could influence the predictions. Cumulative effects of 90 LNG carriers per year to blue whales may be more or may be less than the estimate of direct effects discussed above.

**Critical Habitat**

The proposed action would not affect critical habitat; none has been designated.

#### 4.2.1.4 Conservation Measures

Included in the Jordan Cove LNG Terminal Conservation Measures (see appendix N) is development of a plan to minimize potential ship strikes to cetaceans, and possibly other listed (sea turtles) and non-listed marine species by LNG carriers. LNG carriers would transit to the slip at slow speeds (between 4 to 6 knots once inside the Coos Bay navigation channel) and would result in minimal wakes, such that marine mammals would not be affected by the wakes of passing LNG carriers.

Jordan Cove would request all LNG carriers calling on the LNG terminal to reduce speeds to 10 knots or less within 30 nautical miles of the entrance to Coos Bay during the whale migratory period. During the 96-hour pre-notification process to be followed by all LNG carriers calling on the terminal, Jordan Cove would check with the NMFS for information on the migratory patterns of whales within the route of the LNG carrier and would inform the ship's master of the patterns reported by NMFS. Jordan Cove would request that all LNG carrier operators consult current whale sighting information prior to calling on the LNG terminal and be aware of the reported locations of whales and plan their operations accordingly. LNG carriers would be requested to reduce their speed to 10 knots or less when mother and calf pairs, groups or large assemblages are observed near an underway LNG carrier. LNG carriers would be requested to route around and maintain a 100-yard distance from the whales observed and to avoid crossing in front of the whales and maintain a parallel route, if possible.

Jordan Cove would provide a ship strike avoidance measures package to shippers delivering LNG cargo to the LNG terminal. This package would include the measures proposed by NMFS for avoidance of marine mammals to further reduce the likelihood of adverse effects on these species. Some of the suggested measures include the following:

- Provide training to LNG carrier crews, including the use of a reference guide such as the *Marine Mammals of the Pacific Northwest, including Oregon, Washington, British Columbia and South Alaska* by Pieter Folkens. This is a pamphlet that would be provided to LNG carriers calling on the terminal and would be included as part of the terminal use agreement to the shippers.
- Provide a copy of the NMFS CD-rom-based training program entitled *A Prudent Mariner's Guide to Right Whale Protection* as part of a ship strike avoidance measures package to all LNG carriers calling on the terminal. While this CD-rom-based training program is specific to right whales, NMFS has stated that the guidance and avoidance measures are also applicable to fin, humpback, and sperm whales.
- Require LNG carrier crews to maintain a watch for marine mammals and slow the ship to 10 knots or less to avoid striking protected species.

- When whales are sighted maintain a distance of 90 meters (or 100 yards) or greater from the whale.
- Attempt to maintain a parallel course to the animal and avoid excessive speed or abrupt changes in direction until the animal has left the area.
- Reduce ship speed to 10 knots or less when pods or large assemblages of cetaceans are observed near an underway ship.
- When whales are sighted in a ship's path or in proximity to a moving ship, reduce speed to 10 knots or less or shift the engine to neutral until whales are clear of the area or path of the ship.

LNG carrier masters would be requested to provide reports of sightings of marine mammals while in the EEZ analysis area and to provide the report upon docking at the LNG terminal. This reporting request would be included in the Ship Strike Avoidance Measures Package provided to each LNG carrier calling on the terminal and compliance with the measures and the reporting would be included in all terminal service agreements with shippers.

LNG carrier crews would be asked to report sightings of any injured or dead protected species immediately, regardless of whether the injury or death is caused by the ship. If the injury or death is caused by collision with the ship, appropriate regulatory agencies (FERC or NMFS) would be notified within 24 hours of the incident. Information to be provided would include the date and location (latitude/longitude) of the strike, the ship name, the species or a description of the animal, if possible.

Jordan Cove has been working with the Coast Guard and ODE in the development of an LNG Management Plan. The LNG Management Plan is the primary process used in reducing risk through proper mitigation measures. The interagency group has been given a step by step process in how risk is mitigated in both safety and security issues.

As part of the LNG Management Plan, Jordan Cove is proposing that LNG carriers would not be allowed to move past the 50-mile voluntary traffic lanes offshore unless it is acceptable for them to continue into the LNG terminal. In addition, Jordan Cove is also proposing that LNG carriers would not be allowed to anchor offshore the Oregon coast. The New Carissa incident occurred when a ship inappropriately anchored in heavy seas just off the coast. LNG carriers would only be allowed to enter closer than 50 miles when all conditions are suitable to enter the port. Further, JCEP has committed to providing tractor tugs to escort each LNG into the port and to the berth. This type of tug has not been previously available in the port. These tugs have the capability to fully maneuver the LNG carriers even without ship power.

#### 4.2.1.5 Determination of Effects

**Species Effects**

The Project **may affect** blue whales because:

- Blue whales may occur within the EEZ analysis area during operation of the proposed action.
- The proposed action would increase shipping traffic (LNG carriers) within the EEZ analysis area.

However, the project is **not likely to adversely affect** blue whales because:

- Existing information indicates ship strikes to blue whales within the EEZ analysis area are infrequent.
- The increase in annual ship traffic due to the proposed action is expected to cause an immeasurable increase in ship strikes to blue whales over known frequencies of incidents.
- Jordan Cove would provide a ship strike avoidance measures package to shippers delivering LNG cargo to the LNG terminal. The package consists of multiple measures to avoid striking marine mammals.
- LNG carriers approaching the Port of Coos Bay would be traveling slowly and escorted by tractor tugs from 50 nmi offshore to the Port.
- Noise produced by LNG carriers would contribute to overall noise within the EEZ while en route to the Port of Coos Bay and effects of ship noise on blue whales could exceed NMFS interim noise exposure criteria for Level B single non-pulse noise but would not exceed existing background ship noise levels and would not cause injury.
- Accidental releases of LNG at sea would not cover an area large enough to coincide with expected blue whale presence (based on estimated densities). Ignited LNG would not extend far enough from the LNG pool to cause severe or mild thermal effect to blue whales if they emerged during a fire.

**Critical Habitat Effects**

No critical habitat has been designated or proposed for blue whales.

### 4.2.2 Fin Whale

#### 4.2.2.1 Species Account and Critical Habitat

**Status**

Fin whales were listed as endangered under the Endangered Species Conservation Act on June 2, 1970 (FWS, 1970) and have been listed as endangered throughout its range under the ESA since its implementation in 1973. Two stocks of fin whales are recognized in the North Pacific, and there may be additional subpopulations (NOAA Fisheries, 2012a). The MMPA stock assessment recognizes three stocks of fin whales in the North Pacific, including the California, Oregon, and Washington stock (NOAA Fisheries, 2012a). Fin whales are classified as depleted throughout its range under the MMPA

**Threats**

Commercial whaling was the primary reason for the depletion of the fin whale population; commercial whaling in the North Pacific ended in 1976 (NOAA Fisheries, 2012a). Hybridization between blue whales and fin whales has been documented, and may decrease the fitness of the blue and fin whales that hybridize (Berube and Aguilar, 1998). Ship strikes and disturbance created by vessels and tourism are other threats to fin whales (NMFS, 2010a). From available accounts (Laist et al., 2001; Jensen and Silber, 2003) fin whales collide with ships relatively often, more frequently than 10 other species known to be struck off the U.S. East Coast (Laist et al., 2001) and relatively often on the West Coast (Jensen and Silber, 2003). Between 2007 and 2011 there were eight fin whales killed or injured by vessel strikes along the Pacific west coast, 7 of them off the California coast and one off the Oregon coast (Carretta et al., 2013a). Those estimates are undoubtedly low since many ship strikes with cetaceans are unknown and unreported.

Anthropogenic noise is a habitat concern, identified by NMFS (2010a) as a factor influencing the distribution of fin whales. Noise from ships and boats may interfere and mask cetacean communication, finding prey, avoiding predators, and possibly navigation (Würsig and Richardson, 2009). Coastal development and its associated anthropogenic noise may compromise the migration routes and seasonal areas used by fin whales (NMFS, 2010a). Concerns about the future related to global warming and climate change may impact habitats, the availability of food, breeding behavior, and associated migration patterns (NMFS, 2010a).

Fin whale food sources may be damaged and may be stressed by certain climate changing processes such as global warming. The impacts from climate change could affect everything from phytoplankton up the trophic levels of the ecosystem. The potential impacts from global warming are being studied in an ongoing process from the United States GLOBEC program (Fogarty and Powell, 2002). Stressors from metabolic demands with warmer oceans may impact the health of animals. Shifts of marine populations either towards the poles or in the ocean depths they use are expected. Increased stratification from an increased temperature, and/or increased freshwater inputs may affect nutrient exchange and primary production. There may be reductions in the available nutrient levels and possible changes in the timing and intensity of phytoplankton blooms. There may also be reductions of upwelling and downwelling, thereby limiting the nutrient availability to marine life in specific stratified levels of the ocean. Changes in the California Current have reduced the zooplankton populations, primarily as a result of increased water temperatures which led to intensified stratification and a lowering of mixing and nutrient regeneration in the water column (Fogarty and Powell, 2002).

**Species Recovery**

A recovery plan was finalized in 2010 (NMFS, 2010a) and a 5-year status review was completed in December 2011 (NMFS, 2011a). The goals of the recovery plan (NMFS, 2010a) are to downlist and delist the species by maintaining stable populations in each ocean basin and ensuring that each population satisfies the risk analysis standard for threatened status and that factors which limit population growth have been identified and addressed.

The recovery plan identifies the following necessary actions:

1. Coordinate state, federal, and international actions to implement recovery efforts;
2. Determine population discreteness and stock structure;
3. Develop and apply methods to estimate population size and monitor trends in abundance;
4. Conduct risk analyses;
5. Identify and protect habitat essential to fin whale survival and recovery;
6. Identify causes of and minimize human-caused injury and mortality;
7. Determine and minimize any detrimental effects of anthropogenic noise in the oceans;
8. Maximize efforts to acquire scientific information from dead, stranded, and entangled or entrapped fin whales;
9. Develop a post-delisting monitoring plan.

**Life History, Habitat Requirements, and Distribution**

Fin whales are a baleen whale and the second-longest whale species. They are widely distributed throughout the world's oceans. The gestation period is assumed to be somewhat less than a year, and fin whale calves are nursed for 6 to 7 months. Most mating and calving takes place in winter. In the North Pacific, fin whales appear to prefer a diet of euphausiids and large copepods, followed by schooling fish such as herring, walleye pollock, and capelin (NMFS, 2010a).

Fin whales can be found in groups of three to seven, with records of groups between 50 and 100 in rich feeding grounds. They typically dive between 3 and 15 minutes to between 100 and 230 meters. A series of two to five shallow dives for between 10 and 20 seconds is common (Shirihai and Jarrett, 2006).

The reproductive age of fin whales is believed to have decreased from 12 to 6 years for females and 11 to 4 for males from the 1950s to the mid 1970s as a result of heavy commercial whaling targeting their populations. They are believed to reproduce every 2 to 3 years upon reaching sexual maturity. An estimated average of 0.36 to 0.47 of sexually mature females are pregnant annually (NMFS, 1998a). Fin whales live to be between 85 to 90 years old (Shirihai and Jarrett, 2006).

Migratory patterns of fin whales in the North Pacific are complex since whales occur in many different locations and latitudes in any season. Aggregations of fin whales occur year-round in southern and central California and the Gulf of California and off Oregon during summer. Vocalizations have been detected year-round off northern California, Oregon, and Washington with concentrations from September through February (Carretta et al., 2013b). Concentrations in the North Pacific form along mixing zones between coastal and oceanic waters associated with the continental shelf.

**Population Status**

Data from surveys of fin whale abundance in California, Oregon, and Washington (out to 300 nmi from the coast) indicatde an increasing population trend for fin whales in that stock (Caretta et al., 2013b). The best estimate of the California/Oregon/Washington Stock of fin whales is 3,051 whales (Carretta et al., 2013b). The minimum population is estimated at 2,598 whales (Carretta et al., 2013b). The overall potential biological removal for this fin whale stock is 16 whales per year (Carretta et al., 2013b). The abundance of fin whales off of the West Coast, from Baja California to Washington, has increased between 1991 and 2008 (Carretta et al., 2013b). The survey data include: 2,042 whales in 1996, 2,118 whales in 2001, 3,281 whales in 2005, and 2,825 whales in 2008 (Carretta et al., 2013b).

**Critical Habitat**

Critical habitat for this species has not been designated.

#### 4.2.2.2 Environmental Baseline

**Analysis Area**

The analysis area applicable to fin whales is the EEZ, extending 200 nautical miles offshore from the Coos Bay Head and from San Diego to Cape Flattery, Washington, the same as described above for blue whales (see figure 4.2-1).

**Species Presence**

Line-transect ship surveys conducted off the coasts of California, Oregon, and Washington in summer and fall of 1991, 1993, 1996, 2001, 2005, and 2008 (Barlow and Forney, 2007; Forney, 2007; Barlow, 2010) have been used to estimate populations within the California and Oregon-

Washington strata and to estimate populations for specific stocks. During each of those years (only California waters were surveyed in 1991 and 1993), line-transect locations were pre-determined to survey for pelagic cetaceans within approximately 300 nmi of the West Coast.

The mean density estimates for species in the California stratum are computed as the mean population estimate divided by the area in the surveyed stratum, 819,470 km$^2$ (Barlow, 2010) which is assumed to be the same in all of the years surveyed. The mean density of fin whales in the California stratum is 0.227 whale per 100 km$^2$ or 0.066 whale per 100 nmi$^2$. Similarly, mean population estimates for species in the Oregon-Washington stratum are the geometric means of population estimates derived from surveys conducted in 1996, 2001, 2005 (data from Barlow and Forney, 2007; Forney, 2007) and 2008 (data from Barlow, 2010). The mean density of fin whales in the Oregon-Washington stratum is 0.129 whale per 100 km$^2$ or 0.038 whale per 100 nmi$^2$.

The mean encounter rate (number observed per linear distance of transect) for each cetacean species is the geometric mean of the number of animals counted along line transects in the California stratum during each survey year (1991 through 2008, see above) divided by total transect length in the stratum for each survey year (data from Barlow and Forney, 2007; Forney, 2007; Barlow, 2010). If no individuals were sighted in one or more years, the arithmetic mean was used. The mean encounter rate for fin whales in the California stratum in 2008 is 0.383 whale per 100 km or 0.207 whale per 100 nmi of ship transect. Likewise, the mean encounter rate (number observed per linear distance) for cetaceans observed in the Oregon-Washington stratum is the geometric mean of the number of animals counted along line transects during each survey year (1996 through 2008, see above) divided by total transect length in the stratum for each survey year (data from Barlow and Forney, 2007; Forney, 2007; Barlow, 2010). The mean encounter rate for fin whales in the Oregon-Washington stratum in 2008 is 0.334 whale per 100 km or 0.180 whale per 100 nmi of ship transect.

**Habitat**

Recent observations show fin whales to be present year-round in central and Southern California; year-round in the Gulf of California; and in summer in Oregon. Acoustic signals from fin whales are detected year-round off northern California, Oregon, and Washington, with a concentration of vocal activity between September and February (NMFS, 2010a). Since fin whales feed on euphausiids, similar to blue whales, they may likewise follow primary production blooms of phytoplankton and associated euphausiid biomass increases off the Oregon coast as the blooms advace from south to north (Burtenshaw et al., 2004). Therefore, fin whales are expected to occur in the EEZ analysis area at least during some portions of the year.

**Critical Habitat**

Critical habitat for this species has not been designated.

### 4.2.2.3 Effects by the Proposed Action

**Direct and Indirect Effects**

Direct effects of the proposed action include injury and/or mortality due to ship strikes, anthropogenic underwater noise, and potential adverse effects from an accidental ship release of LNG and fire at sea. Spills and/or released LNG could indirectly affect fin whales by impacting forage species. These effects are addressed below.

Ship Strikes by LNG Carriers

As discussed above for blue whales, there is an ongoing threat of ship strikes to fin whales. Reduction of human-caused injury and mortality to fin whales is a principal objective for the species' recovery (NMFS, 2010a). From available accounts (Laist et al., 2001; Jensen and Silber, 2003) fin whales collide with ships relatively often, more frequently than ten other species known to be struck off the U.S. East Coast (Laist et al., 2001) and relatively often on the West Coast (Jensen and Silber, 2003). The rate of ship-strikes to fin whales and other large cetaceans is assumed to be the product of ship traffic and the cetacean population density within the EEZ. From 2007 to 2011 ship strikes of fin whales averaged 1.4 death or injury per year in California and 0.2 death or injury per year off the Oregon-Washington coast (Carretta et al., 2013a). Jensen and Silber (2003) reported a rate of 0.5 fin whale struck per year off the coasts of California and Washington from 1991 through 2002. Likewise, Douglas et al. (2008) compiled records of ship-stikes of fin whales in Washington State from 1980 to 2006 with an average of 0.07 whale struck per year. Those estimates are undoubtedly minimal since many ship strikes with cetaceans are unknown and unreported.

**Ship Traffic**. A considerable amount of shipping traffic currently occurs within the EEZ analysis area. Past, present, and reasonably foreseeable ship traffic within the EEZ analysis area was discussed for blue whales, above. Ship traffic to U.S. West Coast ports was increasing between 2002 and 2007 but deviated from the established trajectory in 2008, at the onset of the global financial crisis (see figure 4.2-2). The pre-2008 trend predicts 21,530 vessel calls to West Coast ports in 2018 (with 95% prediction intervals ranging from 17,360 to 25,710 vessel calls), the year the JCEP and PCGP projects are expected to be in service.

Applying the yearly percent change in Total Annual Vessel Calls at all West Coast ports based on the regression model in figure 4.2-2 to the total ship-miles along the West Coast beginning in 1999 (5,049,298 ship-miles in table 4.2.1-1), there would be an estimated 8,199,320 ship-miles along the West Coast, expected in 2018.

Similarly, the data from MARAD (2013) were used to estimate ship-miles along the California Coast and along the Oregon-Washington Coast in 2018 from the data in table 4.2.1-1 (under blue whales, above) from 1999 provided by Pacific States/British Columbia Oil Spill Task Force (2002).

- From 2002 to 2007, total vessel calls to California ports increased by a constant number of 251 vessel calls per year (regression model $y = 250.74x - 492{,}585$, $r^2 = 0.78$, $P=0.019$). There were 3,041,597 ship-miles in 1999 within California waters (see table 4.2.1-1); 4,717,894 ship-miles are expected in 2018.
- From 2002 to 2007, total vessel calls to Oregon-Washington ports increased by a constant number of 185 vessel calls per year (regression model $y = 184.6x - 364{,}401$, $r^2 = 0.56$, $P=0.086$). There were 2,007,701 ship-miles in 1999 within Oregon-Washington waters (see table 4.2.1-1); 3,533,752 ship-miles are expected in 2018.

The Project is designed to accommodate 90 LNG tankers a year. If all LNG tankers approach the Jordan Cove terminal by perpendicular transits through the EEZ, they will contribute 36,000 ship miles annually to vessel traffic in the Oregon-Washington stratum in 2018. If all LNG tankers approach the terminal by parallel transits along the California coast, they will contribute 137,160 ship-miles annually to vessel traffic within the California stratum in 2018. Observed and predicted vessel traffic within both strata in 1999, 2007, 2008, and 2018 are provided in table 4.2.2-1, including the addition of project-related LNG tanker traffic in 2018. During the life of the project, there may be years of mixed LNG tanker traffic, some transiting the EEZ perpendicular and other traffic paralleling the coast but such variability can not be estimated.

**Table 4.2.2-1**
**Estimates of Vessel Traffic, Fin Whale Encounter Rates, Relative Ship-Strike Risk, and Estimates of Fin Whales Struck per Year (with Percent Change from the Previous Estimate) in the California and Oregon-Washington Strata of the Project Activity Area.**

| | California Stratum | | | | Oregon-Washington Stratum | | | |
|---|---|---|---|---|---|---|---|---|
| Year and Event | Ship-Miles (nmi) | Whale Encounter Rate (N/100 nmi) | Relative Ship-Stike Risk | Estimate of Whales Struck per Year [5] | Ship-Miles (nmi) | Whale Encounter Rate (N/100 nmi) | Relative Ship-Stike Risk | Estimate of Whales Struck per Year [5] |
| 1999 [1] Baseline Annual Ship Transits | 3,041,597 | N/A | N/A | N/A | 2,007,701 | N/A | N/A | N/A |
| 2007 [2] Predicted Trend with 2002-2007 data | 3,747,406 (+23.2%) | N/A | N/A | N/A | 2,650,249 (+32.0%) | N/A | N/A | N/A |
| 2008 [3] Most Recent Cetacean Survey | 3,316,554 (-11.5%) | 0.207 | 6,860 | 1.40 | 2,495,278 (-5.8%) | 0.180 | 4,495 | 0.20 |
| 2018 [2] Ambient Predicted Ship Traffic | 4,717,894 (+42.3%) | 0.308 (+49.1%) | 14,559 (+112.2%) | 2.971 (+112.2%) | 3,533,752 (+41.6%) | 0.269 (+49.1%) | 9,496 (+111.3%) | 0.420 (+111.3%) |
| 2018 [4] Ambient Traffic with LNG Tanker Traffic | 4,855,054 (+2.9%) | 0.308 (0%) | 14,982 (+2.9%) | 3.057 (+2.9%) | 3,569,752 (+1.0%) | 0.070 (0%) | 9,592 (+1.0%) | 0.424 +1.0%) |

[3] Estimated total vessel calls to California ports and Oregon-Washington ports in 2008 (see Figure 4.2.1-1, above). Source: MARAD, 2013.
[4] Assume 90 LNG tankers with perpendicular transits through West Coast EEZ in Oregon-Washington stratum (36,000 ship-miles per year) or parallel transits through EEZ in California stratum (137,160 ship-miles per year).
[5] Estimates of Whales Struck derived from data reported by Carretta et al., 2013a for ship-strikes in the California and Oregon-Washington EEZ strata.

**Ship-Strike Risk.** An index of relative ship-strike risk within an explicitly defined gridded study area was described by Williams and O'Hara (2009). The approach was adapted to the coarse-scale analysis area by using mean whale encounter rates, described above for fin whales, and shipping intensity as indicated by the total annual ship-miles derived from vessel transits along the West Coast (see table 4.2.2-1) in the California and Oregon-Washington strata.

The encounter rate for fin whales in the California EEZ stratum is significantly ($P < 0.05$) related to the species' density, based on data collected during surveys conducted in in 1991, 1993, 1996, 2001, 2005 (data from Barlow and Forney, 2007; Forney, 2007) and 2008 (Barlow, 2010). Likewise, the encounter rate for fin whales in the Oregon-Washington EEZ stratum is significantly ($P < 0.05$) related to density based on data collected in 1996, 2001, 2005 (data from

Barlow and Forney, 2007; Forney, 2007) and 2008 (data from Barlow, 2010), shown in figure 4.2-5. The relationships supports predictions, below, that future encounter rates (eg, in 2018) would be expected to increase as the fin whale population increases.

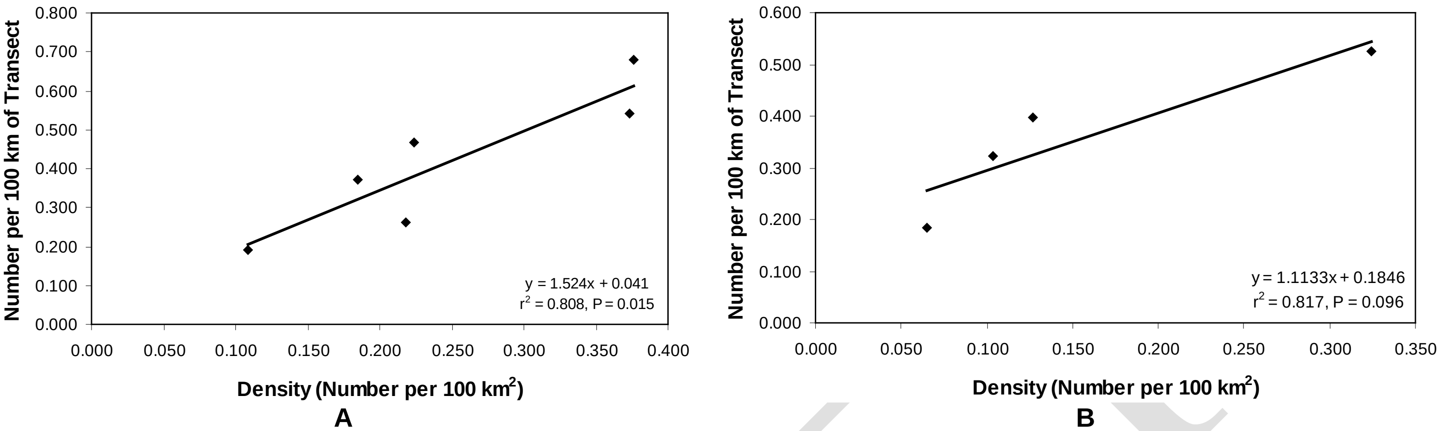

**Figure 4.2-5**
**Relationships of Fin Whale Encounter Rate (Number per 100 km of line-transect) to Density (Number per 100 km$^2$) From Shipboard Surveys Conducted off the Coasts of California (A) and Oregon-Washington (B).**

Relative ship-strike risks during 2008 and 2018 (see table 4.2.2-1) are the products of cetacean species' encounter rates and total ship miles expected in each stratum during the two years. An estimate of the encounter rate in 2018 (beginning of the project operation) is directly proportional to fin whale population and density in that year. Assuming exponential population growth, the population size ($N_t$) at time = t is $N_t = N_0 e^{r t}$ where $N_0$ = the initial population size at t = 0 and r is assumed to be $R_{MAX}$. This approach was used with the default value for $R_{MAX}$ = 0.04 to estimate fin whale encounter rates (as indices of population) in 2018 given the encounter rates of fin whales within the California and Oregon-Washington strata in 2008. In 2008, the fin whale encounter rate in the California stratum was 0.2007 whale per 100 nmi and 0.180 whale per 100 nmi in the Oregon-Washington stratum. Based on assumed population growth between 2008 and 2018, the fin whale encounter rate in California in 2018 is estimated at 0.308 whale per 100 nmi and 0.269 whale per 100 nmi in the Oregon-Washington stratum, an increase of 49 percent from the 2008 encounter rates (see table 4.2.2-1).

In 2008, the relative ship-strike risk in the Califonia stratum would be 0.207 whale per 100 nmi multiplied by 3,316,554 ship-miles = 6,860. In 2018, the assumed growth of the fin whale population increases the encounter rate proportionately to 0.308 whale per 100 nmi. Between 2008 and 2018 ship traffic is also be expected to increase to 4,717,894 ship-miles. The relative ship-strike risk in 2018 would be 14,559 which is 112.2 percent of the 2008 encounter rate (table 4.2.2-1). If all 90 LNG tanker transits occur in the California stratum, the total expeced vessel traffic would be 4,855,054 ship miles in 2018 and the ship-strike risk would increase to 14,982, an estimated increase of 2.9 percent. Similar calculations woud apply to the fin whale population growth, encounter rate, relative ship-strike risk in the Oregon-Washington stratum, provided in table 4.2.2-1.

**Estimated Ship-Strikes to Fin Whales**. Data provided by Carretta et al. (2013a) indicated 7 fin whales were struck in the California EEZ between 2007 and 2011 (1.4 whales per year) and 1 fin whale was struck in the Oregon-Washington EEZ during the same period (0.20 whale per year). Jensen and Silber (2003) reported 6 fin whales struck between 1991 and 2002 along the U.S. Pacific Coast and Douglas et al. (2008) reported 2 strikes off Washington between 1980 and 2006. Using recent ship-strike data from Carretta et al. (2013a), the increased ship-strike risk in 2018 is assumed to increase the annual rate of fin whales struck proportionately in the California stratum to 2.971 per year and to 0.420 per year in the Oregon-Washington stratum (see table 4.2.2-1). The additional project-related LNG tanker traffic would increase the annual rate in California to 3.057 whales per year, an increase of 0.086 ship-strike per year (one injury or death in 12 years) and would increase the annual rate in Oregon-Washington waters to 0.424 whale per year, and increase of 0.004 ship-strike per year (one injury or death in 250 years). Ship-strikes to fin whales by project-related LNG tankers are more likely in California than in the Oregon-Washington EEZ stratum but in both areas, death or injury of fin whales is insignificant and discountable.

<u>Underwater Noise</u>

Determining and minimizing any detrimental effects of anthropogenic underwater noise on fin whales is a principal objective for the species' recovery (NMFS, 2010a). As described for blue whales, above, all vessels produce noise; propeller cavitation produces most of the broadband noise with dominant tones derived from the propeller blade rate. In general, rorquals including blue, fin and minke whales move away, abruptly change direction, or dive to avoid close approach by vessels. When whales are exposed to low-level sounds from distant or stationary vessels, they appear to ignore the sounds. Baleen whales will interrupt normal behavior and swim away from strong or rapidly changing vessel noise, especially if a vessel is headed directly toward the whale (Richardson, 1995). However, radiated ship noise of oncoming ships may not be immediately detected by whales near the surface due to bow null-effect acoustic shadow zones (Allen et al., 2012). Because of acoustic shadow zones, whales may not hear approaching ships to allow time for their avoidance response even though whale auditory ranges overlaps with peak intensities of ship noise.

Ambient noise in the Northeast Pacific Ocean has increased in nearshore and deep ocean environments over the past several decades. The low frequencies generated by ships overlap frequencies of sounds generated by large baleen whales, including the fin whale (Würsig and Richardson, 2009). Noise from ships and boats may interfere and mask cetacean communication, finding prey, avoiding predators, and possibly navigation (Würsig and Richardson, 2009). Anthropogenic noise and vessel disturbance may affect fin whales but there is little evidence available to describe or quantify the impacts of these threats on the species. While anthropogenic noise may threaten other cetaceans, little is known about whether, or how, vessel noise affects fin whales (NMFS, 2010).

The risk of ship noise causing PTS or TTS (see NMFS' interim acoustic thresholds in table 4.2.1-3, under blue whales) for fin whales would be similar to that described for blue whales, above. Noise from a LNG tanker in the Hatch et al. (2008) study produced sound levels (with 1 standard error) of 182 ± 2 dB re: 1 µPa @ 1 meter that attenuated to 160 dB at 35 ± 11 meters and to 120 dB at 16,185 ± 5,359 meters (Hatch et al., 2008). Using those attenuation distances, one LNG tanker transit across the length of the California EEZ stratum for 762 nmi would produce sound levels of ≥160 dB within an area 15.6 ± 4.9 nmi$^2$ and would produce sound levels ≥120 dB but <160 dB within an area 7,175.9 ± 2,376.3 nmi$^2$. Likewise, one LNG tanker transit across the width of the Oregon-Washington EEZ stratum for 200 nmi would produce sound levels of ≥160 dB within an area 4.1 ± 2.6 $nmi^2$ and would produce sound levels ≥120 dB but <160 dB within an area 1,883.4 ± 1,247.4 $nmi^2$.

Based on population growth between 2008 and 2018 described above for fin whale encounter rates, the predicted density of fin whales is 0.099 whale per 100 $nmi^2$ in the California stratum in 2018 and is 0.056 whale per 100 $nmi^2$ in the Oregon-Washington EEZ stratum in 2018. Assuming an LNG tanker transit distance of 762 nmi within the California stratum, the number of fin whales within range of noise levels of 160 dB produced by a single LNG tanker transit through the stratum would be equal to the density (0.099 whale per 100 $nmi^2$) multiplied by the total area of noise effects (15.6 $nmi^2$), equal to 0.015 whale affected (an estimate between 0.006 and 0.025 whale based on the density within distances of ± 2 standard deviations of LNG noise attenuating to 120 dB, from Hatch et al., 2008).

The number of fin whales within range of noise levels of 120 dB (radius of 16,185 m or 4.72 nmi) produced by a single LNG tanker transit through the stratum would be equal to the density (0.099 whale per 100 $nmi^2$) multiplied by the total area of noise effects (7,176 $nmi^2$), equal to 7 whales affected (an estimate between 2 and 12 whales based on the density within distances of ± 2 standard deviations of LNG noise attenuating to 120 dB, from Hatch et al., 2008) by noise levels that could cause behavioral disruptions (see table 4.2.1-3 under blue whales, above).

Similar calculations have been done for fin whales in the Oregon-Washington stratum. Assuming an LNG tanker transit distance of 200 nmi across the Oregon-Washing stratum, the number of fin whales within range of noise levels of 160 dB produced by a single LNG tanker transit through the stratum would be equal to the density (0.056 whale per 100 $nmi^2$) multiplied by the total area of noise effects (4.08 $nmi^2$), equal to 0.002 whale affected. The number of fin whales within range of noise levels of 120 dB produced by a single LNG tanker transit through the stratum would be equal to the density (0.056 whale per 100 $nmi^2$) multiplied by the total area of noise effects 1,883 $nmi^2$), equal to 1 whale affected (an estimate between 0 and 2 whales based on the density within distances of ± 2 standard deviations of LNG noise attenuating to 120 dB, from Hatch et al., 2008) by noise levels that could cause behavioral disruptions (see table 4.2.1-3).

Existing commercial vessels within the West Coast EEZ analysis area produce underwater noise levels that are comparable or exceed noise from the LNG tanker described by Hatch et al. (2008). Noise generated by various types of commercial ships (container ships, crude oil tankers, product tankers, bulk carriers, and others) were recently evaluated by McKenna et al. (2012). Underwater noise levels varied by ship type and also by vessel length, gross tonnage, vessel speed, and to some extent, vessel age (older vessels tended to be louder than newer vessels). For example, a 54,000 Gross Ton (GT) container ship generated the highest acoustic source level of 188 dB re: 1 μPa @ 1 meter while a 26,000 GT chemical tanker had the lowest at 177 dB re: 1 μPa @ 1 meter (McKenna et al., 2012). Noise levels from the vessels examined in that study are assumed to be typical of ship noise in the California and Oregon-Washington EEZ strata and would produce radiated noise levels through the two strata that would exceed the threshold for Level B single non-pulse noise of 120 $dB_{rms}$ (see table 4.2.1-3, above). With the existing levels of background shipping noise and the expected increase in shipping traffic by 2018, effects by project LNG tanker-related noise on fin whales are possible in the in California EEZ stratum but the noise would be commensurate with existing noise levels and would not be expected to cause injury.

Two tractor tugs would guide the LNG tanker from a point approximately 5 nmi offshore the entrance to Coos Bay and to the JCEP LNG terminal. Noise produced by tugs would attenuate to 160 dB at 11 ± 4 meters (upper end) and to 120 dB at 4,992 ± 1,599 meters (upper end) (Hatch et al., 2008). Unlike LNG tankers, project-related tug traffic would only occur in the Oregon-Washington stratum. LNG ship noise and noise from tugs would exceed the ambient noise levels within the West Coast EEZ activity area assuming those range from 64 dB to 72 dB re 1 $\mu Pa^2$ (at 62 Hz, similar to the ocean noise 7 nmi west of San Diego reported by McDonald et al., 2008) but would not cause behavioral disruptions to fin whales.

<u>Releases and Fire at Sea</u>

Characteristics of LNG released at sea were described in Section 4.2.1.3 for blue whales. At the water-vapor LNG pool interface, the cryogenically cooled LNG would begin to vaporize but, because of its relatively high density, the plume would remain at or close to the surface interface; methane is an asphyxiant but with low toxicity, at least to humans (Hightower et al., 2004). If a marine mammal surfaced to breathe at the LNG pool location, it could suffer from oxygen deficiency and potential physiological effects, which have been described for humans - ranging from impaired thinking to loss of consciousness with decreasing oxygen concentrations (Table 39 in Hightower et al., 2004) - but not for marine mammals. Because the estimated densities of marine mammals are generally low within the California and Oregon-Washington strata of EEZ, the chance of an animal becoming asphyxiated by contact with a pool of LNG would extremely remote (see discussion about potential thermal injury, below).

Sandia National Laboratories modeled LNG spills from a standard LNG vessel (with capacity of 125,000 to 140,000 $m^3$) over water and potential injury to humans due to ignition of the fuel (Hightower et al., 2004). Thermal effects from a fire would vary, depending on the size of the LNG pool released. If one LNG tank is accidentally breached, due to collision with another ship, grounding, or ramming, the potential spill of LNG could form a pool with diameter of 685 feet. Ignition could cause a fire to burn for 20 minutes with severe thermal injuries extending to 820 feet away from the center of the pool (based on an exposure of 10 minutes and thermal flux of 37.5 $kW/m^2$) and second-degree skin burns on exposed skin (human) to a distance of 2,572 feet (based on an exposure of 10 minutes and thermal flux of 5 $kW/m^2$) from the center of the burning pool of LNG (see Table 41 in Hightower et al., 2004). Surfacing cetaceans within those distances would be assumed to experience severe burns or mild burns, based on similar thermal fluxes effects on humans although exposures for 10 minutes or more would be unlikely.

Expected densities of fin whales in the California EEZ stratum during 2018 would be 0.099 whale per 100 $nmi^2$ and 0.056 whale per 100 $nmi^2$ in the Oregon-Washington EEZ stratum, the same densities that were used in the analysis of effects due to ship noise, above. Based on the model of accidental LNG release and fire described above (from Hightower et al., 2004), a circular pool of released LNG with diameter of 685 feet would cover an area of 0.010 $nmi^2$. An ensuing fire would cause severe thermal injuries over an area of 0.057 $nmi^2$ and the area where fire coul cause second degree burns would extend to an area of 0.563 $nmi^2$. Considerably fewer than one fin whale would be expected to be present within any of those areas in either of the two EEZ strata during 2018 and injuries to fin whales due to LNG release and fire would be insignificant and discountable

Oil spills at sea or off shore might harm fin whales, although effects of oil spills on fin whales have not been reported (NMFS, 2006b). Effects to food resources including krill, copepods, and various schooling fish such as anchovies (NMFS, 2006b) could occur. However, effects of potential spills from LNG carriers are not comparable to spills from oil tankers for a number of reasons. LNG carriers only carry quantities of oil used for propulsion fuel and not the quantities transported by oil tankers.

### Cumulative Effects

FWS and NMFS describe cumulative effects (50 CFR. § 402.02) as the result of future actions by state or private entities, not involving federal actions, but reasonably certain to occur in the action area considered in this BA. Future federal actions that are unrelated to the proposed action are not considered here because they require separate consultation pursuant to section 7 of the ESA.

As discussed above for blue whales, available information indicates that ship calls to the Port of Coos Bay have been declining since 2002. The observed declining linear trend in total annual vessel traffic over time is significant and, when used to forecast numbers of total vessel calls to Coos Bay in the future, no vessels are predicted to enter Coos Bay in 2018 with between 0 and 17.6 vessels as reasonably foreseeable when the LNG terminal is expected to begin operation in 2018 (see figure 4.2-4 under blue whales). And as discussed above for blue whales, it appears that the background rate of spills off the Oregon coast by fishing vessels, recreation vessels, and other vessel types is generally low, a frequency that would be expected to continue.

The foreseeable cumulative effect of 90 LNG carriers per year with anticipated total vessel traffic in 2018 would be less than effects based on past or present levels of vessel traffic calls to the Port of Coos Bay. Consequently, cumulative effects to fin whales would likely be less than the estimate of direct effects discussed in the previous section. Those effects were judged to be insignificant and discountable.

The volume of annual vessel transits within the EEZ of California, Oregon, and Washington is related to numbers of vessel calls to ports in those states. Total annual calls for all vessels at ports in California, Oregon, and Washington (MARAD, 2013) were plotted above in figure 4.2-2 for 2002 through 2011. Unlike the trend analyzed for calls to Coos Bay (see figure 4.2-4 under blue whales) the observed linear trend in annual vessel traffic (port calls) along the U.S. West Coast was significantly increasing at a rate of 2.1 percent per year between 2002 and 2007. The increasing trend was interrupted by the global economic crisis in 2008 but data through 2011 indicate a return to the established increasing trend prior to 2008. The pre-2008 trend predicts 21,530 vessel calls to West Coast ports in 2018 (with 95% prediction intervals ranging from 17,360 to 25,710 vessel calls), the year the JCEP and PCGP projects are expected to be in service. Even with the uncertainty generated by available data, there is a reasonably foreseeable increasing trend, albeit imprecise, for vessel traffic volume in the future (by 2018) although unforeseen global events such as future economic crises could influence the predictions. Cumulative effects of 90 LNG carriers per year to fin whales may be more or may be less than the estimate of direct effects discussed above.

### Critical Habitat

The proposed action would not affect critical habitat; none has been designated.

#### 4.2.2.4 Conservation Measures

The same Ship-Strike Reduction Plan to minimize potential ship strikes to cetaceans by LNG carriers and LNG Management Plan to minimize risk of spills and releases at sea that were described in Section 4.2.1.4 (blue whales) apply to fin whales.

#### 4.2.2.5 Determination of Effects

**Species Effects**

The Project **may affect** fin whales because:

- Fin whales may occur within the EEZ analysis area during operation of the proposed action.
- The proposed action would increase shipping traffic (LNG) within the EEZ analysis area.

However, the Project is **not likely to adversely affect** fin whales because:

- Existing information indicates ship strikes to fin whales within the EEZ analysis area are infrequent.
- The increase in annual ship traffic due to the proposed action is expected to cause an immeasurable increase in ship strikes to fin whales over known frequencies of incidents.
- Jordan Cove would provide a ship strike avoidance measures package to shippers delivering LNG cargo to the LNG terminal. The package consists of multiple measures to avoid striking marine mammals.
- LNG carriers approaching the Port of Coos Bay would be traveling slowly and escorted by tractor tugs from 50 nmi offshore to the Port.
- Noise produced by LNG carriers would contribute to overall noise within the EEZ en route to the Port of Coos Bay and effects of ship noise on fin whales could exceed NMFS interim noise exposure criteria for Level B single non-pulse noise but would not exceed existing background ship noise levels and would not cause injury..
- Accidental releases of LNG at sea would not cover an area large enough to coincide with expected fin whale presence (based on estimated densities). Ignited LNG would not extend far enough from the LNG pool to cause severe or mild thermal effects to fin whales if they emerged during a fire.

**Critical Habitat Effects**. No critical habitat has been designated or proposed for fin whales.

### 4.2.3 Killer Whale

#### 4.2.3.1 Species Account and Critical Habitat

**Status**

Five killer whale stocks are recognized within Pacific United States waters:

1. Eastern North Pacific Northern Resident stock - occurring from British Columbia through Alaska (unlisted);
2. Eastern North Pacific Southern Resident stock - occurring within the inland waters of Washington and southern British Columbia, listed as endangered under the ESA November, 18, 2005 (NMFS 2005a). The Southern Resident population is classified as depleted under the MMPA; ;

3. Eastern North Pacific Transient stock – occurring from Alaska through California (unlisted);
4. Eastern North Pacific Offshore stock - occurring from Southeast Alaska through California (unlisted); and
5. Hawaiian stock (unlisted).

A status review of Southern Resident killer whales conducted in 2002 concluded that listing as threatened or endangered was not warranted because Southern Resident killer whales were not a species or Distinct Population Segment (DPS) for ESA application (NMFS, 2005a). The status review recognized, however, that the Southern Resident killer whale was a depleted stock under the MMPA. A challenge to NMFS' decision to not the list the species ("not warranted") and subsequent judicial intervention resulted in an updated status review, which found that the Southern Resident killer whale stock is discrete and significant with respect to other resident stocks and should be considered a DPS for listing under ESA (NMFS, 2005a).

NMFS (2012) published a 90-day finding on a petition to remove (delist) the Southern Resident killer whale DPS from the ESA list. The finding determined that the petitioned action might be warranted and NMFS announced their initiation of a status review to determine if the petitioned action is warranted. In 2011, NMFS completed a 5-year review of the status of Southern Residents killer whales and concluded that no change was needed in the species' ESA listing status; the Southern Resident killer whale DPS would remain listed as endangered (NMFS, 2011d).

**Threats**

The Southern Resident killer whale DPS primarily occurs in the inland transboundary waters of British Columbia and Washington in the summer and fall and in outer coastal waters in winter. The NMFS (2008) identified the factors that currently pose a risk for Southern Residents including 1) reductions in quantity or quality of prey, (2) high levels of organochlorine contaminants and increasing levels of many "emerging" contaminants (e.g., brominated flame retardants), putting Southern Residents at risk for serious chronic effects similar to those demonstrated for other marine mammals (e.g., immune and reproductive system dysfunction), (3) sound and disturbance from vessel traffic, and (4) oil spills. Reductions in prey availability, primarily that of salmon, over the past 150 years has limited the carrying capacity for the Eastern North Pacific Southern Resident stock (NMFS, 2008a). Other reasons for the reduction in Southern Resident stock numbers include the live-capture of whales for aquariums, and shooting of whales that were common before 1960 (NOAA Fisheries, 2013c).

Three primary threats to the Southern Resident stock include contaminants, prey availability, and vessel traffic (NMFS, 2008a). High levels of polychlorinated biphenyls (PCBs) have been found in the Southern Resident stock, and increasing levels of polybrominated diphenyl ethers and other contaminants are being found in ocean habitats with increasing frequency (NMFS, 2008a). Ross et al., (2000) found that the Southern Resident stock was one of the most contaminated cetaceans worldwide, and noted that fish-eating marine mammals that are found along industrialized coastal waters are generally high in PCB concentration levels.

Killer whale food sources may be damaged and they may gain new stressors with certain climate changing processes such as global warming. The impacts from climate change could affect everything from phytoplankton up the trophic levels of the ecosystem to keystone predators such as killer whales. Stressors from metabolic demands with warmer oceans may impact the health of animals. Shifts of marine populations either towards the poles or in the ocean depths they use are expected. Increased stratification from an increased temperature, and/or increased freshwater inputs may affect nutrient exchange and primary production. There may be reductions in the available nutrient levels and possible changes in the timing and intensity of phytoplankton blooms. There may also be reductions of upwelling and downwelling, thereby limiting the nutrients available to marine life in specific stratified levels of the ocean. Changes in the California Current have reduced the zooplankton populations, primarily as a result of increased water temperatures, which has led to intensified stratification and a lowering of mixing and nutrient regeneration in the water column (Fogarty and Powell, 2002).

Commercial and recreational vessel traffic, ferries, and whale watching have increased considerably during the past decades. Studies have revealed that whale-watch vessel operations affect killer whale behaviors including foraging, communication, movements and energy expenditures, and increase underwater noise (NMFS, 2008a). Whale-watch vessels also strike and cause injury to killer whales and possibly increase susceptibility to ship strikes by other types of vessels (NMFS, 2011d).

**Species Recovery**

A proposed recovery plan was prepared in 2006 by the NMFS for the Southern Resident killer whales (NMFS, 2006c) and a final plan was published in 2008 (NMFS, 2008a). The goal of the final recovery plan is to remove the species from ESA-listed status. The interim goal is to reclassify the Southern Resident killer whale DPS from endangered to threatened. The following is a list of recovery measures needed to achieve the goals and objectives provided in the recovery plan (NMFS, 2008a):

- Protect the Southern Resident killer whale population from factors that may be contributing to its decline or reducing its ability to recover (salmon stock, pollution, vessel disturbance).
- Protect Southern Resident killer whales from additional threats that may cause disturbance, injury, or mortality, or impact habitat (oil spills, acoustic effects, disease, invasive species).
- Develop public information and education programs.
- Respond to killer whales that are stranded, sick, injured, isolated, pose a threat to the public, or exhibit nuisance behaviors.
- Encourage transboundary and interagency coordination and cooperation.
- Monitor status and trends of the Southern Resident killer whale population.
- Conduct research to facilitate and enhance recovery efforts for Southern Resident killer whales.

**Life History, Habitat Requirements, and Distribution**

The killer whale, or orca, is found in all oceans. These whales can adapt to a wide variety of conditions, and appear to be at home in both open seas and coastal waters. Orcas are toothed whales, and the largest of the dolphins. They have a widely varied diet including salmon, pinnipeds, and even large baleen whales; the diet is often geographic specific. They often hunt in groups using pack-like behavior (Carretta et al., 2013b). Pods for mammal-eating killer whales are generally between 5 and 10 animals, while pods of fish-eating killer whales consist of larger groups. The groups generally include a mixture of age and sex. They generally breathe every 10 to 35 seconds during approximately 12 short dives, and can deep dive for up to 17 minutes (Shirihai and Jarrett, 2006).

Sexual maturity of female killer whales is size dependent and occurs when the whales reach lengths of approximately 15 to 18 feet. Mating appears to occur at any time, with no identified breeding season (American Cetacean Society, 2004). The female Southern Resident killer whales average births every 4.9 to 7.7 years, and are polygamous. Females reproduce throughout their lives upon reaching sexual maturity, and can live up to 40 or 50 years of age. Males tend to have death rates that increase by 18 percent each year after reaching 30 years old (American Cetacean Society, 2004).

**Population Status**

In 1993 there were 96 individual killer whales in the three pods that comprise the Eastern North Pacific Southern Resident stock. The population increased to 99 whales in 1995, then declined to 79 whales in 2001, and most recently numbered 85 whales in 2012 (Carretta et al., 2013b).

It is believed that the entire population is identified and accounted for each year, and so the minimum population estimate is also 85 animals. The recent analysis of long-term population growth, from 1979 to 2011, for the Southern Resident killer whale DPS indicates the maximum annual growth rate is $R_{MAX}$ = 3.2 percent (Carretta et al. 2013b). The potential biological removal, is the maximum number of animals killed (not including natural deaths), that would still allow for the population to achieve its optimum sustainable population (NMFS, 1997b). The potential biological removal for these whales is calculated at 0.14 whale per year and appears to be approaching a rate of zero for human-related mortality and serious injury (Carretta et al. 2013b).

Observations of Southern Resident killer whales in Oregon have been restricted to offshore areas near Depoe Bay (1999 and 2000), near Yaquina Bay (2000), and near the Columbia River (2006) (NMFS, 2006d). The nearest sightings of Southern Resident killer whales in California have been off Point Reyes, 30 miles north of San Francisco (NMFS, 2006c). Therefore, the federally listed Southern Resident killer whale stock may occur in, or travel through the EEZ on an infrequent basis. Killer whales occasionally enter lower Coos Bay in search of prey resources, but rarely occur as far upstream as the LNG terminal (U.S. Army Corps of Engineers, 1994). Since the Eastern North Pacific Southern Resident killer whale stock has been sighted along the Oregon coast and as far south as Monterey Bay, California (Carretta et al., 2013b), individuals entering Coos Bay and within the EEZ off the Oregon and Washington coasts are likely to belong to that DPS.

**Critical Habitat**

Critical habitat for the Eastern North Pacific Southern Resident stock of killer whales was designated on November 28, 2006 (NMFS, 2006c). Three specific areas were designated: 1) the Summer Core Area in Haro Strait and waters around the San Juan Islands; 2) Puget Sound; and 3) the Strait of Juan de Fuca. None of the Critical Habitat Units (CHUs) for the Eastern North Pacific Southern Resident stock occurs within the EEZ analysis area off the Oregon coast or off the Washington coast.

Primary constituent elements of the designated critical habitat are (NMFS, 2006c): 1) Water quality to support growth and development; 2) Prey species of sufficient quantity, quality and availability to support individual growth, reproduction and development, as well as overall population growth; and 3) Passage conditions to allow for migration, resting, and foraging. Fish are the major dietary component of resident killer whales in the northeastern Pacific. Salmon are the preferred prey for the DPS (NMFS, 2006c). Sufficient prey abundance is necessary to support individual growth to reach sexual maturity and reproduction, including lactation and successful rearing of calves. Because of their long life span, position at the top of the food chain, and their blubber stores, killer whales accumulate high concentrations of contaminants including PCBs, DDT, polychlorinated napthalenes, brominated flame retardants, PAHs, dioxins, furans, and heavy metals. Those and others may cause mortality or reproductive failure in Southern Resident killer whales (NMFS, 2006c). Southern Resident killer whales require open waterways that are free from obstruction. In-water structures that block passage, for example, could affect Southern Resident killer whale movement. (NMFS, 2006c).

#### 4.2.3.2 Environmental Baseline

**Analysis Area**

The analysis area applicable to killer whales is the EEZ, extending 200 nautical miles offshore from the Coos Bay Head and from San Diego to Cape Flattery, Washington, the same as described above for blue whales (see figure 4.2-1).

**Species Presence**

Killer whales are known to occur off the Oregon Coast. Most sightings of the ESA-listed Southern Resident killer whales have occurred during summer within inland waters of Washington and southern British Columbia. However, pods belonging to this stock have also been sighted in coastal waters off southern Vancouver Island and Washington and the location of their complete winter range is uncertain (Carretta et al., 2013b). Two of the three pods comprising this stock have been sighted as far south as Monterey Bay and central California in recent years. Observations of Southern Resident killer whales in Oregon have been restricted to offshore areas near Depoe Bay (1999 and 2000), near Yaquina Bay (2000) and near the Columbia River (2006) (NMFS, 2006c). Therefore, Southern Resident killer whales may occur in or travel through the EEZ analysis area on an infrequent basis. Killer whales occasionally enter lower Coos Bay in search of prey resources (U.S. Army Corps of Engineers, 1994).

Line-transect ship surveys conducted off the coasts of California, Oregon, and Washington in summer and fall of 1991, 1993, 1996, 2001, 2005, and 2008 (Barlow and Forney, 2007; Forney, 2007; Barlow, 2010) have been used to estimate populations within the California and Oregon-Washington strata and to estimate populations for specific stocks. During each of those years (only California waters were surveyed in 1991 and 1993), line-transect locations were pre-determined to survey for pelagic cetaceans within approximately 300 nmi of the West Coast.

The mean density estimates for species in the California stratum are computed as the mean population estimate divided by the area in the surveyed stratum, 819,470 km$^2$ (Barlow, 2010) which is assumed to be the same in all of the years surveyed. The mean density of killer whales in the California stratum is 0.036 whale per 100 km$^2$ or 0.010 whale per 100 nmi$^2$. Similarly, mean population estimates for species in the Oregon-Washington stratum are the geometric means of population estimates derived from surveys conducted in 1996, 2001, 2005 (data from Barlow and Forney, 2007; Forney, 2007) and 2008 (data from Barlow, 2010). The mean density of killer whales in the Oregon-Washington stratum is 0.166 whale per 100 km$^2$ or 0.048 whale per 100 nmi$^2$.

The mean encounter rate (number observed per linear distance of transect) for each cetacean species is the geometric mean of the number of animals counted along line transects in the California stratum during each survey year (1991 through 2008, see above) divided by total transect length in the stratum for each survey year (data from Barlow and Forney, 2007; Forney, 2007; Barlow, 2010). If no individuals were sighted in one or more years, the arithmetic mean was used. The mean encounter rate for killer whales in the California stratum is 0.023 whale per 100 km or 0.012 whale per 100 nmi of ship transect. Likewise, the mean encounter rate (number observed per linear distance) for cetaceans observed in the Oregon-Washington stratum is the geometric mean of the number of animals counted along line transects during each survey year (1996 through 2008, see above) divided by total transect length in the stratum for each survey year (data from Barlow and Forney, 2007; Forney, 2007; Barlow, 2010). The mean encounter rate for killer whales in the Oregon-Washington stratum is 0.076 whale per 100 km or 0.041 whale per 100 nmi of ship transect.

**Habitat**

Killer whales are less restrained by depth, temperature, and salinity of the water than other whales (NMFS 2008a). The Southern Resident stock tends to spend more time in deeper water or waters where there is more salmon abundance. Documented occurrences off of Oregon have led to the belief that the California Current ecosystem is used by this stock, and so the Southern Resident stock may be expected to be found in the EEZ (NMFS 2008a).

**Critical Habitat**

None of the CHUs for the Eastern North Pacific Southern Resident stock occurs within the EEZ analysis area off the Oregon coast.

### 4.2.3.3 Effects by the Proposed Action

**Direct and Indirect Effects**

Direct effects of the proposed action include injury and/or mortality due to ship strikes, effects due to ship noise, and potential adverse effects from a ship spill and/or release of LNG at sea. Spills and/or released LNG could indirectly affect killer whales by impacting forage species. These effects are addressed below.

<u>Ship Strikes by LNG Carriers</u>

As discussed above for blue whales, there is an ongoing threat of ship strikes to killer whales. Of ten whale species studied by Jensen and Silber (2003), killer whales were the least likely to be struck by ships: they found one documented occurrence of a killer whale calf being struck by a ship. One vessel strike on a killer whale from the Southern Resident Stock occurred in 2006, but noted that the particular whale (L98) that was struck had become habituated to vessel interaction while it resided in Nootka Sound. In the 5-year period, 2007-2011, no killer whales had been struck by vessels (Carretta et al., 2013a). Douglas et al. (2008) reported one killer whale stranded in Washington during the period from 1980 to 2006 but the cause of death was likely not related to a ship-stike. The available information indicates that killer whales are not susceptible to ship-strike, at least carcasses indicating trauma and/or wounds from boat propellers have not been reported along the Oregon and Washington coasts (Norman et al., 2004). From 1995 to 2006, 10 killer whales were injured (8) or killed (2) with the inland waterways of British Columbia (including killer whale number L98 killed in 2006, see Williams and O'Hara, 2009) but none of the records were from whales struck in the open ocean.

Therefore, there are no data available to estimate risk of ship-strikes in 2018 and possible death or injury due to project-related LNG traffic in the West Coast EEZ analysis area.

<u>Underwater Noise</u>

Determining and minimizing any detrimental effects of anthropogenic underwater noise on killer whales is a principal objective for the species' recovery (NMFS, 2008a). Killer whales are highly vocal, producing a variety of clicks, whistles, and and pulsed calls used for echolocation and social communication (Ford, 2009). As described for blue whales, above, all vessels produce noise; propeller cavitation produces most of the broadband noise with dominant tones derived from the propeller blade rate. Southern Resident killer whales inhabit Puget Sound near Seattle where a large variety of motorized vessels and production of associated underwater noise are prevalent. Studies have shown that killer whales in the DPS increased their call amplitude by 1 dB for every 1 dB increase in background, ambient noise levels (Holt et al., 2008). Boats approaching killer whales causes them to abandon foraging group foraging behaviors (Lusseau et al., 2009) and boat noise could impair communication and cooperative foraging between killer whales over a range of 1–14 km (Foote et al., 2004).

The risk of ship noise causing PTS or TTS (see NMFS' interim acoustic thresholds in table 4.2.1-2) for killer whales would be similar to that described for blue whales, above. LNG ship noise of 182 ± 2 dB dB re 1 µPa @ 1 m would decrease to 35 ± 11 meters and to 120 dB at 16,185 ± 5,359 meters (Hatch et al., 2008). Using those attenuation distances, one LNG tanker transit across the length of the California EEZ stratum for 762 nmi would produce sound levels of ≥160 dB within an area 15.6 ± 4.9 nmi$^2$ and would produce sound levels ≥120 dB but <160 dB within an area 7,175.9 ± 2,376.3 nmi$^2$. Likewise, one LNG tanker transit across the width of the Oregon-Washington EEZ stratum for 200 nmi would produce sound levels of ≥160 dB within an area 4.1 ± 2.6 nmi$^2$ and would produce sound levels ≥120 dB but <160 dB within an area 1,883.4 ± 1,247.4 nmi$^2$.

Based on population growth between 2008 and 2018, the predicted density of killer whales is 0.016 whale per 100 nmi$^2$ in the California stratum and 0.072 whale per 100 nmi$^2$ in the Oregon-Washington stratum in 2018. Assuming an LNG tanker transit distance of 762 nmi within the California stratum, the number of killer whales within range of noise levels of 160 dB produced by a single LNG tanker transit through the stratum would be equal to the density (0.016 whale per 100 nmi$^2$) multiplied by the total area of noise effects (15.6 nmi$^2$), equal to 0.002 whale affected.

The number of killer whales within range of noise levels of 120 dB (radius of 16,185 m or 4.72 nmi) produced by a single LNG tanker transit through the stratum would be equal to the density (0.016 whale per 100 nmi$^2$) multiplied by the total area of noise effects (7,176 nmi$^2$), equal to 1.1 whale affected (an estimate between 0.4 and 1.9 whales based on the density within distances of ± 2 standard deviations of LNG noise attenuating to 120 dB, from Hatch et al., 2008) by noise levels that could cause behavioral disruptions (see table 4.2.1-3).

Similar calculations have been done for killer whales in the Oregon-Washington stratum. Assuming an LNG tanker transit distance of 200 nmi across the Oregon-Washing stratum, the number of killer whales within range of noise levels of 160 dB produced by a single LNG tanker transit through the stratum would be equal to the density (0.072 whale per 100 nmi$^2$) multiplied by the total area of noise effects (4.08 nmi$^2$), equal to 0.003 whale affected (an estimate between 0.001 and 0.005 whale based on the density within distances of ± 2 standard deviations of LNG noise attenuating to 120 dB, from Hatch et al., 2008). The number of killer whales within range of noise levels of 120 dB produced by a single LNG tanker transit through the stratum would be equal to the density (0.072 whale per 100 nmi$^2$) multiplied by the total area of noise effects 1,883 nmi$^2$), equal to 1.4 whale affected (an estimate between 0.5 and 2.3 whales based on the density within distances of ± 2 standard deviations of LNG noise attenuating to 120 dB, from Hatch et al., 2008) by noise levels that could cause behavioral disruptions (see table 4.2.1-3).

Existing commercial vessels within the West Coast EEZ analysis area produce underwater noise levels that are comparable or exceed noise from the LNG tanker described by Hatch et al. (2008). Noise generated by various types of commercial ships (container ships, crude oil tankers, product tankers, bulk carriers, and others) were recently evaluated by McKenna et al. (2012). Underwater noise levels varied by ship type and also by vessel length, gross tonnage, vessel speed, and to some extent, vessel age (older vessels tended to be louder than newer vessels). For example, a 54,000 Gross Ton (GT) container ship generated the highest acoustic source level of 188 dB re: 1 µPa @ 1 meter while a 26,000 GT chemical tanker had the lowest at 177 dB re: 1 µPa @ 1 meter (McKenna et al., 2012). Noise levels from the vessels examined in that study are assumed to be typical of ship noise in the California and Oregon-Washington EEZ strata and would produce radiated noise levels through the two strata that would exceed the threshold for Level B single non-pulse noise of 120 dB$_{rms}$ (see table 4.2.1-3, above). With the existing levels of background shipping noise and the expected increase in shipping traffic by 2018, effects by project LNG tanker-related noise on killer whales are possible in the in California and Oregon-Washington EEZ strata but the noise would be commensurate with existing noise levels and would not be expected to cause injury.

Two tractor tugs would guide the LNG tanker from a point approximately 5 nmi offshore the entrance to Coos Bay and to the JCEP LNG terminal. Noise produced by tugs would attenuate to 160 dB at 11 ± 4 meters (upper end) and to 120 dB at 4,992 ± 1,599 meters (upper end) (Hatch et al., 2008). Unlike LNG tankers, project-related tug traffic would only occur in the Oregon-Washington stratum. LNG ship noise and noise from tugs would exceed the ambient noise levels within the West Coast EEZ activity area assuming those range from 64 dB to 72 dB re 1 µPa$^2$ (at 62 Hz, similar to the ocean noise 7 nmi west of San Diego reported by McDonald et al., 2008) but would not cause behavioral disruptions to blue whales.

Vessel traffic in habitats occupied by Southern Resident killer whales significantly increase noise above ambient levels which can affect whale behavior (Holt, 2008). However, it is unlikely that LNG carriers transiting the EEZ north from Coos Bay would produce noise at levels that could affect Southern Resident killer whales. Also, LNG carriers are not expected to transit designated critical habitat.

<u>Releases and Fire at Sea</u>

Characteristics of LNG released at sea were described in Section 4.2.1.3 for blue whales. At the water-vapor LNG pool interface, the cryogenically cooled LNG would begin to vaporize but, because of its relatively high density, the plume would remain at or close to the surface interface; methane is an asphyxiant but with low toxicity, at least to humans (Hightower et al., 2004). If a marine mammal surfaced to breathe at the LNG pool location, it could suffer from oxygen deficiency and potential physiological effects, which have been described for humans - ranging from impaired thinking to loss of consciousness with decreasing oxygen concentrations (Table 39 in Hightower et al., 2004) - but not for marine mammals. Because the estimated densities of marine mammals are generally low within the California and Oregon-Washington strata of EEZ, the chance of an animal becoming asphyxiated by contact with a pool of LNG would extremely remote (see discussion about potential thermal injury, below).

Sandia National Laboratories modeled LNG spills from a standard LNG vessel (with capacity of 125,000 to 140,000 $m^3$) over water and potential injury to humans due to ignition of the fuel (Hightower et al., 2004). Thermal effects from a fire would vary, depending on the size of the LNG pool released. If one LNG tank is accidentally breached, due to collision with another ship, grounding, or ramming, the potential spill of LNG could form a pool with diameter of 685 feet. Ignition could cause a fire to burn for 20 minutes with severe thermal injuries extending to 820 feet away from the center of the pool (based on an exposure of 10 minutes and thermal flux of 37.5 $kW/m^2$) and second-degree skin burns on exposed skin (human) to a distance of 2,572 feet (based on an exposure of 10 minutes and thermal flux of 5 $kW/m^2$) from the center of the burning pool of LNG (see Table 41 in Hightower et al., 2004). Surfacing cetaceans within those distances would be assumed to experience severe burns or mild burns, based on similar thermal fluxes effects on humans although exposures for 10 minutes or more would be unlikely.

Expected densities of killer whales in the California EEZ stratum during 2018 would be 0.016 whale per 100 $nmi^2$ and 0.072 whale per 100 $nmi^2$ in the Oregon-Washington EEZ stratum, the same densities that were used in the analysis of effects due to ship noise, above. Based on the model of accidental LNG release and fire described above (from Hightower et al., 2004), a circular pool of released LNG with diameter of 685 feet would cover an area of 0.010 $nmi^2$. An ensuing fire would cause severe thermal injuries over an area of 0.057 $nmi^2$ and the area where fire coul cause second degree burns would extend to an area of 0.563 $nmi^2$. Considerably fewer than one killer whale would be expected to be present within any of those areas in either of the two EEZ strata during 2018 and injuries to killer whales due to LNG release and fire would be insignificant and discountable

**Cumulative Effects**

FWS and NMFS describe cumulative effects (50 CFR. § 402.02) as the result of future actions by state or private entities, not involving federal actions, but reasonably certain to occur in the action area considered in this BA. Future federal actions that are unrelated to the proposed action are not considered here because they require separate consultation pursuant to section 7 of the ESA.

As discussed above for blue whales, available information indicates that ship calls to the Port of Coos Bay have been declining since 2002. The observed declining linear trend in total vessel traffic over time is significant and, when used to forecast numbers of vessel calls to Coos Bay in the future, no vessels are predicted to enter Coos Bay in 2018 with between 0 and 17.6 vessels as reasonably foreseeable when the LNG terminal is expected to begin operation in 2018 (see figure 4.2-3). And as discussed above for blue whales, it appears that the background rate of spills off the Oregon coast by fishing vessels, recreation vessels, and other vessel types is generally low, a frequency that would be expected to continue into the foreseeable future.

The foreseeable cumulative effect of 90 LNG carriers per year with anticipated vessel traffic in Coos Bay in 2018 would be less than effects based on past or present levels of vessel traffic calls to the Port of Coos Bay. Consequently, cumulative effects to killer whales would likely be less than the estimate of direct effects discussed in the previous section. Those effects were judged to be insignificant and discountable.

The volume of annual vessel transits within the EEZ of California, Oregon, and Washington is related to numbers of vessel calls to ports in those states. Total annual calls for all vessels at ports in California, Oregon, and Washington (MARAD, 2013) were plotted above in figure 4.2-2 for 2002 through 2011. Unlike the trend analyzed for calls to Coos Bay (see figure 4.2-4 under blue whales) the observed linear trend in annual vessel traffic (port calls) along the U.S. West Coast was significantly increasing at a rate of 2.1 percent per year between 2002 and 2007. The increasing trend was interrupted by the global economic crisis in 2008 but data through 2011 indicate a return to the established increasing trend prior to 2008. The pre-2008 trend predicts 21,530 vessel calls to West Coast ports in 2018 (with 95% prediction intervals ranging from 17,360 to 25,710 vessel calls), the year the JCEP and PCGP projects are expected to be in service. Even with the uncertainty generated by available data, there is a reasonably foreseeable increasing trend, albeit imprecise, for vessel traffic volume in the future (by 2018) although unforeseen global events such as future economic crises could influence the predictions. Cumulative effects of 90 LNG carriers per year to killer whales may be more or may be less than the estimate of direct effects discussed above.

**Critical Habitat**

The proposed action would not affect designated critical habitat the inland transboundary waters of British Columbia and Washington.

#### 4.2.3.4 Conservation Measures

The same Ship-Strike Reduction Plan to minimize potential ship strikes to cetaceans by LNG carriers and LNG Management Plan to minimize risk of spills and releases at sea that were described in Section 4.2.1.4 (blue whale) apply to killer whales.

#### 4.2.3.5 Determination of Effects

**Species Effects**

The Project **may affect** killer whales because:

- Killer whales may occur within the EEZ analysis area during operation of the proposed action.
- The proposed action would increase shipping traffic (LNG carriers) within the EEZ analysis area.

However, the Project is **not likely to adversely affect** killer whales because:

- Existing information indicates ship strikes to killer whales within the EEZ analysis area are infrequent.
- The increase in annual ship traffic due to the proposed action is expected to cause an immeasurable increase in ship strikes to killer whales over known frequencies of incidents.
- Jordan Cove would provide a ship strike avoidance measures package to shippers delivering LNG cargo to the LNG terminal. The package consists of multiple measures to avoid striking marine mammals.
- LNG carriers approaching the Port of Coos Bay would be traveling slowly and escorted by tractor tugs from 50 nmi offshore to the Port.

- Noise produced by LNG carriers would contribute to overall noise within the EEZ en route to the Port of Coos Bay and effects of ship noise on killer whales could exceed NMFS interim noise exposure criteria for Level B single non-pulse noise but would not exceed existing background ship noise levels and would not cause injury.
- Accidental releases of LNG at sea would not cover an area large enough to coincide with expected killer whale presence (based on estimated densities). Ignited LNG would not extend far enough from the LNG pool to cause severe or mild thermal effects to killer whales if they emerged during a fire.

**Critical Habitat Effects**

The Project would have **no effect** on designated CHUs for the Eastern North Pacific Southern Resident stock because:

- None of the designated CHUs occur within the EEZ analysis area off the Oregon or California coasts.
- The nearest critical habitat unit to Coos Bay is the Strait of Juan de Fuca, Washington, more than 390 nmi north.
- No LNG carriers are expected to transit designated critical habitat.

### 4.2.4 Humpback Whale

#### 4.2.4.1 Species Account and Critical Habitat

**Status**

Humpback whales were listed as endangered under the Endangered Species Conservation Act on December 2, 1970 (FWS, 1970) and have been listed as endangered throughout its range under the ESA since its implementation in 1973. Humpback whales are classified as depleted throughout its range under the MMPA. Recent evidence suggests that there are multiple populations of humpback whales in the North Pacific, including:

1. Winter/spring populations in coastal Central America and Mexico, which migrate to the coast of California to southern British Columbia in summer/fall - referred to as the California/Oregon/Washington stock (formerly the Eastern North Pacific stock), and the stock likely to be present off the Oregon coast during migration;
2. Winter/spring populations of the Hawaiian Islands, which migrate to northern British Columbia/Southeast Alaska and Prince William Sound west to Kodiak - referred to as the Central North Pacific stock; and
3. Winter/spring populations of Japan, which likely migrate to waters west of the Kodiak Archipelago, known as the Western North Pacific stock (Carretta et al., 2013b).

**Threats**

Commercial whaling operations were the primary contributor to the decline in humpback whale populations (NMFS, 1991). The primary ongoing threat to humpback whales is entanglement in fishing gear (NMFS, 1991), especially drift gill-nets (Carretta et al., 2013a and 2013b). Whales that use low-frequency sounds may be at an increased risk for disturbance from anthropogenic noise. This noise is listed as a habitat concern for humpback whales (NMFS, 1991; Carretta et al., 2007).

Humpback whale food sources may be damaged and they may gain new stressors with certain climate changing processes such as global warming. Stressors from metabolic demands with warmer oceans may impact the health of animals. Shifts of marine populations either towards the poles or in the ocean depths they use are expected. Increased stratification from an increased temperature, and/or increased freshwater inputs may affect nutrient exchange and primary production (Fogarty and Powell, 2002).

There may be reductions in the available nutrient levels and possible changes in the timing and intensity of phytoplankton blooms. There may also be reductions of upwelling and downwelling, thereby limiting the nutrient availability to marine life in specific stratified levels of the ocean. Changes in the California Current have reduced the zooplankton populations, primarily as a result of increased water temperatures which led to intensified stratification and a lowering of mixing and nutrient regeneration in the water column (Fogarty and Powell, 2002).

**Species Recovery**

A recovery plan was prepared in 1991 by the humpback whale recovery team for the NMFS (NMFS, 1991). The goal of the plan is to be "biologically successful", meaning that humpback whales occupy all of their former range in sufficient numbers to buffer their populations against normal environmental fluctuations or anthropogenic environmental catastrophes. The plan states that the best estimator of biological success would be if the plan is "numerically successful," meaning that populations grow to levels where their population dynamic responses indicate density dependent reductions in productivity. The plan defines "political success" as the time when populations are abundant enough that the species can be downlisted or delisted. The plan's four objectives are:

- Maintain and enhance habitats used by humpback whales currently or historically.
- Identify and reduce direct human-related injury and mortality.
- Measure and monitor key population parameters.
- Improve administration and coordination or recovery program for humpback whales.

**Life History, Habitat Requirements, and Distribution**

The humpback whale is a large baleen whale occupying all ocean basins. Migration and reproduction is tied to seasonal progression (NMFS, 1991). The Pacific humpback whales over-winter in temperate and tropical waters and migrate in summer to waters of high biological productivity in higher latitudes (NMFS, 1991). Breeding and birth likely take place in wintering areas, and it is believed that little feeding takes place in wintering grounds. The humpback whale diet consists of krill, along with fish including cod, pollock, anchovies, and mackerel.

Humpbacks generally travel alone or in pairs consisting of mother and calf. They may be found in groups between 12 and 15 animals. They generally dive between 3 and 15 minutes, but they can dive for up to 40 minutes. They can reach depths of 150 meters, and they display cooperative hunting behavior in what is termed "bubble netting" of their prey (Shirihai and Jarrett, 2006).

Sexual maturity for humpback whales is generally reached between 4 and 6 years of age. Once mature, females tend to give birth every 2 to 3 years with some annual or multi-year intervals beyond 3 years being recorded (NMFS, 1991). The gestation period is between 11 and 12 months, and the calves are weaned at between 6 and 12 months. Calves may continue to associate with their mothers for 1 to 2 years. Information is lacking on lifespan and natural mortality but humpbacks are known to live to be at least 50 years old (Shirihai and Jarrett, 2006).

**Population Status**

The total abundance for humpback whales in the North Pacific has recently been estimated at 21,063 whales, based on mark-recapture estimation using fluke photographs (Barlow et al., 2011). The population has been increasing and may exceed estimates of pre-whaling abundance.

One recent estimate for the California/Oregon/Washington stock was 1,918 whales and the minimum population estimate was calculated to be 1,876 in 2007-2008 (Carretta et al., 2013b). Population estimates for humpback whales in the North Pacific increased from 1,200 in 1966 to 18,000-20,000 whales in 2006. The long-term population increase has been estimated at 7.5 percent per year (Calambokidis et al., 2010). The observed growth rate of the California/Oregon/Washington stock is estimated at 6 to 7 percent per year (Carretta et al., 2013b).

The current calculated potential biological removal for humpback whales is 11 whales per year occurring within the U.S, EEZ (Carretta et al., 2013).

The average number of documented humpback whale deaths by ship strikes for 2007 to 2011 is 1.1 whale per year (Carretta et al., 2013b). That estimate is undoubtedly low since many ship strikes with cetaceans are unknown and unreported.

**Critical Habitat**

Critical habitat for this species has not been designated.

### 4.2.4.2 Environmental Baseline

**Analysis Area**

The analysis area applicable to humpback whales is the EEZ, extending 200 nautical miles offshore from the Coos Bay Head and from San Diego to Cape Flattery, the same as described above for blue whales (see figure 4.2-1 under blue whale).

**Species Presence**

The California/Oregon/Washington stock of humpback whales is separated out from other populations based upon the feeding area off the mainland West Coast of the United States. The northern boundary of this population is the border of Washington and British Columbia, with humpbacks being found throughout the West Coast feeding area and concentrated primarily off of California (Carretta et al. 2007). Four humpbacks were documented to have been stranded in Oregon from 1930 to 2002, and two were stranded in Washington for the same time period (Norman et al., 2004).

Line-transect ship surveys conducted off the coasts of California, Oregon, and Washington in summer and fall of 1991, 1993, 1996, 2001, 2005, and 2008 (Barlow and Forney, 2007; Forney, 2007; Barlow, 2010) have been used to estimate populations within the California and Oregon-Washington strata and to estimate populations for specific stocks. During each of those years (only California waters were surveyed in 1991 and 1993), line-transect locations were pre-determined to survey for pelagic cetaceans within approximately 300 nmi of the West Coast.

The mean density estimates for species in the California stratum are computed as the mean population estimate divided by the area in the surveyed stratum, 819,470 $km^2$ (Barlow, 2010) which is assumed to be the same in all of the years surveyed. The mean density of humpback whales in the California stratum is 0.083 whale per 100 $km^2$ or 0.024 whale per 100 $nmi^2$. Similarly, mean population estimates for species in the Oregon-Washington stratum are the geometric means of population estimates derived from surveys conducted in 1996, 2001, 2005 (data from Barlow and Forney, 2007; Forney, 2007) and 2008 (data from Barlow, 2010). The mean density of humpback whales in the Oregon-Washington stratum is 0.081 whale per 100 $km^2$ or 0.024 whale per 100 $nmi^2$.

The mean encounter rate (number observed per linear distance of transect) for each cetacean species is the geometric mean of the number of animals counted along line transects in the California stratum during each survey year (1991 through 2008, see above) divided by total transect length in the stratum for each survey year (data from Barlow and Forney, 2007; Forney, 2007; Barlow, 2010). If no individuals were sighted in one or more years, the arithmetic mean was used. The mean encounter rate for humpback whales in the California stratum in 2008 is 0.194 whale per 100 km or 0.105 whale per 100 nmi of ship transect. Likewise, the mean encounter rate (number observed per linear distance) for cetaceans observed in the Oregon-Washington stratum is the geometric mean of the number of animals counted along line transects during each survey year (1996 through 2008, see above) divided by total transect length in the stratum for each survey year (data from Barlow and Forney, 2007; Forney, 2007; Barlow, 2010). The mean encounter rate for humpback whales in the Oregon-Washington stratum in 2008 is 0.172 whale per 100 km or 0.093 whale per 100 nmi of ship transect.

**Habitat**

Humpback whales are present primarily during summer months in the EEZ of the western United States (NMFS, 1991). They are present off the coast of the United States in feeding grounds where they search alone or in groups for krill and small fish, and employ “bubble netting” to corral and trap their prey (Shirihai and Jarrett, 2006). Modeled habitat use indicates that humpback whales are strongly associated with latitude and bathymetric features (including depth, slope and distance to the 100-m isobath). Distance to sea-surface-temperature fronts and salinity (climatology) were also constantly selected, and higher numbers of whales seemed to be associated with higher primary productivity for some models (Della Rosa et al., 2012).

**Critical Habitat**

Critical habitat for this species has not been designated.

#### 4.2.4.3 Effects by the Proposed Action

**Direct and Indirect Effects**

Direct effects of the proposed action include injury and/or mortality due to ship strikes, adverse effects from vessel underwater noise, and potential adverse effects from an accidental ship release of LNG and fire at sea. Spills and/or released LNG could indirectly affect humpback whales by impacting forage species. These effects are addressed below.

<u>Ship Strikes by LNG Carriers</u>

As discussed above for blue whales, there is an ongoing threat of ship strikes to humpback whales. From available accounts (Laist et al., 2001; Jensen and Silber, 2003) humpback whales collide with ships relatively often, with calves being particularly vulnerable to ship strikes (Laist et al., 2001). Jensen and Silber (2003) found that humpbacks were second most likely behind fin whales to be struck by ships. Ship strikes of humpback whales averaged 0.2 death per year along the Pacific Coast between 2000 and 2004 (Carretta et al. 2007) and 0.17 death per year within Oregon and Washington waters, combined. From 2007 to 2011 ship strikes of humpback whales averaged 0.6 death or injury per year in California and 0.2 death or injury per year off the Oregon-Washington coast (Carretta et al., 2013a). Jensen and Silber (2003) reported a rate of 0.33 humpback whales struck per year off the coast of California from 1995 through 2000. Likewise, Douglas et al. (2008) compiled records of ship-stikes of humpback whales in Washington State from 1980 to 2006 with an average of 0.04 whale struck per year. Those estimates are undoubtedly minimal since many ship strikes with cetaceans are unknown and unreported.

**Ship Traffic**. A considerable amount of shipping traffic currently occurs within the EEZ analysis area. Past, present, and reasonably foreseeable ship traffic within the EEZ analysis area was discussed for blue whales, above. Ship traffic to U.S. West Coast ports was increasing between 2002 and 2007 but deviated from the established trajectory in 2008, at the onset of the global financial crisis (see figure 4.2-2 under blue whale). The pre-2008 trend predicts 21,530 vessel calls to West Coast ports in 2018 (with 95% prediction intervals ranging from 17,360 to 25,710 vessel calls), the year the JCEP and PCGP projects are expected to be in service.

Applying the yearly percent change in Total Annual Vessel Calls at all West Coast ports based on the regression model in figure 4.2-2 to the total ship-miles along the West Coast beginning in 1999 (5,049,298 ship-miles in table 4.2.1-1 under blue whales, above), there would be an estimated 8,199,320 ship-miles along the West Coast, expected in 2018.

Similarly, the data from MARAD (2013) were used to estimate ship-miles along the California Coast and along the Oregon-Washington Coast in 2018 from the data in table 4.2.1-1 from 1999 provided by Pacific States/British Columbia Oil Spill Task Force (2002).

- From 2002 to 2007, total vessel calls to California ports increased by a constant number of 251 vessel calls per year (regression model y = 250.74x – 492,585, $r^2$ = 0.78, P=0.019). There were 3,041,597 ship-miles in 1999 within California waters (see table 4.2.1-1); 4,717,894 ship-miles are expected in 2018.
- From 2002 to 2007, total vessel calls to Oregon-Washington ports increased by a constant number of 185 vessel calls per year (regression model y = 184.6x – 364,401, $r^2$ = 0.56, P=0.086). There were 2,007,701 ship-miles in 1999 within Oregon-Washington waters (see table 4.2.1-1); 3,533,752 ship-miles are expected in 2018.

The Project is designed to accommodate 90 LNG tankers a year. If all LNG tankers approach the Jordan Cove terminal by perpendicular transits through the EEZ, they will contribute 36,000 ship miles annually to vessel traffic in the Oregon-Washington stratum in 2018. If all LNG tankers approach the terminal by parallel transits along the California coast, they will contribute 137,160 ship-miles annually to vessel traffic within the California stratum in 2018. Observed and predicted vessel traffic within both strata in 1999, 2007, 2008, and 2018 are provided in table 4.2.4-1, including the addition of project-related LNG tanker traffic in 2018. During the life of the project, there may be years of mixed LNG tanker traffic, some transiting the EEZ perpendicular and other traffic paralleling the coast but such variability can not be estimated.

**Table 4.2.4-1**
**Estimates of Vessel Traffic, Humpback Whale Encounter Rates, Relative Ship-Strike Risk, and Estimates of Humpback Whales Struck per Year (with Percent Change from the Previous Estimate) in the California and Oregon-Washington Strata of the Project Activity Area**

| | California Stratum | | | | Oregon-Washington Stratum | | | |
|---|---|---|---|---|---|---|---|---|
| Year and Event | Ship-Miles (nmi) | Whale Encounter Rate (N/100 nmi) | Relative Ship-Stike Risk | Estimate of Whales Struck per Year [5] | Ship-Miles (nmi) | Whale Encounter Rate (N/100 nmi) | Relative Ship-Stike Risk | Estimate of Whales Struck per Year [5] |
| 1999 [1] Baseline Annual Ship Transits | 3,041,597 | N/A | N/A | N/A | 2,007,701 | N/A | N/A | N/A |
| 2007 [2] Predicted Trend with 2002-2007 data | 3,747,406 (+23.2%) | N/A | N/A | N/A | 2,650,249 (+32.0%) | N/A | N/A | N/A |
| 2008 [3] Most Recent Cetacean Survey | 3,316,554 (-11.5%) | 0.105 | 3,481 | 0.60 | 2,495,278 (-5.8%) | 0.093 | 2,312 | 0.20 |
| 2018 [2] Ambient Predicted Ship Traffic | 4,717,894 (+42.3%) | 0.157 (+49.1%) | 7,387 (+112.2%) | 1.273 (+112.2%) | 3,533,752 (+41.6%) | 0.138 (+49.1%) | 4,884 (+111.3%) | 0.423 (+111.3%) |
| 2018 [4] Ambient Traffic with LNG Tanker Traffic | 4,855,054 (+2.9%) | 0.157 (0%) | 7,601 (+2.9%) | 1.310 (+2.9%) | 3,569,752 (+1.0%) | 0.138 (0%) | 4,934 (+1.0%) | 0.427 +1.0%) |

[3] Estimated total vessel calls to California ports and Oregon-Washington ports in 2008 (see Figure 4.2.1-1, above). Source: MARAD, 2013.
[4] Assume 90 LNG tankers with perpendicular transits through West Coast EEZ in Oregon-Washington stratum (36,000 ship-miles per year) or parallel transits through EEZ in California stratum (137,160 ship-miles per year).
[5] Estimates of Whales Struck derived from data reported by Carretta et al., 2013a for ship-strikes in the California and Oregon-Washington EEZ strata.

**Ship-Strike Risk.** An index of relative ship-strike risk within an explicitly defined gridded study area was described by Williams and O'Hara (2009). The approach was adapted to the coarse-scale analysis area by using mean whale encounter rates, described above for humpback whales, and shipping intensity as indicated by the total annual ship-miles derived from vessel transits along the West Coast (table 4.2.4-1) in the California and Oregon-Washington strata.

The encounter rate for humpack whales in the California EEZ stratum is significantly ($P < 0.05$) related to the species' density, based on data collected during surveys conducted in in 1991, 1993, 1996, 2001, 2005 (data from Barlow and Forney, 2007; Forney, 2007) and 2008 (Barlow, 2010), shown in figure 4.2-6. The relationship supports predictions, below, that future encounter rates (eg, in 2018) would be expected to increase as the humpback whale population increases.

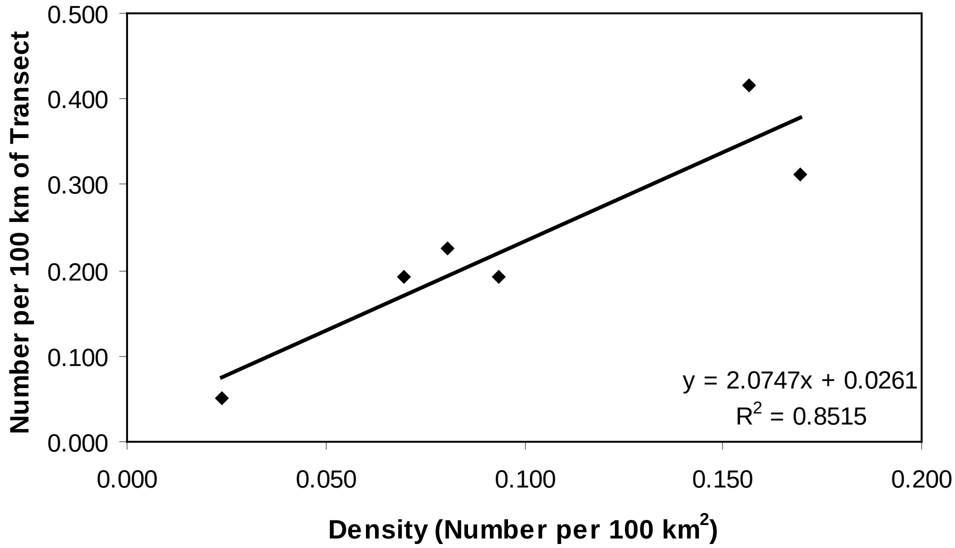

**Figure 4.2-6**
**Relationship of Ship-Transect Encounter Rate with Humpback Whales (Number per 100 km) to Humpack Whale Density (Number per km$^2$ ) in the California EEZ Stratum. Data were Collected in 1991, 1993, 1996, 2001, 2005, and 2008. The Relationship is Significant ($P < 0.01$)**

Relative ship-strike risks during 2008 and 2018 (see table 4.2.4-1) are the products of cetacean species' encounter rates and total ship miles expected in each stratum during the two years. An estimate of the encounter rate in 2018 (beginning of the project operation) is directly proportional to humpback whale population and density in that year. Assuming exponential population growth, the population size ($N_t$) at time = t is $N_t = N_0 e^{r t}$ where $N_0$ = the initial population size at t = 0 and r is assumed to be $R_{MAX}$. This approach was used with the default value for $R_{MAX} = 0.04$ to estimate humpback whale encounter rates (as indices of population) in 2018 given the encounter rates of humpback whales within the California and Oregon-Washington strata in 2008. In 2008, the humpback whale encounter rate in the California stratum was 0.2007 whale per 100 nmi and 0.180 whale per 100 nmi in the Oregon-Washington stratum. Based on assumed population growth between 2008 and 2018, the humpback whale encounter rate in California in 2018 is estimated at 0.308 whale per 100 nmi and 0.269 whale per 100 nmi in the Oregon-Washington stratum, an increase of 49 percent from the 2008 encounter rates (see table 4.2.2-1, above).

In 2008, the relative ship-strike risk in the Califonia stratum would be 0.105 whale per 100 nmi multiplied by 3,316,554 ship-miles = 3,481. In 2018, the assumed growth of the humpback whale population increases the encounter rate proportionately to 0.157 whale per 100 nmi. Between 2008 and 2018 ship traffic is also be expected to increase to 4,717,894 ship-miles. The relative ship-strike risk in 2018 would be 7,387 which is 112.2 percent of the 2008 encounter rate (table 4.2.4-1). If all 90 LNG tanker transits occur in the California stratum, the total expeced vessel traffic would be 4,855,054 ship miles in 2018 and the ship-strike risk would increase to 7,601, an estimated increase of 2.9 percent. Similar calculations woud apply to the humpback whale population growth, encounter rate, relative ship-strike risk in the Oregon-Washington stratum, provided in table 4.2.4-1.

**Estimated Ship-Strikes to Humpback Whales**. Data provided by Carretta et al. (2013a) indicated 3 humpback whales were struck in the California EEZ between 2007 and 2011 (0.60 whale per year) and 1 humpback whale was struck in the Oregon-Washington EEZ during the same period (0.20 whale per year). Jensen and Silber (2003) reported 2 humpback whales struck between 1995 and 2000 along the U.S. Pacific Coast and Douglas et al. (2008) reported 1 strike off Washington between 1980 and 2006. Using recent ship-strike data from Carretta et al. (2013a), the increased ship-strike risk in 2018 is assumed to increase the annual rate of humpback whales struck proportionately in the California stratum to 1.273 per year and to 0.423 per year in the Oregon-Washington stratum (see table 4.2.4-1). The additional project-related LNG tanker traffic would increase the annual rate in California to 1.310 whale per year, an increase of 0.037 ship-strike per year (one injury or death in 27 years) and would increase the annual rate in Oregon-Washington waters to 0.423 whale per year, an increase of 0.004 ship-strike per year (one injury or death in 250 years). Ship-strikes to humpback whales by project-related LNG tankers are more likely in California than in the Oregon-Washington EEZ stratum but in both areas, death or injury of humpack whales is insignificant and discountable.

<u>Underwater Noise</u>

Humpback whales are well known for their vocalizations. Male humpback whales sing long, complex songs that function to attract females and may play roles in establishing dominance hierarchies or cooperative behavior among males (Clapham, 2009). Studies have found that low frequency sounds, whether generated by sonar or ships, cause singing humpback whales to lengthen their singing, perhaps as compensation for the acoustic interference (Miller et al., 2000). Alternatively, humpback whales ceased vocalizing when low-frequency pulses were produced 200 km away from the whales which increased underwater noise levels above ambient levels (Risch et al., 2012). Characteristics of humpback whale songs (duration, tempo or pace, frequency structure) indicated masking of songs by noise from large boats (Norris, 1995).

Determining and minimizing any detrimental effects of anthropogenic underwater noise on humpback whales is a principal objective for the species' recovery (NMFS, 1991). As described for blue whales, above, all vessels produce noise; propeller cavitation produces most of the broadband noise with dominant tones derived from the propeller blade rate. In general, rorquals including blue, fin and minke whales move away, abruptly change direction, or dive to avoid close approach by vessels. When whales are exposed to low-level sounds from distant or stationary vessels, they appear to ignore the sounds. Baleen whales will interrupt normal behavior and swim away from strong or rapidly changing vessel noise, especially if a vessel is headed directly toward the whale (Richardson, 1995). However, radiated ship noise of oncoming ships may not be immediately detected by whales near the surface due to bow null-effect acoustic shadow zones (Allen et al., 2012). Because of acoustic shadow zones, whales may not hear approaching ships to allow time for their avoidance response even though whale auditory ranges overlaps with peak intensities of ship noise.

Ambient noise in the Northeast Pacific Ocean has increased in nearshore and deep ocean environments over the past several decades. The low frequencies generated by ships overlap frequencies of sounds generated by large baleen whales, including the humpback whale (Würsig and Richardson, 2009). Changes in vocal behavior may lead to reductions in foraging efficiency and/or mating opportunities (Weilgart, 2007). Noise from ships and boats may interfere and mask cetacean communication, finding prey, avoiding predators, and possibly navigation (Würsig and Richardson, 2009; Weilgart, 2007).

Noise from a LNG tanker in a study by Hatch et al. (2008) produced sound levels (with 1 standard error) of 182 ± 2 dB re: 1 µPa @ 1 meter that attenuated to 160 dB at 35 ± 11 meters and to 120 dB at 16,185 ± 5,359 meters (Hatch et al., 2008). Using those attenuation distances, one LNG tanker transit across the length of the California EEZ stratum for 762 nmi would produce sound levels of ≥160 dB within an area 15.6 ± 4.9 nmi$^2$ and would produce sound levels ≥120 dB but <160 dB within an area 7,175.9 ± 2,376.3 nmi$^2$. Likewise, one LNG tanker transit across the width of the Oregon-Washington EEZ stratum for 200 nmi would produce sound levels of ≥160 dB within an area 4.1 ± 2.6 nmi$^2$ and would produce sound levels ≥120 dB but <160 dB within an area 1,883.4 ± 1,247.4 nmi$^2$.

Based on population growth between 2008 and 2018 described above for humpback whale encounter rates, the predicted density of humpback whales is 0.044 whale per 100 nmi$^2$ in the California stratum in 2018 and is 0.043 whale per 100 nmi$^2$ in the Oregon-Washington EEZ stratum in 2018. Assuming an LNG tanker transit distance of 762 nmi within the California stratum, the number of humpback whales within range of noise levels of 160 dB produced by a single LNG tanker transit through the stratum would be equal to the density (0.044 whale per 100 nmi$^2$) multiplied by the total area of noise effects (15.6 nmi$^2$), equal to 0.007 whale affected (an estimate between 0.003 and 0.011 whale based on the density within distances of ± 2 standard deviations of LNG noise attenuating to 120 dB, from Hatch et al., 2008).

The number of humpback whales within range of noise levels of 120 dB (radius of 16,185 m or 4.72 nmi) produced by a single LNG tanker transit through the stratum would be equal to the density (0.044 whale per 100 nmi$^2$) multiplied by the total area of noise effects (7,176 nmi$^2$), equal to 3.1 whales affected (an estimate between 1.1 and 5.3 whales based on the density within distances of ± 2 standard deviations of LNG noise attenuating to 120 dB, from Hatch et al., 2008) by noise levels that could cause behavioral disruptions (see table 4.2.1-3 under blue whales, above).

Similar calculations have been done for humpback whales in the Oregon-Washington stratum. Assuming an LNG tanker transit distance of 200 nmi across the Oregon-Washing stratum, the number of humpback whales within range of noise levels of 160 dB produced by a single LNG tanker transit through the stratum would be equal to the density (0.043 whale per 100 nmi$^2$) multiplied by the total area of noise effects (4.08 nmi$^2$), equal to 0.002 whale affected (an estimate between 0.001 and 0.003 whale based on the density within distances of ± 2 standard deviations of LNG noise attenuating to 120 dB, from Hatch et al., 2008). The number of humpback whales within range of noise levels of 120 dB produced by a single LNG tanker transit through the stratum would be equal to the density (0.043 whale per 100 nmi$^2$) multiplied by the total area of noise effects (1,883 nmi$^2$), equal to 0.81 whale affected (an estimate between 0.27 and 1.35 whale based on the density within distances of ± 2 standard deviations of LNG noise attenuating to 120 dB, from Hatch et al., 2008) by noise levels that could cause behavioral disruptions (see table 4.2.1-3, blue whales).

Existing commercial vessels within the West Coast EEZ analysis area produce underwater noise levels that are comparable or exceed noise from the LNG tanker described by Hatch et al. (2008). Noise generated by various types of commercial ships (container ships, crude oil tankers, product tankers, bulk carriers, and others) were recently evaluated by McKenna et al. (2012). Underwater noise levels varied by ship type and also by vessel length, gross tonnage, vessel speed, and to some extent, vessel age (older vessels tended to be louder than newer vessels). For example, a 54,000 Gross Ton (GT) container ship generated the highest acoustic source level of

188 dB re: 1 µPa @ 1 meter while a 26,000 GT chemical tanker had the lowest at 177 dB re: 1 µPa @ 1 meter (McKenna et al., 2012). Noise levels from the vessels examined in that study are assumed to be typical of ship noise in the California and Oregon-Washington EEZ strata and would produce radiated noise levels through the two strata that would exceed the threshold for Level B single non-pulse noise of 120 $dB_{rms}$ (see table 4.2.1-3, above). With the existing levels of background shipping noise and the expected increase in shipping traffic by 2018, effects by project LNG tanker-related noise on humpback whales are possible in the in California and Oregon-Washington EEZ strata but the noise would be commensurate with existing noise levels and would not be expected to cause injury.

Two tractor tugs would guide the LNG tanker from a point approximately 5 nmi offshore the entrance to Coos Bay and to the JCEP LNG terminal. Noise produced by tugs would attenuate to 160 dB at 11 ± 4 meters (upper end) and to 120 dB at 4,992 ± 1,599 meters (upper end) (Hatch et al., 2008). Unlike LNG tankers, project-related tug traffic would only occur in the Oregon-Washington stratum. LNG ship noise and noise from tugs would exceed the ambient noise levels within the West Coast EEZ activity area assuming those range from 64 dB to 72 dB re 1 $\mu Pa^2$ (at 62 Hz, similar to the ocean noise 7 nmi west of San Diego reported by McDonald et al., 2008) but would not cause injury to humpback whales.

<u>Releases and Fire at Sea</u>

Characteristics of LNG released at sea were described in Section 4.2.1.3 for blue whales. At the water-vapor LNG pool interface, the cryogenically cooled LNG would begin to vaporize but, because of its relatively high density, the plume would remain at or close to the surface interface; methane is an asphyxiant but with low toxicity, at least to humans (Hightower et al., 2004). If a marine mammal surfaced to breathe at the LNG pool location, it could suffer from oxygen deficiency and potential physiological effects, which have been described for humans - ranging from impaired thinking to loss of consciousness with decreasing oxygen concentrations (Table 39 in Hightower et al., 2004) - but not for marine mammals. Because the estimated densities of marine mammals are generally low within the California and Oregon-Washington strata of EEZ, the chance of an animal becoming asphyxiated by contact with a pool of LNG would extremely remote (see discussion about potential thermal injury, below).

Sandia National Laboratories modeled LNG spills from a standard LNG vessel (with capacity of 125,000 to 140,000 $m^3$) over water and potential injury to humans due to ignition of the fuel (Hightower et al., 2004). Thermal effects from a fire would vary, depending on the size of the LNG pool released. If one LNG tank is accidentally breached, due to collision with another ship, grounding, or ramming, the potential spill of LNG could form a pool with diameter of 685 feet. Ignition could cause a fire to burn for 20 minutes with severe thermal injuries extending to 820 feet away from the center of the pool (based on an exposure of 10 minutes and thermal flux of 37.5 $kW/m^2$) and second-degree skin burns on exposed skin (human) to a distance of 2,572 feet (based on an exposure of 10 minutes and thermal flux of 5 $kW/m^2$) from the center of the burning pool of LNG (see Table 41 in Hightower et al., 2004). Surfacing cetaceans within those distances would be assumed to experience severe burns or mild burns, based on similar thermal fluxes effects on humans although exposures for 10 minutes or more would be unlikely.

Expected densities of humpback whales in the California EEZ stratum during 2018 would be 0.044 whale per 100 $nmi^2$ and 0.043 whale per 100 $nmi^2$ in the Oregon-Washington EEZ stratum, the same densities that were used in the analysis of effects due to ship noise, above. Based on the model of accidental LNG release and fire described above (from Hightower et al., 2004), a circular pool of released LNG with diameter of 685 feet would cover an area of 0.010 nmi$^2$. An ensuing fire would cause severe thermal injuries over an area of 0.057 nmi$^2$ and the area where fire could cause second degree burns would extend to an area of 0.563 nmi$^2$. Considerably fewer than one humpack whale would be expected to be present within any of those areas in either of the two EEZ strata during 2018 and injuries to humpback whales due to LNG release and fire would be insignificant and discountable

Oil spills at sea or off shore might adversely affect food resources in the immediate area including krill, copepods, and various schooling fish such as anchovies (NMFS, 2006b) could occur. However, effects of potential spills from LNG carriers are not comparable to spills from oil tankers for a number of reasons. LNG carriers only carry quantities of oil used for propulsion fuel and not the quantities transported by oil tankers.

**Cumulative Effects**

FWS and NMFS describe cumulative effects (50 CFR § 402.02) as the result of future actions by state or private entities, not involving federal actions, but reasonably certain to occur in the action area considered in this BA. Future federal actions that are unrelated to the proposed action are not considered here because they require separate consultation pursuant to section 7 of the ESA.

As discussed above for blue whales, available information indicates that ship calls to the Port of Coos Bay have been declining since 2002. The observed declining linear trend in total annual vessel traffic over time is significant and, when used to forecast numbers of vessel calls to Coos Bay in the future, no vessels are predicted to enter Coos Bay in 2018 with between 0 and 17.6 vessels as reasonably foreseeable when the LNG terminal is expected to begin operation in 2018 (see figure 4.2-4). And, as discussed above for blue whales, it appears that the background rate of spills off the Oregon coast by fishing vessels, recreation vessels, and other vessel types is generally low, a frequency that would be expected to continue.

The foreseeable cumulative effect of 90 LNG carriers per year with anticipated vessel traffic in 2018 would be less than effects based on past levels of vessel traffic calls to the Port of Coos Bay which would have exceeded 90 vessels per year in 1992 given the current trend in figure 4.2-2 (under blue whales). Consequently, cumulative effects to humpback whales would likely be less than the estimate of direct effects discussed in the previous section. Those effects were judged to be insignificant and discountable.

The volume of annual vessel transits within the EEZ of California, Oregon, and Washington is related to numbers of vessel calls to ports in those states. Total annual calls for all vessels at ports in California, Oregon, and Washington (MARAD, 2013) were plotted above in figure 4.2-2 for 2002 through 2011. Unlike the trend analyzed for calls to Coos Bay (see figure 4.2-4) the observed linear trend in annual vessel traffic (port calls) along the U.S. West Coast was significantly increasing at a rate of 2.1 percent per year between 2002 and 2007. The increasing trend was interrupted by the global economic crisis in 2008 but data through 2011 indicate a return to the established increasing trend prior to 2008. The pre-2008 trend predicts 21,530 vessel calls to West Coast ports in 2018 (with 95% prediction intervals ranging from 17,360 to 25,710 vessel calls),, the year the JCEP and PCGP projects are expected to be in service. Even with the uncertainty generated by available data, there is a reasonably foreseeable increasing trend, albeit imprecise, for vessel traffic volume in the future (by 2018) although unforeseen global events such as future economic crises could influence the predictions. Cumulative effects of 90 LNG carriers per year to humpback whales may be more or may be less than the estimate of direct effects discussed above.

**Critical Habitat**

The proposed action would not affect critical habitat; none has been designated.

#### 4.2.4.4 Conservation Measures

The same Ship-Strike Reduction Plan to minimize potential ship strikes to cetaceans by LNG carriers and LNG Management Plan to minimize risk of spills and releases at sea that were described in Section 4.2.1.4 (Blue Whale) apply to humpback whales.

#### 4.2.4.5 Determination of Effects

**Species Effects**

The Project **may affect** humpback whales because:

- Humpback whales may occur within the EEZ analysis area during operation of the proposed action.
- The proposed action would increase shipping traffic (LNG carriers) within the EEZ analysis area.

However, the Project is **not likely to adversely affect** humpback whales because:

- Existing information indicates ship strikes to humpback whales within the EEZ analysis area are infrequent.
- The increase in annual ship traffic due to the proposed action is expected to cause an immeasurable increase in ship strikes to humpback whales over known frequencies of incidents.
- Jordan Cove would provide a ship strike avoidance measures package to shippers delivering LNG cargo to the LNG terminal. The package consists of multiple measures to avoid striking marine mammals.
- LNG carriers approaching the Port of Coos Bay would be traveling slowly and escorted by tractor tugs from 50 nmi offshore to the Port.
- Noise produced by LNG carriers would contribute to overall noise within the EEZ en route to the Port of Coos Bay and effects of ship noise on humpback whales could exceed NMFS interim noise exposure criteria for Level B single non-pulse noise but would not exceed existing background ship noise levels and would not cause injury.
- Accidental releases of LNG at sea would not cover an area large enough to coincide with expected humpback whale presence (based on estimated densities). Ignited LNG would not extend far enough from the LNG pool to cause severe or mild thermal effects to humpback whales if they emerged during a fire.

**Critical Habitat Effects**

No critical habitat has been designated or proposed for humpback whales.

### 4.2.5 Sei Whale

#### 4.2.5.1 Species Account and Critical Habitat

**Status**

Sei whales were listed as endangered under the Endangered Species Conservation Act on December 2, 1970 (FWS, 1970) and have been listed as endangered throughout its range under the ESA since its implementation in 1973. Sei whales off the U.S. West Coast are in the Eastern North Pacific stock. Sei whales are classified as depleted throughout their range under the MMPA.

**Threats**

Commercial whaling operations were the primary reason for the reduction in numbers of sei whales (Carretta et al., 2013b). An ongoing threat to sei whales is ship strikes although the current rate of ship strike deaths and serious injuries is zero (Carretta et al., 2013a). Another ongoing threat is offshore gill-net commercial fishing operations, although they accounted for no recorded deaths from 2000 to 2004 (Carretta et al., 2007) or from 2004 to 2008 (Carretta et al., 2013b). Anthropogenic noise in ocean environments has been suggested to be a concern for whales, especially for baleen whales that communicate using low-frequency sound (Carretta et al., 2013b).

Sei whale food sources may be damaged and they may gain new stressors with certain climate changing processes such as global warming similar to those discussed above for blue whales (Fogarty and Powell, 2002). Those impacts include: 1) changes in nutrient exchange and primary production with effects to all trophic levels in the ecosystem, 2) health effects due to metabolic demands from warmer oceans, 3) shifts of marine populations towards the poles or ocean depths, and 4) with changes in available nutrient levels there may be changes in the timing and intensity of phytoplankton blooms. Changes in the California Current have reduced the zooplankton populations, primarily as a result of increased water temperatures, which led to intensified stratification and a lowering of mixing and nutrient regeneration in the water column (Fogarty and Powell, 2002).

**Species Recovery**

A draft plan for recovery the sei whale (and fin whale) was issued in 1998 (NMFS, 1998a) and the plan was finalized in 2011 (NMFS, 2011c). The goal of the recovery plan is to promote recovery of the species in order to eventually downlist and then delist it. The recovery plan (NMFS, 2011c) lists the following tasks as those necessary to achieve the goal:

- Coordinate state, federal, and international actions to maintain international regulation of whaling for sei whales.
- Develop and apply methods to collect sei whale data.
- Support existing studies to investigate population discreteness and population structure of sei whales using genetic analysis.
- Continue to collect data on "unknown" threats to sei whales.
- Initiate new studies to determine population discreteness and population structure of sei whales.
- Estimate population size and monitor trends in abundance.

- Maximize efforts to acquire scientific information from dead, stranded, and entangled sei whales.
- Conduct risk analyses.
- Identify, characterize, protect, and monitor habitat important to sei whale populations in U.S. waters and elsewhere.
- Investigate human-caused threats, and, should they be determined to be medium or high, reduce frequency and severity
- Develop a post-delisting monitoring plan.

**Life History, Habitat Requirements, and Distribution**

The sei whale is a large baleen whale found in both the northern and southern hemispheres. Their diet includes copepods and other small prey types including fish. Calving occurs in midwinter, in low latitude portions of the species' range (OBIS-SEAMAP 2007). Sei whales are generally found alone or in pairs, although sometimes they may be found in groups of up to five. They generally dive between 5 and 20 minutes relatively close to the surface (Shirihai and Jarrett 2006).

Females reach reproductive age when 10 years old. Once mature, females give birth every 2 to 3 years to one calf. The gestation time is between 11 and 13 months, and calves are weaned between 6 and 9 months. It is expected that sei whales live up to 70 years (Shirihai and Jarrett 2006).

**Population Status**

The best abundance estimate of sei whales in California, Oregon, and Washington waters to 300 nautical miles offshore is 126 whales, with a minimum population estimate of 83 whales (Carretta et al., 2013c). There are no estimates for the growth rate of sei whale populations in the North Pacific although the population is expected to have grown since protection was initiation in 1976 (Carretta et al., 2013c).

The only documented occurrence of ship strike mortality of sei whales occurred in Washington in 2003 (Douglas et al., 2008). The average observed annual mortality during the period 2004 to 2008 due to ship strike is zero sei whales per year (Carretta et al., 2013c). The current calculated potential biological removal for sei whales from California to Washington is 0.17 whale per year. There were 0.2 death per year recorded from 2000 to 2004 which exceeded that amount (Carretta et al., 2007), but that rate has apparently not occurred since then.

**Critical Habitat**

Critical habitat for this species has not been designated.

#### 4.2.5.2 Environmental Baseline

**Analysis Area**

The analysis area applicable to sei whales is the EEZ, extending 200 nautical miles offshore from the Coos Bay Head and from San Diego to Cape Flattery, the same as described above for blue whales (see figure 4.2-1).

## Species Presence

Sei whales are found a great distance from shore in temperate waters and do not appear to approach coastal areas. Nine confirmed sightings of sei whales were made in California, Oregon, and Washington waters during extensive ship and aerial surveys between 1991 and 2008 (Carretta et al., 2013). Two of the reported sightings were within the EEZ off the coast of Oregon, and so the sei whale may be present in the EEZ analysis area (Carretta et al., 2007).

Line-transect ship surveys conducted off the coasts of California, Oregon, and Washington in summer and fall of 1991, 1993, 1996, 2001, 2005, and 2008 (Barlow and Forney, 2007; Forney, 2007; Barlow, 2010) have been used to estimate populations within the California and Oregon-Washington strata and to estimate populations for specific stocks. During each of those years (only California waters were surveyed in 1991 and 1993), line-transect locations were pre-determined to survey for pelagic cetaceans within approximately 300 nmi of the West Coast.

The mean density estimates for species in the California stratum are computed as the mean population estimate divided by the area in the surveyed stratum, 819,470 $km^2$ (Barlow, 2010) which is assumed to be the same in all of the years surveyed. The mean density of sei whales in the California stratum is 0.013 whale per 100 $km^2$ or 0.004 whale per 100 $nmi^2$. Similarly, mean population estimates for species in the Oregon-Washington stratum are the geometric means of population estimates derived from surveys conducted in 1996, 2001, 2005 (data from Barlow and Forney, 2007; Forney, 2007) and 2008 (data from Barlow, 2010). The mean density of sei whales in the Oregon-Washington stratum is 0.024 whale per 100 $km^2$ or 0.007 whale per 100 $nmi^2$.

The mean encounter rate (number observed per linear distance of transect) for each cetacean species is the geometric mean of the number of animals counted along line transects in the California stratum during each survey year (1991 through 2008, see above) divided by total transect length in the stratum for each survey year (data from Barlow and Forney, 2007; Forney, 2007; Barlow, 2010). If no individuals were sighted in one or more years, the arithmetic mean was used. The mean encounter rate for sei whales in the California stratum in 2008 is 0.012 whale per 100 km or 0.006 whale per 100 nmi of ship transect. Likewise, the mean encounter rate (number observed per linear distance) for cetaceans observed in the Oregon-Washington stratum is the geometric mean of the number of animals counted along line transects during each survey year (1996 through 2008, see above) divided by total transect length in the stratum for each survey year (data from Barlow and Forney, 2007; Forney, 2007; Barlow, 2010). The mean encounter rate for sei whales in the Oregon-Washington stratum in 2008 is 0.035 whale per 100 km or 0.019 whale per 100 nmi of ship transect.

## Habitat

Sei whales tend to use temperate waters, and do not associate with specific coastal features (Carretta et al., 2007) and are uncommonly associated with waters of continental shelves (Horwood, 2009). Consequently, they are seldom observed within the EEZ. They are known for shying away from boats, and being one of the fastest swimming large whales, capable of speeds up to 26 knots (Laist et al., 2001). They feed in temperate waters on zooplankton (especially copepods and euphausiids), small schooling fish, and squid (Shirihai and Jarrett, 2006).

## Critical Habitat

Critical habitat for this species has not been designated.

### 4.2.5.3 Effects by the Proposed Action

#### Direct and Indirect Effects

Direct effects of the proposed action include injury and/or mortality due to ship strikes, effects from anthropogenic underwater noise, and potential adverse effects from an accidental ship release of LNG and fire at sea. Spills and/or released LNG could indirectly affect sei whales by impacting forage species. These effects are addressed below.

Ship Strikes by LNG Carriers

As discussed above for blue whales, there is an ongoing threat of ship strikes to sei whales. Ship strikes of sei whales averaged 0.2 deaths per year along the Pacific Coast between 2000 and 2004 (Carretta et al., 2007). Recent accounts (Laist et al., 2001; Jensen and Silber, 2003) found that fast-swimming sei whales are struck by ships less often than most other whales, with the exception of killer whales (Jensen and Silber, 2003). Currently, the average observed annual mortality during the period 2004 to 2008 due to ship strike is zero sei whales per year (Carretta et al., 2013c). With so few documented ship strikes, there is insufficient information to estimate how many sei whales might be struck by LNG carriers transiting to and from Coos Bay in 2018 and possible death or injury due to project-related LNG traffic in the West Coast EEZ analysis area.

Underwater Noise

Determining and minimizing any detrimental effects of anthropogenic underwater noise on sei whales is a principal objective for the species' recovery (NMFS, 2011b). As described for blue whales, above, all vessels produce noise; propeller cavitation produces most of the broadband noise with dominant tones derived from the propeller blade rate. In general, rorquals including blue, fin and minke whales move away, abruptly change direction, or dive to avoid close approach by vessels. When whales are exposed to low-level sounds from distant or stationary vessels, they appear to ignore the sounds. Baleen whales will interrupt normal behavior and swim away from strong or rapidly changing vessel noise, especially if a vessel is headed directly toward the whale (Richardson, 1995). However, radiated ship noise of oncoming ships may not be immediately detected by whales near the surface due to bow null-effect acoustic shadow zones (Allen et al., 2012). Because of acoustic shadow zones, whales may not hear approaching ships to allow time for their avoidance response even though whale auditory ranges overlaps with peak intensities of ship noise. Ambient noise in the Northeast Pacific Ocean has increased in nearshore and deep ocean environments over the past several decades.

The low frequencies generated by ships overlap frequencies of sounds generated by large baleen whales, including the sei whale (Würsig and Richardson, 2009). Noise from ships and boats may interfere and mask cetacean communication, finding prey, avoiding predators, and possibly navigation (Würsig and Richardson, 2009). Anthropogenic noise and vessel disturbance may affect sei whales but there is little evidence available to describe or quantify the impacts of these threats on the species. While anthropogenic noise may threaten other cetaceans, little is known about whether, or how, vessel noise affects sei whales (NMFS, 2011c).

The risk of ship noise causing PTS or TTS (see NMFS' interim acoustic thresholds in table 4.2.1-2 under blue whales) for sei whales would be similar to that described for blue whales, above. Noise from a LNG tanker in a study by Hatch et al. (2008) produced sound levels (with 1 standard error) of 182 ± 2 dB re: 1 µPa @ 1 meter that attenuated to 160 dB at 35 ± 11 meters and to 120 dB at 16,185 ± 5,359 meters (Hatch et al., 2008). Using those attenuation distances, one LNG tanker transit across the length of the California EEZ stratum for 762 nmi would produce sound levels of ≥160 dB within an area 15.6 ± 4.9 nmi$^2$ and would produce sound levels ≥120 dB but <160 dB within an area 7,175.9 ± 2,376.3 nmi$^2$. Likewise, one LNG tanker transit across the width of the Oregon-Washington EEZ stratum for 200 nmi would produce sound levels of ≥160 dB within an area 4.1 ± 2.6 nmi$^2$ and would produce sound levels ≥120 dB but <160 dB within an area 1,883.4 ± 1,247.4 nmi$^2$.

Based on population growth between 2008 and 2018 of sei whales, the predicted density of sei whales is 0.006 whale per 100 nmi$^2$ in the California stratum in 2018 and is 0.010 whale per 100 nmi$^2$ in the Oregon-Washington EEZ stratum in 2018. Assuming an LNG tanker transit distance of 762 nmi within the California stratum, the number of sei whales within range of noise levels of 160 dB produced by a single LNG tanker transit through the stratum would be equal to the density (0.006 whale per 100 nmi$^2$) multiplied by the total area of noise effects (15.6 nmi$^2$), equal to 0.001 whale affected (an estimate between 0.000 and 0.001 whale based on the density within distances of ± 2 standard deviations of LNG noise attenuating to 120 dB, from Hatch et al., 2008) .

The number of fin whales within range of noise levels of 120 dB (radius of 16,185 m or 4.72 nmi) produced by a single LNG tanker transit through the stratum would be equal to the density (0.006 whale per 100 nmi$^2$) multiplied by the total area of noise effects (7,176 nmi$^2$), equal to 0.403 whale affected (an estimate between 0.137 and 0.672 whale based on the density within distances of ± 2 standard deviations of LNG noise attenuating to 120 dB, from Hatch et al., 2008) by noise levels that could cause behavioral disruptions (see table 4.2.1-3 under blue whales, above).

Similar calculations have been done for sei whales in the Oregon-Washington stratum. Assuming an LNG tanker transit distance of 200 nmi across the Oregon-Washing stratum, the number of sei whales within range of noise levels of 160 dB produced by a single LNG tanker transit through the stratum would be equal to the density (0.010 whale per 100 nmi$^2$) multiplied by the total area of noise effects (4.08 nmi$^2$), equal to <0.001 whale affected (an estimate between 0.000 and 0.001 whale based on the density within distances of ± 2 standard deviations of LNG noise attenuating to 120 dB, from Hatch et al., 2008). The number of sei whales within range of noise levels of 120 dB produced by a single LNG tanker transit through the stratum would be equal to the density (0.010 whale per 100 nmi$^2$) multiplied by the total area of noise effects 1,883 nmi$^2$), equal to 0.194 whale affected (an estimate between 0.066 and 0.032 whale based on the density within distances of ± 2 standard deviations of LNG noise attenuating to 120 dB, from Hatch et al., 2008) by noise levels that could cause behavioral disruptions (see table 4.2.1-3).

Existing commercial vessels within the West Coast EEZ analysis area produce underwater noise levels that are comparable or exceed noise from the LNG tanker described by Hatch et al. (2008). Noise generated by various types of commercial ships (container ships, crude oil tankers, product tankers, bulk carriers, and others) were recently evaluated by McKenna et al. (2012). Underwater noise levels varied by ship type and also by vessel length, gross tonnage, vessel speed, and to some extent, vessel age (older vessels tended to be louder than newer vessels). For example, a 54,000 Gross Ton (GT) container ship generated the highest acoustic source level of 188 dB re: 1 µPa @ 1 meter while a 26,000 GT chemical tanker had the lowest at 177 dB re: 1 µPa @ 1 meter (McKenna et al., 2012). Noise levels from the vessels examined in that study are assumed to be typical of ship noise in the California and Oregon-Washington EEZ strata and would produce radiated noise levels through the two strata that would exceed the threshold for Level B single non-pulse noise of 120 $dB_{rms}$ (see table 4.2.1-3, above). With the existing levels of background shipping noise and the expected increase in shipping traffic by 2018, effects by project LNG tanker-related noise on sei whales are possible in the in West Coast EEZ analysis area but the noise would be commensurate with existing noise levels and would not be expected to cause injury.

Two tractor tugs would guide the LNG tanker from a point approximately 5 nmi offshore the entrance to Coos Bay and to the JCEP LNG terminal. Noise produced by tugs would attenuate to 160 dB at 11 ± 4 meters (upper end) and to 120 dB at 4,992 ± 1,599 meters (upper end) (Hatch et al., 2008). Unlike LNG tankers, project-related tug traffic would only occur in the Oregon-Washington stratum. LNG ship noise and noise from tugs would exceed the ambient noise levels within the West Coast EEZ activity area assuming those range from 64 dB to 72 dB re 1 $\mu Pa^2$ (at 62 Hz, similar to the ocean noise 7 nmi west of San Diego reported by McDonald et al., 2008) but would not cause behavioral disruptions to fin whales.

Releases and Fire at Sea

Characteristics of LNG released at sea were described in Section 4.2.1.3 for blue whales. At the water-vapor LNG pool interface, the cryogenically cooled LNG would begin to vaporize but, because of its relatively high density, the plume would remain at or close to the surface interface; methane is an asphyxiant but with low toxicity, at least to humans (Hightower et al., 2004). If a marine mammal surfaced to breathe at the LNG pool location, it could suffer from oxygen deficiency and potential physiological effects, which have been described for humans - ranging from impaired thinking to loss of consciousness with decreasing oxygen concentrations (Table 39 in Hightower et al., 2004) - but not for marine mammals. Because the estimated densities of marine mammals are generally low within the California and Oregon-Washington strata of EEZ, the chance of an animal becoming asphyxiated by contact with a pool of LNG would extremely remote (see discussion about potential thermal injury, below).

Sandia National Laboratories modeled LNG spills from a standard LNG vessel (with capacity of 125,000 to 140,000 $m^3$) over water and potential injury to humans due to ignition of the fuel (Hightower et al., 2004). Thermal effects from a fire would vary, depending on the size of the LNG pool released. If one LNG tank is accidentally breached, due to collision with another ship, grounding, or ramming, the potential spill of LNG could form a pool with diameter of 685 feet. Ignition could cause a fire to burn for 20 minutes with severe thermal injuries extending to 820 feet away from the center of the pool (based on an exposure of 10 minutes and thermal flux of 37.5 $kW/m^2$) and second-degree skin burns on exposed skin (human) to a distance of 2,572 feet (based on an exposure of 10 minutes and thermal flux of 5 $kW/m^2$) from the center of the burning pool of LNG (see Table 41 in Hightower et al., 2004). Surfacing cetaceans within those distances would be assumed to experience severe burns or mild burns, based on similar thermal fluxes effects on humans although exposures for 10 minutes or more would be unlikely.

Expected densities of sei whales in the California EEZ stratum during 2018 would be 0.006 whale per 100 $nmi^2$ and 0.010 whale per 100 $nmi^2$ in the Oregon-Washington EEZ stratum, the same densities that were used in the analysis of effects due to ship noise, above. Based on the model of accidental LNG release and fire described above (from Hightower et al., 2004), a circular pool of released LNG with diameter of 685 feet would cover an area of 0.010 $nmi^2$. An ensuing fire would cause severe thermal injuries over an area of 0.057 $nmi^2$ and the area where fire could cause second degree burns would extend to an area of 0.563 $nmi^2$. Considerably fewer than one sei whale would be expected to be present within any of those areas in either of the two EEZ strata during 2018 and injuries to fin whales due to LNG release and fire would be insignificant and discountable

Oil spills at sea or off shore might harm sei whales, although effects of oil spills on sei whales have not been reported (NMFS, 2006a). Effects to food resources including krill, copepods, and various schooling fish such as anchovies (NMFS, 2006a) could occur. However, effects of potential spills from LNG carriers are not comparable to spills from oil tankers for a number of reasons. LNG carriers only carry quantities of oil used for propulsion fuel and not the quantities transported by oil tankers.

**Cumulative Effects**

FWS and NMFS describe cumulative effects (50 CFR § 402.02) as the result of future actions by state or private entities, not involving federal actions, but reasonably certain to occur in the action area considered in this BA. Future federal actions that are unrelated to the proposed action are not considered here because they require separate consultation pursuant to section 7 of the ESA.

As discussed above for blue whales, available information indicates that ship calls to the Port of Coos Bay have been declining since 2002. The observed declining linear trend in total annual vessel traffic over time is significant and, when used to forecast numbers of vessel calls to Coos Bay in the future, no vessels are predicted to enter Coos Bay in 2018 with between 0 and 17.6 vessels as reasonably foreseeable when the LNG terminal is expected to begin operation in 2018 (see figure 4.2-3 under blue whales). And as discussed above for blue whales, it appears that the background rate of spills off the Oregon coast by fishing vessels, recreation vessels, and other vessel types is generally low, a frequency that would be expected to continue into the foreseeable future.

The foreseeable cumulative effect of 90 LNG carriers per year with anticipated vessel traffic in 2018 would be less than effects based on past of vessel traffic calls to the Port of Coos Bay which would have exceeded 90 vessels per year in 1992 given the current trend in figure 4.2-2 (under blue whales). Consequently, cumulative effects to sei whales would likely be less than the estimate of direct effects discussed in the previous section. Those effects were judged to be insignificant and discountable.

The volume of annual vessel transits within the EEZ of California, Oregon, and Washington is related to numbers of vessel calls to ports in those states. Total annual calls for all vessels at ports in California, Oregon, and Washington (MARAD, 2013) were plotted above in figure 4.2-2 for 2002 through 2011. Unlike the trend analyzed for calls to Coos Bay (see figure 4.2-3) the observed linear trend in annual vessel traffic (port calls) along the U.S. West Coast was significantly increasing at a rate of 2.1 percent per year between 2002 and 2007. The increasing trend was interrupted by the global economic crisis in 2008 but data through 2011 indicate a return to the established increasing trend prior to 2008. The pre-2008 trend predicts 21,530 vessel calls to West Coast ports in 2018 (with 95% prediction intervals ranging from 17,360 to 25,710 vessel calls), the year the JCEP and PCGP projects are expected to be in service. Even with the uncertainty generated by available data, there is a reasonably foreseeable increasing trend, albeit imprecise, for vessel traffic volume in the future (by 2018) although unforeseen global events such as future economic crises could influence the predictions. Cumulative effects of 90 LNG carriers per year to sei whales may be more or may be less than the estimate of direct effects discussed above.

**Critical Habitat**

The proposed action would not affect critical habitat; none has been designated.

#### 4.2.5.4 Conservation Measures

The same Ship-Strike Reduction Plan to minimize potential ship strikes to cetaceans by LNG carriers and LNG Management Plan to minimize risk of spills and releases at sea that were described in section 4.2.1.4 (Blue Whale) apply to sei whales.

#### 4.2.5.5 Determination of Effects

**Species Effects**

The Project **may affect** sei whales because:

- Sei whales may occur within the EEZ analysis area during operation of the proposed action.
- The proposed action would increase shipping traffic (LNG carriers) within the EEZ analysis area.

However, the Project is **not likely to adversely affect** sei whales because:

- Existing information indicates ship strikes to sei whales within the EEZ analysis area are infrequent.
- The increase in annual ship traffic due to the proposed action is expected to cause an immeasurable increase in ship strikes to sei whales over known frequencies of incidents.
- Jordan Cove would provide a ship strike avoidance measures package to shippers delivering LNG cargo to the LNG terminal. The package consists of multiple measures to avoid striking marine mammals.
- LNG carriers approaching the Port of Coos Bay would be traveling slowly and escorted by tractor tugs from 50 nmi offshore to the Port.
- Noise produced by LNG carriers would contribute to overall noise within the EEZ en route to the Port of Coos Bay and effects of ship noise on sei whales could exceed NMFS interim noise exposure criteria for Level B single non-pulse noise but would not exceed existing background ship noise levels and would not cause injury.
- Accidental releases of LNG at sea would not cover an area large enough to coincide with expected sei whale presence (based on estimated densities). Ignited LNG would not extend far enough from the LNG pool to cause severe or mild thermal effects to sei whales if they emerged during a fire.

**Critical Habitat Effects**

No critical habitat has been designated or proposed for sei whales.

### 4.2.6 Sperm Whale

#### 4.2.6.1 Species Account and Critical Habitat

**Status**

Sperm whales were listed as endangered under the Endangered Species Conservation Act on December 2, 1970 (FWS 1970) and have been listed as endangered throughout their range under the ESA since its implementation in 1973. For the MMPA stock assessment reports, sperm whales within the Pacific United States EEZ are divided into three discrete, non-contiguous areas: 1) California, Oregon, and Washington waters; 2) waters around Hawaii; and 3) Alaskan waters. Sperm whales are classified as depleted throughout their range under the MMPA.

**Threats**

Commercial whaling operations were the primary reason for listing sperm whales as an endangered species (NOAA Fisheries, 2012b). The offshore drift gill-net fishery is the primary ongoing threat to sperm whales (Carretta et al. 2007). Another threat is ship strikes, although no ship strikes were reported for sperm whales along the Pacific Coast from 2000 to 2004 (Carretta et al. 2007).

Sperm whales are typically found farther offshore and are deep divers for food; they may be susceptible to increased anthropogenic noise (Carretta et al. 2007). Sperm whale food sources may be damaged and they may be stressed by certain climate changing processes such as global warming, similar to those discussed above for blue whales (Fogarty and Powell, 2002). Those impacts include 1) changes in nutrient exchange and primary production with effects to all trophic levels in the ecosystem, 2) health effects due to metabolic demands from warmer oceans, 3) shifts of marine populations towards the poles or ocean depths, and 4) with changes in available nutrient levels there may be changes in the timing and intensity of phytoplankton blooms. Changes in the California Current have reduced the zooplankton populations, primarily as a result of increased water temperatures which led to intensified stratification and a lowering of mixing and nutrient regeneration in the water column (Fogarty and Powell, 2002).

**Species Recovery**

A draft recovery plan was released in June 2006 (NMFS, 2006e) and a 5-year status review was initiated on January 22, 2007 (NMFS, 2007a). The recovery plan was finalized in 2010 (NMFS, 2010b). The goal of the recovery plan is to eventually downlist and then delist the species. To that end, the final recovery plan lists the following recovery measures:

- Coordinate state, federal, and international actions to implement recovery actions and maintain international regulation of whaling for sperm whales.
- Determine population discreteness and population structure of sperm whales.
- Develop and apply methods to estimate population size and monitor trends in abundance.
- Conduct risk analyses.
- Identify and protect habitat essential to the survival and recovery of sperm whale populations in U.S. waters and elsewhere.
- Investigate causes and reduce the frequency and severity of human-caused injury and mortality.
- Determine and minimize any detrimental effects of anthropogenic noise in the oceans.

- Maximize efforts to acquire scientific information from dead, stranded, and entangled or entrapped sperm whales.
- Develop post-delisting monitoring plan.

### Life History, Habitat Requirements, and Distribution

Sperm whales are the largest of the toothed whales and exhibit significant sexual dimorphism. They are a deep water species, and as such, their diet consists of large species that also occur in deep water – primarily squid, but also sharks, skates, and fishes. They are deep divers, with the average dive depth greater than 1,300 feet (NMFS, 2007a). Dives can last for longer than 2 hours. Cows, calves and juveniles can be found in groups of between 10 and 50 animals, and bachelor schools of young males can be found separately (Shirihai and Jarrett, 2006).

The peak breeding season for sperm whales occurs from March or April to May, with some breeding activity earlier and later (December to August). Gestation likely ranges from 15 months to more than a year and a half (NMFS, 2010b). Most sperm whales fully sexually mature in their twenties, although females begin ovulation between the ages of seven and thirteen. Females give birth every 4 to 6 years once sexually mature, with that time period increasing after they reach the age of 40. Sperm whales have a low reproductive rate of increase, with a maximum of no more than two percent per year. They are also unique in that the killing of larger and older sexually mature males has been a significant reason for the reduction of reproductive rates, meaning that both large and older males and females are needed to increase the rate of reproduction (NMFS, 2010).

Sperm whales have been documented to live in excess of 60 years of age. Known natural reasons for mortality include predation, competition, and disease. Calves are susceptible to both killer whales and sharks. Diseases that are believed to have an impact on sperm whales include myocardial infarction, gastric ulceration, and a type of cumulative bone necrosis that is believed to be caused by deep dives and resulting nitrogen bubbles during ascents (NMFS, 2010b).

### Population Status

The most recent abundance estimates are from 2005 and 2008 with 971 sperm whales in the California, Oregon and Washington stock derived ship surveys (Carretta et al., 2013b). The minimum population estimate is 751 sperm whales for this population. The most recent estimate from 2008 is the lowest to date, in sharp contrast to the highest abundance estimates obtained from 2001 and 2005 surveys but the different estimates indicate the species' variability in abundance rather than a significant population trend (Carretta et al., 2013b). Most populations were depleted by modern whaling, and commercial whaling ended in 1988 with a moratorium issued by the International Whaling Commission (NMFS, 2010b). However, Japan continues to take a small number of sperm whales each year (NMFS, 2010b). The only commercial fishery that is considered to likely incidentally take sperm whales is the offshore drift gill-net fishery. From 2000 to 2004, the California and Oregon thresher shark and swordfish drift gill-net fishery accounted for no deaths, but an unknown fishery was found to have caused one death (Carretta et al. 2007). A total of 18 sperm whales were stranded in Washington and Oregon from 1930 to 2002, with seven in Oregon and 11 in Washington (Norman et al., 2004).

### Critical Habitat

Critical habitat for this species has not been designated.

### 4.2.6.2 Environmental Baseline

**Analysis Area**

The analysis area applicable to sperm whales is the EEZ, extending 200 nautical miles offshore from the Coos Bay Head and from San Diego to Cape Flattery, the same as described above for blue whales (see figure 4.2-1).

**Species Presence**

Sperm whales are widely distributed across the entire North Pacific and into the southern Bering Sea in summer, but the majority are thought to be south of latitude 40º N in winter (Carretta et al. 2007). They have been seen in every season except winter (December-February) in Washington and Oregon.

Line-transect ship surveys conducted off the coasts of California, Oregon, and Washington in summer and fall of 1991, 1993, 1996, 2001, 2005, and 2008 (Barlow and Forney, 2007; Forney, 2007; Barlow, 2010) have been used to estimate populations within the California and Oregon-Washington strata and to estimate populations for specific stocks. During each of those years (only California waters were surveyed in 1991 and 1993), line-transect locations were pre-determined to survey for pelagic cetaceans within approximately 300 nmi of the West Coast.

The mean density estimates for species in the California stratum are computed as the mean population estimate divided by the area in the surveyed stratum, 819,470 $km^2$ (Barlow, 2010) which is assumed to be the same in all of the years surveyed. The mean density of sperm whales in the California stratum is 0.146 whale per 100 $km^2$ or 0.043 whale per 100 $nmi^2$. Similarly, mean population estimates for species in the Oregon-Washington stratum are the geometric means of population estimates derived from surveys conducted in 1996, 2001, 2005 (data from Barlow and Forney, 2007; Forney, 2007) and 2008 (data from Barlow, 2010). The mean density of sperm whales in the Oregon-Washington stratum is 0.102 whale per 100 $km^2$ or 0.030 whale per 100 $nmi^2$.

The mean encounter rate (number observed per linear distance of transect) for each cetacean species is the geometric mean of the number of animals counted along line transects in the California stratum during each survey year (1991 through 2008, see above) divided by total transect length in the stratum for each survey year (data from Barlow and Forney, 2007; Forney, 2007; Barlow, 2010). If no individuals were sighted in one or more years, the arithmetic mean was used. The mean encounter rate for sperm whales in the California stratum in 2008 is 0.093 whale per 100 km or 0.050 whale per 100 nmi of ship transect. Likewise, the mean encounter rate (number observed per linear distance) for cetaceans observed in the Oregon-Washington stratum is the geometric mean of the number of animals counted along line transects during each survey year (1996 through 2008, see above) divided by total transect length in the stratum for each survey year (data from Barlow and Forney, 2007; Forney, 2007; Barlow, 2010). The mean encounter rate for sperm whales in the Oregon-Washington stratum in 2008 is 0.081 whale per 100 km or 0.044 whale per 100 nmi of ship transect.

**Habitat**

Sperm whales are considered to be almost cosmopolitan, preferring areas along the continental shelf where water is as deep as 1,000 to 3,000 meters (Shirihai and Jarrett, 2006). They are present off of Oregon in all times of the year except mid-winter, and can feed and use all sections of the water column. However, they prefer to feed on or near the bottom in deep water, show a preference for squid, and they feed throughout the year (NMFS, 2010b).

### Critical Habitat

Critical habitat for this species has not been designated

### 4.2.6.3 Effects by the Proposed Action

### Direct and Indirect Effects

Direct effects of the proposed action include injury and/or mortality due to ship strikes, effects due to anthropogenic underwater noise, and potential adverse effects from an accidental ship release of LNG and fire at sea. Spills and/or released LNG could indirectly affect sperm whales by impacting forage species. These effects are addressed below.

Ship Strikes by LNG Carriers

As discussed above for blue whales, there is an ongoing threat of ship strikes to sperm whales. From available accounts, a one sperm whale was struck by ships in 1967 (Jensen and Silber, 2003), one was killed by ship. However, one sperm whale was reported injured by an apparent ship strike (propeller injury) off the Oregon coast and another was reported as a possible ship-strike in Washington State between 1980 and 2006 (Douglas et al., 2008). During the period from 2007 to 2011, a sperm whale was struck and killed off the Oregon coast and another was injured offshore from Washington, both during 2007 (Caretta et al., 2013a) for an average rate of 0.40 strikes per year..

**Ship Traffic**. A considerable amount of shipping traffic currently occurs within the EEZ analysis area. Past, present, and reasonably foreseeable ship traffic within the EEZ analysis area was discussed for blue whales, above. Ship traffic to U.S. West Coast ports was increasing between 2002 and 2007 but deviated from the established trajectory in 2008, at the onset of the global financial crisis (see figure 4.2-2 under blue whales, above). The pre-2008 trend predicts 21,530 vessel calls to West Coast ports in 2018 (with 95% prediction intervals ranging from 17,360 to 25,710 vessel calls), the year the JCEP and PCGP projects are expected to be in service.

Applying the yearly percent change in Total Annual Vessel Calls at all West Coast ports based on the regression model in figure 4.2-2 to the total ship-miles along the West Coast beginning in 1999 (5,049,298 ship-miles in table 4.2.1-1, under blue whales), there would be an estimated 8,199,320 ship-miles along the West Coast, expected in 2018.

Similarly, the data from MARAD (2013) were used to estimate ship-miles along the California Coast and along the Oregon-Washington Coast in 2018 from the data in table 4.2.1-1 (under blue whales, above) from 1999 provided by Pacific States/British Columbia Oil Spill Task Force (2002).

- From 2002 to 2007, total vessel calls to California ports increased by a constant number of 251 vessel calls per year (regression model $y = 250.74x - 492{,}585$, $r^2 = 0.78$, $P=0.019$). There were 3,041,597 ship-miles in 1999 within California waters (see table 4.2.1-1); 4,717,894 ship-miles are expected in 2018.

- From 2002 to 2007, total vessel calls to Oregon-Washington ports increased by a constant number of 185 vessel calls per year (regression model $y = 184.6x - 364{,}401$, $r^2 = 0.56$, P=0.086). There were 2,007,701 ship-miles in 1999 within Oregon-Washington waters (see table 4.2.1-1); 3,533,752 ship-miles are expected in 2018.

The Project is designed to accommodate 90 LNG tankers a year. If all LNG tankers approach the Jordan Cove terminal by perpendicular transits through the EEZ, they will contribute 36,000 ship miles annually to vessel traffic in the Oregon-Washington stratum in 2018. If all LNG tankers approach the terminal by parallel transits along the California coast, they will contribute 137,160 ship-miles annually to vessel traffic within the California stratum in 2018. Observed and predicted vessel traffic within both strata in 1999, 2007, 2008, and 2018 are provided in table 4.2.6-1, including the addition of project-related LNG tanker traffic in 2018. During the life of the project, there may be years of mixed LNG tanker traffic, some transiting the EEZ perpendicular and other traffic paralleling the coast but such variability cannot be estimated.

**Table 4.2.6-1**
**Estimates of Vessel Traffic, Sperm Whale Encounter Rates, Relative Ship-Strike Risk, and Estimates of Sperm Whales Struck per Year (with Percent Change from the Previous Estimate) in the California and Oregon-Washington Strata of the Project Activity Area**

| | California Stratum | | | | Oregon-Washington Stratum | | | |
|---|---|---|---|---|---|---|---|---|
| Year and Event | Ship-Miles (nmi) | Whale Encounter Rate (N/100 nmi) | Relative Ship-Stike Risk | Estimate of Whales Struck per Year [5] | Ship-Miles (nmi) | Whale Encounter Rate (N/100 nmi) | Relative Ship-Stike Risk | Estimate of Whales Struck per Year [5] |
| 1999 [1] Baseline Annual Ship Transits | 3,041,597 | N/A | N/A | N/A | 2,007,701 | N/A | N/A | N/A |
| 2007 [2] Predicted Trend with 2002-2007 data | 3,747,406 (+23.2%) | N/A | N/A | N/A | 2,650,249 (+32.0%) | N/A | N/A | N/A |
| 2008 [3] Most Recent Cetacean Survey | 3,316,554 (-11.5%) | 0.050 | 1,660 | 0 | 2,495,278 (-5.8%) | 0.044 | 1,019 | 0.40 |
| 2018 [2] Ambient Predicted Ship Traffic | 4,717,894 (+42.3%) | 0.075 (+49.1%) | 3,524 (+112.2%) | 0 (N/A) | 3,533,752 (+41.6%) | 0.065 (+49.1%) | 2,314 (+111.3%) | 0.845 (+111.3%) |
| 2018 [4] Ambient Traffic with LNG Tanker Traffic | 4,855,054 (+2.9%) | 0.075 (0%) | 3,626 (+2.9%) | 0 (N.A) | 3,569,752 (+1.0%) | 0.065 (0%) | 2,338 (+1.0%) | 0.854 +1.0%) |

[3] Estimated total vessel calls to California ports and Oregon-Washington ports in 2008 (see Figure 4.2.1-1, above). Source: MARAD, 2013.
[4] Assume 90 LNG tankers with perpendicular transits through West Coast EEZ in Oregon-Washington stratum (36,000 ship-miles per year) or parallel transits through EEZ in California stratum (137,160 ship-miles per year).
[5] Estimates of Whales Struck derived from data reported by Carretta et al., 2013a for ship-strikes in the California and Oregon-Washington EEZ strata.

**Ship-Strike Risk.** An index of relative ship-strike risk within an explicitly defined gridded study area was described by Williams and O'Hara (2009). The approach was adapted to the coarse-scale analysis area by using mean whale encounter rates, described above for sperm whales, and shipping intensity as indicated by the total annual ship-miles derived from vessel transits along the West Coast (see table 4.2.6-1) in the California and Oregon-Washington strata.

The encounter rate for sperm whales in the California EEZ stratum is significantly ($P< 0.01$) related to the species' density, based on data collected during surveys conducted in in 1991, 1993, 1996, 2001, 2005 (data from Barlow and Forney, 2007; Forney, 2007) and 2008 (Barlow, 2010). Likewise, the encounter rate for sperm whales in the Oregon-Washington EEZ stratum is significantly ($P< 0.05$) related to density based on data collected in 1996, 2001, 2005 (data from Barlow and Forney, 2007; Forney, 2007) and 2008 (data from Barlow, 2010), shown in figure 4.2-7. The relationships support predictions, below, that future encounter rates (eg, in 2018) would be expected to increase as the sperm whale population increases.

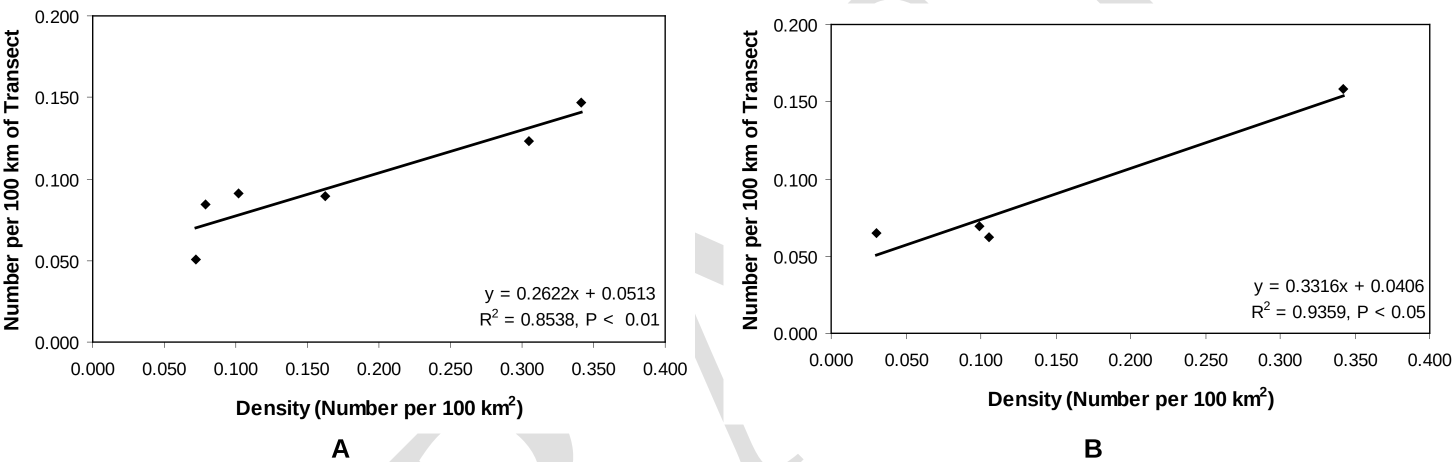

**Figure 4.2-7**
**Relationships of Sperm Whale Encounter Rate (Number per 100 km of line-transect) to Density (Number per 100 km$^2$) From Shipboard Surveys Conducted off the Coasts of California (A) and Oregon-Washington (B).**

Relative ship-strike risks during 2008 and 2018 (see table 4.2.6-1) are the products of cetacean species' encounter rates and total ship miles expected in each stratum during the two years. An estimate of the encounter rate in 2018 (beginning of the project operation) is directly proportional to fin whale population and density in that year. Assuming exponential population growth, the population size ($N_t$) at time = t is $N_t = N_0 e^{r t}$ where $N_0$ = the initial population size at t = 0 and r is assumed to be $R_{MAX}$. This approach was used with the default value for $R_{MAX}$ = 0.04 to estimate sperm whale encounter rates (as indices of population) in 2018 given the encounter rates of sperm whales within the California and Oregon-Washington strata in 2008. In 2008, the sperm whale encounter rate in the California stratum was 0.050 whale per 100 nmi and 0.044 whale per 100 nmi in the Oregon-Washington stratum. Based on assumed population growth between 2008 and 2018, the sperm whale encounter rate in California in 2018 is estimated at 0.075 whale per 100 nmi and 0.065 whale per 100 nmi in the Oregon-Washington stratum, an increase of 49 percent from the 2008 encounter rates (see table 4.2.6-1).

In 2008, the relative ship-strike risk in the Califonia stratum would be 0.050 whale per 100 nmi multiplied by 3,316,554 ship-miles = 1,660. In 2018, the assumed growth of the sperm whale population increases the encounter rate proportionately to 0.075 whale per 100 nmi. Between 2008 and 2018 ship traffic is also be expected to increase to 4,717,894 ship-miles. The relative ship-strike risk in 2018 would be 3,524 which is 112.2 percent of the 2008 encounter rate (table 4.2.6-1). If all 90 LNG tanker transits occur in the California stratum, the total expeced vessel traffic would be 4,855,054 ship miles in 2018 and the ship-strike risk would increase to 3,626, an estimated increase of 2.9 percent. Similar calculations woud apply to the sperm whale population growth, encounter rate, relative ship-strike risk in the Oregon-Washington stratum, provided in table 4.2.6-1.

**Estimated Ship-Strikes to Sperm Whales**. Data provided by Carretta et al. (2013a) indicated that no sperm fin whales were struck in the California EEZ between 2007 and 2011. However, 2 sperm whales were struck in the Oregon-Washington EEZ during that 5-year period (0.40 whale per year). Using recent ship-strike data from Carretta et al. (2013a), the increased ship-strike risk in 2018 is assumed to increase the annual rate of sperm whales struck proportionately in the Oregon-Washington stratum to 0.845 per year but no estimates can be made for increase ship strikes in the California stratum (see table 4.2.6-1). The additional project-related LNG tanker traffic would increase the annual rate in Oregon-Washington waters to 0.854 whales per year, an increase of 0.009 ship-strike per year (one injury or death in 111 years). Ship-strikes to sperm whales by project-related LNG tankers are most likely in the Oregon-Washington EEZ stratum but death or injury of sperm whales is insignificant and discountable.

Underwater Noise

Determining and minimizing any detrimental effects of anthropogenic underwater noise on sperm whales is a principal objective for the species' recovery (NMFS, 2010b). As described for blue whales, above, all vessels produce noise; propeller cavitation produces most of the broadband noise with dominant tones derived from the propeller blade rate. In general, rorquals including blue, fin and minke whales move away, abruptly change direction, or dive to avoid close approach by vessels. Reduced calling or cessation of vocalizations by sperm whales have been documented in response to pingers and military sonar signals, in response to low-frequency ATOC-like sounds, and in response to seismic surveys (Weilgart, 2007). However, sperm whales and other cetaceans have been documented remaining in or returning to high noise environments, probably motivated by forage and/or availability of mates (Weilgart, 2007). In those cases, individual's hearing could be damaged. For example, two sperm whales killed by collision with a ferry in waters off the Canary Islands never responded behaviorally to low frequency sounds generated to test repelling sperm whales from ferry routes. Histological analyses of the inner ears of both animals showed nerve degeneration and fibrous growth in response to low frequency inner ear damage, consistent with prolonged exposure to noise from heavy maritime traffic (André and Degollada, 2003).

When whales are exposed to low-level sounds from distant or stationary vessels, they appear to ignore the sounds. Baleen whales will interrupt normal behavior and swim away from strong or rapidly changing vessel noise, especially if a vessel is headed directly toward the whale (Richardson, 1995). However, radiated ship noise of oncoming ships may not be immediately detected by whales near the surface due to bow null-effect acoustic shadow zones (Allen et al., 2012). Because of acoustic shadow zones, whales may not hear approaching ships to allow time for their avoidance response even though whale auditory ranges overlaps with peak intensities of ship noise.

Ambient noise in the Northeast Pacific Ocean has increased in nearshore and deep ocean environments over the past several decades. The low frequencies generated by ships overlap frequencies of sounds generated by large baleen whales, including the spermn whale (Würsig and Richardson, 2009). Noise from ships and boats may interfere and mask cetacean communication, finding prey, avoiding predators, and possibly navigation (Würsig and Richardson, 2009). Anthropogenic noise and vessel disturbance may affect sperm whales but there is little evidence available to describe or quantify the impacts of these threats on the species. While anthropogenic noise may threaten other cetaceans, little is known about whether, or how, vessel noise affects sperm whales (NMFS, 2010).

The risk of ship noise causing PTS or TTS (see NMFS' interim acoustic thresholds in table 4.2.1-3 under blue whales) for sperm whales would be similar to that described for blue whales, above. Noise from a LNG tanker in study conducted by Hatch et al. (2008) produced sound levels (with 1 standard error) of 182 ± 2 dB re: 1 µPa @ 1 meter that attenuated to 160 dB at 35 ± 11 meters and to 120 dB at 16,185 ± 5,359 meters (Hatch et al., 2008). Using those attenuation distances, one LNG tanker transit across the length of the California EEZ stratum for 762 nmi would produce sound levels of ≥160 dB within an area 15.6 ± 4.9 $nmi^2$ and would produce sound levels ≥120 dB but <160 dB within an area 7,175.9 ± 2,376.3 $nmi^2$. Likewise, one LNG tanker transit across the width of the Oregon-Washington EEZ stratum for 200 nmi would produce sound levels of ≥160 dB within an area 4.1 ± 2.6 $nmi^2$ and would produce sound levels ≥120 dB but <160 dB within an area 1,883.4 ± 1,247.4 $nmi^2$.

Based on population growth between 2008 and 2018 described above for sperm whale encounter rates, the predicted density of sperm whales is 0.064 whale per 100 $nmi^2$ in the California stratum in 2018 and is 0.044 whale per 100 $nmi^2$ in the Oregon-Washington EEZ stratum in 2018. Assuming a LNG tanker transit distance of 762 nmi within the California stratum, the number of sperm whales within range of noise levels of 160 dB produced by a single LNG tanker transit through the stratum would be equal to the density (0.064 whale per 100 $nmi^2$) multiplied by the total area of noise effects (15.6 $nmi^2$), equal to 0.010 whale affected (an estimate between 0.004 and0.016 whale based on the density within distances of ± 2 standard deviations of LNG noise attenuating to 120 dB, from Hatch et al., 2008).

The number of sperm whales within range of noise levels of 120 dB (radius of 16,185 m or 4.72 nmi) produced by a single LNG tanker transit through the stratum would be equal to the density (0.064 whale per 100 $nmi^2$) multiplied by the total area of noise effects (7,176 $nmi^2$), equal to 4.6 whales affected (an estimate between 1.5 and 7.6 whales based on the density within distances of ± 2 standard deviations of LNG noise attenuating to 120 dB, from Hatch et al., 2008) by noise levels that could cause behavioral disruptions (see table 4.2.1-3 under blue whales, above).

Similar calculations have been done for sperm whales in the Oregon-Washington stratum. Assuming an LNG tanker transit distance of 200 nmi across the Oregon-Washing stratum, the number of fin whales within range of noise levels of 160 dB produced by a single LNG tanker transit through the stratum would be equal to the density (0.044 whale per 100 $nmi^2$) multiplied by the total area of noise effects (4.08 $nmi^2$), equal to 0.002 whale affected (an estimate between 0.001 and 0.003 whale based on the density within distances of ± 2 standard deviations of LNG noise attenuating to 120 dB, from Hatch et al., 2008). The number of sperm whales within range of noise levels of 120 dB produced by a single LNG tanker transit through the stratum would be equal to the density (0.044 whale per 100 $nmi^2$) multiplied by the total area of noise effects 1,883 $nmi^2$), equal to 0.84 whale affected (an estimate between 0.28 and 1.39 whales based on the density within distances of ± 2 standard deviations of LNG noise attenuating to 120 dB, from Hatch et al., 2008) by noise levels that could cause behavioral disruptions (see table 4.2.1-3).

Existing commercial vessels within the West Coast EEZ analysis area produce underwater noise levels that are comparable or exceed noise from the LNG tanker described by Hatch et al. (2008). Noise generated by various types of commercial ships (container ships, crude oil tankers, product tankers, bulk carriers, and others) were recently evaluated by McKenna et al. (2012). Underwater noise levels varied by ship type and also by vessel length, gross tonnage, vessel speed, and to some extent, vessel age (older vessels tended to be louder than newer vessels). For example, a 54,000 Gross Ton (GT) container ship generated the highest acoustic source level of 188 dB re: 1 µPa @ 1 meter while a 26,000 GT chemical tanker had the lowest at 177 dB re: 1 µPa @ 1 meter (McKenna et al., 2012). Noise levels from the vessels examined in that study are assumed to be typical of ship noise in the California and Oregon-Washington EEZ strata and would produce radiated noise levels through the two strata that would exceed the threshold for Level B single non-pulse noise of 120 $dB_{rms}$ (see table 4.2.1-3, above). With the existing levels of background shipping noise and the expected increase in shipping traffic by 2018, effects by project LNG tanker-related noise on sperm whales are possible in the in California EEZ stratum but the noise would be commensurate with existing noise levels and would not be expected to cause injury.

Two tractor tugs would guide the LNG tanker from a point approximately 5 nmi offshore the entrance to Coos Bay and to the JCEP LNG terminal. Noise produced by tugs would attenuate to 160 dB at 11 ± 4 meters (upper end) and to 120 dB at 4,992 ± 1,599 meters (upper end) (Hatch et al., 2008). Unlike LNG tankers, project-related tug traffic would only occur in the Oregon-Washington stratum. LNG ship noise and noise from tugs would exceed the ambient noise levels within the West Coast EEZ activity area assuming those range from 64 dB to 72 dB re 1 $\mu Pa^2$ (at 62 Hz, similar to the ocean noise 7 nmi west of San Diego reported by McDonald et al., 2008) but would not cause behavioral disruptions to fin whales.

<u>Releases and Fire at Sea</u>

Characteristics of LNG released at sea were described in Section 4.2.1.3 for blue whales. At the water-vapor LNG pool interface, the cryogenically cooled LNG would begin to vaporize but, because of its relatively high density, the plume would remain at or close to the surface interface; methane is an asphyxiant but with low toxicity, at least to humans (Hightower et al., 2004). If a marine mammal surfaced to breathe at the LNG pool location, it could suffer from oxygen deficiency and potential physiological effects, which have been described for humans - ranging from impaired thinking to loss of consciousness with decreasing oxygen concentrations (Table 39 in Hightower et al., 2004) - but not for marine mammals. Because the estimated densities of marine mammals are generally low within the California and Oregon-Washington strata of EEZ, the chance of an animal becoming asphyxiated by contact with a pool of LNG would extremely remote (see discussion about potential thermal injury, below).

Sandia National Laboratories modeled LNG spills from a standard LNG vessel (with capacity of 125,000 to 140,000 $m^3$) over water and potential injury to humans due to ignition of the fuel (Hightower et al., 2004). Thermal effects from a fire would vary, depending on the size of the LNG pool released. If one LNG tank is accidentally breached, due to collision with another ship, grounding, or ramming, the potential spill of LNG could form a pool with diameter of 685 feet. Ignition could cause a fire to burn for 20 minutes with severe thermal injuries extending to 820 feet away from the center of the pool (based on an exposure of 10 minutes and thermal flux of 37.5 $kW/m^2$) and second-degree skin burns on exposed skin (human) to a distance of 2,572 feet (based on an exposure of 10 minutes and thermal flux of 5 $kW/m^2$) from the center of the burning pool of LNG (see Table 41 in Hightower et al., 2004). Surfacing cetaceans within those distances would be assumed to experience severe burns or mild burns, based on similar thermal fluxes effects on humans although exposures for 10 minutes or more would be unlikely.

Expected densities of sperm whales in the California EEZ stratum during 2018 would be 0.064 whale per 100 $nmi^2$ and 0.044 whale per 100 $nmi^2$ in the Oregon-Washington EEZ stratum, the same densities that were used in the analysis of effects due to ship noise, above. Based on the model of accidental LNG release and fire described above (from Hightower et al., 2004), a circular pool of released LNG with diameter of 685 feet would cover an area of 0.010 $nmi^2$. An ensuing fire would cause severe thermal injuries over an area of 0.057 $nmi^2$ and the area where fire coul cause second degree burns would extend to an area of 0.563 $nmi^2$. Considerably fewer than one sperm whale would be expected to be present within any of those areas in either of the two EEZ strata during 2018 and injuries to fin whales due to LNG release and fire would be insignificant and discountable

Oil spills at sea or off shore might harm sperm whales, although effects of oil spills on fin whales have not been reported (NMFS, 2006d). Effects to food resources including krill, copepods, and various schooling fish such as anchovies (NMFS, 2006d) could occur. However, effects of potential spills from LNG carriers are not comparable to spills from oil tankers for a number of reasons. LNG carriers only carry quantities of oil used for propulsion fuel and not the quantities transported by oil tankers.

**Cumulative Effects**

FWS and NMFS describe cumulative effects (50 CFR § 402.02) as the result of future actions by state or private entities, not involving federal actions, but reasonably certain to occur in the action area considered in this BA. Future federal actions that are unrelated to the proposed action are not considered here because they require separate consultation pursuant to section 7 of the ESA.

As discussed above for blue whales, available information indicates that ship calls to the Port of Coos Bay have been declining since 2002. The observed declining linear trend in total annual vessel traffic over time is significant and, when used to forecast numbers of vessel calls to Coos Bay in the future, no vessels are predicted to enter Coos Bay in 2018 with between 0 and 17.6 vessels as reasonably foreseeable when the LNG terminal is expected to begin operation in 2018 (see figure 4.2-3 under blue whales). And as discussed above for blue whales, it appears that the background rate of spills off the Oregon coast by fishing vessels, recreation vessels, and other vessel types is generally low, a frequency that would be expected to continue.

The foreseeable cumulative effect of 90 LNG carriers per year with anticipated dry bulk vessel traffic in 2018 would be less than effects based on past levels of vessel traffic calls to the Port of Coos Bay which would have exceeded 90 vessels per year in 1992 given the current trend in figure 4.2-2 (under blue whales). Consequently, cumulative effects to sperm whales would likely be less than the estimate of direct effects discussed in the previous section. Those effects were judged to be insignificant and discountable.

The volume of annual vessel transits within the EEZ of California, Oregon, and Washington is related to numbers of vessel calls to ports in those states. Total annual calls for all vessels at ports in California, Oregon, and Washington (MARAD, 2013) were plotted above in figure 4.2-2 for 2002 through 2011. Unlike the trend analyzed for calls to Coos Bay (see figure 4.2-3, under blue whales) the observed linear trend in annual vessel traffic (port calls) along the U.S. West Coast was significantly increasing at a rate of 2.1 percent per year between 2002 and 2007. The increasing trend was interrupted by the global economic crisis in 2008 but data through 2011 indicate a return to the established increasing trend prior to 2008. The pre-2008 trend predicts 21,530 vessel calls to West Coast ports in 2018 (with 95% prediction intervals ranging from 17,360 to 25,710 vessel calls), the year the JCEP and PCGP projects are expected to be in service. Even with the uncertainty generated by available data, there is a reasonably foreseeable increasing trend, albeit imprecise, for vessel traffic volume in the future (by 2018) although unforeseen global events such as future economic crises could influence the predictions. Cumulative effects of 90 LNG carriers per year to sperm whales may be more or may be less than the estimate of direct effects discussed above.

**Critical Habitat**

The proposed action would not affect critical habitat; none has been designated.

#### 4.2.6.4 Conservation Measures

The same Ship-Strike Reduction Plan to minimize potential ship strikes to cetaceans by LNG carriers and LNG Management Plan to minimize risk of spills and releases at sea that were described in Section 4.2.1 (Blue Whale) apply to sperm whales.

#### 4.2.6.5 Determination of Effects

**Species Effects**

The Project **may affect** sperm whales because:

- Sperm whales may occur within the EEZ analysis area during operation of the proposed action.
- The proposed action would increase shipping traffic (LNG carriers) within the EEZ analysis area.

However, the Project is **not likely to adversely affect** sperm whales because:

- Existing information indicates ship strikes to sperm whales within the EEZ analysis area are infrequent.
- The increase in annual ship traffic due to the proposed action is expected to cause an immeasurable increase in ship strikes to sperm whales over known frequencies of incidents.
- Jordan Cove would provide a ship strike avoidance measures package to shippers delivering LNG cargo to the LNG terminal. The package consists of multiple measures to avoid striking marine mammals.
- LNG carriers approaching the Port of Coos Bay would be traveling slowly and escorted by tractor tugs from 50 nmi offshore to the Port.

- Noise produced by LNG carriers would contribute to overall noise within the EEZ en route to the Port of Coos Bay and effects of ship noise on sperm whales could exceed NMFS interim noise exposure criteria for Level B single non-pulse noise but would not exceed existing background ship noise levels and would not cause injury.
- Accidental releases of LNG at sea would not cover an area large enough to coincide with expected sperm whale presence (based on estimated densities). Ignited LNG would not extend far enough from the LNG pool to cause severe or mild thermal effects to sperm whales if they emerged during a fire.

**Critical Habitat Effects**

No critical habitat has been designated or proposed for sperm whales.

### 4.2.7 North Pacific Right Whale

#### 4.2.7.1 Species Account and Critical Habitat

**Status**

North Pacific right whales were listed as endangered under the Endangered Species Conservation Act (35 FR 18319, Dec. 2, 1970) (FWS 1970) and remained endangered throughout its range on the list of endangered species when the Endangered Species Act was passed in 1973 (NMFS 2013a). The North Pacific right whale is also listed as depleted under the MMPA. The National Marine Fisheries Service established the North Pacific right whale and North Atlantic right whale as distinct species in 2008. The North Pacific population has then been further divided into a western population and an eastern population, with the eastern population located in the U.S. Exclusive Economic Zone (NMFS, 2013a).

**Threats**

Little is known about the North Pacific right whale, including threats to the species. Likely threats include ship strikes and entanglements. However, the magnitude of these threats cannot be assessed due to the rarity and scattered distribution (NOAA Fisheries, 2013d). North Pacific right whales are also susceptible to anthropogenic noise generated from ship noise, oil and gas activities and military sonar and explosives (NMFS, 2013a). Impacts from direct hunts as well as loss of prey due to climate change are also largely unknown (NMFS, 2013a).

**Species Recovery**

A recovery plan for the North Pacific right whale was published in June 2013 (NMFS 2013a). Ultimately, the recovery plan was designed to outline methods and strategies to gain more understanding of the right whale through an increase of data collection. First and foremost, information regarding population and potential threats must be obtained. Commercial whaling is currently the greatest known threat to right whales, and this was outlawed in 1949. However, despite this protection it is thought that illegal whaling in the 1960's has greatly reduced the potential recovery of this species. The goals of the recovery plan are to first downlist the right whale from endangered to threatened and then eventually de-list the species all together. These goals are attained through two objectives:

1.) Achieve sufficient and viable populations throughout the ocean basin;
2.) Ensure significant threats are addressed

The recovery plan describes the criterion for determining when the objectives are met, which includes descriptions of factors that may interfere with population growth. The outline for Recovery Action includes:

- Coordinate state, federal, and international actions to maintain international regulation of whaling for North Pacific right whales
- Determine right whale occurrence, distribution, and range
- Identify, characterize, protect, and monitor important to North Pacific right whale populations
- Estimate population size and monitor trends in abundance
- Investigate human-caused threats, and should they be determined to be medium or high, reduce frequency and severity.

The recovery plan includes an assessment that indicates which threats have a known impact on the population growth, but the impacts are low. However, there are several potential threats that require further investigation (NMFS, 2013a).

**Life History, Habitat Requirements, and Distribution**

North Pacific right whales are large, black toothless baleen whales with a stocky body. Not only do these whales lack teeth, but they also lack a dorsal fin. Further distinguishing characteristics include a broad, deeply notched tail and callosities on the head. The few data gathered indicates that right whales generally live for about 50 years with females having their first calf at 9-10 years. Right whales feed on zooplankton; however, their feeding method differs than that of most baleen whales. This species moves through the water open-mouthed and removes prey from patches of zooplankton – a method known as skimming (NMFS, 2013a).

The International Whaling Commission has identified four different habitat categories for the right whale based upon the different purposes they serve. These categories are feeding, calving, nursery, and breeding. Breeding habitats are not known, however, right whales are primarily found in shallow coastal waters. Calving takes place in the winter and during this time right whales can often be found in lower latitudes, whereas in spring and summer they are found in higher latitudes (NMFS, 2013b).

Historic populations of North Pacific right whales occupied the Gulf of Alaska, eastern Aleutian Islands, south central Bering Sea, Sea of Okhotsk, and Sea of Japan. Right whales have been regularly spotted in Bristol Bay, south Bering Sea since 1996 and as far south as Hawaii in the central North Pacific and California in the eastern North Pacific. Sightings of this species are rare due to commercial whaling through the 1960s (NMFS, 2013b).

**Population Status**

The rarity of sightings and few individuals see in any one year indicate the eastern North Pacific population is very small. The most individuals detected in a single year were 17 whales from multiple ship surveys in 2004. An estimate of 31 individuals was made for the population using mark-recapture data from the Bering Sea and Aleutian Islands (NMFS, 2012a). A minimum population estimate of 25.7 was made for the North Pacific right whale in the year 2008 (Allen and Angliss 2011). However, there are no current and reliable population estimates for this species (NMFS, 2013a). There are no data on population trends and calf sightings are extremely rare. Historically this stock exceeded 11,000 whales.

**Critical Habitat**

Two areas have been designated as critical habitat for the North Pacific right whale. One area is within the Gulf of Alaska and the other area is within the Bering Sea (NMFS, 2013a).

### 4.2.7.2 Environmental Baseline

**Analysis Area**

The analysis area applicable to North Pacific right whales is the EEZ, extending 200 nautical miles offshore from the Coos Bay Head and from San Diego to Cape Flattery, the same as described above for blue whales (see figure 4.2-1).

**Species Presence**

There are historical records of right whales in southern California but those were vagrant individuals; since 1950, there have been at least three sightings from Washington, 12 from California, and two from Baja California, Mexico (NMFS, 2012a). No abundance or density estimates are available for California, Oregon, or Washington (Forney, 2007). Right whales have been sighted off the California coast and coastal Baja California during winter (January to early April) and spring (April to June)

**Habitat**

The global distribution of North Pacific right whales includes the U.S. West Coast extending south along the Baja California Pacific Coast (NOAA Fisheries, 2013d). Right whales have been sighted off the California coast and coastal Baja California during winter (January to early April) and spring (April to June) and may indicate a seasonal pattern of migration to southwestern coast during winter (Gendron et al., 1999). Based on habitat preferences during calving in the Atlantic Ocean, the Southern Califonia Coast and Baja Penninsula were judged to provide suitable calving habitat for North Pacific right whales (Good and Johnston, 2009) but no evidence of calving is present in historical records (Gendron et al., 1999).

**Critical Habitat**

Two areas have been designated as critical habitat for the North Pacific right whale, one within the Gulf of Alaska, the other within the Bering Sea (NMFS, 2013a).

### 4.2.7.3 Effects by the Proposed Action

**Direct and Indirect Effects**

Direct effects of the proposed action include injury and/or mortality due to ship strikes, effects due to ship noise, and potential adverse effects from an accidental ship release of LNG and fire at sea. Spills and/or released LNG could indirectly affect North Pacific right whale by impacting forage species. These effects are addressed below.

<u>Ship Strikes by LNG Carriers</u>

As discussed above for blue whales, there is an ongoing threat of ship strikes to North Pacific right whales but no data (NMFS, 2013a) exists to estimate how many right whales might be struck by LNG carriers transiting to and from Coos Bay in 2018, the year when the proposed project is expected to be operational.

Underwater Noise

Determining and minimizing any detrimental effects of anthropogenic underwater noise on right whales is a principal objective for the species' recovery (NMFS, 2013a). As described for blue whales, above, all vessels produce noise; propeller cavitation produces most of the broadband noise with dominant tones derived from the propeller blade rate. In general, rorquals including blue, fin and minke whales move away, abruptly change direction, or dive to avoid close approach by vessels. Baleen whales will interrupt normal behavior and swim away from strong or rapidly changing vessel noise, especially if a vessel is headed directly toward the whale (Richardson, 1995). Existing data indicates that right whale response to noise disturbance and vessel activities depends on their behavior at the time; feeding or courting right whales may be relatively unresponsive to loud sounds and slow to react to approaching vessels (NMFS, 2013a).

Ambient noise in the Northeast Pacific Ocean has increased in nearshore and deep ocean environments over the past several decades. The low frequencies generated by ships overlap frequencies of sounds generated by large baleen whales, including the right whale whale (Würsig and Richardson, 2009). Noise from ships and boats may interfere and mask cetacean communication, finding prey, avoiding predators, and possibly navigation (Würsig and Richardson, 2009). Anthropogenic noise and vessel disturbance may affect right whales but there is little evidence available to describe or quantify the impacts of these threats on the species.

The risk of ship noise causing PTS or TTS (see NMFS' interim acoustic thresholds in table 4.2.1-2) for right whales would be similar to that described for blue whales, above. Noise from a LNG tanker in a study by Hatch et al. (2008) produced sound levels (with 1 standard error) of 182 ± 2 dB re: 1 µPa @ 1 meter that attenuated to 160 dB at 35 ± 11 meters and to 120 dB at 16,185 ± 5,359 meters (Hatch et al., 2008). Using those attenuation distances, one LNG tanker transit across the length of the California EEZ stratum for 762 nmi would produce sound levels of ≥160 dB within an area 15.6 ± 4.9 $nmi^2$ and would produce sound levels ≥120 dB but <160 dB within an area 7,175.9 ± 2,376.3 $nmi^2$. Likewise, one LNG tanker transit across the width of the Oregon-Washington EEZ stratum for 200 nmi would produce sound levels of ≥160 dB within an area 4.1 ± 2.6 $nmi^2$ and would produce sound levels ≥120 dB but <160 dB within an area 1,883.4 ± 1,247.4 $nmi^2$.

Existing commercial vessels within the West Coast EEZ analysis area produce underwater noise levels that are comparable or exceed noise from the LNG tanker described by Hatch et al. (2008). Noise generated by various types of commercial ships (container ships, crude oil tankers, product tankers, bulk carriers, and others) were recently evaluated by McKenna et al. (2012). Underwater noise levels varied by ship type and also by vessel length, gross tonnage, vessel speed, and to some extent, vessel age (older vessels tended to be louder than newer vessels). For example, a 54,000 Gross Ton (GT) container ship generated the highest acoustic source level of 188 dB re: 1 µPa @ 1 meter while a 26,000 GT chemical tanker had the lowest at 177 dB re: 1 µPa @ 1 meter (McKenna et al., 2012). Noise levels from the vessels examined in that study are assumed to be typical of ship noise in the California and Oregon-Washington EEZ strata and would produce radiated noise levels through the two strata that would exceed the threshold for Level B single non-pulse noise of 120 $dB_{rms}$ (see table 4.2.1-3, above). With the existing levels of background shipping noise and the expected increase in shipping traffic by 2018, effects by project LNG tanker-related noise on North Pacific right whales are possible in the in California

EEZ stratum but the noise would be commensurate with existing noise levels and would not be expected to cause injury.

The extremely low densities of right whales off the combined Oregon/Washington coast (too few for density estimation), right whales in the EEZ analysis area are not expected to be exposed to ship noise that would cause PTS or TTS (see table 4.2.1-2) although right whales,if present, would likely detect LNG carriers transiting the EEZ.

Releases and Fire at Sea

Characteristics of LNG released at sea were described in Section 4.2.1.3 for blue whales. At the water-vapor LNG pool interface, the cryogenically cooled LNG would begin to vaporize but, because of its relatively high density, the plume would remain at or close to the surface interface; methane is an asphyxiant but with low toxicity, at least to humans (Hightower et al., 2004). If a marine mammal surfaced to breathe at the LNG pool location, it could suffer from oxygen deficiency and potential physiological effects, which have been described for humans - ranging from impaired thinking to loss of consciousness with decreasing oxygen concentrations (Table 39 in Hightower et al., 2004) - but not for marine mammals. Because the estimated densities of marine mammals are generally low within the California and Oregon-Washington strata of EEZ, the chance of an animal becoming asphyxiated by contact with a pool of LNG would extremely remote (see discussion about potential thermal injury, below).

Sandia National Laboratories modeled LNG spills from a standard LNG vessel (with capacity of 125,000 to 140,000 $m^3$) over water and potential injury to humans due to ignition of the fuel (Hightower et al., 2004). Thermal effects from a fire would vary, depending on the size of the LNG pool released. If one LNG tank is accidentally breached, due to collision with another ship, grounding, or ramming, the potential spill of LNG could form a pool with diameter of 685 feet. Ignition could cause a fire to burn for 20 minutes with severe thermal injuries extending to 820 feet away from the center of the pool (based on an exposure of 10 minutes and thermal flux of 37.5 $kW/m^2$) and second-degree skin burns on exposed skin (human) to a distance of 2,572 feet (based on an exposure of 10 minutes and thermal flux of 5 $kW/m^2$) from the center of the burning pool of LNG (see Table 41 in Hightower et al., 2004). Surfacing cetaceans within those distances would be assumed to experience severe burns or mild burns, based on similar thermal fluxes effects on humans although exposures for 10 minutes or more would be unlikely.

Expected densities of North Pacific right whales in the California and Oregon-Washington EEZ strata during 2018 are expected to be so low that the chance of a right whale surfacing in an area of pooled LNG or close enough to a fire to be injured is insignificant and discountable.

**Cumulative Effects**

FWS and NMFS describe cumulative effects (50 CFR § 402.02) as the result of future actions by state or private entities, not involving federal actions, but reasonably certain to occur in the action area considered in this BA. Future federal actions that are unrelated to the proposed action are not considered here because they require separate consultation pursuant to section 7 of the ESA.

As discussed above for blue whales, available information indicates that ship calls to the Port of Coos Bay have been declining since 2002. The observed declining linear trend in total annual vessel traffic over time is significant and, when used to forecast numbers of vessel calls to Coos Bay in the future, no vessels are predicted to enter Coos Bay in 2018 with between 0 and 17.6

vessels as reasonably foreseeable when the LNG terminal is expected to begin operation in 2018 (see figure 4.2-4 under blue whales). And as discussed above for blue whales, it appears that the background rate of spills off the Oregon coast by fishing vessels, recreation vessels, and other vessel types is generally low, a frequency that would be expected to continue.

The foreseeable cumulative effect of 90 LNG carriers per year with anticipated dry bulk vessel traffic in 2018 would be less than effects based on past levels of vessel traffic calls to the Port of Coos Bay which would have exceeded 90 vessels per year in 1992 given the current trend in figure 4.2-2. Consequently, cumulative effects to right whales would likely be less than the estimate of direct effects discussed in the previous section. Those effects were judged to be insignificant and discountable.

The volume of annual vessel transits within the EEZ of California, Oregon, and Washington is related to numbers of vessel calls to ports in those states. Total annual calls for all vessels at ports in California, Oregon, and Washington (MARAD, 2013) were plotted above figure 4.2-2 for 2002 through 2011. Unlike the trend analyzed for calls to Coos Bay (see figure 4.2-4) the observed linear trend in annual vessel traffic (port calls) along the U.S. West Coast was significantly increasing at a rate of 2.1 percent per year between 2002 and 2007. The increasing trend was interrupted by the global economic crisis in 2008 but data through 2011 indicate a return to the established increasing trend prior to 2008. The pre-2008 trend predicts 21,530 vessel calls to West Coast ports in 2018 (with 95% prediction intervals ranging from 17,360 to 25,710 vessel calls), the year the JCEP and PCGP projects are expected to be in service. Even with the uncertainty generated by available data, there is a reasonably foreseeable increasing trend, albeit imprecise, for vessel traffic volume in the future (by 2018) although unforeseen global events such as future economic crises could influence the predictions. Cumulative effects of 90 LNG carriers per year to North Pacific right whales may be more or may be less than the estimate of direct effects discussed above.

**Critical Habitat**

The proposed action would not affect critical habitat; none has been designated within the EEZ analysis area.

#### 4.2.7.4 Conservation Measures

The same Ship-Strike Reduction Plan to minimize potential ship strikes to cetaceans by LNG carriers and LNG Management Plan to minimize risk of spills and releases at sea that were described in section 4.2.1 (Blue Whale) apply to right whales.

#### 4.2.7.5 Determination of Effects

**Species Effects**

The Project **may affect** North Pacific right whales because:

- Right whales may occur within the EEZ analysis area during operation of the proposed action.
- The proposed action would increase shipping traffic (LNG carriers) within the EEZ analysis area.

However, the Project is **not likely to adversely affect** right whales because:

- There is no existing information to indicate that ship strikes to right whales occur within the EEZ analysis area.
- The increase in annual ship traffic due to the proposed action is expected to cause an immeasurable increase in ship strikes to right whales over known frequencies of incidents.
- Jordan Cove would provide a ship strike avoidance measures package to shippers delivering LNG cargo to the LNG terminal. The package consists of multiple measures to avoid striking marine mammals.
- LNG carriers approaching the Port of Coos Bay would be traveling slowly and escorted by tractor tugs from 50 nmi offshore to the Port.
- Noise produced by LNG carriers would contribute to overall noise within the EEZ en route to the Port of Coos Bay and effects of ship noise on right whales could exceed NMFS interim noise exposure criteria for Level B single non-pulse noise but would not exceed existing background ship noise levels and would not cause injury.
- Accidental releases of LNG at sea would not cover an area large enough to coincide with expected right whale presence (based on estimated densities). Ignited LNG would not extend far enough from the LNG pool to cause severe or mild thermal effects to right whales if they emerged during a fire.

**Critical Habitat Effects**

No critical habitat has been designated within the EEZ analysis area.

### 4.2.8 Gray Wolf

#### 4.2.8.1 Species Account and Critical Habitat

**Status**

The gray wolf was listed as endangered in 1974 (FWS, 1974). FWS delisted the gray wolf within the Northern Rocky Mountain (NRM) DPS on May 5, 2011, including wolves in the eastern one-third of Oregon (FWS, 2011b). However, some gray wolves in the Pacific Northwest, including western Washington, western Oregon, and northern California, are not included in the NRM DPS and are still listed as endangered. New information on gray wolf taxonomy, cited by FWS (2013b), indicates that the gray wolf subspecies in the contiguous United States does not warrant listing under the ESA and FWS (2013) published a proposed rule to remove the gray wolf from the list of endangered and threatened wildlife.

**Threats**

Wolves in the Pacific Northwest (Oregon and Washington) were pursued and killed by humans through the 1940s and were primarily restricted to remote mountanouse areas, primarily in National Forests of the Cascades, before they were completely extirpated from the region (FWS, 2012b).

**Recovery**

FWS released a recovery plan for gray wolves in the NRM DPS in 1987. The plan focused on recovery in Montana, Wyoming, and Idaho. Although eastern Oregon and eastern Washington coincided with the historical distribution of wolves in the NRM DPS, no recovery areas were designated for either state. However, recovery goals of the NRM DPS of equitably distributed wolf population containing at least 300 wolves and 30 breeding pairs in 3 recovery areas within Montana, Idaho, and Wyoming for at least 3 consecutive years were reached in 2002 (FWS et al., 2013). By 2012, the entire NRM DPS was delisted and wolves were managed under State authority in Montana, Idaho, Wyoming eastern one-third of Washington and Oregon, and a small part of north central Utah (FWS et al., 2013).

No recovery plan has been developed for ESA-listed gray wolves in western Oregon. Wolves are classified as endangered under the Oregon State Endangered Species Acts (ORS 496.171 to 496.192 and 498.026). ODFW (2010) has developed a Wolf Conservation and Management Plan (OWP) to achieve recovery of the species and manage wolves in the state once they became de-listed from the ESA.

The OWP established recovery goals to protect wolves from overutilization for commercial, recreational, scientific, and educational purposes. The plan would serve as a deterrent to illegal killing of wolves by the public in the absence of Federal protections. With the de-listing of the NRM DPS in 2011, the OWP applies to wolves in the eastern one-third of the state. The boundary between east and west wolf management zones is defined by U.S. Highway 97 from the Columbia River to the junction of U.S. Highway 20, southeast on U.S. Highway 20 to the junction with U.S. Highway 395, and south on U.S. Highway 395 to the California border (ODFW, 2010). Wolves west of that boundary are still under federal protection.

**Life History, Habitat Requirements, and Distribution.**

Gray wolves are predators of large ungulates and occasionally of other, smaller prey. Wolves are highly social and their formation of packs, centered on male-female pair bonding, is essential to successful reproduction, survival of offspring, and predation (FWS, 1987). Most packs produce one litter per year ranging from one to nine pups. Wolf pairs (packs) establish home ranges/territories, centered on the den location, and are defended against other wolves (ODFW, 2013a). Habitats supporting wolves historically varied considerably, but extant populations in the NRM DPS and British Columbia utilize forest habitats adjacent to open habitats (meadows, prairies, tundra) but prey availability and minimal human presence and/or harassment are important components of suitable habitat (WDFW, 2009).

Because of the proximity of northeastern Oregon to Idaho packs, dispersing wolves initially occupied areas in northeastern Oregon. Wolf breeding pairs in these areas could be considered more secure and stable because of their proximity and connectivity to the wolves in Idaho. Wolf movement and dispersal between the two populations would allow gene flow between the populations. Oregon's close proximity to the Idaho and Greater Yellowstone populations that number more than 840 wolves provides certainty that dispersing wolves will continue to enter Oregon at an unknown rate (ODFW, 2010).

**Population Status**

Oregon's wolf population increased in both distribution and abundance in 2013. In December, the minimum wolf population was 64 wolves in eight packs. This represents a 33 percent increase from the previous year in total wolves, and two new pacts. 2013 also marks the second consecutive year that the conservation population objective number was reached, as defined in the OWP which sets a population objective of four breeding pairs for three consecutive years in eastern Oregon before delisting from the state's endangered species act can be considered (ODFW, 2014a). A breeding pair of wolves is defined as an adult male and an adult female with at least two pups surviving to the end of December.

The Imnaha Pack was first documented in 2009 and is one of Oregon's oldest contemporary packs (ODFW, 2014b). The first wolves of the pack migrated from Idaho. GPS radio collaring shows a use area of approximately 740 square miles in the Imnaha River drainage (ODFW, 2014a). During winter and spring, the Imnaha pack tends to occupy lower-elevation areas consisting of a mix of private and public lands. In summer and fall, the wolves spend most of their time on public lands at higher elevations (CDFW, 2014).

The minimum population for the pack in 2009 was 10, 15 in 2010, 5 in 2011, 8 in 2012, and 6 in 2013 (ODFW, 2014b). Four radio-collared wolves (including OR-7) have dispersed from the pack since December 2010. The locations and fates of five uncollared pack members are currently unknown. It is likely that some or all of these wolves may have dispersed from the pack. The dispersal of younger individuals from a pack is common. Dispersing wolves generally attempt to join other packs, create new territories within occupied habitat, or form their own pack in unoccupied habitat. In addition to OR-7, known dispersers from the Imnaha pack include OR-5, OR-9 and OR-3 (CDFW, 2014).

The pack produced seven pups in 2013. However, none were documented in the last few months of the year despite multiple observations of the pack. Therefore the pack was not counted as a breeding pair (ODFW, 2014a). The pack has had three breeding-pair years in the past (2009, 2010, and 2012) (ODFW, 2014b). Two GPS radio-collars remain in the pack, the breeding male and a sub-adult female. During 2013, 32 percent of the pack's location data points occurred on private land, an increase from 15 percent in 2012 and 29 percent in 2011 (ODFW, 2014a).

### Critical Habitat

Critical habitat for the gray wolf has not been designated in Oregon.

## 4.2.8.2 Environmental Baseline

### Analysis Area

The action area includes all areas that would be affected directly or indirectly by the proposed action and not just the immediate area involved in the action. Because the proposed action potentially can affect such a variety of species inhabiting diverse habitats within marine, estuarine, riverine, and various terrestrial locations, there are multiple components of the action area that have been defined as species' analysis areas, the areas where individual or groups of listed species are affected by the proposed action. The gray wolf analysis area is specific to a solitary gray wolf, OR-7, that has an area of known activity in Jackson, Klamath, and Douglas counties. The analysis area for OR-7 extends as far as project-related noise attenuates to ambient noise, assumed to be 40 dB on both sides of the construction right-of-way distance of

### Species Presence

A 4-year old male gray wolf (known as OR-7) currently occupies portions of southwestern Oregon and northwestern California. The wolf was born in northeastern Oregon in spring 2009, a member of the Imnaha pack that inhabits the Imnaha River drainage in Wallowa County, Oregon (CDFW, 2013a). OR-7 dispersed from the Imnaha pack in September 2011 and was located (via radio telemetry) within Baker, Grant, Harney, Deschutes, Lake, Klamath, and Douglas counties during its migration. OR-7 traveled more than 373 miles in a straight line distance from where he was born to northern California (FWS, 2013b). The wolf has been living in the southern Cascades in Jackson, Klamath, and Douglas counties, Oregon (ODFW, 2013b) and in Siskiyou, Modoc, Shasta, Lassen, Tehama, Butte, and Plumas counties, California (CDFW, 2013b).

ODFW (2013b) has defined an Area of Known Wolf Activity for OR-7 which extends north from the Oregon-California border for almost 95 miles into Douglas County, Oregon. At present, OR-7 is solitary (ODFW, 2013b).

**Habitat**

Black-tailed deer and Rooseveldt elk occur within the Area of Known Wolf Activity for OR-7. Those big game species are likely to provide a prey base for OR-7, especially during winter when animals are concentrated and old, sick individuals are more easily preyed on and/or carrion is more readily available. Often, big game will remain on or near winter ranges during parturition which also would provide OR-7 with accessible prey (neo-nates). The Known Wolf Activity Area coincides with multiple big game winter ranges:

- Elk and deer winter range in the Keno Wildlife Management Area.
- Very Sensitive Wildlife Areas (big game winter ranges) in the Rogue Wildlife Management Area.
- Very Sensitive Wildlife Areas (big game winter ranges) and Sensitive Big Game Ranges in the Dixon Wildlife Management Area.
- Sensitive Big Game Ranges in the Indigo Wildlife Management Area.

The PCGP pipeline right-of-way crosses the OR-7 Known Wolf Activity Area for 33.07 miles, from MP 147.66 to MP 180.73. The pipeline will cross Very Sensitive Wildlife Areas in the Rogue Wildlife Management Area for 8.11 miles from MP 147.66 to MP 155.77.

Based on ODFW population index data, black-tailed deer in the Rogue Wildlife Management Area Unit have been significantly increasing ($P<0.01$) between 1998 and 2012. In western Oregon, black-tailed deer are found in heavy brush areas at the edges of forests and chaparral thickets, but not in dense forests. Black-tailed deer prefer early successional stages created by clear-cuts or burns, providing grasses, forbs, and shrubs (ODFW, 2006b; Csuti et al. 2001). Most black-tailed deer that summer in the high Cascades winter at lower elevations on the west slope, although some may winter east of the Cascade crest (ODFW, 2006b).

**Critical Habitat**

Critical habitat for the gray wolf has not been designated in Oregon.

#### 4.2.8.3 Effects by the Proposed Action

The portion of the PCGP Project that coincides with wolf OR-7 Known Activity Area is construction Spread 4. In some areas, timber clearing would only be conducted between October and March if within 0.25 mile of northern spotted owl nests, otherwise timber would be cleared from October in one year through October the following year. Construction along Spread 4 would extend from April one year through September the following year. Construction of the PCGP Project will produce noise, will cause locally concentrated human activities, and will remove forested habitat that might be used by some species that are preyed on by OR-7.

Specific impacts to the gray wolf from noise generated from construction of a pipeline have not been conducted; however, it is expected that construction noise in remote areas that are relatively free from noise would have a greater potential to disturb wildlife. Ambient sound levels in much of the PCGP Project area probably would be similar to the Washington Fish and Wildlife Office's determination (FWS, 2003e) of 40 dB in the Olympic National Forest. Considering ambient sound as a base, noise levels associated with some common machines and activities which would be present during pipeline construction are included in table 4.2.8-1. Distances at which noise would attenuate to ambient levels would depend on local conditions such as tree cover and density, topography, weather (humidity), and wind, all of which can alter background noise conditions.

**Table 4.2-8-1**
**Common Sound Levels for Equipment/Activities Potentially Associated with the PCGP Project**

| Measured Sound Source | Range of Reported dB Values (at Distance Measured 50ft) | Relative Sound Level [1] |
|---|---|---|
| Chain Saw (various types/conditions) | 61 – 93 | Low - Very High |
| Pickup Truck (idle to driving) | 55 – 71 | Very Low - Moderate |
| Mowers | 68 – 85 | Low - High |
| Log Truck | 77 – 97 | Moderate - Very High |
| Dump Truck | 84 – 98 | High - Very High |
| Rock Drills | 82 – 98 | High - Very High |
| Pumps, Generators, Compressors | 87 | High |
| Drill Rig | 88 | High |
| General Construction | 84 – 96 | High - Very High |
| Track Hoe | 91 – 106 | Very High - Extreme |
| Helicopter or Airplane (various types/conditions) | 96 – 112 | Very High - Extreme |
| Rock Blast | 112 [2] | Extreme |

Source: FWS, 2006.
1 A general, subjective ranking of noise levels created by the sources considered when used for analysis of relative noise effects on species.
2 Blasting required for the PCGP Project would be underground and muffled which should result in a lower dB value at 50 feet.

These project-related noises could disturb OR-7 if close enough to detect the noise above ambient levels, assumed to be 40 dB. If noise due to helicopter or blasting is the highest level produced during construction (112 db), those noise levels would be expected to attenuate to ambient levels as far as 38,800 feet away (assuming no intervening topography or vegetation and a noise reduction rate of 7.5 dB for every doubling of distance from the source). On the other hand, noise from a pickup truck generating 70 dB while driving would attenuate to ambient levels 800 feet away (with the same assumptions as above). Response of OR-7 to project-related noise would probably be similar as response to other anthropogenic noise including noise related to recreation, hunting, and logging that already occur within the Known Wolf Activity Area. There is no information, however, about OR-7's response to existing anthropogenic noise.

The portion of the PCGP Project that coincides with wolf OR-7 Known Activity Area passes through several types of forested habitats including Southwest Oregon Mixed Conifer-Hardwood Forest for15.28 miles; Westside Oak and Dry Douglas-fir Forest and Woodlands for 0.29 mile; Ponderosa Pine Forest and Woodland for 6.90 miles; and Montane Mixed Conifer Forest for 6.46 miles (habitat categories follow Johnson and O'Neil, 2001). Most of the Project passes through forested habitats that are regenerating (11.52 miles), clearcut (0.50 miles), mid-seral (5.09 miles), late successional (6.37 miles) or old growth (5.46 miles). The Proposed Action would remove

124.47 acres of old growth. Across the OR-7 Known Activity Area, the Project will remove 124. 47 acres of old-growth forest (more than 175 years old), 118.00 acres of late successional forest (80 to 175 years old), 94.33 acres of mid-seral forests (40 to 80 years old), 303.14 acres of regenerating forest (5 to 40 years old) , and 10.88 acres of recent clear-cut forest (0 to 5 years old). The project would create a corridor through those forest-woodland types and seral stages.

Corridors created within forested habitats are used for movement and foraging by big game species. A study conducted in Alberta by Brusnyk and Westworth (1985) focused on forage and browse production on a 17-year old pipeline right-of-way and on a 2-year old right-of-way and big game use. Deer appeared to utilize browse in the 17-year old corridor but returned to adjacent undisturbed forest, probably utilizing available hiding or thermal cover. Deer utilized the corridors for travel in early winter prior to limiting snow depths. Elk utilized forage on the 2-year old right-of-way primarily where portions were adjacent to forested habitats. The principal conclusion of this study was that pipeline corridors increased local habitat diversity and that diversity – juxtapositions of browse or forage to undisturbed forested habitat – influenced use of the corridors by ungulates, not necessarily due to increased vegetative production, *per se*, within pipeline rights-of-way. Increased herbivore density provides a food source for predators (Forman, 1995), so predator density can be increased along the edge created by the corridor as well.

Food enticements associated with human presence during construction activities could also increase predator populations within the vicinity of the Pacific Connector pipeline. In addition, some wildlife species may be directly impacted by construction of the PCGP Project if they are killed by vehicles traveling to and from construction sites. Species most susceptible to vehicle-related mortality include those that are more active at dusk and dawn such as deer (Leedy, 1975; Bennett, 1991; Forman and Alexander, 1998; Trombulak and Frissel, 2000). OR-7 could be drawn to conflict situations brought about by construction of the PCGP Project if attracted to garbage at the workplace and/or drawn to roadside carrion killed by project vehicles. However, carcasses of prey species (e.g., deer and elk) naturally occur on the landscape usually associated with road kills or wildlife killed by natural causes (ODFW, 2010).

**Cumulative Effects**

No specific foreseeable state or private actions have been identified within the gray wolf analysis area. OR-7 was born in spring 2009. By the time the proposed action would be initiated in 2017, OR-7 would be eight years old and, if still alive, would have exceeded the average life span of 4 years for wolves in the Northern Rocky Mountains (FWS, 2010). If OR-7 remains alive and solitary through 2017, there would likely be no future state or private actions that would constitute a cumulative effect past the duration of pipeline construction.

**Critical Habitat**

Critical habitat for the gray wolf has not been designated in Oregon.

#### 4.2.8.4 Conservation Measures

All trash, food waste, and other items attractive to predators and scavengers would be picked up and removed from the project area on a daily basis to minimize potential attraction of predators, including the gray wolf.

#### 4.2.8.5 Determination of Effects

**Species Effects**

The Project **may affect** the gray wolf because:

- One gray wolf's Known Activity Area coincides with the PGCP Project
- That solitary wolf is currently protected as endangered under ESA.

However, the Project is **not likely to adversely affect** the gray wolf because:

- Noises generated during constructions may be detected and would disturb OR-7, but project-related noises are not likely to be substantially different form noises produced by existing recreation, hunting, and logging land uses.
- The pipeline corridor is likely to increase local habitat diversity, forage, and be used for movements by ungulates, possibility increase habitat suitability for gray wolves
- On-site trash and carrion caused by animal-vehicle collisions could attract the gray wolf to the project area and create conflict situations but trash would be removed on a daily basis and roadside carrion is expected to be present as an existing condition. Project-related effects to the gray wolf would be insignificant and discountable.

**Critical Habitat Effects**

Critical habitat for the gray wolf has not been designated in Oregon.

## 4.3 BIRDS

### 4.3.1 Short-tailed Albatross

#### 4.3.1.1 Species Account and Critical Habitat

**Status**

The short-tailed albatross was designated as endangered in Japan under Appendix A of the Endangered Species Conservation Act of 1969 in October 1970 (FWS, 2000b). The species was proposed for listing in the United States in 1980 under the ESA and was listed as endangered throughout its range in the United States on July 31, 2000 (FWS, 2000b).

**Threats**

Factors responsible for the species' decline were not described in the original listing document (FWS 1970). The primary threat leading to the species' decline and ultimate listing was over-harvest for their feathers in the early 1900s (FWS 2000b), but that threat is no longer present. Another major threat to the short-tailed albatross is their small population size and the existence of only two breeding populations, one of which is threatened by volcanic activity on Torishima Island (Japan) as well as by mudslides and erosion (FWS, 2005a and 2008). Petroleum development occurs in many parts of the short-tailed albatross' marine range, and oil spills are a threat to conservation and recovery.

Possibility of volcanic eruption on Torishima remains the primary ongoing threat to short-tailed albatross because 80 to 85 percent of the breeding population nests there (FWS, 2005b). Typhoons and monsoon rains generating erosion slides threaten extant nesting colonies on a regular basis. Secondary threats include adverse effects related to global climate change (oceanic circulation and patterns of upwelling, incidental take by commercial fisheries (longline fisheries trawl fishing in the North Pacific), ingestion of plastic debris (especially beverage bottle caps), contamination by oil and other pollutants (metals, pesticides, PCBs), vulnerability to predation by non-native species, and other human actions including collisions with airplanes (FWS, 2005a). When populations are small and confined to only a few locations such as the known breeding colonies for short-tailed albatrosses, there is a heightened risk of catastrophic loss from random or unpredictable events (environmental stochasticity).

**Species Recovery**

The FWS drafted a recovery plan for the short-tailed albatross in October 2005 (FWS, 2005b), describing actions necessary to achieve conservation and survival of the species. Human harvest of the short-tailed albatross no longer is a threat to the species existence, nor are human-related limitations. Therefore, focus for recovery is on protection and creation of safe breeding colonies (i.e., without potential for volcanic eruption or massive erosion) on remote islands in the Pacific Ocean (FWS, 2008a). The goal of the plan is to recover the species to the point that protection of the ESA is no longer required. The plan listed the following recovery tasks:

- Support ongoing population monitoring and habitat management on Torishima.
- Monitor Senkaku population.
- Conduct telemetry studies.
- Establish one or more nesting colonies on non-volcanic islands.
- Continue research on fisheries operations and mitigation measures.
- Conduct other research.
- Conduct other management-related activities.
- Conduct outreach and international negotiations as appropriate.
- Develop models and protocols for all aspects of recovery work.

**Life History, Habitat Requirements, and Distribution**

The short-tailed albatross nests on flat or sloped sites with sparse or full vegetation on isolated windswept offshore islands with limited human access (FWS, 2000b). It requires remote islands for breeding (FWS, 2005b). The only terrestrial area within U.S. jurisdiction where the short-tailed albatross is currently nesting is the Midway Atoll. After a courtship of nearly three years, a pair of adult short-tailed albatross successfully raised and fledged a juvenile from a nest site within the Midway Atoll National Wildlife Refuge (Papahānaumokuākea Marine National Monument) in spring 2012 (FWS, 2012c).

In the North Pacific, the coastal habitat for the short-tailed albatross is in high-productivity areas with expansive deep water beyond the continental shelf. Short-tailed albatrosses eat squid, fish, eggs of flying fish, shrimp, and other crustaceans (FWS, 2000b). Short-tailed albatross foraging areas are closely associated with shelf-edge habitats where tidal currents and steep bottom topography generate strong vertical mixing of ocean waters. Areas are most prominent along the Aleutian Archipelago but also include several locations along the US west coast inlong the Santa Barbara Channel and Montery Bay Canyon in California and the Juan de Fuca Canyon near Vancouver Island (Piatt et al., 2006).

**Population Status**

Prior to the publication of the Final Rule, FWS (2000b) estimated a worldwide population of 600 breeding age birds and 600 immature birds (younger than 6 years old) for a total of 1,200 individuals. In 2005-06, there were an estimated 500 breeding pairs and approximately 2,000 individual short-tailed albatrosses (FWS, 2005b). Recent (2008-2009) population estimates incicate 418 breeding pairs (836 breeding adults) on Torishima with a total adult population of 1,045 and an estimated adult population on Minami-kojima of 200 during the 2008-2009 nesting season. The worldwide total adults of breeding age in 2008-2009 was 1,245 birds and 1,327 birds of sub-breeding age (under age 5 or 6) (FWS, 2009a).

**Critical Habitat**

Critical habitat has not been designated for the short-tailed albatross. Designation of critical habitat is "not prudent" given, overall, the lack of habitat-related threats to the species within the United States and its territories and absence of specific areas under U.S. jurisdiction that could serve as critical habitat (FWS, 2005b).

### 4.3.1.2 Environmental Baseline

**Analysis Area**

The analysis area within which the proposed action could affect the short-tailed albatross is the EEZ, which extends 200 nautical miles offshore. Within the analysis area, effects to the short-tailed albatross would be associated with LNG carriers which are assumed to transect the EEZ perpendicularly - east and west - as they approach and depart from Coos Bay (see the discussion above under Section 4.2.1.3, Blue Whale).

**Species Presence**

The short-tailed albatross has not been documented within 25 miles of the proposed JCEP LNG project or Pacific Connector pipeline (ORBIC, 2012) and the nearest known nesting population is within the Hawaiian Islands, on the Midway Atoll. Three percent of locations for sub-adult short-tailed albatrosses tagged with satellite transmitters in Alaskan waters were along the continental shelf margin, within the EEZ, of the U.S. Pacific west coast (Suryan et al., 2007). Most recent records for the species in Oregon have been at sea in the vicinity of Perpetua Bank which is 32 miles west of Yachats, Lincoln County (Marshall et al. 2006). Short-tailed albatrosses have also been observed at Heceta Bank (Audubon Society of Portland, 2013), 15-30 miles off th central Oregon coast, part of the same seamount ridge formation as Perpetua Bank, promoting upwelling of ocean currents interacting with seafloor topography with concomitant primary production.

**Habitat**

Short-tailed albatrosses spend much of their time feeding in nutrient-rich areas of ocean upwelling which often occur at continental shelf breaks (FWS, 2005b). In Oregon, the continental shelf extends from 10 miles off the coast at Cape Blanco to 46 miles from the Oregon central coast (Oregon Ocean-Coastal Management Program, 2008). The Perpetua Bank and Heceta Bank are within the continental shelf break zone and ocean upwelling presumably occurs in the vicinity to support foraging by short-tailed albatross. Similar habitat is expected within the EEZ analysis area.

**Critical Habitat**

Critical habitat has not been designated for the short-tailed albatross.

#### 4.3.1.3 Effects by the Proposed Action

**Direct and Indirect Effects**

None of the factors that have threatened the short-tailed albatross in the past or that are ongoing threats to the species would be produced by any components of the proposed action.

However, Laysan or black-footed albatross (but not short-tailed albatross) may have been killed by colliding with airplanes on Midway Atoll (FWS, 2008a). Seabirds collide with fishing trawlers in the North Pacific although take of short-tailed albatross has not been reported (FWS, 2009). Collisions of seabirds with stationary objects (including off-shore wind energy turbines) are possible, either by collisions of ships with birds on the ocean surface or collisions of birds in flight with ship structures although empirical data are limited (Wilson et al., 2007). Collisions between short-tailed albatrosses and LNG carriers are possible but not likely within the EEZ analysis area.

Oil spills at sea or offshore can harm short-tailed albatrosses (FWS, 2009a). However, effects of potential spills from LNG carriers are not comparable to spills from oil tankers for a number of reasons. LNG carriers only carry quantities of oil used for propulsion fuel and not the quantities transported by oil tankers. Unlike oil tankers, LNG carriers are double hulled, such that a grounding would not rupture the cargo tanks. In addition, LNG is not like oil, in that it would vaporize as soon as it hits the warmer water. The effects by the proposed action to short-tailed albatrosses are insignificant and discountable (FWS and NMFS, 1998).

**Cumulative Effects**

FWS and NMFS describe cumulative effects (50 CFR § 402.02) as the result of future actions by state or private entities, not involving federal actions, but reasonably certain to occur in the action area considered in this BA. Future federal actions that are unrelated to the proposed action are not considered here because they require separate consultation pursuant to section 7 of the ESA.

As discussed above for blue whales, available information indicates that ship calls to the Port of Coos Bay have been declining since 2002. The observed declining linear trend in total annual vessel traffic over time is significant and, when used to forecast numbers of vessel calls to Coos Bay in the future, 1.6 vessels are predicted to enter Coos Bay in 2017 with between 0 and 20.3 vessels as reasonably foreseeable when the LNG terminal is expected to begin operation in 2017 (see figure 4.2-3).

The foreseeable cumulative effect of 90 LNG carriers per year would be less than effects based on past or present levels of vessel traffic calls to the Port of Coos Bay which would have exceeded 90 vessels per year in 1992 given the current trend in figure 4.2-2. Consequently, cumulative effects to short-tailed albatross would likely be less than the estimate of direct effects discussed in the previous section.

The volume of annual vessel transits within the EEZ of California, Oregon, and Washington is related to numbers of vessel calls to ports in those states. Total annual calls for all vessels at ports in California, Oregon, and Washington (MARAD, 2013) were plotted above in figure 4.2-2 for 2002 through 2011. Unlike the trend analyzed for calls to Coos Bay (see figure 4.2-3) the observed linear trend in annual vessel traffic (port calls) along the U.S. West Coast was significantly increasing at a rate of 2.1 percent per year between 2002 and 2007. The increasing trend was interrupted by the global economic crisis in 2008 but data through 2011 indicate a return to the established increasing trend prior to 2008. The pre-2008 trend predicts 21,100 vessel calls to West Coast ports in 2017 (with 95% prediction intervals ranging from 17,200 to 25,000 vessel calls), the year the JCEP and PCGP projects are expected to be in service. Even with the uncertainty generated by available data, there is a reasonably foreseeable increasing trend, albeit imprecise, for vessel traffic volume in the future (by 2017) although unforeseen global events such as future economic crises could influence the predictions. Cumulative effects of 90 LNG carriers per year to short-tailed albatross may be more or may be less than the estimate of direct effects discussed above.

Releases of diesel fuel and/or gasoline by commercial and recreational vessels are possible. According to annual reports published by the Pacific States/British Columbia Oil Spill Task Force (2002), ODEQ reported 34 spills from fishing vessels or other harbor craft in 2002, 38 spills in 2003, and 7 spills from fishing vessels plus spills from 27 other vessel types in 2004. Those relatively consistent incidences apparently increased in 2005 with 18 spills from fishing vessels, 20 from recreational vessels, and 27 spills by other vessel types. By contrast in 2006, there were 3 spills from fishing vessels, 6 spills from recreational vessels, and only 6 spills from other vessel types. Though not known, it appears that the background rate of spills off the Oregon coast (incidence of spills in proportion to total vessel operation) by fishing vessels, recreation vessels, and other vessel types is generally low. Based on existing information, future rates of offshore releases are also expected to be low and potential for short-tailed albatross to be affected by contamination by oil and other pollutants is not expected to increase above existing levels.

**Critical Habitat**

No critical habitat would be affected by the proposed action; none has been designated.

#### 4.3.1.4 Conservation Measures

No measures have been included in the proposed action to specifically conserve short-tailed albatross. However, the same Ship-Strike Reduction Plan that was described in Section 4.2.1.4 (Blue Whale) to minimize potential ship strikes to cetaceans by LNG carriers could benefit short-tailed albatross within the EEZ analysis area.

#### 4.3.1.5 Determination of Effects

**Species Effects**

The Project **may affect** short-tailed albatross because:

- Short-tailed albatross may occur within the EEZ analysis area during operation of the proposed action.
- The proposed action would increase shipping traffic (LNG carriers) within the EEZ analysis area.

However, the Project is **not likely to adversely affect** short-tailed albatross because:

- Short-tailed albatross have infrequently collided with airplanes in flight but collisions with ships are unknown and are expected to be highly unlikely.
- The increase in annual ship traffic due to the proposed action is expected to cause an immeasurable increase for potential ship strikes to short-tailed albatrosses.

- LNG carriers approaching the Port of Coos Bay would be traveling slowly and escorted by tractor tugs from 50 nmi offshore to the Port.
- Spills or releases of LNG at sea would not cause the water column to cool to the point of affecting the potential food species (squid, fish, eggs of flying fish, shrimp, and other crustaceans) in the water. Ignited LNG would affect species on the water but not species submerged in the water. Short-tailed albatrosses are expected to avoid ignited LNG.

**Critical Habitat Effects**

No critical habitat has been designated or proposed for the short-tailed albatross.

### 4.3.2 Western Snowy Plover

#### 4.3.2.1 Species Account and Critical Habitat

**Status**

The Pacific Coast population of western snowy plover has been listed as a threatened species under the ESA since March 5, 1993 (FWS, 1993a). In March 2004, FWS issued an initial 90-day review in response to a petition to de-list the western snowy plover. However, in April 2006 after further review, the de-listing petition was found to be unwarranted (FWS, 2006c).

**Threats**

Historic records indicate that western snowy plovers nested in at least 29 locations on the Oregon coast (FWS, 2009b). At the time of the species' listing Final Rule, there were only six (FWS, 1993a). The breeding population in Oregon declined from 139 adults in 1983 to 30 adults in 1992. Similar declines within wintering habitats were also reported in Southern California (FWS, 1993a). Active nesting areas and breeding and wintering populations declined due to habitat degradation caused by urban development (industrial, residential, recreational facilities including homes, parking lots, and commercial establishments), introduced beachgrasses used to stabilize sand dunes, expanding predator populations particularly corvids (crows, ravens), and non-native red foxes, and human disturbance (beach walking and jogging, ORV use, horseback riding, beach raking, pet walking – FWS, 2001). Nesting from mid-March through mid-September corresponds with the period of intensive human use of beaches during summer, which has been documented to adversely affect adult survival as well as reproduction and fledging success. Western snowy plovers in Oregon are designated as threatened under state statute though habitat and birds have not been adequately protected (FWS, 1993a).

Habitat destruction and degradation continue as the primary threats to western snowy plovers along the Pacific coast (FWS, 2007f). Beach stabilization efforts have continued with permanent habitat losses due to homes, resorts, parking lots, and increased human recreational use of beaches. Other human-related threats include sand mining, disposal of dredged materials that also alter beach habitat dynamics and increase recreational access to habitats, driftwood removal (for firewood, decoration), camping and campfires, reduction in sand delivery to beach by water diversions or waterbody impoundments, and maintenance of salt ponds. Non-native beachgrasses continue to degrade the landscape along the Oregon coast by changing patterns of dune stabilization, making beach habitats less suitable for nesting and brood-rearing snowy plovers (FWS, 2007d).

**Species Recovery**

In 2001, the FWS drafted a recovery plan for the western snowy plover, Pacific Coast population, with the primary objectives to increase the numbers and productivity of breeding adults throughout the Pacific Coast and to provide for long-term protection of breeding and winter plovers and their habitat. The recovery plan provides management goals for six recovery units established within the breeding range of the Pacific Coast population in Washington, Oregon, and California. Recovery Unit 1, specifically population OR-10 (Coos Bay North Spit), is near the proposed action. The management goal for this unit is 54 breeding plovers (FWS, 2001 and 2005c). There were 61 total nests within OR-10 reported during the 2012 nesting season (Lauten et al., 2012). A final recovery plan was released in 2007 (FWS, 2007d). The recovery plan's primary objective is to remove the species from the List of Endangered and Threatened Wildlife and Plants by:

- Increasing population numbers distributed across the range of the Pacific coast population.
- Conducting intensive ongoing management for the species and its habitat and developing management mechanisms.
- Monitoring western snowy plover populations and threats to determine success and refine management actions.

The recovery plan lists the following necessary actions:

- Monitor breeding and wintering populations and habitats of the Pacific coast population of the western snowy plover to determine progress of recovery actions to maximize survival and productivity.
- Manage breeding and wintering habitat of the Pacific coast population of the western snowy plover to ameliorate or eliminate threats and maximize survival and productivity.
- Develop mechanisms for long-term management and protection of western snowy plovers and their breeding and wintering habitat.
- Conduct scientific investigations that facilitate the recovery of the western snowy plover.
- Conduct public information and education programs about the western snowy plover.
- Review progress towards recovery of the western snowy plover and revise recovery efforts, as appropriate.
- Dedicate FWS staff to allow the Arcata Fish and Wildlife Office to coordinate western snowy plover recovery implementation.
- Establish an international conservation program with the government of Mexico to protect western snowy plovers and their breeding and wintering locations in Mexico.
- Coordinate with other survey, assessment, and recovery efforts for the western snowy plover throughout North America.

**Life History, Habitat Requirements, and Distribution**

The Pacific Coast breeding population of the western snowy plover includes Oregon. Coastal populations, including those in Oregon, typically consist of resident and migratory birds. Large concentrations of migratory snowy plovers winter primarily in coastal California, Baja California, and along the coastal mainland of Mexico (FWS, 1993a). The Pacific coast population of the western snowy plover includes the birds which nest adjacent to tidal waters, including all nesting birds on the mainland coast, peninsulas, offshore islands, adjacent bays, estuaries, and coastal rivers (FWS, 1993a). They breed on coastal beaches from southern Washington to southern Baja California, Mexico, from early March through late September (FWS, 1993a and 2001). This habitat is often unstable because of unconsolidated soils, high winds, storms, wave action, and colonization by plants. Preferred nesting sites include sand spits, dune-backed beaches, beaches at creek and river mouths, and salt pans at lagoons and estuaries (Wilson, 1980; Stenzel et al., 1981). Less frequently, western snowy plovers nest on bluff-backed beaches, dredged material disposal sites, salt pond levees, dry salt ponds, and river bars (FWS, 2001). In 1990, one western snowy plover nest was documented at Menasha dredge spoils along the east side of Pony Slough at its confluence with Coos Bay (ORBIC, 2012). The nest failed in 1990 and was not reinitiated in 1991.

Nesting in Oregon may occur as early as mid March but peak nest initiation occurs from mid-April through mid-July (Wilson-Jacobs and Meslow, 1984). Nests typically occur in flat, open areas with sandy or saline substrates; vegetation and driftwood are usually sparse or absent (Wilson, 1980). Nests consist of a shallow scrape or depression lined with beach debris (e.g., small pebbles, shell fragments, plant debris, and mud chips); nest lining progresses as incubation progresses.

Usual clutch size is three eggs but can vary from two to six. Both males and females incubate the eggs. After losing a clutch or brood (i.e., group of chicks) or successfully hatching a nest, western snowy plovers may re-nest at the same site or move substantial distances to nest at other sites (Wilson, 1980; Warriner et al., 1986).

Eggs hatch within 30 days. Young are very precocial and ready to leave the nest within 1 to 3 hours of emergence at which point the attending parent would lead them to suitable feeding grounds. Broods rarely remain in the nesting area and have been observed on the North Spit as far as three miles north of the jetty at the mouth of the bay (Todd, 2007). Chicks are able to fly approximately one month after hatching (FWS, 2007d). Plovers feed on small invertebrates in wet sand areas of the intertidal zone, along the wrack line, in dry sandy areas above the high tide line and along surf-cast driftwood and kelp.

**Population Status**

Along the Oregon Coast there are eight main nesting areas though several other areas may be utilized in some years (FWS, 2007f). Lowest population estimates for nesting plovers on the Oregon Coast averaged 33 individuals annually between 1991 and 1993. Since 1993, the Oregon Coast population of adults has significantly increased to 206 birds following an exponential trend (see figure 4.3-1). In 2012, nesting success for those breeding sites was the highest recorded since monitoring began in 1990, with 173 birds fledging in 2012 compared to only three birds that fledged in 1990 (Lauten et al., 2012).

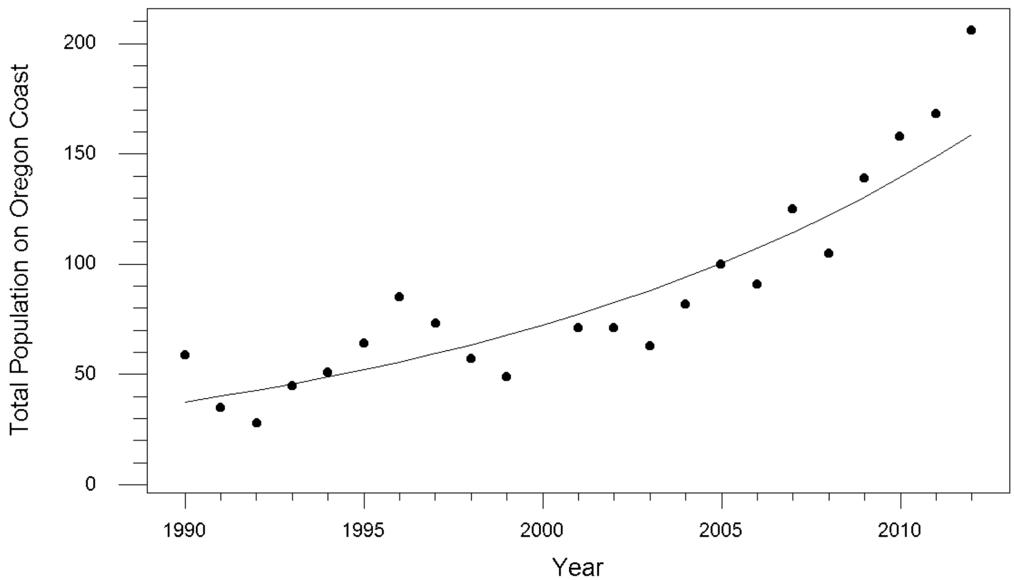

**Figure 4.3-1**
**Number of Adult Western Snowy Plovers Observed During the Breeding Season on the Oregon Coast, 1990 to 2012. The exponential relationship is significant ($r^2$ = 0.79, P<0.001). Source: Lauten et al., 2012**

In 2008, the estimate of total fledglings on the Oregon Coast was only 71, possibly due to 1) cool, wet weather during the early breeding period, 2) a relatively large proportion of young inexperienced birds in the breeding population, and/or 3) increased predation on young (BLM, 2008a). Nevertheless, production of fledglings on the Coos Bay North Spit was 40, over 50 percent of the Oregon Coast total (BLM, 2008a).

**Critical Habitat**

Critical habitat for the western snowy plover was designated on January 6, 2000 (FWS, 1999a), including 278 acres in Coos Bay, and re-designated in 2005 (FWS, 2005c). The most recent revised designation of critical habitat for the western snowy plover was in June 2012 (FWS, 2012d). The closest critical habitat to the PCGP Project is Unit OR-10 which occupies 273 acres on the Coos Bay North Spit, approximately 5.1 miles southwest of MP 1.47R of the PCGP Project. A second critical habitat Unit OR-9, at the mouth of Tenmile Creek on the Siuslaw Nation Forest, is 6.9 miles northwest of MP 3.51R. Both critical habitat units were occupied by western snowy plovers at the time of listing (1993) and in 2012. Approximately 25 breeding adults occupied Unit OR-9 in 2011, while 59 breeding snowy plovers were documented with Unit OR-10 on the North Spit in 2011 (FWS, 2012d). Both units include features essential to the conservation of the species, including expansive sparsely vegetated interdune flats (used for nesting and foraging), areas of sandy beach above and below the high tide line with occasional surf-cast wrack supporting small invertebrates (for nesting and foraging), and close proximity to tidally influence estuarine areas (for foraging).

Based on the Pacific Coast western snowy plover's requirements for reproduction, feeding, forage and shelter, the FWS (2012d) identified the following essential physical and biological features of designated critical habitat: 1) sparsely vegetated areas above daily high tides that are relatively undisturbed by the presence of humans, pets, vehicles or human-attracted predators; 2) sparsely vegetated sandy beach, mud flats, gravel bars or artificial salt ponds subject to daily tidal inundation, but not under water, that support small invertebrates; and, 3) surf or tide-cast organic debris such as seaweed or driftwood located on open substrates. Critical habitat in the vicinity of the project area (Unit OR 9, Coos Bay North Spit), contains expansive, sparsely vegetated interdune flats, areas of sandy beach above and below the high tide line with occasional surf-cast wrack supporting small invertebrates, and close proximity to tidally influenced estuarine areas (FWS, 2012d).

Threats that may require special management in this unit are introduced European beachgrass that encroaches on the available nesting and foraging habitat; disturbance from humans, dogs and off-highway vehicles (OHVs) in important foraging and nesting areas; and predators such as the American crow and common raven (FWS, 2005c).

#### 4.3.2.2 Environmental Baseline

**Analysis Area**

The LNG terminal analysis area extends for 1.7 miles beyond the perimeter of the LNG terminal project area (see figure 4.3-2) to include western snowy plover nesting habitat on the North Spit.

**Species Presence**

Western snowy plovers have been recorded on the National Audubon Society's Christmas Bird Counts in the Coos Bay count circle every year since 2000, and sporadically in earlier surveys. Since 2000, an average of 5.4 snowy plovers have been counted per year; the most reported in any annual survey were 10 counted during 160 observation hours (0.06 counted per hour of observation) in 2005. Western snowy plovers are known to nest at the upper edge of the beach below the foredunes, on bare spits at small estuary mouths and on old dredge spoils (Marshall et al., 2006). No western snowy plovers were detected during field surveys of the Jordan Cove Project site (LBJ Enterprises, 2006).

In summer 2012, 16 total adults (8 males, 8 females) were documented by the Forest Service on the Tenmile Creek Unit OR-9 and 52 adults (35 males, 17 females) were documented by personnel with BLM and Army Corps of Engineers on the Coos Bay North Spit, critical habitat unit OR-10. In 2012, the nest success rate on the North Spit was 87 percent, similar to 2011, and the highest rate on the Oregon Coast since predator management was implemented in 2002 (Lauten et al., 2012). Nesting success at the Tenmile Creek unit has been very poor; only 13 percent of nests were successful in 2012, mostly due to depredations by corvids (common ravens) and great horned owls (Lauten et al., 2012). The total number of nests documented on the North Spit has significantly increased between 1998 and 2012 (see figure 4.3-3).

### Habitat

The northern end of critical habitat on the North Spit is approximately 2.6 miles from the LNG terminal site. Nesting habitat, reported by ORBIC (2012), extends north of the North Spit designated critical habitat for nearly 2 miles along the beach. The northern end of that nesting habitat is approximately 1.1 miles from the LNG project area boundary.

The Pacific Connector pipeline terminus is approximately 2.6 miles east of the largest and most consistent western snowy plover nesting areas (ORBIC, 2012) and 4.0 miles northeast of the designated critical habitat on Coos Bay North Spit (FWS, 2012d). In 1990, one western snowy plover nest was documented at Menasha Spoils at the mouth and along the east side of Pony Slough at its confluence with Coos Bay (ORBIC, 2012), approximately 0.6 mile south of MP 1.72R. Since 1990, vegetation has invaded the Menasha Spoils site and the site may no longer be suitable as snowy plover nesting habitat since it is no longer an expanse of sparsely vegetated interdune flats. The nest was unsuccessful and there have been no nest sites documented within the Coos Bay estuary since 1990.

The existing land use of the LNG project area site is open. It has been disturbed by past and present activities. The site area has been filled in the past as evidenced by deposits of clamshells and wood chips. Other disturbances have and are presently occurring from recreational off road vehicle usage. Elevation ranges from near sea level to an approximate elevation of 67 feet. Topography is variable, ranging from low lying deflation basins to semi-stable dunes. Existing vegetation is comprised of upland coniferous dune forests and upland herbaceous dominated areas.

**Critical Habitat**

No designated critical habitat for western snowy plover is present in the LNG terminal analysis area. The northern end of critical habitat (OR-10) on the North Spit is located approximately 2.6 miles from the LNG project area.

### 4.3.2.3 Effects by the Proposed Action

**Direct Effects**

Direct effects of the proposed action include increased noise associated with construction of the LNG terminal and operation activities associated with shipping.

Noise

Noise associated with construction and operation of the facility is the only direct effect to plovers associated with the proposed action. The 2007 western snowy plover recovery plan states that: "sources of noise that would disturb snowy plovers should be avoided," but the levels of noise likely to disturb plovers are not provided. The recovery plan identifies noise associated with dredging as having a potentially negative effect on breeding and wintering western snowy plovers; noise associated with driftwood removal, especially if chainsaws and vehicles are used, can disrupt nesting; noise from beach cleaning machinery, from beach pyrotechnics, and from aircraft overflights (especially helicopters) can also cause adverse effects (FWS, 2007d).

Ambient noise levels in the vicinity of the LNG terminal were measured continuously for 24 hours between August 31 and September 1, 2005 at two residences (noise sensitive areas), one of which was 1.4 miles south of the terminal and the other 2.3 miles east. Ambient noise levels at the terminal site or on the Coos Bay North Spit were not reported (Resource Report 9, JCEP LNG Terminal Project). Average noise levels ranged from 35 dBA (night) to 54 dBA (day) south of the terminal site and from 49 dBA (night) to 66 dBA (day) east of the site. Local conditions such as aircraft, vehicle traffic, vegetation, topography, breaking waves, and winds characteristic of the location can alter background noise conditions. Sound levels (decibels – dB) at outdoor rural residential locations of about 40 dB, averaged for day and night periods (see for example, EPA, 1974) have been accepted as standard. More than likely, ambient noise levels on the North Spit, near breaking waves, will be higher than 40 dB; noise generated by breaking wavecreses in the surf zone can be 15 dB higher than background levels (Dean, 1999). Daytime ambient noise is typically 10 dB higher that night levels (EPA, 1974).

Construction

Construction of the JCEP LNG terminal and South Dunes Power Plant would increase local noise levels. Noise levels 50 feet away from typical construction equipment that might be used during terminal construction, are provided in table 4.3.2-1.

The standard for noise reduction from point sources such as construction machinery is 6 dBA per doubling of distance under hard site conditions (over calm water, hard, smooth ground survace) and 7.5 dBA per doubling of distance under soft site conditions (because of roughened ground and/or vegetation cover) (WSDOT, 2011a). Based on the data in table 4.3.2-1, noise produced by construction activities would attenuate to daytime ambient noise levels in the vicinity of western snowy plover nests (estimated at 55 dBA because of breaking wave noise) within distances of 230 feet to 2,850 feet, depending on equipment/actions and hard site or soft site reduction ground surface conditions. Obscuring vegetation (tree cover), topography (interruption of line-of-sight), and atmospheric conditions (wind, air temperature, humidity) also affect noise reduction but can be highly variable between locations and over time and are generally not taken into account in estimates of noise attenuation over short distances (Resource Report 9, JCEP LNG Terminal Project). Consequently, predictions of noise levels some distance from the noise source are likely to be higher than actual noise levels.

Prior to the excavation work starting for the LNG carrier slip, an open cell sheet pile bulkhead and retaining wall will be installed. The sheetpile system will serve as a retaining wall for the shoreline on the east side and support the LNG ship loading dock and associated berthing and mooring facilities. The open cell sheet pile wall system consists of face sheetpiles for retaining the soils as well as tailwalls for anchorage of the retaining wall. All sheetpiles and tailwalls will be driven from the land while the slip construction activities are isolated from Coos Bay. Sheet piling is typically installed with a vibratory pile driver. Average maximum noise in air of a vibratory pile driver is 101 dBA at 50 feet (WSDOT, 2011a). Vibratory pile driver noise would likely attenuate to 55 dBA at 3,510 feet (soft site reduction) or 10,159 feet (hard site reduction) and would attenuate to 40 dBA at 14,039 feet (soft site reduction) or 57,469 feet (hard site reduction). Consequently, noise generated during installation of sheet piling could be above background noise at the northern end of the western snowy plover nesting habitat (depending on effects of surf noise on ambient noise levels), approximately 1.1 mile from the LNG slip construction site but not likely at the northern end of critical habitat on the North Spit, approximately 2.6 miles from the LNG terminal site.

**Table 4.3.2-1**
**Average Maximum Noise (Lmax) at 50 feet from Construction Equipment and Estimated Distance to Attenuate to Ambient Levels near the Surf Zone on the North Spit [1]**

| Construction Activity | Equipment | Noise dBA (Lmax measured at 50 feet) [2] | Distance (feet) to Attenuate to Assumed Ambient Noise Level of 55 dBA [1] | |
|---|---|---|---|---|
| | | | Soft Site Reduction at 7.5 dBA per double of distance | Hard Site Reduction at 6 dBA per double of distance |
| Clearing and Grading | Grader | 85 | 800 | 1,600 |
| | Scraper | 84 | 729 | 1,425 |
| | Warning Horn | 83 | 665 | 1,270 |
| | Dozer | 82 | 606 | 1,131 |

[1] WSDOT, 2011
[2] Federal Highway Administration, 2006

Construction of the LNG terminal and slip is expected to take 42 months (see Resource Report 1, JCEP LNG Terminal Project). Piling driving activities will take place over approximately an eight-month period and are expected to occur on a schedule of two shifts, six days per week (see Resource Report 9, JCEP LNG Terminal Project). Sheet pile driving will occur initially followed by the on-shore berthing structures as the marine foundation work begins. Sheet piling could be installed during the snowy plover breeding, nesting or rearing periods. Based on the distance of construction from western snowy plover critical habitat and potential nesting sites on the North Spit, acoustic disturbances from the proposed action are not expected to significantly affect western snowy plover breeding, nesting or rearing activities.

Construction of the PCGP across Haynes Inlet will occur between October 1 and February 15, the ODFW-recommended in-water construction window (ODFW, 2008a), which is outside of the nesting and fledgling season for the species on the Oregon coast (early April through August; FWS, 2001). It is not possible to anticipate any local occurrence of western snowy plover in the project area at the time of construction

Operation

Approximately 90 LNG ships will transit to the Project on an annual basis. Since it is not possible to identify which LNG ships will transit to the Project, exact noise levels cannot be determined at this time. For analysis purposes, noise levels have been determined for the 138,000 $m^3$ LNG ships which are typical of the LNG ships anticipated to transit the waterway to the Project. A noise level of 63 dB at 100 yards (82 dBA at 50 feet under soft-site conditions, 79 dBA at 50 feet under hard-site conditions) was determined for the 138,000 $m^3$ LNG ship (Resource Report 9, JCEP LNG Terminal Project). However, LNG ships transiting the waterway to the LNG terminal would be under tow by high bollard pull tractor tugs for which noise estimates have not been presented. Nevertheless, noise from tugs and/or LNG ships entering and exiting Coos Bay are expected to generate noise above ambient levels within the southern portion of critical habitat unit OR-10 which extends to the southern extent of the North Spit, approximately 100 feet from the edge of the North Jetty and Coos Bay channel.

In addition to LNG ships, the following major noise-producing equipment will normally be in operation at the Project (Resource Report 9, JCEP LNG Terminal Project):

- Four (4) refrigerant compressors / motors / piping;
- Four (4) refrigerant compressor interstage coolers;
- Four (4) refrigerant condensers;
- LNG expanders;
- Ship BOG return blowers;
- Six (6) BOG compressors / motors;
- Two (3) BOG compressor coolers; and
- Various other condensers, coolers, pumps and valves.

Additionally, the following noise-producing nonjurisdictional South Dunes Power Plant equipment packages will normally be in concurrent operation with the Project equipment:

- Six (6) combustion turbine generators (GE LM6000);
- Six (6) heat-recovery steam generators;
- Two (2) steam turbine generators;
- Two (2) air-cooled condensers;
- Twelve (12) boiler feed pumps;

- Two (2) fuel gas compressors;
- Fuel gas compressor cooler; and
- Steam piping, various motors, valves, air compressors, etc.

The above equipment packages have been specified to meet sound level requirements appropriate to support an overall far-field Project sound level that does not exceed the applicable FERC regulatory limits. As explained in Section 9.2.2.1 of Resource Report 9 (JCEP LNG Terminal Project), a constant Project sound level of less than 48 dBA would ensure compliance with all applicable regulations, including the FERC requirement limiting the average day/night noise level at the nearest residential noise sensitive areas to ≤55 dBA. With that restriction, it is assumed that noise generated by equipment at the functioning LNG site and South Dunes Power Plant will not exceed 55 dBA at western snowy plover breeding, nesting or rearing habitat on the North Spit.

During operations of the PCGP, aerial inspection of the pipeline will occur within the permanent right-of-way. Nesting snowy plovers are not expected to be impacted since the closest nesting population is more than three miles from proposed aerial inspections and air traffic is a constant disturbance with the existing North Bend Municipal Airport within less than three miles of the nesting habitat on North Spit. If the pipeline within the bay requires maintenance, activities and repair would occur in-water and within the permanent easement; therefore, impacts from maintenance activities should not impact snowy plovers any time of the year.

**Indirect Effects**

Project-related indirect effects to western snowy plovers which are caused by the action (induced by the action as human presence and use increase) and are later in time or farther removed in distance, but are still reasonably foreseeable are indirect effects. All indirect effects to western snowy plovers are expected to be secondary effects (Comer, 1982) due to an increased human population base, whether as a result of the requirements of the action itself (the workforce needed to construct or operate the Project) or as a consequence of the action (need for ancillary goods, services, opportunities resulting from the Project). Potential indirect or secondary effects by a project include increased recreation demand (including ORV use), increased habitat conversion, habitat degradation by human encroachment, and increased illegal harvest (Comer, 1982).

The following indirect effects by the proposed action to western snowy plovers are anticipated: 1) increased human presence, and 2) increased predation of western snowy plovers due to increased human presence. In addition, increased human presence may lead to destruction of nests and/or disturbance of plovers from the following activities: OHV usage, visitors or their dogs, predators such as crows and ravens (that are attracted to areas with humans and their garbage), beach walking or jogging, horseback riding, and beach raking.

Human Presence

The Coos Bay North Spit is currently utilized by a variety of recreational users for OHV driving, beach combing, boating, bay-shore clamming and crabbing, day hiking, picnicking, kayaking, surfing, and fishing (Natural Resource Trustees, 2006). In addition, the North Spit has become one of the most popular horseback riding areas in the region (BLM, 2005). Snowy plover habitat on the North Spit is currently owned by the BLM and COE and managed by the BLM, USFS, and Oregon Parks and Recreation Department (OPRD). This area is known as the Coos Bay

North Spit Recreation Management Area (CBNS RMA) and extends 3.37 miles north from the southern tip of the North Spit along the ocean-side shoreline, encompassing some, but not all, of the Plover Critical Habitat on the North Spit.

According to the OPRD 2007 Plover Habitat Conservation Plan, the peak number of visitors to the 15.62 miles of beach from Ten Mile Creek to Coos Bay (the beach segment including the CBNS RMA) was 3.84 people per mile (OPRD, 2005 and 2007), and the distribution of these visitors was described as "dispersed." The number of visitors per mile at the eight recreational management areas currently utilized by nesting plovers ranged from 3.45 to 13.22 (OPRD, 2007). The Habitat Conservation Plan for Western Snowy Plovers published by the OPRD in September 2007 states (with regard to the CBNS RMA), "This beach is open to street legal vehicle driving only, but is closed during the breeding season. There is illegal ATV [all-terrain vehicle] use on this beach. Recreation use here is low, but higher than other RMAs due to its close proximity to Coos Bay/North Bend/Charleston. The area is a popular surfing site."

The primary reasons that the public accessed the North Spit beach were to walk/run (16 percent) or to relax (21 percent). Of those surveyed, 4 percent reported bringing dogs to the beach, and none reported flying kites (OPRD, 2007). The percentage of people with dogs was significantly lower than the statewide average of 35 percent. All of the human-caused disturbances listed above can result in destruction of nests (by dogs or through inadvertent trampling and deliberate vandalism) and in diverse plover responses to human presence, including: flushing from and abandonment of nests, separation from broods, shifting to marginal habitat, cessation of foraging and adoption of vigilant or cryptic behaviors (FWS, 2007f).

The number of people employed on the North Spit in 2007 was approximately 110 (Southport Lumber Products – 70, Roseburg Forest Products – 20, DB Western Marine Division – 20). The Project would result in a large but temporary increase in people employed on the North Spit during construction (an average of 741 construction workers over the four year construction period) and a much smaller long-term increase of operations staff (150 employees at the LNG terminal). Construction would take 42 months, and the number of construction personnel would peak at 2,937 workers in project months 30 to 33 (Resource Report 5, JCEP LNG Terminal Project).

It is difficult to predict how the increase in short-term and long-term employment due to the future development of the North Spit would translate into increased recreational use of areas near snowy plover habitat. However, it is reasonable to assume that the Jordan Cove operations staff, their family and friends would be introduced to the area, and some minor increases in recreational use could occur. This increase in recreational use could result in increased plover disturbance. Recreation on the beach has been shown to cause a reduction in plover productivity. In total, it was estimated that between 2000 and 2006, recreational activities on the Oregon Coast resulted in the loss of 30 hatchlings and 11 fledglings per year, which equated to an annual loss of 5 adult equivalents (Jones and Stokes, 2007).

<u>Predators</u>

In the 2006 Coos Bay Annual Program Summary and Monitoring Report, BLM reports that corvids (crows, ravens and their allies), skunks and feral cats are the primary predators on the North Spit. However, the exact nature of predation pressures on snowy plover on the North Spit shifts annually, and during 2007 coyotes became a greater threat than they had been previously (Castelein, 2008). The BLM and OPRD have jointly managed a predator prevention program since 1990, which focuses on the removal of predators and the protection of nests via exclusion devices.

In 2006 on the Oregon Coast, plover nests that were covered by predator exclosures (n=68) had a 60 percent success rate, and unexclosed nests (n=79) had a 40 percent success rate. In 2012, the nesting success rate for exclosed nests (n = 22) was 82 percent but for unexclosed nests (n = 289) the success rate was 42 percent (Lauten et al., 2012). Fencing and public education have also been employed to help reduce inadvertent aid to potential predators. The relatively remote location of the CBNS RMA has helped to minimize the presence of scavengers and predators, most of which are encouraged or attracted by human disturbance such as campsites, garbage dumps, work sites or even footprints in the sand. Significant predators at this nesting site include corvids, coyotes, striped skunk, and feral cats. Although red fox were significant plover predators at other nesting sites, fox have not been significant predators at the CBNS RMA.

Increased foot traffic through snowy plover nesting has been shown to increase scavenger predation (Buick and Paton, 1989; Castelein, 2008). Therefore increased recreational use of the North Spit ocean beaches by off duty employees could create additional predation pressure. Food enticements associated with human presence could increase predator populations on the North Spit. Corvids, coyotes, cats and skunks are all curious, adaptable animals attracted to food waste and non-food human refuse. Increased human presence could also increase the potential for more dumping of unwanted pets in the area. An increase in the numbers of these predators could be detrimental to the recovery of snowy plover populations.

**Cumulative Effects**

Additional projects within the action area (estuarine analysis area and the Port-LNG terminal Analysis Area) are anticipated as human population growth continues in the region. Associated road and commercial development, as well as maintenance and upgrading of existing infrastructure within the Estuary, are likely to occur in the foreseeable future. For example, the Port of Coos Bay owns and operates the Charleston Marina, the Charleston Marina RV Park, and Charleston Shipyard. As a component of the Port’s economic development, the focus of the Charleston Marina Master Plan is to develop commercial fishing and seafood processing, recreational fishing and boating, tourism, and growth in the retail and commercial sectors. Other, similar economic developments in the region could occur and, if they did, could contribute to the region’s human population growth which could be detrimental to western snowy plovers within and around the Coos Bay estuary.

A standard of “reasonably certain to occur” is clarified as “those actions that are likely to occur, bearing in mind the economic, administrative, or legal hurdles which remain to be cleared”. Further, NMFS provides that “speculative actions that are factored into the cumulative effects analysis add needless complexity into the consultation process…” (51 FR 19933). No specific state or private actions have been identified within the action area that meet this standard. Further, activities described above are somewhat speculative in nature and cannot be quantified here. Therefore, a logical conclusion is that there would be no cumulative effects to western snowy plover associated with the proposed action.

Within the action area and estuarine analysis area, gradual habitat and water quality improvements may also occur over time as federal, state and private conservation and habitat enhancement efforts are implemented. There are a number of potential federally permitted projects (e.g. repair of the entrance jetties and widening and deepening of the lower portion of the Coos Bay navigation channel) that could result in cumulative effects. However, because these projects would require federal permits, their impacts would be evaluated through the federal permitting process when and if they occur.

**Critical Habitat**

The northern end of critical habitat on the North Spit, OR-10, is located approximately 2.6 miles from the LNG terminal. The proposed action would not directly or indirectly affect designated critical habitat or any of the essential physical and biological features within OR-10 that might be utilized by western snowy plovers. Cumulative effects due to increased human presence may occur within the action area but the certainty and extent of such secondary impact is speculative.

#### 4.3.2.4 Conservation Measures

Stockpiling material dredged from the slip area was going to occur as part of the import terminal project. Due to the snowy plover population on the North Spit, there was a concern that this Port stockpile area could attract snowy plover individuals from this population. To address this concern JCEP participated in the development of a number of conservation measures to reduce the potential effects on the North Spit snowy plover population due to the construction of the Project. Although the construction activity that was of the greatest concern for the snowy plover population is no longer part of the Project, JCEP will still commit to the proposed conservation measures as described in the following paragraphs.

Current management activities and use restrictions within the Coos Bay North Spit Recreation Management Area include:

- Predator management (i.e. nest exclosures, lethal and non-lethal predator removal and hazing);
- Symbolic fencing (ropes and signs installed around nesting areas);
- Habitat restoration (removal of European beachgrass, placement of shell hash, maintenance of gaps through the dunes);
- Public outreach and education provided by BLM staff;
- Monitoring of snowy plover populations; and
- Recreational use restrictions in place from March 15 – September 15 each year, including:
  - Seasonal re-routing of the foredune road;
  - Vehicles, camping, and dogs are prohibited.
  - Kite flying would be prohibited under the draft conservation plan.
- Non-prohibited recreational use (i.e. jogging, beach combing, horseback riding) is restricted to the wet sand outside of roped and signed breeding areas.

JCEP reviewed a list of conservation measures provided by the FWS, the BLM, and the ODFW through the Sediment Placement subgroup of the the Jordan Cove/Pacific Connector Interagency Task Force Working Group and agreed to provide funding as enumerated below. The funding would be provided to the entity as defined by the agencies and it would be the responsibility of the particular entity to administer the funding. It should be noted that these measures were developed partially in response to the concern that the Port stockpile site would provide potential habitat. The Port stockpile site is no longer part of the Project. JCEP is requesting that the funding of these conservation measures be used in part to contribute to other habitat mitigation requirements imposed by the ODFW.

Year 1 (when construction begins) – provide $60K for:

- Fencing (~$30K)
- Signage
- Application of shell hash
- Tree removal
- One year of maintenance – $10K

Years 2 and 3 – provide $30K (each year) for:

- Annual maintenance – $10K
- Beach grass elimination grant (minimum of $10K)
- Shell hash

Years 4 (to 2018) – provide $10K for:

- Annual maintenance

In addition to these conservation measures, Jordan Cove has agreed to mitigate Project impacts to western snowy plovers through implementation of 1) best management practices (BMPs), and 2) education and outreach programs.

Increased predator density related to increased human presence and habitat removal were identified as potential concerns related to Project construction. JCEP will address these concerns through these BMPs.

Best Management Practices

During construction and operation, the facility would be kept clear of construction debris and food wastes that could attract predators. Covered, animal proof receptacles would be provided in eating and break areas, parking lots, and at appropriate locations around the construction site. During construction the site would be policed on a daily basis to remove any food or other debris left by construction workers. During operations the facility and grounds would be regularly inspected to assure that no garbage is allowed to accumulate.

Structures associated with the LNG terminal and the Port's slip would be monitored to discourage use by avian predator species. Frequent inspections would ensure that nests are not being constructed and all nests found would be removed immediately. It is anticipated that there would be sufficient inspections and other activities mandated by safety and security requirements to keep the structures nest free. However, in the unlikely event that a nest becomes established and it is not discovered until young birds are present, the disposition of the nest would be handled in accordance with the provisions of the Migratory Bird Treaty Act.

The dredged material placement areas will be regularly policed to insure that no predator denning is occurring in the hillocks. This should not be as significant a concern as it was previously for the Port stockpile site as these placement areas will be part of the construction activities and the continuous activities will discourage use by individual birds. If necessary, nylon mesh or other exclusion fencing would be installed around the perimeter of the placement areas to prevent the establishment of coyote or skunk dens until the slopes are stabilized or constructed upon.

Education and Outreach

Surveys conducted in 2002 indicated that 76 percent of beach visitors were unaware of restrictions associated with snowy plovers (OPRD, 2007). This indicates that increased education could have a significant impact on public awareness of issues surrounding snowy plovers. Furthermore, the USFS at the Oregon Dunes National Recreation Area and the BLM staff have reported that the majority of contacted individuals are more willing to comply with beach-use restrictions after better understanding the reasons for them (FWS, 2007d).

JCEP would train all construction and operations staff on the need for snowy plover conservation; current snowy plover regulations and recreational use restrictions; and the importance of conservation measures, including: litter control, avoidance of nesting and foraging areas, keeping pets on-leash, and remaining on established roads and trails. The training program would be developed based on guidance provided in Appendix K of the 2007 Plover Recovery Plan, or would be contracted for through state/local agencies or organizations (such as the Oregon Coast Aquarium, National Park Service, Western Snowy Plover Working Team, or Oregon Coast Community College) who may have pre-existing plover education and outreach programs. Prior to implementation, the training program would be submitted for comment to members of the Western Snowy Plover Working Team.

Environmental training would also be provided to operational personnel to ensure that all personnel are aware of and comply with the management tools in place to affect the recovery and maintenance of the snowy plover population on the North Spit. Printed educational materials would be posted at the proposed facilities for the life of the LNG terminal. Materials would also be distributed to existing North Spit employers for their use in training their personnel. The types of educational materials may vary, but could include posters, table tents, maps, brochures, or factsheets. Numerous sources for existing educational materials are provided in Appendix K of the Plover recovery plan (FWS, 2007d).

Monitoring

JCEP would fund one additional entry level Wildlife Services position dedicated to snowy plover predator monitoring and control during the 36-month construction period. This staff member would be employed by Oregon Wildlife Services, which is administered by the U.S. Department of Agriculture and Animal and Plant Health Inspection Services. The specific duties of this additional staff member would be determined by Wildlife Services based on Coos Bay North Spit management needs, but would concentrate on predator management. This additional position would allow Wildlife Services to better evaluate predator densities and more quickly and effectively respond in the unlikely event that predator pressure on the CBNS increases during Project construction.

### 4.3.2.5 Determination of Effects

**Species Effects**

The Project **may affect** western snowy plovers because:

- Active nesting by western snowy plovers occurs farther than 2.5 miles from the Port-LNG terminal analysis area. However, use of the Port-LNG terminal analysis area by western snowy plovers would be limited to infrequent occurrences.

- Snowy plovers nesting on the North Spit are currently affected by human use of the area whether due to destruction of nests by dogs, inadvertent trampling or deliberate vandalism and to diverse plover responses to human presence.
- Snowy plovers nesting on the North Spit are currently affected by scavengers and predators which may be attracted to nesting areas by human actions.
- The Project would result in a large but temporary increase in people employed on the North Spit during construction (up to 2,937 construction workers) and a much smaller long-term increase of operations staff (150 permanent employees at the LNG terminal).
- It is reasonable to assume that the LNG terminal construction and operations personnel would increase recreational uses of the North Spit. Increased recreational use could result in increased plover disturbance.
- Scavengers and predators (corvids, coyotes, striped skunk, feral cats), most of which are encouraged or attracted by human disturbance such as campsites, garbage dumps, work sites or even footprints in the sand may increase effects to nesting plovers as human use of the North Spit increases.

The project is **not likely to adversely affect** western snowy plover because:

- The nesting areas on the North Spit used by western snowy plover are approximately 1.1 miles from LNG terminal construction sites. Noise at nesting areas and critical habitat due to sheet pile driving is not expected be above ambient levels;
- Jordan Cove would minimize potential secondary effects to the critical habitat PCE that identifies disturbance by humans, pets, vehicles or human-attracted predators through implementation of 1) BMPs to minimize predator density related to increased human presence and habitat removal, and 2) education and outreach programs intended to train all construction and operations staff on the need for snowy plover conservation; current snowy plover regulations and recreational use restrictions; and the importance of conservation measures, including: litter control, avoidance of nesting and foraging areas, keeping pets on-leash, and remaining on established roads and trails.

**Critical Habitat Effects**

The Project **may affect** designated critical habitat for the western snowy plover even though the northern end of critical habitat OR-10 on the North Spit is located approximately 2.6 miles from the LNG terminal.

- Essential physical and biological features of designated critical habitat includes the following PCE: sparsely vegetated areas above daily high tides that are relatively undisturbed by the presence of humans, pets, vehicles or human-attracted predators.
- Snowy plovers nesting on the North Spit are currently affected by human use of the area whether due to destruction of nests by dogs, inadvertent trampling or deliberate vandalism and to diverse plover responses to human presence.
- Snowy plovers nesting on the North Spit are currently affected by scavengers and predators which may be attracted to nesting areas by human actions.

However, the Project is **not likely to adversely affect** designated critical habitat for the western snowy plover because:

- Conservation measures provided by the FWS, the BLM, and the ODFW through the Sediment Placement subgroup of the Jordan Cove/Pacific Connector Interagency Task Force Working Group would be funded by Jordan Cove to enhance critical habitat by installing fencing, signage, applying shell hash, removing tree, eliminating beach grass and annual maintenance through 2020.
- Funding would be provided to the entity as defined by the agencies and it would be the responsibility of the particular entity to administer the funding.
- Jordan Cove would minimize potential secondary effects to the critical habitat PCE that identifies disturbance by humans, pets, vehicles or human-attracted predators through implementation of 1) BMPs to minimize predator density related to increased human presence and habitat removal, and 2) education and outreach programs intended to train all construction and operations staff on the need for snowy plover conservation; current snowy plover regulations and recreational use restrictions; and the importance of conservation measures, including: litter control, avoidance of nesting and foraging areas, keeping pets on-leash, and remaining on established roads and trails.

### 4.3.3 Marbled Murrelet

#### 4.3.3.1 Species Account and Critical Habitat

**Status**

Marbled murrelets (MAMUs) in Washington, Oregon, and California were listed as threatened under the ESA on October 1, 1992 (FWS, 1992a). The Final Rule cited loss and modification of nesting habitats, mostly by commercial timber harvest of late successional and old-growth forests, as the principal threat to the species, along with effects of coastal oil spills and gill-net fishing operations off the Washington coast (FWS, 1992a).

**Threats**

There are two components of marbled murrelet habitat that are biologically important: 1) terrestrial nesting habitat and associated stands, and 2) marine foraging habitat, including prey spawning and concentration areas. Threats to MAMU are apparent in both the terrestrial nesting environment and the marine foraging environment. Extensive harvest of late-successional and old-growth forest was the primary reason for listing the murrelet as threatened in 1992 (FWS, 1992a). In 1992, the amount of old-growth forest in western Oregon and Washington had been reduced by about 82.5 percent from pre-harvest levels. Because MAMUs utilize old-growth forests for nesting, this dramatic loss of older forested habitats is a serious threat to these birds. Harvesting within previously contiguous areas of old-growth forest causes habitat fragmentation on large and small scales. As forest fragmentation increases, the threat of habitat loss due to windthrow is likely to increase. Fire has also affected older coastal forests; however, unlike clearcut timber harvest, fire often allows diverse structural characteristics to develop in regenerating forests, such as scattered surviving old-growth trees that can be utilized by MAMUs for nesting (FWS, 1992a).

Predation is expected to be the principal factor limiting murrelet reproductive success and nest site selection (Ralph et al., 1995; Nelson and Hamer, 1995). Known predators of MAMU adults, chicks, and eggs in the terrestrial environment include great horned owls, peregrine falcon, sharp-shinned hawk, northern goshawk, bald eagle, Stellar’s jays, ravens and other corvids. Common ravens account for the majority of egg depredation (Nelson and Hamer, 1995).

Predation rates are influenced mainly by habitat stand size, habitat quality, nest placement (on the edge of a stand versus the interior of a stand), and proximity of the stand to human activity centers. Fragmentation of forested stands by timber harvest increases the potential for avian predation (FWS, 1992a). An increase in susceptibility of adults to predation can have greater impacts on MAMU populations than predation on eggs or young, as recent demographic modeling for MAMUs demonstrates (McShane et al., 2004).

Because MAMUs feed offshore, gill-net fisheries, especially for salmon, was an important mortality factor in 1992, primarily in Washington and British Columbia. New gill-netting regulations in northern California and Washington have reduced the threat to MAMUs (McShane et al., 2004). Off-shore oil spills, such as the *Exxon Valdez,* have also adversely affected MAMUs by causing direct mortality (FWS, 1992a). The 1999 oil spill associated with the grounding and wreck of the *New Carissa* on the Oregon coast near Coos Bay killed 252 MAMUs, the highest mortality for any spill during the 1993 to 2003 period (McShane et al., 2004). Oil spills and related mortality of MAMUs are believed to have remained constant since the species was listed. Although there has been a moratorium on offshore oil drilling off the California, Oregon, and Washington coastlines, there has been increased shipping traffic, including oil tankers, carrying the risk of future spills (McShane et al., 2004).

Other factors contributing to demographic threats and population viability include: 1) loss of genetic variation as a result of low population numbers and low immigration rates, 2) low potential for recolonization or recovery from local disturbances due to low immigration rates, and 3) bacterial, fungal, parasitic, and viral diseases, including potentially West Nile Virus (McShane et al., 2004).

**Species Recovery**

FWS published a recovery plan for the MAMU in 1997 for Washington, Oregon, and California (FWS, 1997). The objective of the recovery plan is to stabilize population size at or near current levels by increasing population productivity and removing and/or minimizing threats to survivorship. In the short-term, specific actions necessary to stabilize the population include maintaining occupied habitat, maintaining large blocks of suitable habitat, maintaining and enhancing buffer habitat, decreasing risks of nesting habitat loss due to fire and windthrow, reducing predation, and minimizing disturbance. Long-term conservation actions include increasing productivity and population size, increasing the amount, quality, and distribution of suitable nesting habitat, protecting and improving the quality of the marine environment, reducing or eliminating threats to survivorship, reducing predation in the terrestrial environment, and reducing anthropogenic sources of mortality at sea (FWS, 1997).

The recovery plan divided the range of the marbled murrelet into six Conservation Zones that extend inland a distance of up to 35 miles, coinciding with the “Inland Zone 1” boundary line described by the FEMAT for the NWFP: Puget Sound (Conservation Zone 1), Western Washington Coast Range (Conservation Zone 2), Oregon Coast Range (Conservation Zone 3), Siskiyou Coast Range (Conservation Zone 4), Mendocino (Conservation Zone 5), and Santa Cruz Mountains (Conservation Zone 6). FEMAT Inland Zone 1 contains large blocks of suitable habitat critical to the recovery of the marbled murrelet within California, Oregon, and Washington. The proposed action occurs within the highest density zones along Oregon’s coast (Conservation Zones 3 and 4), although the largest populations of murrelets are in Puget Sound and Strait of Juan de Fuca of Washington – Zone 1 (Huff et al., 2006). Management for

Conservation Zones 3 and 4 recommend the following: maintain designated occupied sites, minimize loss of unoccupied but suitable habitat, and decrease the time for development of new habitat. Specific recovery efforts should focus on maintenance of suitable and occupied marbled murrelet nesting habitat in BLM-administered forests (FWS, 1997).

FWS (2006e) concluded that the maintenance and/or increase of suitable nesting MAMU habitat in relatively large, contiguous blocks, whether occupied or unoccupied, would be needed to recover the MAMU, since unoccupied suitable habitat in proximity to occupied habitat could be used by dispersing MAMUs. Despite the above protection measures, an approximate 7 percent decline in the amount of available, higher suitable nesting habitat has been observed since the NWFP was implemented (1994 to 2006/2007). Stand-replacing fires on federal lands and habitat removal on nonfederal lands have been identified as the primary causes of more recent habitat loss (Raphael et al., 2011). Based on habitat modeling using 2006 habitat data, Raphael et al. (2011) estimated that there are approximately 1.4 million acres of moderately high to high suitable habitat available within the following states: Washington (802,700 acres), California (97,600 acres), and Oregon (486,200 acres).

**Life History, Habitat Requirements, and Distribution**

The MAMU is a long-lived, small seabird that spends most of its life in the marine environment, but utilizes a distinct nesting habitat type from other Alcidae (guillemots, puffins, auklets and murres), nesting primarily in coastal, old growth forests characterized by large trees, multi-storied stands, and moderate-to-high canopy coverage from Alaska to Monterey Bay, California (FWS, 2006e). They are also known to nest in mature forests with old-growth characteristics. Trees must have large branches or deformities such as high, moss-covered branches or branches with growths of dwarf mistletoe, which serve as nest platforms (Binford et al., 1975; Marshall, 1988a; Naslund, 1993; FWS, 1997). Old-growth conifers generally provide requisite conditions for MAMU nesting: 1) openings in forest canopies for nest access, 2) nest platforms on large branches or tree deformities, 3) substrate (mosses or epiphytes) for a nest cup, 4) horizontal and vertical cover at the nest site, and 5) enough height above ground to allow for “drop take-offs” and “stalled drop-in” landings (McShane et al., 2004). Generally, forests that provide suitable nesting habitat and nest trees require 200 to 250 years to develop (FWS, 2006e).

The distance inland that MAMUs breed is variable and influenced by a number of factors such as habitat availability, climate suitability, foraging range, and predation rates (McShane et al., 2004). In Oregon, MAMU nest sites and occupied stands are located as far as 30 to 40 miles from salt water (Mack et al., 2003), although most often sites are found within 12 miles of the ocean (FWS, 1996a). Social interactions may also play an important role in determining nesting location, since research has indicated that MAMUs in California and southern Oregon were less likely to occupy old-growth habitat if it was isolated from other nesting MAMUs by more than 3 miles (Meyer et al., 2002a). Murrelets do not form dense colonies, which is atypical for most seabirds; this is most likely to avoid detection by predators (Ralph et al., 1995). Also, in Oregon, MAMU occupied stands and nest sites are generally located away from high-contrast edge created by certain timber harvest practices and adjacent immature forests, most likely to reduce predation risk on eggs and juvenile MAMUs (Ripple et al., 2003). Meyer et al. (2002a) found at least a few years passed before birds abandoned fragmented forests. In northern California and southern Oregon, Meyer et al. (2002a) concluded that MAMU occupancy was most related to availability of low elevation, unfragmented old-growth forests within the fog zone that were close to highly productive marine areas. Federal lands account for the majority of suitable MAMU habitat in California, Oregon, and Washington (McShane et al., 2004).

These small seabirds spend most of their lives in the marine environment where they forage in shallow off-shore and inland saltwater areas on a variety of small fish and invertebrates, and large pelagic invertebrates (Marshall, 1988a, 1988b, and 1989; Becker, 2001). In Oregon and Washington, anchovy, sand lance, and smelt appear to be the major prey types provided to chicks (McShane et al., 2004). Murrelets generally forage within 3 miles of shore in western North America, although during the breeding season they stay closer to the coast, e.g., within 1.2 miles in Oregon (McShane et al., 2004). Courtship, loafing, molting, and preening also occur in near-shore marine waters (Nelson, 1997). The proposed action is within the zone of highest density of MAMUs along Oregon's coast, although the largest populations of MAMUs are in the Puget Sound and Strait of Juan de Fuca of Washington (Huff et al., 2006).

MAMUs are usually present year-round in California, Oregon, and Washington, whereas farther north in their breeding range, seasonal migration is common. Murrelets would migrate back to breeding grounds in the north in early to mid-April (McShane et al., 2004). Research suggests that MAMUs demonstrate site fidelity (Huff et al., 2006).

Breeding is asynchronous in the MAMU, varying regionally, although generally occurring between April and September (McShane et al., 2004; Huff et al., 2006). Both sexes share the incubation and foraging duties, usually with duty exchanges occurring at dawn. One to two days after hatching the chick will be left alone while both parents forage at sea. The chick will receive 1 to 8 meals per day, with the majority of the meals delivered in the morning, usually before sunrise. Additional meals are delivered at dusk and occasionally throughout the day. Murrelet chicks fledge from the nest 27 to 40 days after hatching, usually at dusk (McShane et al., 2004). Existing data do not provide information on how far or where fledglings disperse.

Sex ratios of juveniles and adults are equal and breeding begins when birds are 2 to 5 years old; only 1 egg is laid per breeding season (McShane et al., 2004). A substantial proportion of nests is known to fail (Nelson and Hamer, 1995); breeding success has been documented as high as 0.46 chicks per breeding pair in southern British Columbia but lower in northern California where telemetry studies documented between 0.135 and 0.324 chicks per pair (McShane et al., 2004). Such low breeding success is not expected to sustain populations in which adult survivorship ranges from 0.83 to 0.93. The mean lifespan of MAMUs is 10 years (McShane et al., 2004).

**Population Status**

The exact population size of MAMUs is not known; however, the North American population is currently thought to be about 950,000 birds, based on counts at sea (Huff et al., 2006). In the early 1990s, murrelet abundance in Washington, Oregon, and California had been estimated at 18,550 to 32,000 (Ralph et al., 1995). In the late 1990s, population survey protocols were established to provide a consistent methodology for estimating murrelet population and population trends. From 2000 to 2010, marbled murrelet population estimates within five conservation zones (Zones 1 through 5) in California, Oregon, and Washington ranged from 23,700 birds in 2002 to a low of 16,700 birds in 2010, representing a significant, average rate of decline of 3.7 percent annually (Miller et al., 2012). Within Conservation Zones 3 and 4 (which extend from northern California to Coos Bay and from Coos Bay the Columbia River), an average annual decline of 1.5 and 0.9 percent have been observed, respectively, although the trends are not significant (Miller et al., 2012). Using the data and trends provided in Miller et al. (2012) and other sources for time intervals [(2009-2010) Falxa et al, 2011, (2008) Falxa et al., 2009, (2000-2007) Marbled Murrelet Effectiveness Monitoring Program, 2008] a predicted estimate of marbled murrelets within Conservation Zones 3 and 4 by the proposed JCEP LNG terminal in-service year (2018) is 9,058 birds, but could range from 4,878 to 13,238 birds, based on 95 percent prediction intervals (estimated interval within which future observations are likely occur with a 95 percent probability, based on what was already observed and applied in the regression analysis). Figure 4.3-4 shows the declining population trend from 2000 to 2010 in Conservation Zones 3 and 4, combined, as well as projections of murrelet populations through construction of the Project (through 2017) using data from Miller et al. (2012) and other sources (see above).

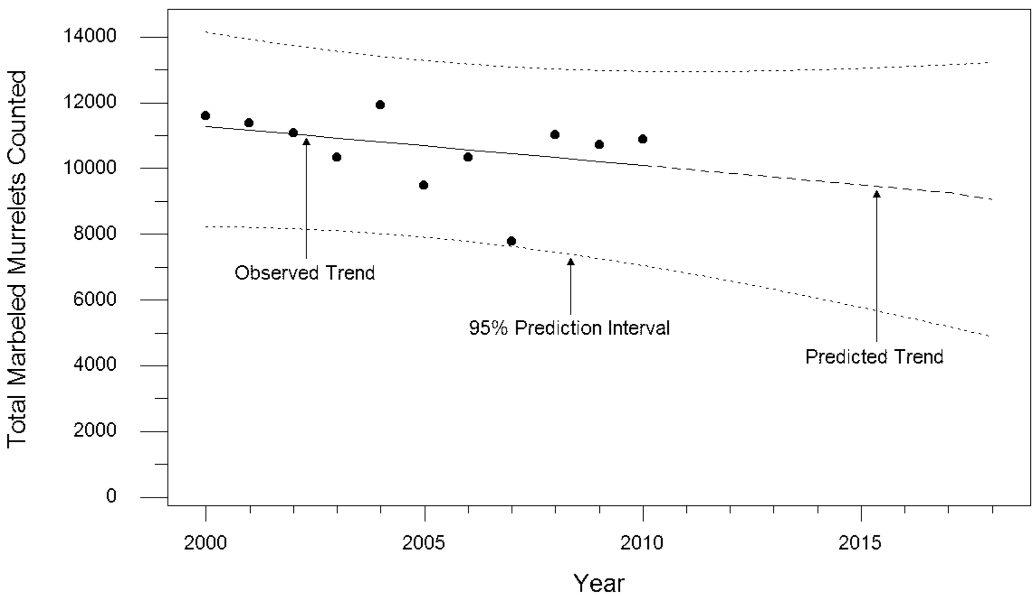

**Figure 4.3-4**
**Marbled Murrelet Population Trends from 2000 to 2010, and Predicted Estimates through Initial Operation of the JCEP LNG Project (through 2018) Based on Population Estimates Recorded for Conservation Zones 3 and 4, as well as 95% prediction intervals from 2000 through 2018 (see Miller et al., 2012)**

### Critical Habitat

Critical habitat for the MAMU was designated in Washington, Oregon, and California on May 24, 1996 and included 3,887,000 acres in 32 critical habitat units (CHUs; FWS, 1996a). On July 31, 2008, FWS proposed a revision to the 1996 critical habitat designation, proposing to remove approximately 254,070 acres in northern California and Oregon. This proposal was based on new information indicating that these areas do not meet the definition of critical habitat (FWS, 2008b). Critical habitat for the marbled murrelet was revised in 2011, removing approximately 189,671 acres in northern California and southern Oregon from the 1996 designation (FWS, 2011a). Habitat removed from the 1996 designation included areas in northern California within Inland Zone 2 that did not have historical or current survey records documenting marbled murrelet presence, and habitat in southern Oregon that is not associated with the hemlock/tanoak zone. The revised critical habitat includes approximately 3,698,100 acres in 22 CHUs within Washington, Oregon, and California.

There are two components of MAMU habitat that are biologically important: 1) marine foraging habitat, including prey spawning and concentration areas, and 2) terrestrial nesting habitat and associated stands. Because FWS is unable to define specific marine areas essential to the conservation of the species, only terrestrial habitat is considered for designation as critical habitat. Throughout the forested portion of their range, MAMU habitat use is positively associated with the presence and abundance of mature and old-growth forests, large core areas of old-growth, low amounts of edge and fragmentation, proximity to the marine environment, and increasing forest age and height, although the presence of platforms is the most important characteristic of nesting habitat (FWS, 2006e). As a result, the FWS designated the following as primary constituent elements (FWS, 2006e) that remain applicable to the revised critical habitat designated for the marbled murrelet (FWS, 2008b and 2011a): 1) forested stands containing large-sized trees, generally greater than 32 inches in diameter with potential nesting platforms at sufficient heights (≥ 33 feet); and 2) surrounding forested areas within 0.5 mile of these stands with a canopy height of at least one-half the site-potential tree height. In Oregon, trees with platforms have been greater than 19 inches diameter-at-breast-height and at least 98 feet tall (FWS, 2006e).

**NWFP Late-Successional Reserves**

Additional habitat protection for the marbled murrelet was established when the BLM and Forest Service in Washington, Oregon, and northern California adopted the NWFP in 1994. The NWFP defined the nesting portion of the marbled murrelet range into two inland zones: 1) Inland Zone 1, which is a 10- to 35-mile zone closer to the coast where the majority of murrelet nests and detections are located, and 2) Inland Zone 2 where detection data indicated only a small fraction of the murrelet population nests (Forest Ecosystem Management Assessment Team – FEMAT, 1993). Large amounts of Forest Service and BLM-administered lands were allocated for LSRs, of which the primary objective is to protect and enhance conditions of late-successional and old-growth forest ecosystems. These lands could then serve as habitat for old-growth-related species including the MAMU, while maintaining diversity associated with native species and thus providing a network of fully functioning LSRs in National Forests throughout the Pacific Northwest (USFS and BLM, 1994). The goals for LSR management are consistent with the function of CHUs to contribute to recovery of MAMUs. Management of LSRs should not only protect habitat currently suitable to MAMUs, but also promote the development of additional MAMU habitat on the landscape. A good portion of the federally designated critical habitats for MAMUs has an overlap with LSR designation.

The NWFP Standards and Guidelines also state that sites occupied by MAMUs and known northern spotted owl activity centers (100-acre areas identified by BLM and Forest Service), but occur within NWFP-designated matrix lands, are considered "unmapped LSRs" and managed as lands allocated as LSRs by the NWFP. Coos Bay and Roseburg BLM Districts also provide more specific management direction within their respective resource management plans to protect MAMUs and their habitat, including (Resource Management Plans; BLM, 1995a and 1995b): 1) protect and enhance contiguous, recruitment habitat within 0.5 mile of an occupied stand, and 2) restrict timber harvest within occupied marbled murrelet stands.

### 4.3.3.2 Environmental Baseline

**Analysis Area**

MAMU habitat can be categorized into various components, based on the life cycle needs of the species. Three main components that may be affected by Project-related activities are outlined below.

Terrestrial Nesting Analysis Area

Per direction provided in the FWS Conservation Framework (Trask & Associates, 2013 in appendix Z4), there are two components that are included in the Terrestrial Nesting Analysis Area: one for habitat removal or modification, and a second for disturbance/disruption of MAMU during the breeding season. The two components are combined together to create the Terrestrial Nesting Analysis Area. The Terrestrial Nesting Analysis Area extends inland along the Pacific Connector pipeline route to include MAMU Inland Zone 1 – MPs 1.47R to 53.73 - and MAMU Inland Zone 2 – MPs 53.73 to 75.64 and is shown in figure 4.3-5. The FWS Conservation Framework introduces MAMU suitable habitat units (SHUs) that define an area associated with each MAMU stand. The MAMU SHU consists of three elements (Trask & Associates, 2013): 1) MAMU stands considered for analysis within this BA, 2) a 300-foot buffer around each MAMU stand, and 3) federally-designated critical habitat that occurs within a 0.5-mile buffer of MAMU stands that are within 0.5 mile of critical habitat removal. Critical habitat located within the 0.5-mile buffer is an area considered important to the recovery of the species (see Trask & Associates, 2013 in appendix Z4). The 300-foot buffer incorporates an area that should maintain the integrity of the MAMU stand from windthrow or other environmental disturbances as well as provide protection from potential predation (FWS, 1997; ODF, 2004).

**Habitat Removal or modification:** This portion of the analysis area applies to all proposed action components that have the potential to remove or modify habitat, including construction of the LNG facilities and PCGP Project, as well as a 100-meter (328 feet) wide buffer along each edge of the area of habitat impact (e.g., edge of right-of-way, temporary extra work areas, new roads built for project access, etc.) in recruitment or capable habitat throughout the entire range of MAMU. It also includes MAMU SHUs that are included for analysis within this BA.

**Disturbance/Disruption (breeding season only):** The Terrestrial Nesting Analysis Area also includes all lands within 0.25 mile of the Project components (including identified access roads). Access roads considered do not include paved roads that are used regularly by the public (i.e., county roads, state highways). The size of this analysis area considers the maximum distance at which MAMUs could be harassed during the breeding season (April 1 through September 15) by noise generated from general construction, operation, and maintenance activities, smoke from burning slash piles, blasting, and/or Boeing Chinook (CH-47) or Boeing Vertol 107 (CH-46) helicopter use of the proposed action, or use of access roads (FWS, 2003b; Noise Report, appendix P).

Estuarine Analysis Area

The second component is the Coos Bay Estuarine analysis area (see figure 4.3-6) which encompasses all estuarine waters (and substrates) that are within the estuary between the North Jetty and South Jetty at the Coos Head entrance to the bay. The Estuarine analysis area includes 1) operational activities by LNG tankers entering and exiting Coos Bay, 2) approximately 3.1 miles downstream from the proposed LNG Terminal to a point 2.2 miles upstream from that site (distances were estimated for potential worst-case dispersion of turbidity, as provided by Moffatt and Nichol, 2006a), and 3) the 2.45-mile within-estuary route of the Pacific Connector pipeline after leaving the Weyerhauser property at MP 1.7R, crossing Haynes Inlet to where the pipeline emerges from the estuary at MP 4.1R.

EEZ Analysis Area

The third area which could be affected by the proposed action is the EEZ (see figure 4.2-1), which extends 200 nautical miles offshore. Within the analysis area, effects to the MAMU would be associated with LNG tankers which are assumed to transect the EEZ perpendicularly - east and west - as they approach and depart from Coos Bay (see the discussion above under Section 4.2.1, Blue Whale).

**Species Presence**

The proposed action occurs within Marbled Murrelet Inland Zone 1 and Marbled Murrelet Inland Zone 2; marbled murrelet nesting has been documented within the two inland zones in and near the Terrestrial Nesting Analysis Area. MAMU nesting behavior is cryptic, however, resulting in few nests being located by biologists. As a result, documented behaviors assumed to be associated with nesting, such as MAMUs flying into the canopy or circling very close above the canopy are used to infer nesting activity and thus occupancy of MAMU stands. Since these occupied behaviors are not detected during every visit to a stand, the Pacific Seabird Group inland MAMU survey protocol (Mack et al., 2003) recommends several visits to a stand that contains potential MAMU nest trees (up to 9 per year) for a duration of two years in order to determine with some certainty that a timbered stand is occupied or unoccupied. When occupied behavior is identified, the managing agency delineates the occupied stand and provides a master site number (MSNO). That stand is then considered "occupied" in perpetuity (Mack et al., 2003).

Pacific Connector obtained GIS data layers from Coos Bay and Roseburg BLM Districts (BLM, 2006; Espinosa, 2007 and 2008; Guetterman, 2007 and 2008a, b; NSR, 2012) to determine areas with known MAMU occupancy. Additionally, Pacific Connector requested murrelet survey data from private landowners within the project area; in 2008 Weyerhaeuser Timber Company provided Pacific Connector GIS files with areas of known MAMU occupancy and these areas have been incorporated into this BA. Within Marbled Murrelet Zones 1 and 2 along the Coast Range Province a total of 341 occupied MAMU stands were delineated, of which 261 were located within the Coos Bay and Roseburg BLM Districts. Overall, 46 occupied MAMU stands are considered for analysis within this BA. With the exception of two occupied stands identified/delineated on private timber lands, all occupied stands occur on BLM-administered lands within either Coos Bay or Roseburg BLM Districts, including 10 stands identified during surveys conducted by Pacific Connector in 2007 and 2008, and six stands identified during surveys conducted by Pacific Connector in 2013. See Pacific Connector survey details, below.

Pacific Connector Marbled Murrelet Surveys (2007/2008 and 2013/2014)

To determine known or presumed species presence within the proposed PCGP Project area, Pacific Connector contracted surveyors [Siskiyou BioSurveyors, Inc. (SBS) and Rogers & Associates (R&A)] to conduct two-year surveys within habitat containing suitable nesting structures as described by Mack et al. (2003).

Prior to surveys in 2007, habitat within 50 miles of the coast and within 0.25 mile of the proposed action was assessed by Richard Brock, Botanist and GIS Specialist for SBS, to determine all potential suitable MAMU nesting habitat within the analysis area. This analysis determined where MAMU surveys should be conducted for the PCGP Project. Delineation of suitable habitat was accomplished using a combination of aerial photographs (circa 2006), BLM FOI GIS data, local knowledge of on-the-ground habitat, and LIDAR that was flown in a corridor including 0.25 mile on either side of the proposed PCGP Project. As the proposed route changed, habitat was reassessed and included in survey efforts, if necessary.

A LIDAR data set was generated that displayed all trees with a canopy height greater than 107 feet. Polygons were derived from these data to indicate possible suitable MAMU nesting habitat and/or trees. Within 20 miles of the coastline a single tree qualified as potential nesting habitat (see SBS, 2008a). Further inland, clusters of 6 or more large trees within a floating 5 acre window were considered potential habitat. These polygons were reviewed using aerial photos and BLM FOI data to determine which stands were apparent habitat and which were uncertain habitat that required on-the-ground examination (referred to as "gray habitat"). To represent gray habitat, separate polygons were created. Areas with potential suitable habitat identified within 0.25 mile of the proposed Project were then plotted on maps.

**Initial Surveys – 2007/2008:** In areas where permission to survey had been granted, R&A conducted on-the-ground surveys to determine whether timber stands exhibited the characteristics of nesting habitat outlined in the Pacific Seabird Group protocol (Mack et al., 2003). Overall, 65 of 118 identified stands were examined, of which 46 of 65 (71 percent) timber stands and/or trees were determined not to exhibit the necessary nest tree characteristics and were removed from the list of stands/acreage to be surveyed for this Project. Two of these areas had been harvested in 2007 or 2008. In stands that exhibited potential nesting habitat and had landowner survey permission, R&A initiated the Pacific Seabird Group two-year survey protocol to detect occupied MAMU behavior during the MAMU nesting period from May 1 through August 5, 2007 (see Mack et al., 2003). Second year surveys were conducted in 2008 in stands that had survey permission in 2007 but did not have occupied behavior detected. Also in 2008, where ground-truthing identified suitable nesting structures in timbered stands within one mile of helicopter use and trench-blasting sites, first year surveys were conducted. Surveys were not conducted in 52 stands due to access denial by landowners of the proposed route as analyzed in the 2009 FERC FEIS. Additionally, ground-reconnaissance and/or protocol surveys were not conducted in 20 stands that were delineated in two reroutes analyzed in the final EIS (WC1A – upland Coos Bay route and Southern Route Alternative-R).

MAMU survey stations were set up on property where access was allowed and timber stands exhibited the characteristics of nesting habitat outlined in the Pacific Seabird Group protocol (Mack et al., 2003). Survey stations were positioned in such a manner that all of the potential habitat in a given stand could be seen, and that any MAMUs present would be able to be seen against the sky. Overall, R&A documented MAMU occupied behavior in 10 stands. Nine stands surveyed in 2007 and 2008 did not exhibit occupied behavior, and therefore were considered unoccupied.

Identified trees and/or timbered stands with potential suitable habitat located within the Terrestrial Nesting Analysis Area had either 1) one year of surveys conducted in 2008 and no occupied behavior detected (GS05), or 2) did not have survey access permission. Potentially suitable MAMU habitat that remains unsurveyed because of landowner access denial or incomplete surveys (e.g., only one year completed or no surveys) are considered "presumed occupied" for this biological assessment (see "Unsurveyed Suitable Habitat" in PC Trask & Associates, 2013 in appendix Z4).

**Additional Surveys – 2012/2013/2014:** In 2012, Pacific Connector reviewed 2012 aerial photography to determine if the 2007/2008 "presumed occupied" stands within the current Terrestrial Nesting Analysis Area were still forested; three had been harvested and removed for consideration as presumed occupied stands. Five other areas considered in 2007 that were determined not to provide suitable nesting habitat for the murrelets had also been harvested since 2006.

Also in 2012, where permission was received within the WC1A – upland Coos Bay route and Southern Route Alternative-R, R&A conducted on-the-ground surveys to determine whether timber stands exhibited the characteristics of nesting habitat outlined in the Pacific Seabird Group protocol (Mack et al., 2003). Twelve "stands" were ground-truthed in the WC1A Upland Coos Bay route and no suitable nesting habitat was observed (R&A, 2012); subsequently the 12 stands have been removed for consideration as "presumed occupied" for analysis in this BA. In the Southern Route Alternative-R one stand (MAMU Stand ALTR-A) on BLM-managed lands was determined to provide suitable nesting habitat for marbled murrelets and was surveyed in 2013 (see below), whereas three other stands did not provide suitable nesting structures for marbled murrelets and were removed from consideration as "presumed occupied" for this BA (R&A, 2012). Five stands within the 2009 FERC FEIS proposed reroutes that were not permitted survey access remain as "presumed occupied" stands for analysis in this BA.

Pacific Connector initiated additional surveys in suitable marbled murrelet nesting habitat where surveys were permitted to determine presence or absence of occupied behavior in accordance with the Pacific Seabird Group two-year survey protocol for marbled murrelets (see Mack et al., 2003). Surveys included five areas surveyed in 2007 and 2008 that did not detect occupied behavior (unoccupied stands: B02, B03, B07, B13, and B14), as well as three areas where suitable nesting habitat is present, but surveys in 2007 and/or 2008 did not occur [i.e., Southern Route Alternative-R (ALTR-A stand), Weaver Ridge reroute (EAR 46.51_A), and an area that received one year of surveys in 2008 (GS05)]. These areas are all located on BLM-administered lands. Six of the eight stands surveyed in 2013 were determined to be occupied by MAMU (R&A and SBS, 2014), including three stands that were considered "unoccupied" from surveys conducted in 2007 and 2008 (B02, B03, and B07). Coos Bay and Roseburg BLM Districts were provided the appropriate survey results; each Distirict has delineated the occupied stands and provided an MSNO for each MAMU stand that are included in analysis for this BA. Both the survey stand numbers and the MSNO provided by each BLM District for the stands documented in 2013 are included in this BA (B02 = C1080, B03 = C3163, B07 = C3165, GS05 = C3164, ALTR-A = R3036, and EAR 46.51_A = R3035). [Note: the private portion of "presumed occupied" stand ALTR-A was not surveyed and remains "presumed occupied]. Surveys will continue in the other two unoccupied stands (B13 and B14) in 2014. If additional "presumed occupied" stands receive permission to be surveyed and exhibit suitable nesting habitat, full protocol surveys will be initiated in 2014 and continue through 2015. When additional information on the status of these potential trees and/or timbered stands is acquired, Pacific

Connector would advise the FWS of the updated status, including whether it is determined to have suitable nesting structures, determined to be occupied or unoccupied, or determined to not be suitable habitat for nesting MAMUs.

One large "presumed occupied" (G50) received permission to survey in 2013; ground-truthing stand structures determined that no suitable nest trees were present (R&A and SBS, 2014). This presumed occupied stand has been subsequently removed from this BA analysis.

<u>Additional Stands Delineated – No Survey</u>

Additional direction was provided by the FWS and BLM Districts (Roseburg and Coos Bay) to identify and include additional unsurveyed suitable habitat that was not previously identified along PCGP proposed existing access roads, and additional stands that may be within 0.25 mile of construction activities, but not within 100 meters (328 feet) of timber removal (see survey guidance provided by FWS in SBS, 2008a). On BLM-administered lands, additional "presumed occupied" stands were delineated using MAMU-specific GIS layers provided by Coos Bay and Roseburg BLM Districts, in conjunction with BLM FOI data, a Pacific Connector delineated vegetation layer, and previous Pacific Connector ground-truthing survey efforts. Additional stands were delineated on private lands where the new MAMU habitat model (see below) had a dense grouping of modeled "value 4" pixels ("highest suitability") and forested habitat was present in an obvious stand that could be delineated, and which had not been harvested; 2012 aerial photography and a Pacific Connector GIS vegetation layer was used to help delineate these areas. The additional "presumed occupied" stands on BLM-administered and private lands were either provided a "PO" and sequential number from west to east along the proposed PCGP pipeline, or an existing access road name from the PCGP Project (i.e. EAR and MP range) plus a letter if within close proximity to a proposed existing access road. These areas will not be surveyed but Pacific Connector will assume they are occupied (i.e., presumed occupied stand) for analysis within this BA, particularly in relation to disturbance from the proposed action.

<u>Marbled Murrelet Stands Considered for Analysis within the Terrestrial Nesting Analysis Area</u>

Overall, 173 MAMU stands have been included for analysis within this BA. MAMU stands were included if located within 0.25 mile of the proposed action, including 0.25 mile from PCGP proposed existing access roads (excluding paved public roads used regularly by the public – i.e., county roads or state highways). Marbled murrelet stands were also included for analysis if located within 0.5 mile of federally-designated critical habitat that would be affected by the proposed action. Forty-six occupied stands (as defined by occupied behavior) are considered for analysis, including 16 stands detected during survey efforts by Pacific Connector within the proposed Project area in 2007, 2008, or 2013. Twenty-five occupied stands are only included because they are within 0.25 mile of proposed existing access roads, including two stands determined to be occupied during PCGP 2007/2008 MAMU survey efforts. Three stands analyzed in this draft BA are considered "unoccupied" – either surveyed in 2007/2008 (one stand) or surveyed again 2013 (two stands) with no occupied behavior detected. The other 124 stands included for analysis in this BA are "presumed occupied" - they either have had survey permission denied by the private landowner (36 stands) or have been recently incorporated into the analysis based on new information (BLM GIS data layers and MAMU habitat model) and direction from BLM and FWS (88 stands).

The number of "presumed occupied" stands present within the analysis area is most likely an overestimation. Pacific Connector does not expect presumed occupied stands between MPs 8.0R and 30.0 to have suitable habitat present based on 1) on-the-ground surveys adjacent to those stands with no suitable nesting habitat (see maps included in appendix Z1), 2) location of those identified stands within narrow riparian buffers surrounded by clear-cuts and/or residences, and/or 3) proximity of presumed occupied stands greater than 3.0 miles from known occupied stands. Presumed occupied stands with an asterisk next to their “Site ID” in tables Q-1 and Q-2 in appendix Q identify stands that exhibit at least one of the factors listed above. Additionally, FWS (2006e) indicated that generally, forests that provide suitable nesting habitat and nest trees require 200 to 250 years to develop. The majority of stands identified as “presumed occupied” do not occur in old-growth forest.

Table 4.3.3-1 below summarizes the number of MAMU stands (and status) considered for this analysis within each Marbled Murrelet Zone, by landowner in the Terrestrial Nesting Analysis Area. The table also tallies the number of stands that are included because of its proximity to proposed habitat removal and/or access roads for each Zone. Table Q-1 in appendix Q provides details for each stand, including location in relation to proposed action, distance from proposed action including access roads, landowner, land allocation, and overall acres in stand by Marbled Murrelet Inland Zone. Figure 1 in appendix Q shows an overview of occupied, unoccupied, and presumed occupied stands within the Analysis Area (occupied stands provided by Coos Bay and Roseburg BLM Districts, as well as North State Resources (NSR, 2012) are also depicted beyond the analysis area).

**Table 4.3.3-1**
**Summary of Marbled Murrelet Occupied, Unoccupied, or Presumed Occupied Stands within the Terrestrial Analysis Area that Will Be Analyzed in this Biological Assessment**

| Status of MAMU Stand [1] | Landowner | Marbled Murrelet Inland Zone 1 | | | Marbled Murrelet Inland Zone 2 | | | Total | | |
|---|---|---|---|---|---|---|---|---|---|---|
| | | Stands in Zone 1 | Habitat Affected [2] | Access Roads [3] | Stands in Zone 2 | Habitat Affected [2] | Access Roads [3] | Total Stands | Habitat Affected [2] | Access Roads [3] |
| Occupied | Federal | 44 | 20 | 44 | 1 | 1 | 1 | 45 | 21 | 45 |
| | Non-Federal | 1 | 0 | 1 | 0 | 0 | 0 | 1 | 0 | 1 |

| Presumed Occupied Total | | 116 | 58 | 109 | 8 | 5 | 7 | 124 | 63 | 116 |
| Overall Total | Federal | 116 | 35 | 103 | 11 | 8 | 10 | 117 | 43 | 113 |
| | Non-Federal | 49 | 44 | 52 | 0 | 0 | 0 | 56 | 44 | 52 |
| Overall Total | | 162 | 79 | 153 | 11 | 8 | 10 | 173 | 87 | 165 |

[1] “Occupied”: delineated stand that has identified occupied behavior during protocol surveys; “Unoccupied”: forested stand that provides suitable MAMU nesting structures but no occupied behavior has been detected during survey efforts; “Presumed Occupied”: forested stand has not been surveyed and habitat present is expected to provide suitable nesting structures.

[2] Habitat Affected considers MAMU stands located within 0.25 mile of all proposed disturbance, including uncleared storage areas (UCSAs), as well as stands within 0.5 mile of federally-designated critical habitat removal.

[3] Access roads considered does not include paved roads that are used regularly by the public (i.e., County Roads, State Highways). MAMU stands are included if the stand is within 0.25 mile of a proposed access road.

Table Q-1 in appendix Q provides details for each stand, including location in relation to proposed action, distance from proposed action including access roads, landowner, land allocation, and overall acres in stand by Marbled Murrelet Inland Zone.

Marbled Murrelet Presence within the Estuarine and EEZ Analysis Areas

Because occupied MAMU stands have been documented within the proposed Terrestrial Nesting Analysis Area (see table 4.3.3-1), and MAMUs have been recorded on the National Audubon Society's Christmas Bird Counts in the Coos Bay count circle that occurs within the delineated Estuarine and EEZ Analysis Areas (see available map at: http://audubon.maps.arcgis.com/apps/OnePane/basicviewer/index.html?appid=5c9c077ced02489587f4606488045a6b), MAMUs are expected to forage within the Project's Estuarine and EEZ analysis areas throughout the year. The most MAMUs reported in any survey were 16 counted during 95 observation hours (0.2 counted per hour) in 1992. On average, MAMUs have been recorded 3.1 times per count since 1977.

**Habitat**

The proposed action traverses two MAMU habitat inland zones designated by FEMAT. Inland Zone 1 encompasses a strip of land along the coast approximately 0 to 35 miles from the coast, and Inland Zone 2 includes areas along the western fringe of the species' range, about 35 to 50 miles from the coast. The most suitable habitat is expected to occur within MAMU habitat Inland Zone 1, and recent surveys provide evidence to support this (Raphael, 2006). The proposed action also occurs within Conservation Zones 3 and 4 as described by the MAMU Recovery Plan (FWS, 1997). Figure Q-1 in appendix Q provides the location of each MAMU Inland Zone and Conservation Zone within the Terrestrial Nesting Analysis Area.

Three categories of MAMU habitat have been identified within 1.5 miles of the proposed action within marbled murrelet Inland Zones 1 and 2: suitable nesting habitat, recruitment habitat, and habitat capable of becoming suitable nesting habitat (capable habitat). The following definitions were considered to classify MAMU habitat considering direction provided in several documents (Trask & Associates, 2013; FWS, 1996; BLM, 1995a and 1995b) to provide standardization of terms for habitat categories: 1) suitable habitat includes coniferous forest that provides structures, or may provide structures and/or a forested buffer necessary for nesting marbled murrelets, and generally consist of late seral forest; 2) recruitment habitat is coniferous forested stands greater than 60 years of age that do not provide suitable nesting structures for marbled murrelets and could become suitable habitat within 25 years; and 3) capable habitat is coniferous forested stands from 0 to 60 years of age that could become suitable habitat.

MAMU habitat within the Terrestrial Nesting Analysis area was developed in four steps, building upon each layer. Suitable nesting habitat was identified first, then recruitment; all other coniferous forest not included in the previous two categories was considered capable habitat. Non-forested habitat and deciduous forest was considered non-capable. The vegetation file developed for the PCGP Project was used as the base file. Vegetation cover types were digitized with GIS from 2012 aerial photography and delineated based on the predominate vegetation physiognomy (e.g., trees, shrubs, herbaceous vegetation) and the dominant species present. Forested vegetation was assigned an age class using available GIS data (BLM Forest Operations Inventory [FOI] database, Gradient Nearest Neighbor [GNN] raster data set [developed by Landscape Ecology, Modeling, Mapping & Analysis - LEMMA: http://www.fsl.orst.edu/lemma, and Moeur et al., 1996) LANDSAR late successional old-growth coverage. Age class was also reviewed by BLM and Forest Service biologists on their respective lands with specific focus on verifying/classifying late seral forest stands (Habitat Quality subtask group, 2007 through 2008), as well as verified/revised by Siskiyou BioSurvey, Inc. who conducted biological surveys for Pacific Connector. Age class for forested stands was categorized within five age ranges: clearcut (0-5 years), regenerating (5-40 years), mid-seral

(40-80 years), late successional (80-175 years), and old-growth (175+ years) (Lint, 2005). Areas of regenerating forest that appear to be "clearcut" on the aerial photography were identified as "early-regenerating" forest. The Pacific Connector vegetation file extends at least 100 meters (328 feet) from the proposed action and consists of smooth polygons following obvious vegetation breaks. Outside of the PCGP vegetation layer and outside BLM-managed lands, the MAMU habitat file becomes more pixelated (25 meter by 25 meter squares) and less refined because it relied on MAMU habitat modeled from Raphael et al. (2011) (see Habitat Modeling, Pacific Northwest Research Station below).

Table 4.3.3-2 provides a summary of MAMU habitat developed for the proposed action within the Terrestrial Nesting Analysis Area by MAMU Inland Zone, Recovery Plan Conservation Zone, and general landownership. Also, available habitat within the Terrestrial Nesting Analysis Area by habitat located within SHUs and outside of SHUs.

[1] Federal Landowners include Coos Bay BLM and Roseburg BLM Districts, Non-Federal Landowners include private and State lands.
[2] Suitable Habitat: generally late-seral forested stands that provide or are presumed to provide nesting structures for marbled murrelet based on modeling and other available GIS data.
[3] Recruitment Habitat: forested land not currently suitable for marbled murrelet nesting that may be capable of becoming suitable marbled murrelet habitat within the next 25 years (FWS, 2006e; BLM, 1995a and b); generally forested stands 60 years or greater (Trask & Associates, 2013).
[4] Capable Habitat: forested land that has the capability of becoming suitable nesting marbled murrelet habitat, generally includes forest stand age 0 to 60 years (Trask & Associates, 2013).

Estimate of Suitable Habitat

Suitable habitat was incorporated into the MAMU habitat GIS file first. For this BA, suitable habitat includes all habitat that occurs within BLM delineated occupied stands (BLM, 2006; Espinosa, 2007 and 2008; Guetterman, 2007 and 2008a, b; NSR, 2012) and private occupied stands (e.g., Weyerhaeuser), regardless of habitat type and age class (in some instances, stands have been delineated to include younger forest). Potential suitable habitat identified by SBS for MAMU surveys within the PCGP Project area that have not been field-verified as suitable (see species presence section, above) were also included in the MAMU habitat file as suitable habitat. Based on the vegetation file developed for PCGP, these stands include coniferous forest ranging from mid-seral to old-growth. On BLM lands, additional suitable habitat was incorporated into the MAMU habitat file where GIS data provided by Coos Bay and Roseburg BLM Districts identified suitable habitat based on BLM FOI coverage (includes coniferous stands at least 80 years of age); these areas correspond to presumed occupied and unoccupied stands described above for species presence. On non-federal lands, additional suitable habitat was identified using a MAMU habitat model developed by the Pacific Northwest Research Center (see Raphael et al., 2011). Within 0.25 mile of the proposed action, areas modeled with "highest" suitable habitat potential (value 4 in the Raphael et al., 2011 model) and where obvious late seral stands were present (2012 aerial photography and Pacific Connector GIS vegetation layer) were included in the MAMU habitat file developed for the proposed action. Additional description of the MAMU habitat model developed at the Pacific Northwest Research Center is included, below. Suitable habitat included in the MAMU habitat GIS file consists of coniferous forest in the following age classes: old-growth (175+ years), late successional (80 to 175 years), and mid-seral (40 to 80 years).

Based on the proportion of suitable habitat known to be occupied by nesting MAMUs either as surveyed per protocol (see Mack et al., 2003), or expected to be occupied based on survey history in the area and the application of an occupancy index to unsurveyed areas, FWS estimated that approximately 408,621 acres of suitable MAMU habitat (51 percent of reported suitable habitat) are likely occupied in Oregon (McShane et al., 2004). Also, 97 percent of the stands identified by SBS that were potential MAMU nesting habitat were determined to be non-suitable nesting habitat after on-the-ground habitat surveys by R&A in 2007; most of those areas are uniform 40-60 year old stands. Therefore, the estimates of suitable nesting habitat included in the MAMU habitat file and summarized in table 4.3.3-2, are probably an over-estimation.

<u>Estimate of Recruitment Habitat</u>

Recruitment habitat was included into the MAMU habitat file next and only included areas not considered "suitable habitat", as described above. Delineation of recruitment habitat relied on several sources: Roseburg BLM District's MAMU-specific GIS layer, BLM FOI database, SBS habitat delineation for the PCGP Project and on-the-ground survey results, Pacific Connector's delineated vegetation GIS file, Pacific Northwest Research Center's MAMU habitat model developed by Raphael et al. (2011), and NRF and High NRF modeled for the NSO habitat model (discussed below in Section 4.3.4, for NSO).

First, areas that were identified as potential suitable habitat (gray habitat) based on LIDAR and aerial photography by SBS in 2007/2008/2013 but had subsequently been ground-truthed and determined to not provide suitable nesting structures were included as "recruitment" habitat. Next, habitat was identified as recruitment habitat on BLM-administered lands where forest had not been recently harvested (review of 2012 aerial photography) and 1) coniferous forest and mixed forest habitat was 60 years or greater (BLM FOI data, 2012), and/or 2) where Roseburg BLM District's MAMU-specific GIS layer identified the area as recruitment habitat.

On non-federal lands not included in the previous steps, the Pacific Connector vegetation GIS file was used to identify additional recruitment habitat. All coniferous late successional and old-growth forest not previously incorporated into the MAMU habitat GIS file as suitable habitat were included as recruitment habitat. Mid-seral habitat included in the vegetation GIS file located on non-federal lands and not previously identified as suitable habitat was included as "recruitment habitat." Outside of Pacific Connector vegetation GIS file, recruitment habitat was incorporated in the MAMU habitat file where Raphael et al. (2011) pixel values were classed as "moderately high" potential to be suitable MAMU habitat (pixel value 3). Recruitment habitat included in the MAMU habitat GIS file consists of coniferous forest in the following age classes: old-growth (175+ years), late successional (80 to 175 years), and mid-seral (40 to 80 years).

Estimate of Capable Habitat

Capable habitat incorporated into the MAMU habitat GIS file includes all other coniferous forested habitat not previously identified as suitable or recruitment habitat (see above). This includes coniferous forest areas that have been clearcut and are regenerating. On BLM-administered lands, mid-seral coniferous forest between 40 and 60 years of age not previously included as suitable or recruitment habitat was also included as capable in the MAMU habitat file. Capable habitat included in the MAMU habitat GIS file consists of coniferous forest in the following age classes: mid-seral (40 to 60 years), regenerating (5 to 40 years), and clearcut (0 to 5 years).

Non-Capable Habitat

This category includes all areas that are non-forested habitat (i.e., waterbodies, agriculture fields, existing rights-of-ways and corridors, grasslands/shrublands) and deciduous forest, as delineated within Pacific Connector's vegetation GIS layer.

Habitat Modeling, Pacific Northwest Research Station

Modeling of potential suitable MAMU nesting habitat has been generated by the Pacific Northwest Research Station (see Raphael et al., 2006; General Technical Report PNW-GTR-650) with the objective to estimate a baseline amount and distribution of potential nesting habitat at the inception of the NWFP in 1994 (USFS and BLM, 1994). Raphael et al. (2006) used vegetation data derived from satellite imagery to model MAMU habitat suitability to establish the habitat baseline. Raphael et al (2011) updated the baseline model focusing on results of a new approach for estimating baseline potential nesting habitat, and on changes to date from the original 2006 baseline. To model relative suitability of MAMU nesting habitat, Raphael et al. (2011) used recently developed habitat suitability modeling software called Maxtent (Phillips et al. 2006, Phillips and Dudík 2008) which estimates probabilities of occurrence at unobserved locations by using information at the observed locations and assuming as little as possible about background sites for which there is not information (Baldwin 2009). The resulting model included four habitat classes: highest (value 4), moderately high (value 3), marginal (value 2), and lowest (value 1).

**Critical Habitat**

The proposed action coincides with MAMU designated critical habitat unit OR-06-d (FWS, 2011a). CHUs OR-06-b, OR-06-c, and OR-06-d are within the Terrestrial Nesting Analysis Area located on lands of the Coos Bay and Roseburg BLM Districts (FWS, 2011a). Habitat modeled for the proposed action (see discussion, above) was intersected with each CHU to determine the amount of MAMU habitat available within the Terrestrial Nesting Analysis Area and CHU. Table 4.3.3-3 summarizes the MAMU habitat associated with the CHUs, and identifies known occupied stands within each CHU (both within the entire CHU and CHU within the Terrestrial Nesting Analysis Area). Primary constituent elements (PCE) are included in table 4.3.3-3 and below:

- PCE 1 includes individual trees with potential nest platforms, including supporting trees delineated as occupied or suitable (comparable to suitable habitat);

- PCE 2 includes forest lands of at least one half site-potential tree height, within 0.5 mile of individual trees/suitable habitat stand that are recruitment or capable habitat (comparable to recruitment habitat) not currently suitable for marbled murrelet nesting that may be capable of becoming suitable marbled murrelet habitat within the next 25 years (FWS, 2006e; BLM, 1995a and b); generally forested stands 60 years or greater (Trask & Associates, 2013).

Suitable MAMU nesting habitat within the proposed analysis area is considered equivalent to the MAMU critical habitat designation primary constituent element 1 for analysis within this BA – individual trees [and delineated stands] with potential nesting platforms. Recruitment habitat (or primary constituent element 2 is defined by FWS (2011a) as coniferous forested land not currently suitable for marbled murrelet nesting that may be capable of becoming suitable marbled murrelet habitat within the next 25 years. FWS (2011a) considers all forests within 0.5 mile of an occupied stand containing trees with at least one-half the site-potential tree height of the occupied stand to be recruitment habitat. Recruitment habitat is essential to provide and support suitable nesting habitat for successful reproduction of the marbled murrelet. Benefits of this habitat include reducing the differences in microclimates associated with forested and unforested areas, reducing the potential for windthrow during storms, and providing a landscape that has a higher probability of occupancy by marbled murrelets. FWS (Trask & Associates, 2013 – personal communication) has requested that for this BA that PCE2 consider recruitment and capable habitat as defined above in the habitat section.

Only 8,504 acres, or 11.3 percent of 75,334 acres available within MAMU CHUs OR-06-b, OR-06-c, and OR-06-d, occur within the proposed terrestrial nesting analysis area, of which approximately 4,490 acres (52.8 percent of the analysis area) are presumed to provide suitable nesting habitat for marbled murrelets (see table 4.3.3-3). The other portion of CHUs are comprised of recruitment habitat and forested stands capable of becoming suitable habitat (approximately 10.7 percent and 15.5 percent of available CHU in the terrestrial analysis area, respectively). The majority of CHU within the analysis area is located on federal lands designated as LSRs. The overlap of CHU with LSR affords a greater degree of protection to the designated critical habitat as the NWFP protections for LSRs are automatically imposed on those LSR acres that are found within a CHU. Thus, marbled murrelets located within these land allocations also benefit from increased protection. Eleven occupied marbled murrelet stands occur within CHU OR-06 (b, c, and d) within the proposed terrestrial analysis area, including four occupied stands detected during Pacific Connector survey efforts in 2007, 2008, and 2013. Twenty-eight other stands have also been delineated as presumed occupied stands within designated critical habitat in the terrestrial analysis area: OR-06-b (one stand), OR-06-c (three stands), and OR-06-d (24 stands; one unoccupied stand, too). Table Q-1 in appendix Q provides land allocations, including CHU that each MAMU stand (occupied, unoccupied, and presumed occupied) analyzed within this BA is associated, if applicable.

<u>NWFP Late Successional Reserves</u>

LSR RO261 is a large LSR complex (70,611 acres) within BLM-managed checkerboard lands on Coos Bay and Roseburg BLM Districts. Approximately 8,526 acres (12.1 percent) occur within the Terrestrial Nesting Analysis Area, of which 4,543 acres (53.3 percent) provides suitable nesting habitat, 908 acres (10.6 percent) provides recruitment habitat, and 2,988 acres (35.0 percent) is comprised of forested areas capable of becoming suitable habitat. Table 4.3.3-4, below provides a summary of MAMU habitat that occurs within LSR RO261 in the Terrestrial Nesting Analysis Area.

## Table 4.3.3-3

[1] Suitable Habitat: generally late-seral forested stands that provide or are presumed to provide nesting structures for marbled murrelet based on modeling and other available GIS data.

[2] Recruitment Habitat: forested land not currently suitable for marbled murrelet nesting that may be capable of becoming suitable marbled murrelet habitat within the next 25 years (FWS, 2006e; BLM, 1995a and b); generally forested stands 60 years or greater (Trask & Associates, 2013).

[3] Capable Habitat: forested land that has the capability of becoming suitable nesting marbled murrelet habitat, generally includes forest stand age 0 to 60 years (Trask & Associates, 2013).

Note: Unmapped LSRs include marbled murrelet occupied stands that occur on matrix lands (included in BLM and Forest Service LUA coverage, as well as stands determined to be occupied during PCGP survey efforts in 2007, 2008, and 2013 that occur on NWFP matrix lands but were not included in the LUA coverage) and BLM delineated known northern spotted owl activity centers on NWFP matrix lands.

Additionally, approximately 4,543 acres of unmapped LSRs occur within the terrestrial nesting analysis area, including 4,825 acres associated with occupied marbled murrelet stands and 127 acres of unmapped LSRs associated with known owl (NSO) activity centers (KOAC) located on Matrix lands. MAMU stands that have been determined to be occupied during PCGP survey efforts in 2007, 2008, and 2013 that occur on Matrix lands have also been included in the total of "unmapped LSR". As expected, the majority of unmapped LSRs provide suitable nesting habitat since the majority of unmapped LSRs within MAMU Inland Zones 1 and 2 are occupied murrelet stands that occur on NWFP matrix lands (see table 4.3.3-4).

Much of the LSRs (and unmapped LSRs) within the provincial analysis area overlap the FWS designated critical habitat units for MAMU. The overlap of LSRs with federally designated MAMU critical habitat affords a greater degree of protection to the MAMU and its critical habitat as the NWFP protections for LSRs are automatically imposed on those LSR acres that are found within a CHU. Thus, MAMUs located within these land allocations also benefit from increased protection. Table Q-1 in appendix Q provides land allocations, including LSRs and unmapped LSRs that each MAMU stand (occupied, unoccupied, and presumed occupied) analyzed within this BA is associated, if applicable.

### 4.3.3.3 Effects by the Proposed Action

### Direct Effects – EEZ and Estuarine Analysis Areas

MAMUs that forage offshore (EEZ Analysis Area) and/or within Coos Bay (Estuarine Analysis Area) could be directly affected by 1) underwater noise generated during construction of the LNG terminal and noise generated by LNG carriers transiting the EEZ and estuary, 2) disturbance during feeding by LNG vessel traffic, and 3) collisions with aboveground transmission lines at the LNG terminal during daily flights to and from foraging areas.

**Underwater Noise**

All vessels produce noise; propeller cavitations produce most of the broadband noise with dominant tones derived from the propeller blade rate. Propellers create more noise if damaged, if operating asynchronously, or operating without nozzles. Engines and auxiliary machinery can also radiate noise during operation which is related to ship size (larger ships are noisier than small ones), speed (noise increases with ship speed), and mode of operation (ships underway with full loads, towing or pushing loads, are noisier than unladen ships) (Greene and Moore, 1995).

Underwater noise due to pile driving is expected to cause hearing loss in marbled murrelets. Estimates of auditory injury from underwater pile driving noise are assumed to cause a temporary hearing impairment (demonstrated with pinnipeds by Kastak et al., 2005) termed TTS for temporary threshold shift rather than PTS, the abbreviation for permanent threshold shift. Repeated TTS may lead to PTS in which sensory hair cells in the inner ear are destroyed with damage to the cochlea (Nordmann et al., 2000).

The Federal Highway Administration, FWS, and Washington State Department of Transportation (2011b) developed and agreed to underwater noise level criteria for injury to marbled murrelets from noise. The criteria are for underwater sound resulting from impact pile driving of steel piles and/or repetitive impulsive underwater sounds (see table 4.3.3-5). However, FWS considers the sound levels in table 4.3.3-5 to be used as guidelines in effects analysis rather than threshold criteria for foraging murrelets. Other factors, including duration, are important to consider whether exposure in the zones will result in adverse effects. The thresholds do not apply to non-impact, non-impulsive underwater sounds such as ship noise. In this analysis however, they serve as references for potential effects of ship noise produced by LNG carriers on diving murrelets.

**Table 4.3.3-5**
**Current In-water Acoustic Thresholds for Marbled Murrelets**

| Criterion Zone | Threshold [1] |
|---|---|
| Auditory Injury Threshold | 202 dB SEL [2] |
| Non-auditory Injury Threshold | 208 dB SEL |
| Non-injurious Hearing Threshold Shift Zone | 183 dB SEL |
| Potential Behavioral Effects Zone | 150 $dB_{rms}$ [3] |

[1] All decibels (dB) referenced to 1 micro-Pascal (re: 1uPa).
[2] SEL – Sound level exposure – reported as the cumulative amount of exposure for a single pile driving event.
[3] Rms – the root mean squared for pile driving during a single pile driving impulse pressure event.

A review of LNG carriers in service during 2013 (Colton, 2013; MarineTraffic, 2013) revealed there are 267 vessels with capacities of 148,000 $m^3$ or less, the current size limit for LNG carriers utilizing the Jordan Cove terminal (although the LNG carrier berth was designed to accommodate LNG carriers up to 217,000 $m^3$). Hatch et al. (2008) determined underwater noise levels from various commercial ships while transiting the Stillwagen Bank National Marine Sanctuary off the Massachusetts coast. Estimates of sound levels from one ship, an LNG Taker (the Berge Everett also known as the BW Suez Everett) built in 2003 with 138,028 $m^3$ capacity (93,844 gross tonnage), are used here to estimate exposure of marine mammals to project-related shipping noise. Also, Hatch et al. (2008) reported noise for three tugs in the same area and used here as the standard for the following analysis of noise effects on marbled murrelets within the West Coast EEZ analysis area.

The ocean or waterway offshore from the entrance to Coos Bay is partially within the southern portion of offshore Conservation Zone 3 and partially within the northern portion of offshore Conservation Zone 4, as defined by Miller et al. (2012). In those portions of the Northern California- Oregon coast, the researchers estimated at-sea densities of MAMUs per $km^2$ of ocean surveyed from 2000 through 2010. Density estimates from 2000 through 2010 indicate a slight decline in zones 3 and 4, combined but the declining trend was not significant (see figure 4.3-4 and discussion in Section 4.3.3.1). However, the observations were used to forecast offshore densities from 2011 through 2018. In that first year of the Project's operation, 3.29 MAMUs per $km^2$ were estimated off the coasts of Northern California and Oregon, down from 3.95 MAMUs per $km^2$ in 2010. Because of the variability in data from 2000 through 2010, the forecast of 3.29 lies within a range between 1.77 and 4.80 MAMUs per $km^2$ in 2018 (see discussion in Section 4.3.3.1, above).

The LNG tanker in the Hatch et al. (2008) study produced sound levels (with 1 standard error) of 182 ± 2 dB re: 1 µPa @ 1 meter that attenuated to 160 dB at 35 ± 11 meters and to 120 dB at 16,185 ± 5,359 meters (Hatch et al., 2008). Based on the estimated densities of marbled murrelets off the combined Oregon/Washington coast in 2018 (3.29 murrelets per $km^2$ with estimates between 1.77 and 4.80 (95% prediction intervals) per $km^2$, see figure 4.3-4 above and Miller et al. 2012), marbled murrelets diving and feeding in the EEZ analysis area are not expected to be exposed to ship noise that would cause harm (see table 4.3.3-5) although murrelets would likely detect noise from LNG carriers transiting the EEZ. In 2018, an estimate of 4 marbled murrelets (estimated between 1 and 6 murrelets based on the density within distances of ± 2 standard deviations of LNG noise attenuating to 160 dB, from Hatch et al., 2008) would be exposed to noise levels of 160 dB which could cause potential behavioral effects due to LNG tanker noise. However, since marbled murrelets forage in shallow off-shore areas, they would not be expected to be exposed to LNG tanker noise but would be in areas of potential exposure to tug noise.

Two tractor tugs would guide each LNG tanker from a point approximately 5 nmi offshore the entrance to Coos Bay and to the JCEP LNG terminal. Noise produced by tugs would attenuate to 160 dB at 11 ± 4 meters (upper end) and to 120 dB at 4,992 ± 1,599 meters (upper end) (Hatch et al., 2008). Areas that are 5 nmi long by the widths of the different noise attenuation distances are used to estimate numbers of marbled murrelets that might be exposed to specific noise levels, given the density of 3.29 murrelets per $km^2$ during 2018. An estimate of 1 marbled murrelet would be exposed to noise levels of 160 dB which could cause potential behavioral effects due to tug noise. Similarly, an estimate of 14 marbled murrelets (estimated between 6 and 24 murrelets based on the density within distances of ± 2 standard deviations of tug noise attenuating to 120 dB, from Hatch et al., 2008) would be exposed to noise levels of 120 dB. Exposure to that noise level would not be expected to cause potential behavioral effects due to tug noise, as indicated in table 4.3.3-5. No underwater noise harassment from pile driving is expected to diving murrelets in the Estuarine Analysis Area because piling for marine structures at the LNG carrier berth would be "in-the-dry", concurrent with the dredging of the slip.

**Vessel Traffic**

Marbled murrelets are expected to forage in the Estuarine Analysis Area and probably within the EEZ Analysis Area at the same time LNG vessels would be in transit to and from the LNG terminal. No information has been found that describes marbled murrelet response to ships' presence and/or ship above-water noise. However, responses of Kittlitz's murrelet (Brachyramphus brevirostris, a congeneric of marbled murrelet) to ships' approach were studied in Glacier Bay, Alaska (Agness, 2006). The study reported that Kittlitz's murrelets were observed to immediately fly away from vessels; they flew 30 times more from vessels than in the absence of vessels and non-breeding birds (birds not holding fish) were more likely to take flight than breeding birds, those holding a fish (Agness, 2006). Modeled estimates of energy expense showed that non-breeding murrelets had a greater increase in energy expenditure when disturbed (up to 30 percent increase under the average scenario of ship traffic and greater than 50 percent increase under the peak scenario of ship traffic) than breeders (up to 10 percent and 30 percent increases under the average and peak vessel traffic scenarios, respectively). Likewise, non-breeding birds were more likely to experience chronic increases in energy expense (i.e. a greater percentage of days with an increase in energy expenditure) than breeding birds which would be expected to adversely affect energy partitioning for reproduction and survival behaviors (Agness et al., 2013).

Similar responses by foraging marbled murrelets to LNG vessel traffic would be expected once the JCEP terminal is operative in 2018. As discussed above in Section 4.2.1.3 for blue whales, available information indicates that ship calls to the Port of Coos Bay have been declining since 2002. The observed declining linear trend in total annual vessel traffic over time is significant and, when used to forecast numbers of vessel calls to Coos Bay in the future, no vessels are predicted to enter Coos Bay in 2018 with 0 and 17.6 vessels as reasonably foreseeable when the

LNG terminal is expected to begin operation in 2018 (see figure 4.2-4, above for blue whales). The foreseeable cumulative effect of 90 LNG carriers per year would exceed current vessel-related disturbance, if it occurs, to foraging marbled murrelets in the Coos Bay estuary and nearshore habitats in the vicinity of the Coos Bay channel in the EEZ Analysis Area.

**Power Line Collision**

Marbled murrelets fly at an average of 246 meters (807 feet) above ground level, although the lowest flight height reported was 63 meters (203 feet); less than 0.01 percent of all birds were observed flying at or below the height of typical transmission lines (Stumpf et al., 2011). Many different bird species have been documented colliding with transmission lines, including those the size of the 115 kilovolt (kV) overhead power transmission line proposed to connect the South Dunes Power Plant and the LNG Terminal (see Resource Report 1, JCEP LNG Terminal Project). Waterfowl, shorebirds, large birds with poor maneuverability (cranes, herons, swans, pelicans), and passerines have been killed by collisions with transmission lines (Manville, 2005). Seabirds are also killed by collisions with overhead lines (Avian Power Line Interaction Committee, 2012). Although documentation is lacking, marbled murrelets may be susceptible to power line collisions due to their rapid flight speeds which average 65 miles per hour when flying to the sea, but 55 miles per hour on return, landward flights (Stumpf et al., 2011). Murrelets fly faster than other species frequently killed by power line collisions. Also, marbled murrelet flights to and from nesting areas occur mainly near dawn and dusk with peak activity occurring well before sunrise (Manley et al., 1992; Burger, 2001) when light levels are low and coastal fog limits visibility.

The proposed transmission line is designed for two bottom 13.8 kV conductors (one on each side of a pole), the 115 kV double circuit with six phase conductors (three on a side), and two top shield or static wires, one on each side (see Figure 1.1-7, Resource Report 1, JCEP LNG Terminal Project), extending for 6,370 feet between the South Dunes Power Plant and the LNG Terminal (see Figure 1.1-2, Resource Report 1, JCEP LNG Terminal Project), using single poles between 76 and 111 feet tall, depending on terrain elevation. Flight height data for marbled murrelet (Stumpf et al., 2011) suggests that flight would be above the top shield wires of the power poles, but flight heights would be expected to decline as murrelets approach feeding sites within the Coos Bay estuary or Pacific Ocean. The proposed power line would be within 400 feet of open water in Coos Bay at its closest point and within the average distances of power lines from waterbodies where waterfowl, pelicans, sandhill cranes, and great blue herons have been documented colliding with powerlines (see Table 4.2 in Avian Power Line Interaction Committee, 2012).

Most studies have shown a reduction in collisions and/or an increase in behavioral avoidance at marked lines when compared to unmarked lines, but that is dependent on factors such as location, type of line marking device, and bird species (Avian Power Line Interaction Committee, 2012). JCEP has proposed to apply Bird Flight Diverters, manufactured by Preformed Line Products, or similar. Diverters would be installed on the shield wires to reduce risk of bird collisions with power lines. Typically they are installed at 30-foot intervals on both shield wires. The locations of the diverters on the two shield wires are staggered so that there is a diverter approximately every 15 feet along the length of the line segment, maximizing visibility of both wires. Studies of marker effectiveness have reported that birds responded (detected) marked lines at greater distances than unmarked lines and more flew higher than at line levels. Mortalities due to line collision were variable but several studies reported reduction in bird mortality by 55 percent or greater (see Table 6.8 in Avian Power Line Interaction Committee, 2012).

**Ship-Strike**

There are no records or any indication that MAMUs offshore are susceptible to ship-strikes. Seabirds collide with fishing trawlers in the North Pacific. Collisions of seabirds with stationary objects (including off-shore wind energy turbines) are possible, either by collisions of ships with birds on the ocean surface or collisions of birds in flight with ship structures although empirical data are limited (Wilson et al., 2007). Collisions between marbled murrelets and LNG carriers are possible but not likely within the EEZ analysis area.

**Release and Fire at Sea**

Characteristics of LNG released at sea were described in Section 4.2.1.3 for blue whales. At the water-vapor LNG pool interface, the cryogenically cooled LNG would begin to vaporize but, because of its relatively high density, the plume would remain at or close to the surface interface; methane is an asphyxiant but with low toxicity, at least to humans (Hightower et al., 2004). If a marbled murrelet surfaced to breathe at the LNG pool location, it could suffer from oxygen deficiency and potential physiological effects, which have been described for humans - ranging from impaired thinking to loss of consciousness with decreasing oxygen concentrations (Table 39 in Hightower et al., 2004) - but not for other species. Because the estimated densities of marbled murrelets are generally low within the California and Oregon-Washington strata of EEZ, the chance of an marbled murrelet becoming asphyxiated by contact with a pool of LNG would extremely remote (see discussion about potential thermal injury, below).

Marbled murrelets generally forage within 3 miles of shore in western North America, although during the breeding season they stay closer to the coast, e.g., within 1.2 miles in Oregon (McShane et al., 2004). If an accidental release of LNG occurred within that nearshore distance, foraging marbled murrelets could be affected.

Sandia National Laboratories modeled LNG spills from a standard LNG vessel (with capacity of 125,000 to 140,000 $m^3$) over water and potential injury to humans due to ignition of the fuel (Hightower et al., 2004). Thermal effects from a fire would vary, depending on the size of the LNG pool released. If one LNG tank is accidentally breached, due to collision with another ship, grounding, or ramming, the potential spill of LNG could form a pool with diameter of 685 feet. Ignition could cause a fire to burn for 20 minutes with severe thermal injuries extending to 820 feet away from the center of the pool (based on an exposure of 10 minutes and thermal flux of 37.5 $kW/m^2$) and second-degree skin burns on exposed skin (human) to a distance of 2,572 feet (based on an exposure of 10 minutes and thermal flux of 5 $kW/m^2$) from the center of the burning pool of LNG (see Table 41 in Hightower et al., 2004). Foraging underwater, then surfacing, marbled murrelets within those distances would be assumed to experience severe burns or mild burns, based on similar thermal fluxes effects on humans although exposures for 10 minutes or more would be unlikely.

If offshore densities were 3.95 murrelets per $km^2$ during 2010 and the overall population declines in 2018, the expected offshore density in 2018 will be 3.29 murrelets (between 1.77 and 4.80) per $km^2$. Based on the model of accidental LNG release and fire described above (from Hightower et al., 2004), a circular pool of released LNG with diameter of 685 feet would cover an area of 0.010 $nmi^2$. An ensuing fire would cause severe thermal injuries over an area of 0.057 $nmi^2$ and the area where fire could cause second degree burns would extend to an area of 0.563

nmi$^2$. Considerably fewer than one marbled murrelet would be expected to be present within those areas in the Oregon-Washington EEZ stratum during 2018 except 1 murrelet could be within range of low thermal flux during an LNG fire (causing second degree burns to humans). Injuries to marbled murrelets due to LNG release and fire are highly unlikely and would be insignificant and discountable.

**Indirect Effects – EEZ and Estuarine Analysis Areas**

Foraging Habitat

Murrelets forage in shallow off-shore and inland saltwater areas on a variety of small fish and invertebrates, including large pelagic invertebrates (Marshall, 1988a, 1988b, and 1989; Becker, 2001). In Oregon and Washington, anchovy, sand lance, and smelt appear to be the major prey types provided to chicks (McShane et al., 2004). Turbidity associated with dredging activities within Coos Bay may affect MAMU forage/prey species and their habitat. Dredging of the access channel is planned from October 1 through February 15 following ODFW's recommendation, and timing of these activities should minimize impact to MAMU forage/prey species.

During summers in 1992 and 1993, the majority of MAMUs off the Oregon coast were observed within 3,280 feet (1000 meters) from shore (Strong et al., 1995). Given the distribution of MAMUs close to shore, it is not surprising that they are susceptible to adverse effects from industrial pollution (Fry, 1995) and off-shore oil spills (Carter and Kuletz, 1995). Indeed, oil released during the grounding and break-up of the *New Carissa* near Coos Bay likely killed 262 MAMUs in February 1999 (Skrabis, 2005).

The potential for similar effects from LNG cargo is quite different from the potential for effect by crude or refined petroleum cargo. Based on the double hulled construction of LNG carriers and the outstanding operating and safety record of LNG carriers, the probability of any incidents that could result in the loss of LNG cargo is extremely low. Any potential spills that could occur and that could affect MAMUs offshore would more likely be fuels or lubricants associated with the operation of the LNG carrier. These products are kept in relatively small quantities on ships and would not result in the types of effects associated with a spill from an oil tanker.

Characteristics of LNG released at sea were described in Section 4.2.1.3 for blue whales and above for marbled murrelets. At the water-vapor LNG pool interface, the cryogenically cooled LNG would begin to vaporize but, because of its relatively high density, the plume would remain at or close to the surface interface (Hightower et al., 2004). The cooling effects of the LNG plume on murrelet prey species are unknown but are expected to be localized. Similarly, effects of a fire on prey species would likely be very limited to the ocean – LNG pool interface.

Oil spills at sea or off shore might adversely affect food resources in the immediate area including schooling fish such as anchovies (NMFS, 2006a). However, effects of potential spills from LNG carriers are not comparable to spills from oil tankers for a number of reasons. LNG carriers only carry quantities of oil used for propulsion fuel and not the quantities transported by oil tankers.

**Direct Effects – Terrestrial Nesting Analysis Area**

MAMUs could be directly affected by 1) removal of nest trees or potential nest trees during the breeding season (April 1 through September 15) and 2) human presence and noise disturbance during the breeding period.

Habitat (Nest) Removal during Breeding Season

Removal of habitat during the breeding season within an occupied or presumed occupied stand could result in the potential death of nestlings if the nest tree is removed. Removing suitable nesting habitat outside of the entire breeding season (September 16 through March 31) would eliminate any direct impact to individual MAMUs or nestlings. Pacific Connector met with FWS on June 5, 2008 to review and discuss the proposed action and construction schedule and identify areas where the project and schedule could be adjusted to avoid or further decrease the disturbance impacts to MAMUs while allowing for a constructible pipeline Project that considered 1) MAMU seasonal and daily timing restrictions, 2) safety of the construction crew, and 3) meeting the targeted in-service date within a two-year construction period. FWS provided a preference of activities associated with timber removal and construction, including the following specific to habitat removal, listed below in descending order of importance:

- Felling nest trees outside the entire breeding season.
- No removal of habitat within an occupied stand during the entire breeding season.
- No fragmentation of an occupied stand (i.e., clipping the edge of the stand is not as bad as dissecting through the middle).

Pacific Connector moved and adjusted the proposed project to avoid and/or minimize effects to MAMU, where feasible. Appendix V (Marbled Murrelet and Northern Spotted Owl Avoidance and Minimization Plan) identifies the additional measures that have been incorporated into the project design in relation to occupied MAMU stands or potentially suitable MAMU habitat. Also, considering the factors above, Pacific Connector developed a timber removal and construction schedule that would minimize effects to MAMU, as well as ensure the safety of the timber removal and construction crew and meet the in-service date (see figures 3.2-1 and 3.2-3). Pacific Connector will remove forested habitat within 300 feet of an occupied stand, unoccupied stand, or presumed occupied stand outside of the entire breeding season to eliminate direct impact to individual MAMUs or nestlings. Timber will be removed beginning fourth quarter 2015, and if necessary, continue the following fall after the breeding season. This includes habitat that would be removed or potentially removed from 25 MAMU stands (14 occupied, two unoccupied, and nine presumed occupied stands). Habitat will also be removed within 0.25 mile of a northern spotted owl activity center outside of the breeding season (from October 1 through February 28); within the range of the MAMU, this includes forested habitat between MPs 37.33 and 37.87 and MPs 64.00 and 64.40. Elsewhere in the range of the MAMU, timber removal would precede construction and could occur during the breeding season; however, direct effects to MAMUs or nestlings would not be expected because suitable nesting habitat would have been removed outside of the breeding season.

Table 4.3.3-6 below tabulates the number of occupied, unoccupied, and presumed occupied stands by Murrlet Inland Zone that would have timber cleared within 300-feet of the MAMU stand outside of the breeding season, including 25 MAMU stands that would have suitable habitat removed from the stand. Although table 4.3.3-6 identifies 25 MAMU stands that would have habitat removed, it is expected that suitable habitat would not be removed in five of these stands (3 occupied, 1 unoccupied, and 1 presumed occupied) because the construction activity should be confined to the road through the stand or construction would occur adjacent to the MAMU stand in non-suitable habitat.

**Table 4.3.3-6**
**Number of Occupied, Unoccupied, and Presumed Occupied Stands that Will Have Habitat Removed Outside of the Breeding Season, Including the 300-foot Buffer**

| Status Of MAMU Stand | Number of MAMU Stands Stand | 300-foot Buffer | Total |
|---|---|---|---|
| **Marbled Murrelet Inland Zone 1** | | | |
| Occupied | 14 | 2 | 16 |
| Unoccupied | 0 | 0 | 0 |
| Presumed Occupied | 9 | 23 | 32 |
| **Total** | **23** | **25** | **48** |
| **Marbled Murrelet Inland Zone 2** | | | |
| Occupied | 0 | 0 | 0 |
| Unoccupied | 2 | 0 | 2 |
| Presumed Occupied | 0 | 0 | 0 |
| **Total** | **2** | **0** | **2** |
| **Overall Total** | | | |
| Occupied | 14 | 2 | 16 |
| Unoccupied | 2 | 0 | 2 |
| Presumed Occupied | 9 | 23 | 32 |
| **Total** | **25** | **25** | **50** |

No suitable MAMU nesting habitat would be removed during the construction of the LNG Terminal or South Dunes Power Plant; no direct effects to MAMUs would be expected from these proposed actions.

Noise and Visual Effects

Noise associated with timber clearing, construction, and operation of the proposed Project could disturb nesting MAMUs and negatively affect productivity. The term "disruption" was alluded to in the ESA, under the definition of "harassment" (50 CFR §§ 17.3) as:

> "an intentional or negligent act or omission which creates the likelihood of injury by annoying it (the organism) to such an extent as to significantly disrupt normal behavior patterns which include but are not limited to, breeding, feeding or sheltering".

The term "disturbance" was not included in the ESA but a reasonable working definition was provided by Leal (2006) and has been incorporated into this BA:

> "any potential auditory or visual stimuli or deviation from ambient/baseline conditions [that] an individual bird, at a given site, is likely to detect and potentially react to."

There is limited information on distances from sound (noise) and/or visual stimuli at which MAMUs react or flush from the nest, or the effect of such disturbance on productivity (FWS, 2003b). Most data gathered for disturbance on MAMUs have been obtained from observations incidental to other research (e.g., Long and Ralph, 1998). The sensitivity of an individual MAMU to noise and/or visual disturbance is likely related to levels of disturbance to which the bird is accustomed, including the level and proximity of the disturbance (Hamer and Nelson, 1998) as well as the timing of disturbance (time of day, time of year, and time within breeding season). The available research and anecdotal accounts show tha the effects of noise and vehicles on roads elicit disturbance-responses from marbled murrelets but not disruption-responses such as flushing, flight and/or missed feedings of chicks in nests to a level that would interfere with normal behavior patterns including but not limited to, breeding, feeding or sheltering. The following are brief summaries of available research and anecdotal accounts:

- No visible response to vehicles driving past MAMU nests 70 meters away from a paved, “well traveled park road” (Singer et al., 1995 in Long and Ralph, 1998)
- MAMU in nests in Big Basin Redwoods State Park showed no response to passing cars during several days of observation in 1989 (Nelson, personal communication, in Long and Ralph, 1998)
- MAMU nests 70 meters from lightly used logging road show little to no response when observers drove by in light trucks (Chinnici, personal communication, in Long and Ralph, 1998)
- MAMU in nests across river from road with moderate traffic (30 cars/day) showed no reactions when vehicles passed (Nelson, personal communication, in Long and Ralph, 1998)
- Adult MAMU reacted least to trucks on U.S. Highway 101 even though truck noise averaged 84 dB and usually reacted to automobiles only with noticeable response, auto noise averaged 72 dB (adults showed severe response ≈3% of all responses to autos); MAMU chick showed only low response to cars/trucks (Hamer and Nelson, 1998).
- Field study to measure behavioral responses of MAMU adults and chicks to disturbance produced by trail users, proximity to paved highways, and experimental disturbances produced by maintenance activities (chainsaws) (Hébert and Golightly, 2006):
  - Ambient sound at nest sites was <50 dB before and after exposure to chainsaw noise. Experimental noise was >65 dB generated by chainsaws.
  - MAMU chicks and adults in nests exposed to significantly louder experimental noise than before or after trial.
  - Adult MAMU spent less time at rest during disturbance than before and after.
  - Adult MAMU spent more time with head raised during disturbance than before and after.
  - MAMU chicks spent similar times at rest before, during, and after chainsaw noise trials.
  - Hatching success at control nests was 39%; hatching success at experimental nests (exposed to chainsaw noise) was 67%
  - Fledging success at control nests was 25-50%; fledging success at experimental nest was not significantly different.
  - Overall, MAMU avoided nesting close to high volume roads (U.S. Highway 101).
  - Concluded that vehicular traffic may have little or no effect on MAMU nesting success.

Available research suggests that marbled murrelets may be more sensitive to visual disturbances than to auditory disturbance conditioned by predators in the vicinity that may cause aborted or delayed feedings (Phifer, 2003; Bednarz and Hayden, 1994). Human presence attracts corvids, which increases the predation risk at MAMU nest sites that are located near project activities. Studies from other bird species suggest that disturbance can affect productivity by causing nest abandonment, egg and hatchling mortality due to exposure and predation, longer periods of incubation, premature fledging or nest evacuation, depressed feeding rates of adults and offspring, reduced body mass or slower growth of nestlings, and avoidance of otherwise suitable habitat (Henson and Grant, 1991; Rodgers and Smith, 1995, cited in BLM and USFS, 2008).

**Auditory and Visual Disturbance - FWS Guidance.** FWS (2003b and 2006f) established distances within which sound levels and visual disturbance for various activities may result in injury or harassment of MAMUs by significantly disrupting the normal behavior pattern of individuals or breeding pairs. FWS determined that visual disturbances within 100 yards of MAMU nest sites could lead to increased predation of nests by corvids when humans are present during project-related activities and would constitute a disruption of the nest site (Phifer, 2003).

FWS identified distances within which activities may "disrupt" nesting MAMUs (noise and/or visual disturbance). Disruption distances identify a distance from activities that FWS have determined would likely cause a MAMU to be distracted to such an extent as to significantly disrupt normal behavior and increase the likelihood of breeding season failure. The threshold disruption distances applied to marbled murrelets during the critical breeding period are either the same or extend farther (i.e., more conservative) than distances provided by FWS (2003b and 2006f; see Noise Evaluation in Appendix Z3). Other actions, including use of existing roads and large helicopters were added after 2006. Activities that occur beyond the disruption distances may "disturb" MAMU but should minimize effects and not result in harm or "disrupt" reproductive activities. Activities may disturb MAMU if the activities occur within 0.25 mile of MAMU; disturbance distances have often been applied as seasonal buffers to minimize impacts of projects to nesting MAMUs. FWS determined that activities occurring beyond these disturbance distances would not likely cause MAMUs to be distracted from their normal activity. Table 4.3.3-7 provides the threshold distances beyond which noise and visual disturbances are unlikely to result in disruption or disturbance to nesting murrelets during the breeding season (April 1 through September 15), which are generally based on distances to which noise levels and/or human presence are expected to disrupt or disturb nesting MAMU. In addition to the temporal and spatial restrictions presented in table 4.3.3-7, FWS also recommends limiting Project-related disturbance to two hours after sunrise until two hours before sunset near occupied and presumed occupied stands. Adhering to this daily timing restriction (DTR) minimizes the potential to disrupt adult MAMUs delivering meals to chicks at dawn and dusk. Application of DTRs during the breeding season should minimize effects from project activities, and would result in no disturbance or disruption for most activities if applied in the late breeding period, as identified in table 4.3.3-7.

Disruption and disturbance distances and temporal applications identified in table 4.3.3-7 are not the same as commonly used in FWS consultations with BLM (see Coos Bay FY2008-2013 Programmatic Consultation #13420-2008-F-0118). For example, BLM does not consider disruption or disturbance effects to occur to MAMU from use of existing access roads throughout the entire breeding season. Additionally, BLM generally does not consider disturbance effects to MAMU for certain activities (heavy equipment, chainsaw use, and small helicopter or use) in the late breeding season (see Coos Bay FY2008-2013 Programmatic Consultation #13420-2008-F-0118).

**Table 4.3.3-7**
**Threshold Distances Beyond Which Noise and Visual Disturbances are Unlikely to Result in Disruption or Disturbance to Nesting Marbled Murrelets during the Breeding Season [1]**

| Activity | **Disruption Threshold Distances From Occupied or Presumed Occupied Stands** | | | **Disturbance Threshold Distance From Occupied or Presumed Occupied Stands** | | |
|---|---|---|---|---|---|---|
| | **MAMU Critical Breeding Season [2]** | **MAMU Late Breeding Season – No DTRs [2, 3]** | **MAMU Late Breeding Season – With DTRs [2, 3]** | **MAMU Critical Breeding Season [2]** | **MAMU Late Breeding Season – No DTRs [2, 3]** | **MAMU Late Breeding Season – With DTRs [2, 3]** |
| Existing Road Use | 35 yards (105 feet) | No Disruption Anticipated | No Disruption Anticipated | 0.25 mile | 0.25 mile | No Disturbance Anticipated |
| Chainsaws | 100 yard (300 feet) | 100 yard (300 feet) | No Disruption Anticipated | 0.25 mile | 0.25 mile | No Disturbance Anticipated |
| Heavy equipment [4] | 100 yard (300 feet) | 100 yard (300 feet) | No Disruption Anticipated | 0.25 mile | 0.25 mile | No Disturbance Anticipated |
| Rock Ditching Equipment [5] | 120 yards (360 feet) | 120 yards (360 feet) | No Disruption Anticipated | 0.25 mile | 0.25 mile | No Disturbance Anticipated |
| Blasting – more than 2 lbs with mitigation measures | 120 yards (360 feet) | 120 yards (360 feet) | 120 yards (360 feet) | 0.25 mile | 0.25 mile | 0.25 mile |
| Small Helicopter/Airplanes | 120 yards (360 feet) | 120 yards (360 feet) | No Disruption Anticipated | 0.25 mile | 0.25 mile | No Disturbance Anticipated |
| Large/Transport Helicopters with mitigation measures [6] | 240 yards (720 feet) | 240 yards (720 feet) | 240 yards (720 feet) | 0.25 mile | 0.25 mile | 0.25 mile |

[2] Marbled MAMU breeding period is from April 1-September 15; critical breeding period is considered from April 1-August 5; late breeding season is considered from August 6 – September 15.
[3] DTRs (Daily Timing Restrictions) – restricting activity between 2 hours after sunrise and 2 hours before sunset.
[4] Heavy equipment includes: back trackhoes, side-booms, bulldozers, semi-trucks, pneumatic hammers.
[5] Rock Ditching Equipment includes: auger drill rig, mounted impact hammer, rock drill, and blasting (mitigated or less than 2 lbs).
[6] Transport helicopters proposed for this Project include: Boeing Chinook (CH-47) and Boeing Vertol 107-II (CH-46)

FWS (2003b and 2006f) reviewed available scientific literature on behavioral and physiological responses of different bird species to various noise sources. They determined that birds would likely detect noises that were 4 decibels or more above ambient noise levels. FWS (2006f) also determined that anthropogenic noise attenuating to within 25 dB above ambient sound level would be the threshold above which harassment to individual murrelets is likely to occur. That determination, however, was based on one account of Mexican spotted owls responding to chainsaw noise (Delaney et al., 1999) and one account of a colonial nesting seabird (crested tern, Brown, 1990) responding to simulated aircraft noise. In both situations, the subject birds were exposed to human presence prior to exposure to noises and response to noises were not controlled for visual disturbances. Using those two studies however, FWS (2006) subtracted the noise level that elicited a harassment-indicating behavior (flight or flushing) from the minimum ambient noise at the respective sites and decided that action-generated noise levels that are 25 dB above ambient levels will constitute the sound level threshold above which harassment is likely to occur (FWS, 2006e). From that exercise, FWS (2006) decided that a noise level of 70 dB would be a disturbance threshold and noise ≥70 dB would be disruptive, based entirely on the responses of crested terns to simulated aircraft noise (Brown, 1990), as above. That conclusion appears to be arbitrary (WSDOT, 2011), has not been tested, and is not supported by field studies of marbled murrelets (see available research and anecdotal accounts, above). Consequently, Pacific Connector has not accepted or applied the FWS (2006) sound threshold of 25 dB above ambient noise or noise ≥70 dB as a decibel level above which harassment is likely to occur.

Injury to individuals of either species would occur if a threshold of 92 dBA occurs or is exceeded (FWS, 2003b). FWS (2006f) defined a "tolerance threshold" of 82 dB for marbled murrelets. The tolerance threshold assumes that respective nest sites become "intolerable" to the species and harassment occurs due to the total sound level the species must endure. However, no time duration component was associated with the tolerance threshold.

FWS (2003b) did not analyze injury threshold distances for noise associated with blasting or large helicopters. Rather, a conservative assumption was used for blasting with charges of 2 pounds or less; for larger blasts (greater than 2 pounds) a conventional 1-mile distance was considered due to the lack of dB information. During informal consultation with FWS (Smith et al., 2007; Wille et al., 2006), restricting the use of large helicopters to remove large timber and transport pipe to the construction right-of-way to a 1-mile disturbance threshold distance was considered as well. However, FWS also suggested that if additional studies could demonstrate that use of larger blasts (greater than 2 pounds) and large helicopters attenuated to less than 92 dB, and preferably 70 dB (disturbance threshold versus 92 dB disruption threshold) within a mile, the report and additional data demonstrating this would be considered to reduce the disturbance threshold distances for those activities (Smith et al., 2007; Wille et al., 2006).

**Blasting and Helicopter Noise Levels.** Pacific Connector has prepared a noise report (see appendix P) that analyzes the distances at which conventional blasting required for trenching within rock substrate for pipeline construction and transport helicopters attenuates to 92 dB, the threshold for injury to individual murrelets and is the sound level above which MAMU are likely to respond with behavior that indicate harassment (FWS, 2006f). Under the worst case conditions, with common and appropriate mitigation measures applied to trench blasting operations, it is expected that blasting noise would attenuate to 92 dB within 200 feet of the source and to 70 dB within 1,025 feet of the blast source in soft rock. Large transport helicopters would attenuate to 92 dB within 700 feet. The greater distance for helicopter use is due to the directional aspects of blade slap noise that is directed toward the ground.

Mitigation for helicopter noise includes operational restrictions such as maintaining a high altitude and keeping away from noise sensitive areas whenever possible. Analyses for MAMUs in this draft BA consider the distances for larger blasts and large helicopters to be more conservative than what the noise report suggests. Pacific Connector has used a disruption threshold distance for blasting greater than 92 dB but with mitigation measures discussed in appendix P applied to be the same disruption distance expected for smaller blasts (less than 92 dB) – 120 yards or 360 feet – more conservative than the noise report describes, and the disturbance threshold distance associated with large blasts to be expected within 0.25 mile of blasting activity (see table 4.3.3-7). It is expected that these distances be considered throughout the entire breeding season (April 1 – September 15), regardless of the application of DTRs, because of the sudden onset of noise associated with blasting activities. Pacific Connector has used a disruption threshold distance for large/transport helicopter use with proposed mitigation techniques discussed in appendix P to be slightly farther than the report suggests, considering a disruption distance of 240 yards or 720 feet and a disturbance threshold distance of 0.25 mile (see table 4.3.3-7). Even though FWS (2003b) provided some evidence suggesting that noise that builds in intensity, such as a helicopter approaching from a distance, may result in less risks and does not anticipate effects for smaller aircraft after the critical breeding period with DTRs applied, for analysis within this assessment, Pacific Connector anticipated that similar to large blasts (greater than 2 pounds) use of large/transport helicopters may disrupt or disturb MAMUs throughout the entire breeding season (April 1–September 15), regardless of the application of DTRs. In a memorandum provided to TetraTech, contractor to FERC (FWS, September 16, 2008), FWS indicated that if noise level above 92 dB is recorded at 0.25 mile of the blasting activities, that blasting operations should cease until more effective mitigation measures can be employed. Pacific Connector would ensure its contractor complies with all ESA-related noise restrictions along the proposed project.

**Noise Evaluation Procedure**. Pacific Connector is aware of the temporal and spatial restrictions recommended by FWS (see table 4.3.3-7); however, due to construction constraints within the range of the MAMU, safety of construction crew, and adherence to the in-service date, Pacific Connector cannot adhere to all recommended restrictions. Further, the distances were derived under forested situations and are not applicable to many of the field situations and habitats through which the PCGP project passes. Also, available research and anecdotal reports do not support use of fixed distances between a noise source and marbled murrelet behavioral response indicating disruption. Noise levels attenuate differently under various conditions which are not accounted for in the FWS guidance. Since the spatial restrictions included in table 4.3.3-7 have been established based on noise levels and attenutation at the MAMU stand (i.e., 92 dB), Pacific Connector evaluated expected noise levels at a particular MAMU stand from activities associated with construction of the Proposed Action and distance of the MAMU stand from activities (see site-specific Noise Evaluation, appendix Z3). The noise evaluation was used to assist in evaluating noise effects of proposed construction activities for each MAMU Stand within the Terrestrial Nesting Analysis Area, considering reviewed available scientific literature on behavioral and physiological responses of bird species to various noises, as well as the ambient noise level near each MAMU stand. The noise evaluation estimates noise attenuation at the closest edge of each MAMU stand to the proposed activities based on guidance provided by FWS (2006) due to hard site (hard, smooth surfaces intervening between source and receptors) and soft site (irregular, vegetated surfaces) conditions, intervening tree cover, topography, and/or differential elevations allowing lines-of-sight between sources and receptors. This noise evaluation has been used as an adjustment factor of direct effects (disturbance and disruption) for individual MAMU Stands in the impact assessments located in appendix Z1 and included in table Q-2 in appendix Q.

**Disruption and Disturbance – Timber Clearing, Pipeline Construction, Existing Road Use**. Pacific Connector will clear timber within MAMU Stands and a 300-foot buffer of MAMU stands outside of the entire breeding season (between September 16 and March 31) to avoid direct effects to murrelets, chicks, or eggs within MAMU stands and adjacent habitat. This includes approximately 52.5 miles of forested habitat within the range of the MAMU. Timber removal is expected to occur during Year 1 of the PCGP construction window; however, if timber removal is not completed prior to MAMU breeding season (April 1), timber removal would continue in Year 2 outside of the breeding season (between September 16 and March 31). Noise, visual disturbance, and in some instances large helicopter use associated with timber removal outside of the breeding season would be consistent with the temporal and spatial restrictions recommended by FWS to protect nesting murrelets (see table 4.3.3-7) and would not be expected to disturb or disrupt MAMUs.

Pacific Connetor, however, cannot adhere to the temporal and spatial restrictions recommended by FWS (see table 4.3.3-7) within 0.25 mile of all occupied and presumed occupied stands, and safely construct the pipeline within two years. Therefore, approximately 35.11 miles of construction activities along the proposed route, including an additional 15.52 miles of timber clearing (greater than 300 feet but within 0.25 mile of MAMU Stand), could occur during the MAMU breeding period within 0.25 mile of 20 occupied, three unoccupied, and 56 presumed occupied MAMU stands (see table 4.3.3-8). As a result, acoustic and visual disturbances from the proposed action could affect MAMU nesting and rearing activities. Pacific Connector has proposed to apply DTRs recommended by FWS for timber removal and construction activities that occur within 0.25 mile of a MAMU stand through the critical breeding period (April 1 through August 5), which would reduce direct effects from noise and visual disturbance. DTRs would be applied to large transport helicopters in the late breeding period (August 6 through September 15), if use of helicopters is necessary during that time period. Although timber removal and construction activities would likely occur within one breeding season in the proximity of each MAMU Stand, Pacific Connector conservatively assumes that each MAMU Stand could experience effects from activities for two years.

**Table 4.3.3-8**
**Total Miles Crossed by the Proposed Action within the MAMU Stand, and the 300-foot and 0.25 mile Buffer of MAMU Stands**

| Location of Project Activity | Marbled Murrelet Habitat (miles crossed) | | | | Total Miles Crossed |
|---|---|---|---|---|---|
| | Suitable | Recruitment | Capable | Not Habitat | |
| **Total MAMU Inland Zone 1** | | | | | |
| MAMU Stand [1] | 5.8 | 0 | 0 | 0 | 5.8 |
| 300-foot Buffer [1] | 0 | 4.4 | 6.0 | 3.5 | 13.9 |
| 0.25-mile Buffer | 0 | 3.6 | 16.8 | 7.2 | 27.7 |
| MAMU Inland Zone 1 Total | 5.8 | 8.0 | 22.8 | 10.7 | 47.4 |
| **MAMU Inland Zone 2** | | | | | |
| MAMU Stand [1] | 0.9 | 0 | 0 | 0 | 0.9 |
| 300-foot Buffer [1] | 0 | 0.5 | 1.2 | 0.3 | 1.9 |
| 0.25-mile Buffer | 0 | 0.8 | 0.5 | 1.0 | 2.4 |
| MAMU Inland Zone 2 Total | 0.9 | 1.3 | 1.7 | 1.4 | 5.2 |
| **Overall MAMU Range** | | | | | |
| MAMU Stand [1] | 6.7 | 0.00 | 0.00 | 0.01 | 6.7 |
| 300-foot Buffer [1] | 0.00 | 4.9 | 7.2 | 3.8 | 15.8 |
| 0.25-mile Buffer | 0.00 | 4.4 | 17.3 | 8.3 | 30.1 |
| **Overall Total MAMU Range** | **6.7** | **9.3** | **24.5** | **12.1** | **52.5** |

[1] Timber will be harvested outside of the entire breeding season (between September 16 and March 31); this includes habitat associated with 50 MAMU Stands (see table 4.3.3-6).

**Expected Disturbance Effects.** Noise expected during each phase of pipeline construction as it relates to equipment associated with each phase is provided in table 3.1.3.3-2, and applied to each MAMU stand individually in the Noise Evaluation (see appendix Z3). Impact assessments for each MAMU stand analyzed within this BA (appendix Z1) identify existing access roads within or within 0.25 mile of occupied, unoccupied, or presumed occupied stands, including distance from roads, expected improvements within the stand or 0.25 mile buffer, and surface of existing roads, including maps of the particular stand. The impact assessments also identify how far a MAMU stand is in relation to proposed construction activities, including large helicopter use and blasting. Many of the MAMU Stands occur in areas with higher existing disturbance (i.e., residential, commercial, and agricultural areas) and noise associated with construction of the project would be detectible, but often times not disruptive (see Noise Evaluation, appendix Z3). Informal consultations with FWS (June 5, 2008 meeting; see NSO and MAMU Avoidance Plan) identified disturbance from travel on existing roads to be less of an impact than other actions associated with the proposed Project, especially if farther than 35 yards (105 feet). Although use of existing roads may be detectible by MAMU within 0.25 mile, it is not expected that use of every existing road would disturb nesting murrelets and use of existing roads would not significantly disrupt normal behavior patterns and lead to harassment under the ESA, described above (see Pacific Connector's Noise Evaluation in appendix Z3). Therefore, Pacific Connector assumes that use of existing access roads (EARs) would be a potential disturbance to MAMU and could result in temporary reduced habitat suitabilility, but would not disrupt breeding behaviors.

Table Q-2 in appendix Q provides distances from actions and timing of those actions that are expected to occur within the occupied, unoccupied, or presumed occupied stands during proposed project activities (timber clearing, construction activities, road use) and through the life of the Project (i.e., maintenance and operation activities). Since nest locations within MAMU stands are not known, analyses in this BA have assumed that murrelets are nesting along the closest edge to disturbance or existing road from the marbled murrelet stand which is unlikely but, absent specific nest locations, is the most conservative approach. Additionally, table Q-2 in appendix Q provides the expected effect from noise and visual presence of proposed project activities (disruption, disturbance, no disturbance, or no effect) and rationale for each occupied, unoccupied, or presumed occupied stand based on timing and distance from the Project activities for each proposed activity (based on disturbance distances from table 4.3.3-7 and adjusted, if applicable, from site-specific analysis in the Noise Evaluation in appendix Z3).

Maps 1 through 10 in appendix Q show the locations of occupied, unoccupied, and presumed occupied stands in relation to different Project components and identify spatial buffers (360 feet and 0.25 mile buffers) associated with a MAMU stand. Rationale for location of the proposed Pacific Connector pipeline within each known occupied stand, presumed occupied stand, and unoccupied stand is located in the Marbled Murrelet and Northern Spotted Owl Avoidance and Minimization Plan (see appendix V).

Table 4.3.3-9 provides a summary of occupied, unoccupied, and presumed occupied stands within the Terrestrial Nesting Analysis Area that may be affected by the proposed Project and is based on the timing of activities (summarized from table Q-2 in appendix Q) and site-specific noise analysis. Stands that have not had surveys conducted to date because they have been denied access by the landowner or were identified for this BA have been presumed occupied for this analysis. If stands are surveyed and no suitable nesting structures are present, then no disturbance effect would be expected. Table 4.3.3-9 provides a conservative estimate of the stands likely to be disturbed by activities associated within the proposed action, because Pacific Connector does not expect the majority of presumed occupied stands on private lands to have suitable nesting habitat present based on 1) on-the-ground surveys adjacent to those stands with no suitable nesting habitat identified, 2) location of those identified stands within narrow riparian buffers surrounded by clear-cuts and/or residences, and/or 3) proximity of presumed occupied stands greater than 3.0 miles from known occupied stands. Additionally, activities will not occur simultaneously along the proposed route, and as a result some activities near MAMU stands may occur outside of the breeding period and/or within the latter part of the breeding season within the DTR timing window. Also, disturbance or disruption associated with construction activities will likely only occur in one year; however, Pacific Connector cannot guarantee that activities would only occur in one year (there may be unforeseeable circumstances that result in two years of activities), therefore, Pacific Connector has identified that disruption and disturbance activities could occur in both Years 1 and 2. Stands considered “unoccupied” for this BA will be surveyed again in 2014; it is not expected that these stands will document occupied behavior because three years of surveys (2007, 2008, and 2013) have not observed behavior to suggest MAMU occupancy or presence.

Marbled murrelet stands identified in the timber and removal/construction column could also experience effects during reclamation; however, reclamation activities within 0.25 mile of MAMU Stands would occur outside of the marbled murrelet breeding season (September 15 through March 31). Effects by reclamation to nesting murrelets would not be expected.

**Table 4.3.3-9**
**Number of Occupied or Presumed Occupied Stands within the Marbled Murrelet Zones with Expected Disturbances from Noise and/or Visuals Associated with Activities Proposed within 0.25 mile of Stands [1]**

| Status of Marbled Murrelet Stand | General Landowner | Total Number of Stands | Construction Activities and Road Use[2] | | Construction Activities Only[3] | | Road Use Only[4] | | None[5] |

[1] Summarized from table Q-2 in appendix Q.
[2] Construction Activities and Road use: both proposed activities occur within 0.25 mile of MAMU Stands
[3] Construction Activities Only: includes general construction activities, blasting (> 2lbs explosives), and large transport helicopter use; no proposed road use within 0.25 mile of MAMU Stands
[4] Road use only: no construction activities proposed within 0.25 mile of MAMU Stands
[5] None: construction and proposed road use > 0.25 mile of MAMU Stands

**Maintenance and Operation.** No activities associated with general maintenance and operations of the proposed action are expected to affect occupied MAMU stands. FERC requires that vegetation maintenance activities occur only between August 1 and April 15 of any year (see appendix C); generally, outside of the critical breeding season. Pacific Connector would apply DTRs during activities during the late breeding season (August 5 through September 15) to ensure no effects to MAMU (see table 4.3.3-7); therefore, no disturbance is expected. Routine clearing of vegetation greater than 6 feet in height within the 30-foot permanent right-of-way would not occur more frequently than every 3 years. A 10-foot corridor centered over the pipeline may be maintained annually in an herbaceous state to facilitate periodic corrosion and leak surveys. Pacific Connector would also require pilots conducting annual aerial inspection (small plane/helicopter) of the pipeline to adhere to the spatial restrictions recommended in the vicinity of occupied stands (no overflight within 1,300 feet AGL during the critical breeding season (April 1 through August 5), resulting in no adverse effect from aerial pipeline inspection. However, some routine activities such as pipeline right-of-way inspection may require pipeline personnel to visit the right-of-way at any time; these visits along the right-of-way would be by a vehicle or via walking and adhere to DTRs.

Helicopter Rotor Wash

Strong winds can adversely affect MAMUs (FWS, 1990) by directly removing habitat from windthrow that could fragment forests and increase edge effects (risk of predation, microclimatological changes). Wind can also cause direct mortality by blowing chicks out of nests (FWS, 1992a). Helicopter drive rotors produce high velocity vortices (winds) that extend from the center of the helicopter outward in all directions. Vertical downwash of air (rotor wash) close enough to the ground produces surface winds that dissipate with distance away from the helicopter (sidewash). Induced winds caused by helicopter rotor wash may exceed hurricane force velocities that would be expected to adversely affect nesting MAMUs on a local level. Since induced rotor downwash and surface sidewash are functions of helicopter size, rotor surface area, helicopter weight, flight speed, and height above ground (Teske et al., 1997; Gordon et al., 2005), effects to nesting birds can be minimized or avoided by routing helicopter flight paths and staging locations far enough away from nests so that induced winds would not adversely affect nests or nestlings.

Maximum induced surface velocities produced by downwash and sidewash from various helicopters were measured in the field to determine the decay function of rotor-produced vortices near ground level (Teske et al., 1997). Field studies included measurements on three helicopter models that might be utilized during construction of the Pacific Connector pipeline: 1) the twin-rotor CH-47 (civilian variant is the Boeing HH-47 Chinook) with rotor diameter 59.1 feet, 2) the single rotor CH-54 with a rotor diameter of 72 feet (civilian variant is the Sikorsky S-64 Skycrane), and 3) the twin-rotor CH-46 (civilian variant Boeing Vertol 107) with a rotor diameter of 49.9 feet (Teske et al., 1997). Using parameters derived from the field trials, estimates of maximum induced surface velocities were made for each of the three helicopter models at varying heights above ground while flying at different ground speeds. In general, maximum induced surface velocities increase with rotor diameters, decrease with distance above ground, and decrease with faster ground speeds.

Results of modeling maximum induced surface velocities (model described in Teske et al., 1997) produced by a Chinook helicopter are shown in figure 4.3-7 for drop heights (heights above ground level at which the helicopter would discharge a payload of foam, water, or retardant during wild fire control) ranging from 10 to 320 feet while flying at ground speeds ranging from 5 to 25 miles per hour (mph). Included in figure 4.3-6 are four wind speed categories on the Beaufort Scale (NOAA: http://www.spc.noaa.gov/faq/tornado/beaufort.html) which was developed to describe damage associated with wind forces ranging from calm to hurricane forces. On the Beaufort Scale, induced surface winds of 9 to 11 mph produced by rotor wash would be equivalent to a "gentle breeze" during which leaves and small twigs would be constantly moving and light flags would be extended. Wind velocities of 19-24 mph are classified as a "fresh breeze" (small trees in leaf would sway). Winds 39 to 46 mph are "gale" force strength: difficult to walk against, twigs and small branches blown off trees. Winds greater than 74 mph are classified as a hurricane.

Figure 4.3-7 shows the heights above ground that Chinook helicopters would produce maximum induced surface winds with velocities equivalent to a "fresh breeze" while traveling at ground speeds of 5, 10, 15, 20 or 25 mph. For example, if traveling at a ground speed of 5 mph, the Chinook would have to be approximately 185 feet above ground to produce a maximum induced surface velocity of 24 mph, equivalent to a "fresh breeze". If traveling at ground speed of 25 mph, the Chinook could be 75 feet above ground and still induce a maximum surface velocity of 24 mph.

In the Project area, wind speeds reported by the Western Regional Climate Center (available online at http://www.wrcc.dri.edu/htmlfiles/westwind.final.html#OREGON) at the North Bend airport averaged 10.2 mph in June, 11.2 mph in July and 9.9 mph in August, the three months with highest average wind velocities during the period from 1996 to 2006. During the same period, winds in Roseburg averaged 5.0 mph in June, 5.2 mph in July, and 4.4 mph in August. These data indicate that winds as strong as a fresh breeze (19 to 24 mph) would be expected along the Oregon Coast and most likely inland during the period when MAMUs are nesting. We assume that induced winds the strength of a fresh breeze would not adversely affect young or nests.

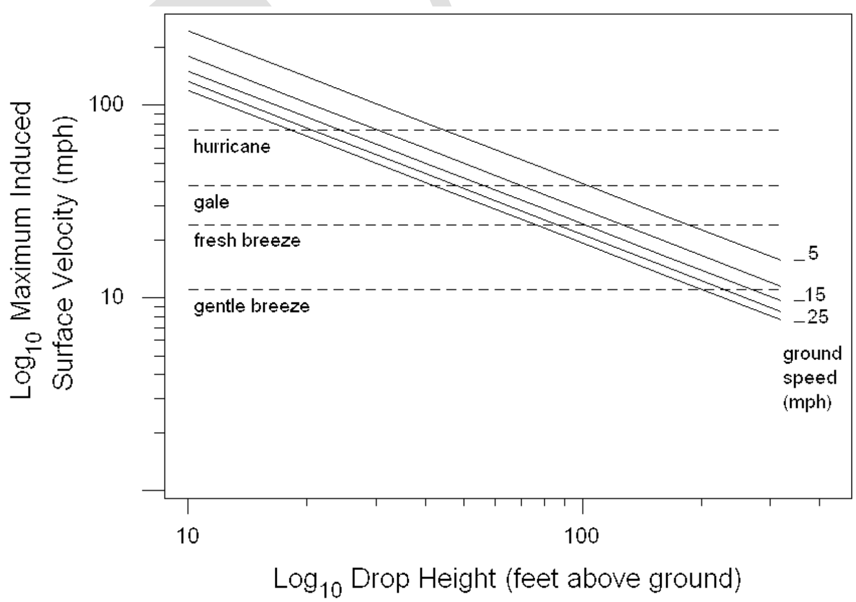

**Figure 4.3-7**
**Modeled Maximum Surface Velocities Induced by Chinook C-47 Helicopters while Flying at Ground Speeds From 5 to 25 mph at Heights From 10 to 320 feet Above Ground. (Modeled from data in Teske et al., 1997)**

Incoming or outgoing Chinook helicopters flying at 5 mph while 185 feet above a tree with a nest would most likely produce winds with velocities less than a fresh breeze at the tree top because there would be no resistance by the ground to induce maximum sidewash vortices.

Similar results were produced by the Boeing Vertol 107 (see figure 4.3-8) even though it is smaller than the Chinook (rotor diameter 49.9 feet compared to 59.1 feet). The Vertol 107, flying at a ground speed of 5 mph, would have to be approximately 200 feet above ground to produce a maximum induced surface velocity of 24 mph, equivalent to a fresh breeze. If traveling at ground speed of 25 mph, the Vertol 107 could be 82 feet above ground and still induce a maximum surface velocity of 24 mph. Overall, the Vertol 107 produces slightly greater maximum induced surface velocities than the Chinook CH-47 even though its maximum equipment weight is less than the Chinook.

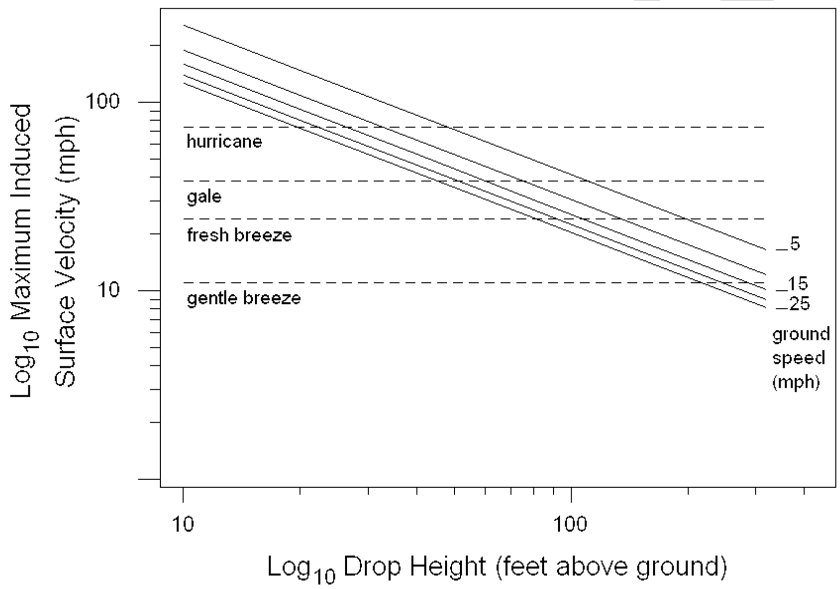

**Figure 4.3-8**
**Modeled Maximum Surface Velocities Induced by Boeing Vertol 107 Helicopters while Flying at Ground Speeds From 5 to 25 mph at Heights From 10 to 320 feet Above Ground (Modeled from data in Teske et al., 1997**

The single rotor S-64 Skycrane has the largest rotor diameter (72 feet diameter) of the three models. As modeled in figure 4.3-9, the Skycrane would produce greater maximum induced surface velocities while flying at the same ground speeds and same drop heights as the other two helicopter models.

Flying at a ground speed of 5 mph, the Skycrane would have to be approximately 233 feet above ground to produce a maximum induced surface velocity of 24 mph, equivalent to a fresh breeze. The Chinook and Vertol 107 helicopters would induce similar maximum surface velocities flying at heights of 185 feet and 200 feet above ground, respectively. If traveling at ground speed of 25 mph, the Skycrane could be 95 feet above ground to induce a maximum surface velocity of 24 mph.

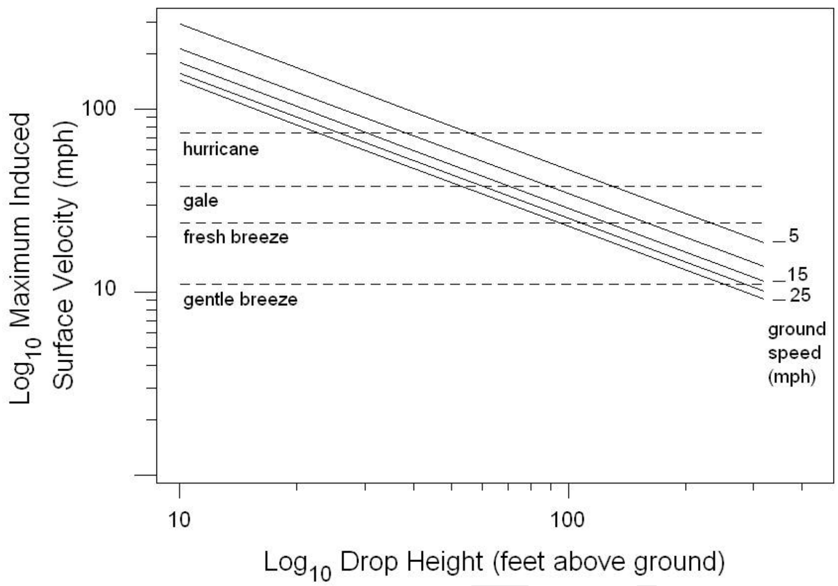

**Figure 4.3-9**
**Modeled Maximum Surface Velocities Induced by Skycrane S-64 Helicopters while Flying at Ground Speeds From 5 to 25 mph at Heights From 10 to 320 feet Above Ground. (Modeled from data in Teske et al., 1997**

Actual downwash and sidewash vortices produced by Chinook CH-47 and Skycrane (CH-54) helicopters were measured during field tests (Leese and Knight, 1974) while aircraft were hovering at 40-50 feet and 80-90 feet above ground level (agl) while under maximum loads of 36,000 pounds (CH-47) and 45,000 to 47,000 pounds (CH-54). The Vertol 107 (CH-46) was not included in the field tests.

With a 47,000-pound load, the single rotor CH-54 hovering at 40 feet agl produced a maximum sidewash velocity of 87 mph 50 feet away from the rotor hub; at 80 feet agl, the maximum sidewash was 74 mph, also measured at 50 feet from the hub though the gross weight was 45,000 pounds during that particular trial. Both maximum sidewash measurements were at heights of 0.3 feet above ground (Leese and Knight, 1974). Under the specified load conditions, the CH-54 produced a sidewash of 11 mph 170 feet away from the rotor hub while hovering at 40 feet agl and a sidewash of 9 mph 150 feet away from the hub while hovering at 80 feet agl. Maximum sidewash velocities of 74 to 87 mph that were associated with the CH-54 helicopter while it was hovering, are within the range of hurricane force winds on the Beaufort Scale while winds of 9 to 11 mph produced by rotor sidewash would be described as a “gentle breeze”. Sidewash velocities between 9 and 11 mph at distances 150 to 170 feet away from a CH-54 helicopter (Skycrane) would be unlikely to blow young MAMUs from their nests.

Downwash and sidewash velocities measured for the CH-47 helicopter (Chinook) were greater than 100 mph up to 70 feet horizontally from the rotor hub when it was hovering at 90 feet agl with maximum load of 36,000 pounds (Leese and Knight, 1974). The twin rotor CH-47 produced sidewash velocities as high as 56 mph 190 feet away from the rotor hub when it was hovering at 90 feet agl. The Beaufort Scale classifies winds between 55 and 63 mph as a “storm,” with trees uprooted and structural damage likely. The greater strength of winds produced by the CH-47 is likely due to the interaction of descending air produced by the two rotors (Fabey, 2008); sidewash winds are generally strongest at 120 and 240 degrees (4 o'clock and 8 o'clock, respectively) relative to the helicopter's heading (data in Leese and Knight, 1974).

Sidewash wind velocities produced by the CH-47 at various distances away from the rotor hub (Leese and Knight, 1974) were used to predict the distance at which the helicopter would be far enough to avoid adversely affecting MAMU nests and young. The prediction is based on the sidewash wind velocities produced by the CH-47, averaged for wind measurements made 0.3 feet above ground at angles of 120 and 240 degrees while the helicopter was hovering 90 feet agl under a load of 36,000 pounds. The prediction is shown below in figure 4.3-10 in which a sidewash velocity of 0 mph would occur 293 feet away from the rotor hub. Due to the observed variation in sidewash winds at different distances away from the rotor hub (solid circles in figure 4.3-10), the upper 95 percent prediction interval on that predictive estimate of 0 mph at 293 feet from the hub would be 23.8 mph. A wind velocity of 23.8 mph is classified as a fresh breeze on the Beaufort Scale. One can be 95 percent certain that a stronger wind, potentially adversely affect nesting MAMUs, would not occur.

These estimates clearly suggest that greater distances would be required to avoid adverse effects to MAMUs if Chinook helicopters, rather than Skycranes, are employed for heavy lifting along remote sections of the Pacific Connector pipeline construction right-of-way. Based on the similarities of maximum induced surface velocities between Chinook and Vertol 107 helicopters, sidewash velocities induced while hovering are likely to be similar as well. However, if known nest trees or stands can be avoided by at least 200 feet above tree tops by heavy-lifting helicopters in transit, and avoided horizontally by at least 300 feet while helicopters hover above staging sites, no adverse effects to the species from rotor downwash and induced sidewash would be expected.

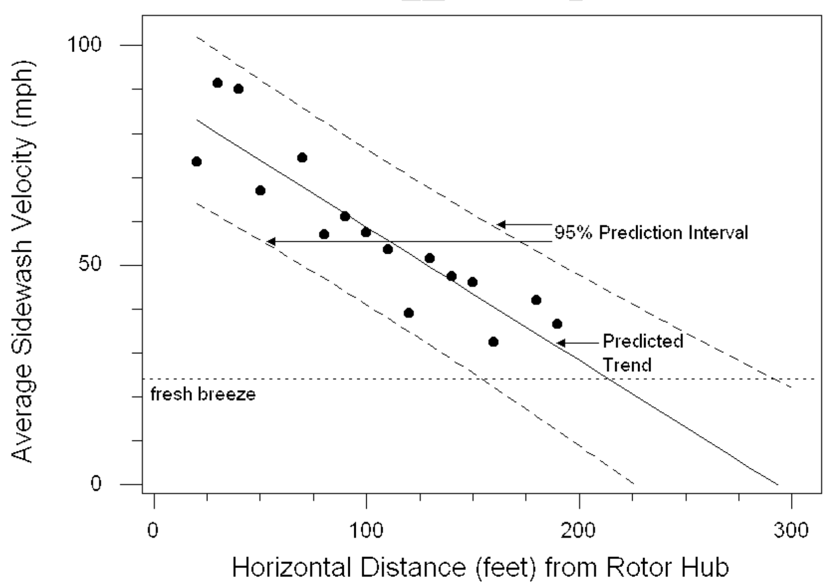

**Figure 4.3-10**
**Average Sidewash Wind Velocities Produced by the CH-47 at Varying Horizontal Distances from the Rotor Hub While Hovering 90 feet agl Under a Load of 36,000 pounds. The Observed Averages (solid circles) were used to Predict Sidewash Winds at Distances Out to 300 feet. (Source: Leese and Knight, 1974)**

Eleven MAMU stands occur within 0.25 mile of proposed helicopter use, of which seven stands are within 300 feet of proposed helicopter use (five occupied stands – C3073, C3090, C3094, C3095, and R3035 [EAR 46.51_A]; one unoccupied stand – B14; and one presumed occupied stand – G31). Helicopter use for timber extraction within 300 feet of a MAMU stand would occur outside of the entire breeding season (between September 16 and March 31); no adverse effects from rotor wash of large helicopters are expected during timber extraction. Adverse effects to MAMUs in the six stands identified above could occur from rotor wash of large helicopters during pipe delivery during construction of the proposed action, since activity could occur during the entire breeding season and may be within 200 feet above nest trees and horizontally within 300 feet of nest trees (the nest site is unknown within these stands but potential nest trees have been identified adjacent to the construction right-of-way and rotor wash could affect MAMU if present).

Burning and Smoke

Whether by prescribed burning as a habitat enhancement procedure or by burning slash, effects of smoke on MAMUs have not been studied. However, FWS et al. (2007) have declared (see Table 15, FWS et al. 2007) "that smoke can cause [northern spotted owl] adults to move off nest sites, therefore leaving eggs or young exposed to predation or resulting in lost feedings reducing the young's fitness." In the absence of reliable information, one would reasonably assume that the same effects apply to MAMUs.

According to BLM and Forest Service (2008, page 35), MAMUs "are potentially affected by fire control activities and drifting smoke during burning. The threshold distance for disturbance from smoke is 0.25 mile for MAMUs," which also would be subject to smoke-related disturbance during the critical breeding period (April 1 through August 5). Pacific Connector would not conduct slash burning during the critical breeding season within 0.25 mile of an occupied or presumed occupied MAMU stand. No direct effect to MAMUs due to slash burning is expected.

**Indirect Effects**

Project-related effects to MAMUs that are caused by the action (induced by the action and by human presence and use increase) and are later in time or farther removed in distance, but are still reasonably foreseeable are indirect effects. A primary indirect effect to MAMUs would be removal of suitable nesting habitat, and could also include removal of recruitment or capable habitat. Removal of MAMU habitat would be a long-term impact to MAMUs and would be expected to last at least 5 years or more. Short-term impact is expected with the use of UCSAs and is likely to last from the initiation of timber clearing until 1 to 5 years after restoration/revegetation. Other indirect or secondary effects by the Project could include increased human presence as a result of the requirements of the action itself (the workforce needed to construct or operate the Project), increased recreation (including ORV use, hunting), and habitat degradation (Comer, 1982).

Focus of Effects Analyses

Meyer et al., 2002a have indicated that social interactions may play an important role in determining nesting locations, in addition to available suitable habitat, since research has indicated that MAMU in California and southern Oregon were less likely to occupy old-growth habitat if it was isolated from other nesting MAMU by more than 3 miles. The FWS (FWS, 2008b and 2011a) and BLM (BLM, 1995a and 1995b) recognize that forested habitat within 0.5

mile of an occupied stand are important to recruit additional nesting habitat for the marbled murrelet in the future (e.g., potential nesting habitat within 25 years; BLM, 1995a and 1995b).

Indirect effects analyzed within this Draft BA are considered within three habitat areas defined by FWS as a Suitable Habitat Unit - SHU (PC Trask & Associates, 2013), which include habitat that could play an important role in maintaining and expanding MAMU populations: 1) the MAMU Stand with known or presumed suitable nesting structures; 2) a 300-foot buffer around the MAMU stand that includes forested habitat to protect/provide a buffer to nesting MAMUs as described by the MAMU Recovery plan (FWS, 1997); and 3) federally-designated critical habitat within a 0.5-mile buffer around a MAMU stand that is within 0.5 mile of critical habitat removal by the proposed action. This latter defined area includes forested habitat proximal to the MAMU stand that could provide suitable nesting structures in the future for the MAMU and has been federally protected through critical habitat designation. Within the Terrestrial Nesting Analysis Area where MAMU stands are in close proximity of each other (i.e., less than 300 feet or adjacent), SHUs overlap. Therefore, analyses provided in this Draft BA consider the SHUs within the Terrestrial Nesting Analysis Area collectively to eliminate duplication of acres of impact. Impacts to individual MAMU SHUs are included in appendix Z1. Figure 1 in appendix Z1 shows the MAMU SHUs in relation to the proposed action and Marbled Murrelet Inland Zones 1 and 2.

Nesting Habitat Removal/Modification

**Long-Term Effects to Habitat**. Removal of suitable nesting habitat by harvest of old-growth timber has been cited as the primary reason for the species' decline (FWS, 1992a). Implementation of the NWFP and late successional reserves, and the designation of critical habitat were designed to increase the amount of late successional forest habitat available for the long term, thus increasing potential nesting habitat for murrelets. The Coos Bay and Roseburg BLM Resource Management Plans (BLM, 1995a and 1995b) also identify the importance of forested habitat within 0.5-mile of occupied MAMU stands and state that removal of habitat within occupied stands should not occur and other forested habitat within a 0.5 mile radius of any occupied stand should be protected for recruitment of nesting habitat for marbled murrelets (i.e., stands that are capable of becoming marbled murrelet habitat within 25 years). Since 2003, effects to MAMU suitable habitat have been minimal (BLM and USFS, 2006a). Suitable murrelet nesting habitat takes a long time to develop (more than 250 years on average); therefore, any removal of suitable habitat or recruitment habitat may affect the recovery of the murrelet since recent trends indicate that murrelets may be declining (see Section 4.3.3.1).

Based on MAMU habitat delineated for the PCGP Project, construction of the proposed action will remove approximately 925.65 acres of MAMU habitat, including 57.98 acres of "suitable habitat" removed from 25 MAMU stands (14 occupied MAMU stands, two unoccupied MAMU stands, and nine presumed suitable stands; see table 4.3.3-9). Removal of 57.98 acres of suitable MAMU habitat amounts to approximately 0.4 percent of the 14,044 acres of suitable habitat available in the Terrestrial Nesting Analysis Area (see table 4.3.3-11). It is expected that recruitment habitat within SHUs, especially forested habitat greater than 60 years located on federally-managed lands, would provide potential nesting habitat for marbled murrelets in the future (BLM, 1995 a and b; PC Trask & Associates, 2013; FWS, 2008a and 2011b). The removal of suitable habitat would indirectly affect marbled murrelets over the long-term, for longer that the expected 40-year life of the project.

**Short-Term Effects to Habitat**. Additionally, 118.62 acres of MAMU habitat (12.68 acres of suitable habitat) have been identified for use by the PCGP Project as UCSAs that may be used to store forest slash, stumps, and dead and downed log materials that will be removed and scattered across the right-of-way after construction during restoration (see UCSA Column – table 4.3.3-10). Use of the UCSAs will be a short-term modification of understory species and will not affect the nesting habitat or characteristics.

**Summary of Effects to Habitat**. Table 4.3.3-10 below summarizes the amount of suitable habitat, recruitment habitat, and capable habitat that will be directly removed or used as UCSAs within and outside of SHUs.

Table 4.3.3-10 (summarized from table Q-3 in appendix Q) also identifies 201.70 acres of MAMU habitat that occur within the designated 30-foot maintenance corridor (16.00 acres of suitable habitat, 65.25 acres of recruitment habitat, and 120.45 acres of capable habitat) within Marbled Murrelet Inland Zones 1 and 2. After construction of the pipeline, approximately 723.95 acres of forested habitat within Marbled Murrelet Inland Zones 1 and 2 outside of the 30-foot maintenance corridor (see Suitable, Recruitment, and Capable in table 4.3.3-10, computed by subtracting areas in the 30-foot Corridor from areas in the Removed columns) will be replanted with tree species and effects of edge will decrease over time; Douglas-firs (12-inch seedlings in 1 gallon containers or bare root) will be planted on dry sites and western hemlock (12-inch seedlings in 1 gallon containers) will be planted on moist sites (see ECRP – appendix F). It is expected that 12-inch Douglas-firs and western hemlocks planted the year of or year after pipeline construction could be approximately 70 feet tall in 50 years (expected end of the PCGP Project life). During the first 30 years or so, coastal Douglas-fir are expected to grow at an average rate of 24 inches per year and may grow at a continuous rate of 6 to 9 inches per year to age 120 (McArdle et al., 1961; Hermann and Lavender, 2004). Young, unthinned stands of Douglas-fir (38 to 70 years old) were documented between 115 and 154 feet tall while young, thinned stands (40 to 73 years old) were 121 to 151 feet tall (Tappeiner et al., 1997). Western hemlock are highly productive; trees in Oregon were 140 feet tall at 100 years old (an approximate height growth rate of 16-17 inches per year). Marbled murrelet habitat within the 30-foot corridor will remain in an early seral state, maintained free of vegetation greater than 6 feet in height, through the life of the project.

Figure 1 in appendix Q provides an overview of MAMU habitat (suitable, recruitment, and capable) within the proposed Terrestrial Nesting Analysis Area and includes known occupied, presumed occupied, and unoccupied stands, designated critical habitat, NWFP LSRs, and unmapped LSRs within Marbled Murrelet Zones 1 and 2 and Conservation Zones 3 and 4. Table 4.3.3-11 summarizes the amount of MAMU habitat affected by the proposed Project within the Terrestrial Nesting Analysis Area pre- and post-action. The proposed action will remove the greatest percentage of available MAMU habitat within the Terrestrial Nesting Analysis Area on non-federal lands outside of SHUs; however, it is not expected that habitat on non-federal lands would provide suitable nesting structures, or that capable or recruitment habitat would mature to provide suitable MAMU nesting structures based on review of timber harvest practices in Oregon (Zhou, et al., 2005; Rasmussen, et al., 2012). These studies noted that forest harvest practices on non-federal lands typically occurs between 45 and 65 years of age.

1 General Location identifies areas within Marbled Murrelet SHUs – marbled murrelet stands – occupied, unoccupied, unsurveyed, presumed and appropriate buffers and areas outside of Marbled Murrelet SHUs within the range of the marbled murrelet.
2 Suitable Habitat: generally late-seral forested stands that provide or are presumed to provide nesting structures for marbled murrelet based on modeling and other available GIS data.
3 Recruitment Habitat: forested land not currently suitable for marbled murrelet nesting that may be capable of becoming suitable marbled murrelet habitat within the next 25 years (FWS, 2006e; BLM, 1995a and b); generally forested stands 60 years or greater (PC Trask & Associates, 2013).
4 Capable Habitat: forested land that has the capability of becoming suitable nesting marbled murrelet habitat, generally includes forest stand age 0 to 60 years (Trask & Associates, 2013).
5 Non-Capable habitat: not forested and not capable of becoming forest, or deciduous forest stands.
6 Project components considered in calculation of habitat "Removed": Pacific Connector construction right-of-way, temporary extra work areas, aboveground facilities, permanent and temporary access roads (PAR, TAR), pipe storage yards, and hydrostatic locations.
7 Acres identified as UCSAs have been incorporated into the 100-meter indirect effects. UCSAs would not be cleared of trees during construction and will not affect nesting structures or characteristics. These areas would be used to store forest slash, stumps and dead and downed log materials that would be removed and scattered across the right-of-way after construction during restoration and are considered as temporary insignificant understory habitat effects.
8 Acres of habitat that would be maintained in an early seral / shrub state during the life of the project within the 30-foot maintenance corridor.

Summarized from table Q-3 in appendix Q, which also provides project effects by land allocation and within and outside of interior forest.

**Table 4.3.3-11**
**Summary of Effects to Marbled Murrelet Habitat within Marbled Murrelet Zones 1 and 2 and Recovery Plan Conservation Zones 3 and 4 within the Defined Terrestrial Nesting Action Area as a Result of the Proposed Project**

1 Federal Landowers include Coos Bay BLM and Roseburg BLM Districts; Non-Federal Landowners include Private and State.
2 Suitable Habitat: generally late-seral forested stands that provide or are presumed to provide nesting structures for marbled murrelet based on modeling and other available GIS data.
3 Recruitment Habitat: forested land not currently suitable for marbled murrelet nesting that may be capable of becoming suitable marbled murrelet habitat within the next 25 years (FWS, 2006e; BLM, 1995a and b); generally forested stands 60 years or greater (Trask & Associates, 2013).
4 Capable Habitat: forested land that has the capability of becoming suitable nesting marbled murrelet habitat, generally includes forest stand age 0 to 60 years (Trask & Associates, 2013).

Temporary Loss of Habitat - Noise and Human Presence

There is a potential that indirect and temporary loss of approximately 6,841.34 acres of suitable nesting habitat (occupied, presumed occupied, and unoccupied MAMU stands) within the Terrestrial Nesting Analysis area could occur from noise and visual disturbance where proposed project activities, including existing road use occur within 0.25 mile of suitable habitat (MAMU stands) during the breeding season (April 1 through September 15; table 4.3.3-12). Project activities within the range of the MAMU could occur during the breeding season and would generally begin in Year One from April 1 and continue through Year Two (weather-permitting; see figures 3.2-1 and 3.2-3), with DTRs applied for timber removal and construction during the critical breeding season (April 1 through August 5) to minimize effects to MAMU. Pacific Connector would continue to apply DTRs in the late breeding season for use of large transport helicopter use, if necessary. Proposed activities would not occur simultaneously within MAMU Inland Zones 1 and 2, and therefore, actual temporary, indirect habitat loss would be less than estimated within table 4.3.3-12.

Based on the proportion of suitable habitat known to be occupied by nesting MAMUs either as surveyed per protocol (see Mack et al., 2003), or expected to be occupied based on survey history in the area and the application of an occupancy index to unsurveyed areas (51 percent of reported suitable habitat are likely occupied in Oregon; see McShane et al., 2004), approximately 3,489.08 acres (51 percent of suitable habitat; 6,841.34 acres in table 4.3.3-12) is likely occupied and could be indirectly impacted. It is not expected that use of existing access roads would disrupt or disturb MAMU to the extent of expected nest failure during the breeding season (see discussion above in Direct Effects Section).

**Table 4.3.3-12**
**Amount (acres) of Suitable Nesting Habitat [1] Indirectly Affected within 0.25 mile of Proposed Disturbance from Timber Removal and Construction During the Entire Breeding Season (April 1 through September 15)**

| Landowner | Length of Pipeline / EARs within 0.25 mile of MAMU Stands | | Suitable Nesting Habitat (MAMU Stands) within 0.25 mile of Proposed Project Activities | | | |

[1] Acres of suitable habitat (MAMU Stands - occupied, presumed occupied, unoccupied) includes only the area of MAMU stands considered for analysis within this BA within 0.25 mile of proposed activitites.

Habitat Fragmentation

In addition to impact by surface disturbances, fragmentation of connected, contiguous habitats will occur. Fragmentation of MAMU habitat can reduce the amount and heterogeneous nature of the habitat, forest patch size, and amount of interior or core habitat, and can increase the amount of edge, isolate remaining habitat patches, and create "sink" habitats (FWS, 2006e). The ecological consequences of these habitat changes to MAMUs can include effects on population viability and size, local or regional extinctions, displacement, fewer nesting attempts, failure to breed, reduced fecundity, reduced nest abundance, lower nest success, increased predation and parasitism rates, and reduced adult survival (FWS, 2006e).

**Habitat Edge.** One manifestation of fragmentation is the amount of edge created through otherwise contiguous habitats. In the context of habitat fragmentation, edge is the portion of habitat (or ecosystem on a larger scale) "near its perimeter, where influences of the surroundings prevent development of interior environmental conditions" (page 38 in Forman, 1995). As compared to interior habitats, edge habitats generally support different species composition, structure, and species' abundance (Forman and Godron, 1986). For example, higher levels of flower and fruit production often occur along the edge (Forman, 1995) and vertebrate species richness (bird and amphibian) has positively associated with edges in fragmented Douglas-fir forests (Rosenberg and Raphael, 1986). Edges play a crucial role in controlling ecosystem interactions and landscape function, including the distribution of plants and animals, fire spread, vegetation structure, wildlife habitat conservation, and physical environments.

Research indicates that MAMUs within southern Oregon tend to nest in stands that are generally located away from high-contrast edge created from timber stand harvests and adjacent immature forests (Ripple et al., 2003; Meyer et al., 2002b). In Canada, Zharikov et al. (2006) found MAMUs commonly nesting in stands near edges, although when edge increased in the nest patch, more nests failed (Zharikov et al., 2007). Alternatively, a study conducted in British Columbia found no evidence suggesting that nesting near forest edges, especially natural edges, reduced reproductive success in marbled murrelets (Bradley, 2002). In addition, nests at edges of clearcuts, old growth, and second growth transitional forests were generally more successful than not successful. In that study, increased reproductive success at natural edges compared to interior forest stands was thought to be related to ease of nest tree accessibility have greater benefit to marbled murrelets than the risk of nest predation (Bradley, 2002).

Increase in edge within occupied or presumed occupied stands from construction of the Pacific Connector pipeline may result in reduced nest success. Also, since MAMUs may nest close to the edge of a stand (easier access to nest), removal of suitable habitat on the edge of an occupied or presumed occupied stand may result in removal of a nest or potential nest tree. Fragmentation of an occupied or presumed occupied stand may also result in eventual abandonment of the stand. Meyer et al. (in review) indicate that MAMUs appear to abandon newly fragmented areas smaller than 124 acres, but because of site fidelity, abandonment may occur sometime after fragmentation happens (i.e., 5 to 20 years later). The Terrestrial Nesting Analysis Area has already been subjected to extensive fragmentation by past land uses including transportation corridors, timber harvest and associated activities (i.e., road construction), and urban development. Table Q-4 in appendix Q identifies the location of MAMU Stands and associated SHU habitat areas in relation to existing rights-of-ways and corridors. Within MAMU Inland Zone 1 and Zone 2 (MP 1.47R to MP 75.64), the Pacific Connector pipeline would be located within or parallel to existing corridors for approximately 31.76 miles (40 percent of proposed action in MAMU range; see table Q-4 in appendix Q), thus minimizing fragmentation within known or potential suitable MAMU nesting habitat. However, additional fragmentation will occur within suitable nesting habitat (occupied, presumed occupied, and unoccupied stands), as well as recruitment and capable habitat due to the proposed project.

Twenty-five marbled murrelet stands (occupied, unoccupied, and presumed occupied) will be affected by construction of the PCGP Project. With the exception of seven marbled murrelet stands (six occupied and one unoccupied) most suitable habitat affected by construction of the PCGP Project either occurs on the edge of the marbled murrelet stand or between the interface of the older occupied stand and an adjacent young, regenerating stand and/or existing access roads. The proposed action would bisect six occupied stands and one unoccupied stand (see asterisk in table 4.3.3-13). Table 4.3.3-13 summarizes the length that each marbled murrelet stand is crossed by the proposed pipeline, how much each stand is reduced in size, and if habitat is removed from one or more edges, if any, as well as resulting habitat patches within seven MAMU stands that would be bisected by the project. Table Q-1 in appendix Q, as well as the MAMU Impact Categorization for each MAMU Stand in appendix Z1 identifies the suitable, recruitment, and/or capable MAMU habitat that would be removed within the 300-foot Buffer of each MAMU Stand outside of the MAMU breeding season (see also maps of each MAMU Stand located within appendix Z1).

The proposed Project occurs in MAMU recovery plan Conservation Zones 3 and 4, of which the recommended management to aid in recovery includes maintaining designated occupied sites and minimizing loss of unoccupied but suitable habitat (FWS, 1997). Pacific Connector has adjusted the proposed route to minimize impact to MAMU stands by 1) rerouting the pipeline to avoid occupied stands documented during 2007 and 2008 survey efforts, 2) incorporating minor alignment adjustments to reduce habitat removed occupied stands, 3) modifying or moving temporary extra work areas, and 4) restricting the pipeline construction right-of-way to roads within occupied, presumed occupied, and unoccupied stands. Approximately 57.68 acres of suitable habitat would be removed from occupied, presumed occupied, and unoccupied stands, removing a total of 0.4 percent from available suitable habitat within the analysis area (14,044 acres; see table 4.3.3-11, above) within the defined Terrestrial Nesting Analysis Area. Overall, 2.2 percent of habitat within delineated MAMU stands would be removed (see table 4.3.3-13). The integrity of known occupied stands within the terrestrial analysis area, especially those stands with large acreages, would likely be maintained.

Pacific Connector surveyed 17 occupied and unoccupied stands located on BLM-managed lands in fall 2013 to identify potential nest trees that may occur within the proposed action (see R&A and SBS, 2014). Trees with adequate nesting platform structures, as outlined in the Pacific Seabird Group protocol (Mack, et al., 2003) were considered "potential nest trees" and included: 1) mature (with or without an old-growth component) and old-growth coniferous trees, or 2) younger coniferous trees that have platforms. A nesting platform consists of a relatively flat surface (at least 4 inches in diameter) that occurs at least 33 feet from the ground in the live crown of a coniferous tree and can include a wide bare branch, moss or lichen covered a branch, mistletoe, witches brooms, or other deformities (i.e., squirrel nests). Additional description in table 4.3.3-13 describes the potential nest trees that were identified within the proposed construction area, if any. Additional maps have been prepared and included in appendix Z1 for the 25 MAMU stands that would potentially have suitable habitat removed by the proposed action. The maps include locations of potential nest trees located within the vicinity of the proposed action during survey efforts in fall 2013, and were available (23 of 25 MAMU stands), are produced with a Lidar background that depicts the structure and height of the MAMU stand. Based on these maps and the potential nest trees documented within the vicinity of the Project right-of-way, it can be assumed that each stand contains trees outside of the proposed project effects that could provide suitable nesting habitat (i.e., trees greater than 200 feet in height).

**Interior Forest Habitat**. Indirect effects from construction of the Pacific Connector pipeline are also expected within habitat adjacent to the PCGP construction right-of-way, including within interior forest that the marbled murrelet relies on for nesting habitat. The conversion of large tracts of old-growth forest to small, isolated forest patches with large edge areas can create changes in microclimate, vegetation species, and predator-prey dynamics. In general, microclimates along edges differ from those in forest interiors. Two main physical factors affecting and creating an edge microclimate are sun and wind (Forman, 1995; Chen et al. 1995; Harper et al., 2005). Compared to the forest interior, areas near edges receive more direct solar radiation during the day, lose more long-wave radiation at night, have lower humidity, and receive less short-wave radiation. Other physical factors affecting edge includes edge orientation (Chen et al., 1995). For example, the general orientation of the PCGP Project is from northwest to southeast. Therefore, edge effects will be most pronounced on the southwest-facing edges and weakest along the northeast-facing edges (see discussion in Chen et al., 1995). Harper et al. (2005) reported that the mean distance of edge influence could occur to approximately 100 meters (328 feet) and result in 1) tree mortality, damage, recruitment, growth rate, canopy foliage, understory foliage, and seedling mortality, 2) amounts of canopy trees, canopy cover, snags and logs, understory tree density, herbaceous cover, and shrub cover, and 3) stand composition metrics such as species, exotics, individual species and species diversity. In other younger coniferous forests or mixed forests with deciduous species, edge effects compared to interior forests have been much less pronounced (Heithecker and Halpern, 2007; Harper and Macdonald, 2002). The importance of interior forest habitat to marbled murrelets is unclear. Suitable nest trees may be present within interior forest but reproductive success may be lower than at forest edges if access to interior forest nest trees is problematic, decreasing site suitability (Bradley, 2002).

To determine indirect effects to marbled murrelet habitat (suitable, recruitment, capable) from construction of the PCGP Project, Pacific Connector assessed effects to marbled murrelet habitat within 100 meters (328 feet) of proposed habitat removal, including effects to interior forest. This distance has been recommended by FWS (Trask & Associates, 2013), which is similar to 300 feet considered in discussions within the Habitat Quality subtask force to analyze effects to interior forests (2007 and 2008), and the 295 feet used as an edge assessment by Raphael et al. (2011) within the NWFP 15 Year Monitoring Report for nesting marbled murrelet habitat. This assessment considers the indirect effects of the newly constructed right-of-way on marbled murrelet habitat within 100 meters of habitat removal, including interior forest. To determine which tracts of forested land (late regenerating, mid-seral, late successional, and old-growth) should be considered interior forest, existing edges, such as wide-surface roads, large rivers, early seral forest, and nonforested habitat were buffered by 100 meters, and forested habitat included in the buffered area was identified as forested habitat currently affected by existing edge (Trask & Associates, 2013; Trask & Associates, 2013 – personal communication, December 20, 2013). Smaller roads with existing canopy cover were buffered by 50 feet per direction of FWS (Trask and Associates, 2014). Forested habitat (late regenerating to old-growth forest) that was not included in buffered "curenntly affected" area was classified as "interior forest" and incorporated into the interior forest model.

**Table 4.3.3-13**
**Suitable Nesting Habitat removed from Occupied, Presumed Occupied, or Unoccupied Stands Affected by the Proposed Action**

| MSNO or Site ID[1] | Status[2] | Project Location (mp range in stand) | Land owner | Land Allocation[3] | Overall Acres in the Stand | Length Crossed | | Edge Created | Suitable Habitat Affected in MAMU Stand | | Additional Description (see Maps in appendix Z1) |
|---|---|---|---|---|---|---|---|---|---|---|---|
| | | | | | | feet | miles | | Acres | Percent of Stand | |
| **MARBLED MURRELET ZONE 1** | | | | | | | | | | | |
| WC1A-F | Presumed | 8.60R-8.69R | Private | None | 70.56 | 484.85 | 0.09 | 0 | 1.51 | 2.1 | Habitat on both sides of 100' powerline corridor; ROW adjacent to powerline corridor; habitat removed on edge of "stand" - will not create additional edge; other "gray habitat" in area determined not suitable |
| WC1A-G | Presumed | 8.79R-8.85R | Private | None | 2.92 | 307.68 | 0.06 | 0 | 0.59 | 20.2 | Habitat on edge of 100' powerline corridor; ROW follows existing road ~ 50-100 feet from powerline corridor; will remove habitat either side of two-track road, generally reducing or removing all potential habitat in one lobe of WC1A-G between road and powerline corridor; other permitted 'gray' habitat around stand determined "not suitable'; no new edge created |
| G16 | Presumed | 12.27-12.29; 12.46-12.47 | Private | None | 5.13 | 143.24 | 0.03 | 0 | 0.38 | 7.4 | Habitat generally in "mid-seral" habitat as delineated; within mosaic of shrubs/trees; in close proximity to residences; will remove portion of "stands" - lobes that extend into shrub/grass areas; other "gray habitat" around the stand determined not suitable; no new edge created |
| G31 | Presumed | 18.91-18.92 | Private | None | 1.50 | 0 | 0 | 0 | 0.01 | 0.7 | Habitat 'mid-seral' as delineated; lidar indicated some taller trees; will most likely not remove any trees from delineated 'potential' stand; adjacent "gray habitat" determined not suitable; no new edge created |
| G33 | Presumed | 20.64-20.70; 20.74-20.78; 20.85-20.92; scattered north and south of ROW | Private | None | 65.43 | 863.65 | 0.16 | 2 | 2.59 | 3.9 | Habitat in serveral 'lobes' on either side of ~220' powerline corridor; ROW adjacent to or parallels (~200' from corridor) existing corridor; bisects one small lobe of stand and creates two additional edges; removes habitat from another lobe but does not further fragment; adjacent BLM habitat determined not suitable |
| G38* | Presumed | 23.08-23.14; EAR 23.09 | Private | None | 3.82 | 306.58 | 0.06 | 1 | 0.48 | 12.6 | Habitat 'mid-seral' as delineated; lidar indicated some taller trees; does not fragment stand but creates new edge - removes habitat from edge; however, contiguous with other older habitat around delineated stand; adjacent "grayhabitat" determined not suitable |
| C1080 (B02)* | Occupied - Jully 2013 | 27.13-27.48 | Coos Bay BLM | Matrix | 135.87 | 1810.2 | 0.34 | 2 | 4.10 | 3.0 | Project would bisect stand - no other existing fragmentation; resulting two lobes = 17.08 acres and 114.78 acres; approximately 93 potential nest trees were identified in the vicinity of the Project, of which 75 would likely be removed during construction (R&A and SBS, 2014) |
| G44 | Presumed | 29.17-29.19; 29.48-29.50; four scattered stands | Private | None | 1.38 | 194.12 | 0.04 | 4 (2 lobes) | 0.40 | 29.0 | Several lobes along existing timber road within riparian buffer; two small "lobes" bisected/removed; questionable if habitat - adjacent to road and/or residence |
| C3098* | Occupied - PCGP 07/08 | 32.04 - 32.47 | Coos Bay BLM | Unmapped LSR - Pacific Connector | 128.42 | 2294.2 | 0.43 | 2 | 4.99 | 3.9 | Project would bisect stand increasing fragmentation of stand-existing road crosses stand; resulting two lobes = 106.68 acres and 16.47 acres; occupied behavior detected ~625 feet north of habitat removal; 5 potential nest trees were identified in the vicinity of the Project, of which 3 trees would likely be removed during construction (R&A and SBS, 2014) |

[1] Asterisk (*) indicates proposed project would bisect stand and create at least two new edges.
[2] "Occupied" – areas/stands delineated that occupied marbled murrelet behavior has been documented. Stands have been provided by Coos Bay BLM, Roseburg BLM, and Northern States Resources (2012). "Unoccupied" – areas with suitable nesting habitat but surveys in 2007, 2008, and 2013 did not document occupied behavior. "Presumed" – these are areas that may provide suitable nesting habitat as determined through 1) lidar, 2) identified by Coos Bay and/or Roseburg BLM Districts, and/or 3) suitable habitat modeling (Raphael et al., 2006; habitat value 4).
[3] Land Allocation: LSR = Northwest Forest Plan (NWFP) late-successional reserves (LSR); Unmapped LSR = occupied marbled murrelet stand or northern spotted owl known activity center that occur in NWFP Matrix lands (identified by BLM and Forest Service, as well as other occupied marbled murrelet stands that have been included as unmapped LSRs by Pacific Connector).; CHU = Marbled Murrelet Critical Habitat Unit OR-06-d; Other = NWFP landuse allocations except for LSR; None = marbled murrelet stand on Private or Native American lands and do not have NWFP LUA or designated CHU.

Table 4.3.3-14 identifies the distance that MAMU habitat is crossed by the proposed project within and outside of interior habitat, summarizes the acreage of MAMU habitat directly removed and indirectly affected within 100 meters of the PCGP Project (habitat removal) by Marbled Murrelet Inland Zones 1 and 2, landowner, and within and outside of SHUs (summarized from table Q-3 in appendix Q). Approximately 5,412 acres of marbled murrelet habitat (490 acres of suitable habitat, 1,801 acres of recruitment habitat, and 3,121 acres of capable habitat) occur within 100 meters of habitat removal, of which 882 acres (16.3 percent) of interior murrelet habitat would be indirectly affected (219 acres of suitable habitat, 323 acres of recruitment habitat, and 340 acres of capable habitat; table 4.3.3-14). The majority of marbled murrelet habitat indirectly affected occurs outside of SHUs: 4,264 acres (78.8 percent) of all murrelet habitat within 100 meters of habitat removal, which includes 556 acres of interior marbled murrelet habitat and 3,708 acres of murrelet habitat currently affected by existing edge. Table Q-3 in appendix Q identifies the acres of marbled murrelet habitat affected 100 meters from habitat removal by Marbled Murrelet Inland Zone, Recovery Plan Conservation Zone, land allocations (critical habitat and LSR effects), and landowner within SHUs and interior forest. Effects to marbled murrelet habitat adjacent to the construction right-of-way will decrease as the forested area (approximately 724 acres; table 4.3.3-14) outside of the 30-foot maintenance corridor are replanted with trees and return to early regenerating stands. Based on the table below, it can be assumed that at least 8.1 miles of interior forest will experience fragmentation as a result of the proposed project, creating at least 16.2 miles (8.1 miles x 2) of additional edge in approximately 55.3 miles of MAMU habitat crossed by the project; this considers interior forest crossed by the proposed project within older regenerating forest to old-growth forest (see Trask & Associates, 2013). Additional fragmentation of approximately 15.5 miles within forest currently affected by existing disturbance ("other" forest in table 4.3.3-14) could be affected since approximately 40 percent (31.8 miles) of the project within the range of MAMU occurs within or is adjacent/parallels existing disturbance (see co-locate table Q-4 in appendix Q; 47.3 miles minus 31.8 miles), creating approximately 31.0 miles of additional edge in forest already affected by existing disturbance. In addition to MAMU habitat crossed and affected within the MAMU range, approximately 24.3 miles of non-capable habitat will be crossed and remove approximately 981 acres (see table Q-3 in appendix Q). Figure 4.3-11, below provides an example of how indirect effects to murrelet habitat, both within and outside of interior forest are considered within the range of the MAMU.

## Table 4.3.3-14
## Summary of Indirect Effects from Construction of the Proposed Action to Marbled Murrelet Habitat (Suitable, Recruitment, Capable), Including Interior Forest within and outside Marbled Murrelet SHUs by Landowner

| Landowner[1] | General Location[2] | Interior Forest[3] | Suitable Habitat[4] | | | | | Recruitment Habitat[5] | | | | | Capable Habitat[6] | | | | | Total MAMU Habitat | | | | |

1 Landowner: Federal includes Coos Bay and Roseburg BLM Districts; Non-Federal includes State and Private lands.
2 General Location identifies areas within Marbled Murrelet SHUs– occupied, unoccupied presumed occupied and areas outside of Marbled Murrelet SHUs within the range of the marbled murrelet.
3 Interior Forest: not affected by existing disturbance (i.e., roads, existing corridors) or adjacent landuse/vegetation type (i.e., agriculture, non-forest, early regenerating forest); Other Forest Type includes forested habitat that is currently affected by existing disturbance or adjacent landuse/vegetation types within 100 meters of stand/MAMU habitat type.
4 Suitable Habitat: generally late-seral forested stands that provide or are presumed to provide nesting structures for marbled murrelet based on modeling and other available GIS data.
5 Recruitment Habitat: forested land not currently suitable for marbled murrelet nesting that may be capable of becoming suitable marbled murrelet habitat within the next 25 years (FWS, 2006e; BLM, 1995a and b); generally forested stands 60 years or greater (PC Trask & Associates, 2013).
6 Capable Habitat: forested land that has the capability of becoming suitable nesting marbled murrelet habitat, generally includes forest stand age 0 to 60 years (Trask & Associates, 2013).
7 Total Habitat: only includes forested MAMU habitat
8 Project components considered in calculation of habitat "Removed": Pacific Connector construction right-of-way, temporary extra work areas, aboveground facilities, permanent and temporary access roads (PAR, TAR), pipe storage yards, and hydrostatic locations.
9 Acres identified as UCSAs have been incorporated into the 100-meter indirect effects. Indirect Effects considers habitat within 100-meters of habitat removal as measured from the edge of habitat removal/edge of right-of-way/TEWA.
10 UCSAs would not be cleared of trees during construction and will not affect nesting structures or characteristics. These areas would be used to store forest slash, stumps and dead and downed log materials that would be removed and scattered across the right-of-way after construction during restoration and are considered as temporary insignificant understory habitat effects.
11 30-foot Maintenance Corridor will be kept in a shrub/sapling state for the life of the project; all other habitat outside of the 30-foot maintenance corridor will be revegetated.

Note: Table summarized from table Q-3 in appendix Q, which includes effects by general landowner, by Conservation Zones 3 and 4 and Marbled Murrelet Inland Zones 1 and 2. Habitat effects are also broken out marbled murrelet habitat type and within and outside of marbled murrelet SHUs (occupied, unoccupied, and presumed).

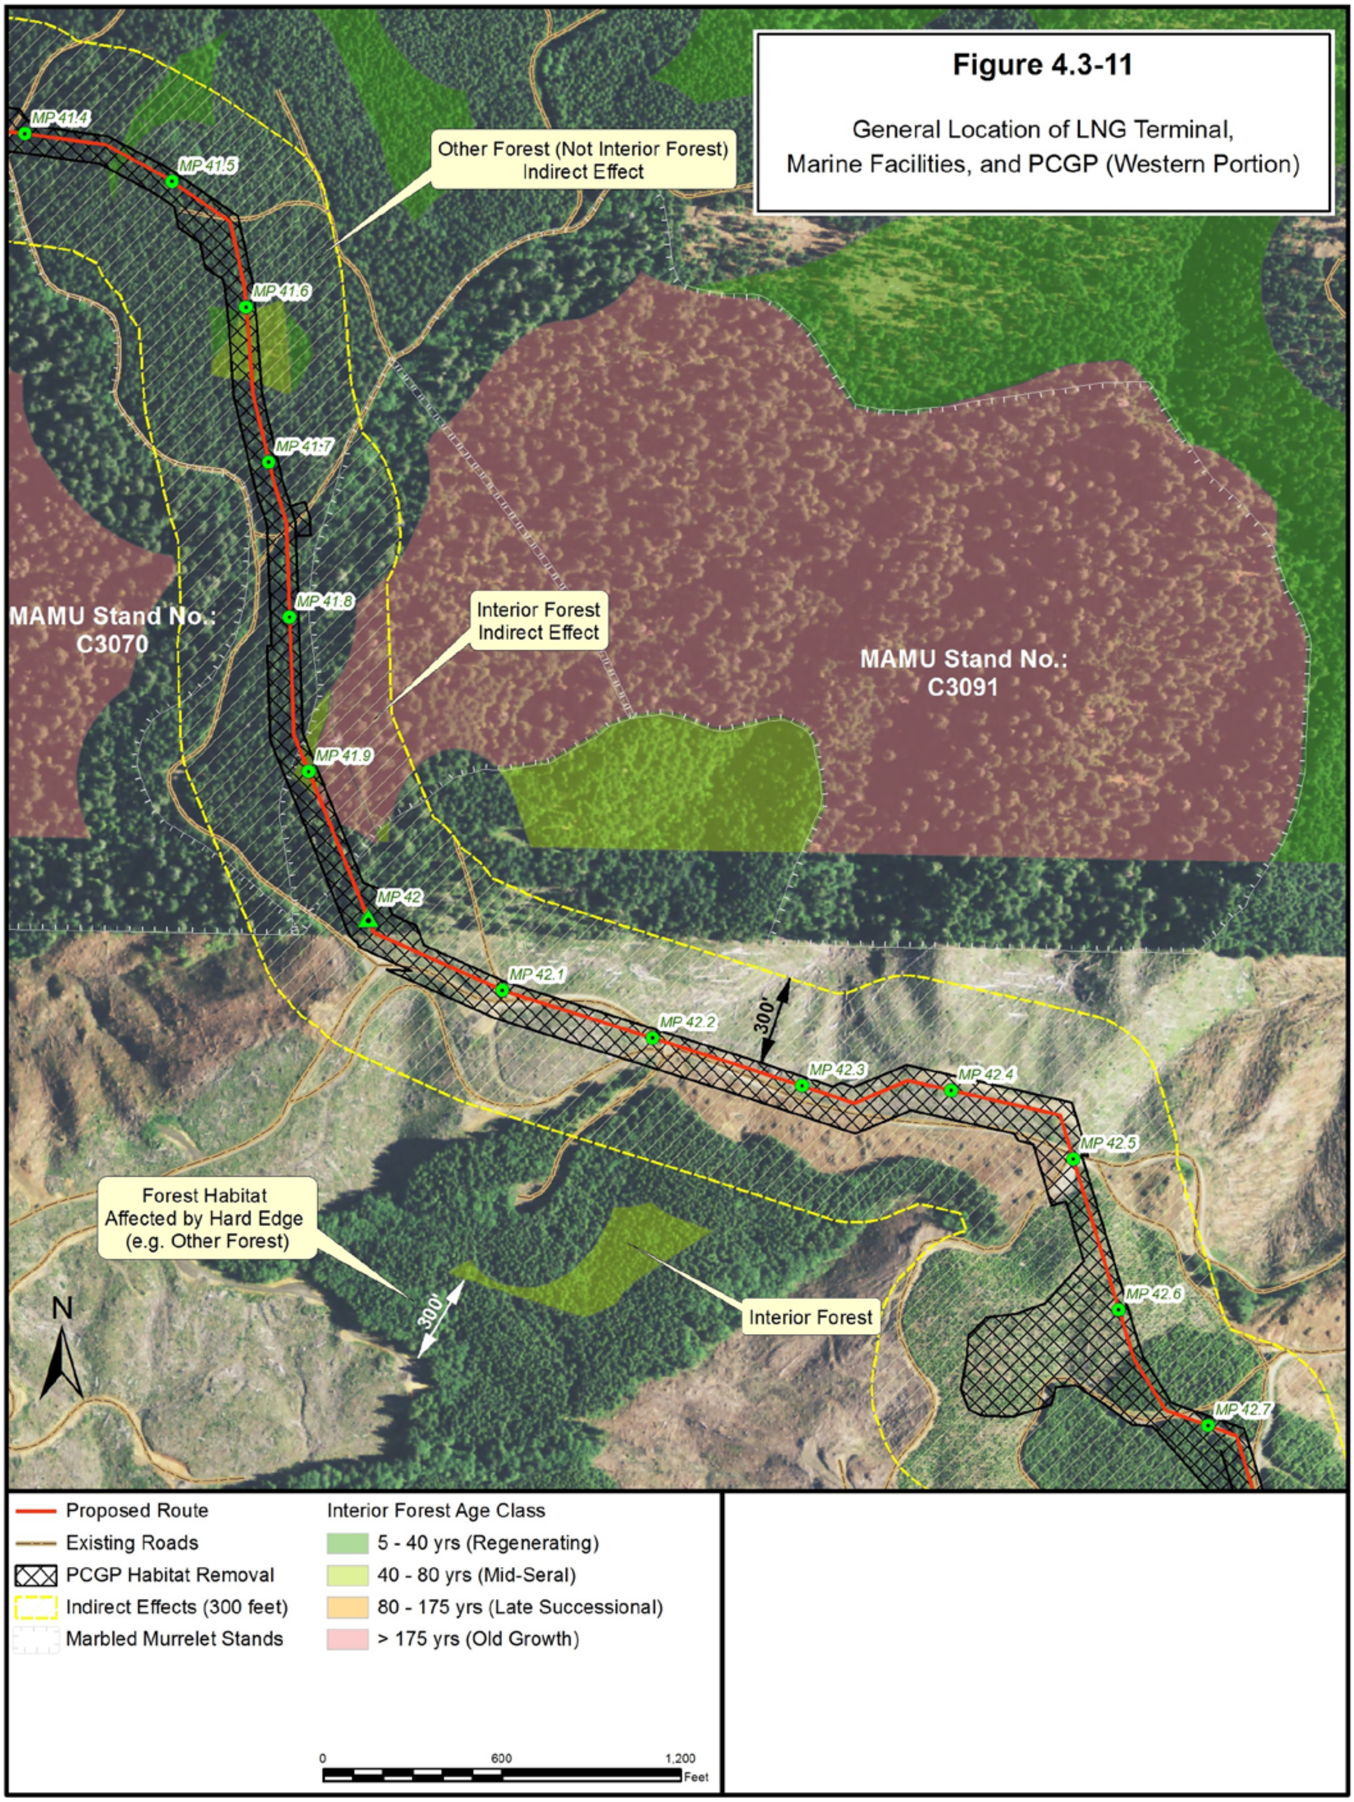
General Location of LNG Terminal, Marine Facilities, and PCGP (Western Portion)



Predation and Edge

A long-held tenet of bird conservation is that habitat fragmentation with concomitant exposure of nests at habitat edges increases risks of nest predation and/or nest parasitism and ultimately affects species' population growth. However, various reviews of available literature have supported that relationship (Paton, 1994) while other reviews have found no relationships or ambiguous associations between fragmentation and nest predation (Murcia, 1995; Lahti, 2001). A common theme among reviews is poor representation of studies with tested hypotheses on the edge-predator hypothesis (Chalfoun et al., 2002). Some of the disparate results among studies come from forest characteristics, predator species, and predated species which makes generalizations about effects of fragmentation difficult; in western forests, fragmentation may reduce the abundance of some nest predating species while increasing the abundance of others (Tewksbury et al., 1998).

Early studies of fragmentation effects on predation of MAMU nests yielded mixed results (Meyer and Miller, 2002a). In British Columbia, murrelet nests greater than 150 meters (492 feet) from the edge of fragmented nest stands did not fail because of nest predation (Manley and Nelson, 1999 in Nelson, 2005). Nelson and Hamer (1995) found that murrelet nest success was higher for nests greater than 50 meters (164 feet) from forest edge. However, an experimental study using artificial nests in Washington did not detect differences in nest predation within fragmented or continuous forest stands (Marzuluff and Restani, 1999 cited in Meyer and Miller, 2002).

More recent investigations have given new support for the relationship between fragmentation, edges, and predation on marbled murrelet nests. Predation at experimental murrelet nests located at fragment edges and at forest interiors was recorded by cameras. Disturbances by avian predators (Steller's jay, *Cyanocitta stelleri*) were significantly more frequent at hard edges (between old growth and clearcut forest) relative to interiors, but less frequent at soft edges (between old growth and regenerating forest). There were no edge effects at natural-edged sites associated with riparian forest (Malt and Lank, 2007).

Nest disturbance probability at hard edges was 2.5 times that of interior sites, but soft edges had less than half the disturbance probability of interiors (Malt and Lank, 2009). The study also showed that the negative effects of fragmentation decrease over time as managed forests regenerate, changing edge characteristics from hard to soft contrasts with older forest stands. Further, the study found Steller's jay to be the dominant avian predator of simulated nests and abundance of Steller's jay increased across the landscape as old-growth forest cover declined (Malt and Lank, 2009). That study and another by Marzluff et al. (2004) demonstrated that Steller's jays prefer fragmented habitat and high contrast edges, often sites associated with residential sites and campgrounds, locations where jays are more likely to successfully forage and fledge young. Study results reported by Malt and Lank (2009) suggested that larger areas of habitat would lessen negative effects of hard edges, including surrounding or embedding small reserves of suitable murrelet nesting habitat within a protective matrix of surrounding regenerating forest that would reduce predation risks to nesting murrelets as well as to the conservation of other old-growth associated bird species (Malt and Lank, 2009). However in Oregon, Luginbuhl et al. (2001) found that predator densities and rates of nest predation are higher in areas with a variety of tree ages, so nest success is reduced in areas intermixed with young trees or brush habitat (Raphael, 2006).

In addition to Steller's jay, common ravens (*Corvus corax*) have been observed preying on marbled murrelet nestings and eggs (Nelson and Hamer, 1995; Peery and Henry, 2010). Significant increasing regional trends of corvids within the Pacific Connector pipeline vicinity, including Steller's jay and common raves have been observed during the National Audubon Society Christmas Bird Counts since the early 1990s (see figure 4.3-12) and have likely contributed to existing but undocumented nest predation of marbled murrelets and other bird species (see Liebezeit and George, 2002 for a comprehensive review of corvid predation). Population viability modeling of marbled murrelets in central California included various nest predation rates by corvids (Peery and Henry, 2010). With only a 40 percent reduction in predation, the extinction risk was dramatically reduced from 96 percent to 5 percent over 100 years and a 60 percent reduction resulted in a stable marbled murrelet population with assumed modest proportion of breeders, renesting rates, and corvid predation rates. The modeled population viability analysis revealed that nest predation would only need to be reduced by 40 percent to produce a stable population if corvid management was coupled with a modest increase in after-hatch-year survival rate (Peery and Henry, 2010). Corvid control resulted in greater gains in murrelet population size when the maximum number of breeders was allowed to increase over time, similar to what would be expected if the amount of old-growth nesting habitat increased over time (Perry and Henry, 2010). The authors and others (Liebezeit and George, 2002) advocate evaluating local corvid populations, local conditions that may subsidize artificially high population levels (eg., food, garbage), and marbled murrelet nest site vulnerability to develop a corvid management plan that may or may not include lethal removal if an immediate short-term solution to predation is required (eg., Liebezeit and George, 2002).

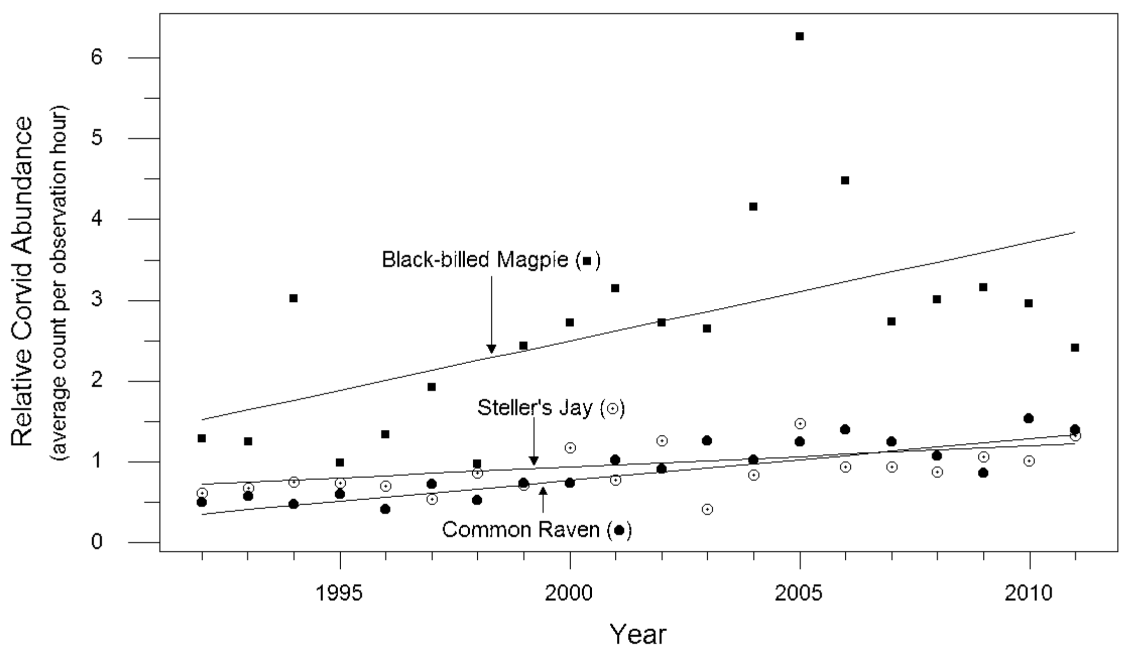


**Figure 4.3-12**
**Relative Abundance for Three Species of Corvids Surveyed During the National Audubon Society Christmas Bird Counts within the Pacific Connector Pipeline Vicinity, 1992 through 2011, with Significant Increasing Trends (Black-billed Magpie, P<0.01; Steller's Jay, P<0.01; Common Raven, <0.001).**

Creation of a 30-foot shrub/grass utility corridor could increase current corvid densities and result in reduced nest success, although revegetation (tree planting) outside of the 30-foot maintenance corridor and subsequent regrowth to reduce the effects of a hard edge may minimize predation on nesting MAMU. Food enticements associated with human presence during construction activities could also increase predator populations within the vicinity of the Pacific Connector pipeline. All trash, food waste, and other items attractive to ravens, jays, magpies, and other corvids would be picked up and removed from the Project area on a daily basis to minimize potential predation of MAMU nestlings.

**Critical Habitat/Late Successional Reserves**

The FWS (1996a, 2011a) determined the physical and biological habitat features associated with the terrestrial environment that support nesting, roosting, and other normal behaviors essential to the conservation of the MAMU. Within areas essential for successful MAMU nesting, FWS utilized the following physical and biological habitat features to identify critical habitat: PCE 1 – individual trees with potential nest platforms (comparable to suitable habitat within this draft BA); and PCE 2 – forest lands of at least one half site-potential tree height, within 0.5 mile of individual trees/suitable habitat stand that are recruitment or capable habitat (within a MAMU Group/SHU). Within this analysis, PCE 2 is comparable to recruitment habitat delineated (personal communication with FWS, 2013d).

A variety of ongoing or proposed activities that disturb or remove physical and biological habitat features may adversely affect, remove or modify MAMU critical habitat. Such activities include, but are not limited to: (1) forest management activities that greatly reduce stand canopy closure, appreciably alter the stand structure, or reduce the availability of nesting sites; (2) land disturbance activities such as mining, sand and gravel extraction, and road building; and (3) harvest of certain types of commercial forest products (e.g., moss).

Those activities have the following effects on the primary constituent elements of MAMU critical habitat:

1. Removal or degradation of individual trees with potential nesting platforms, or the nest platforms themselves, that results in a significant decrease in the value of the trees for future nesting use. Moss may be an important component of nesting platforms in some areas.
2. Removal or degradation of trees adjacent to trees with potential nesting platforms that provide habitat elements essential to the suitability of the potential nest tree or platform, such as trees providing cover from weather or predators.
3. Removal or degradation of forested areas with a canopy height of at least one-half the site-potential tree height and regardless of contiguity, within 0.5 mile of individual trees containing potential nest platforms. This includes removal or degradation of trees currently unsuitable for nesting that contribute to the integrity of the potential nest area (e.g., trees that contribute to the canopy of the forested area). These trees provide the canopy and stand conditions important for MAMU nesting (FWS, 1996a).

The proposed Pacific Connector pipeline crosses one federally designated critical habitat unit (OR-06-d) five times for a total of 2.14 miles see table 4.3.3-15, although not all habitat within designated ciritcial habitat is forested habitat (i.e., "non-capable" in tables Q-3 and Q-5 in appendix Q). Additionally four rock source and disposal sites occur within critical habitat: Signal Tree Road Quarry (Section 3 MP 45.86), Weaver Road Quarry Sites 1 and 2 (MP 47.00), and Signal Tree Road Quarry (Section 35, MP 47.00). These are existing quarries and provide no murrelet habitat; no additional MAMU habitat would be removed adjacent to these sites. Overall, construction of the proposed PCGP Project would remove 4.11 acres of suitable marbled murrelet nesting habitat (PCE-1) and 5.29 acres of recruitment (PCE-2) within CHU OR-06-d (see table 4.3.3-15), all within marbled murrelet SHUs. Additionally, approximately 0.85 acres of suitable habitat (PCE-1), and 1.04 acres of recruitment habitat within CHU OR-06-d have been identified for use by the PCGP Project as UCSAs that may be used to store forest slash, stumps, and dead and downed log materials that would be removed and scattered across the right-of-way after construction during restoration (see UCSA Column, table 4.3.3-15). Use of the UCSAs would be a short-term disturbance of understory vegetation within suitable and potentially suitable habitat and would not affect potential nesting stand structures or characteristics. After construction of the pipeline, approximately 24.81 acres of MAMU habitat within CHU OR-06-d outside of the 30-foot maintenance corridor will be replanted with tree species and effects of edge will decrease over time. A detailed table of critical habitat unit OR-06-d affected by the project within and outside of MAMU SHUs and interior forest, as well as non-capable habitat that is affected and occurs in designated critical habitat is located in table Q-5 in appendix Q.

Designated critical habitat only occurs within MAMU Inland Zone 1. The majority (92 percent) of forested habitat within CHU OR-06-d affected by the proposed action overlaps with NWFP LSR unit RO 261 in Coos Bay and Roseburg BLM Districts, or unmapped LSRs (see table Q-3 in appendix Q). An additional 28.68 acres of forested land (suitable, recruitment, and capable habitat) within unmapped LSRs will be removed by construction of the proposed PCGP Project (see table 4.3.3-16). Likewise, an additional 6.84 acres of unmapped LSRs will be disturbed in UCSAs. Approximately 45 acres of forested habitat within NWFP LSRs and unmapped LSRs will be replanted with trees outside of the 30-foot maintenance corridor which will reduce the edge effects of edge over time (see table 4.3.3-16). Table 4.3.3-16 identifies the MAMU habitat that would be affected within LSR Unit RO 261 and within the unmapped LSR units from construction of the proposed Project. A detailed table of NWFP LSRs and unmapped LSRs affected by the project within and outside of MAMU SHUs and interior forest, as well as non-capable habitat that is affected and occurs in LSRs and unmapped LSRs is provided in table Q-6 in appendix Q. Table Q-3 in appendix Q provides the acres of marbled murrelet habitat affected within Marbled Murrelet Inland Zones 1 and 2 and Recovery Plan Conservation Zones 3 and 4, including landowner, and identifies the area that FWS-designated critical habitat unit OR-06-d overlaps with NWFP LSRs and unmapped LSRs within and outside of marbled murrelet SHUs.

Within Murrelet Inland Zones 1 and 2 where federal land is checker-boarded, Pacific Connector considered locations of NWFP LSRs and occupied MAMU stands when routing the proposed pipeline and tried to avoid those tracts of lands if another constructible route was feasible to minimize impacts to MAMU habitat (see MAMU and NSO Avoidance Plan). Minimizing effects to LSRs also minimizes effects to MAMU designated critical habitat since a lot of overlap of MAMU CHU OR-06-d and LSR RO 261 occurs. Table 4.3.3-17 summarizes the location of the project and MAMU habitat affected in relation to MAMU designated critical habitat unit OR-06-d.

## Table 4.3.3-15
## Summary of Marbled Murrelet Critical Habitat Unit OR-06d that will be Affected During Construction and Operation of the Proposed Action by Recovery Plan Conservation Zones and Landowner

| Land Owner | Land Owner | PCE1 / Suitable Habitat[1] | | | | | PCE2 / Recruitment Habitat[2] | | | | | PCE2 / Capable Habitat[3] | | | | | Total Acres | | | | |

| Total Critical Habitat | | 0.28 | 4.11 | 69.31 | 0.85 | 1.01 | 0.26 | 5.29 | 35.78 | 1.04 | 1.00 | 1.41 | 22.43 | 123.11 | 1.06 | 5.01 | 1.94 | 31.83 | 228.20 | 2.95 | 7.02 |

1 PCE1/Suitable Habitat: individual trees with potential nest platforms, including supporting trees delineated as occupied or suitable (comparable to suitable habitat)
2 PCE2/Recruitment Habitat: forest lands of at least one half site-potential tree height, within 0.5 mile of individual trees/suitable habitat stand that are recruitment or capable habitat (comparable to recruitment habitat) not currently suitable for marbled murrelet nesting that may be capable of becoming suitable marbled murrelet habitat within the next 25 years (FWS, 2006e; BLM, 1995a and b); generally forested stands 60 years or greater (Trask & Associates, 2013).
3 PCE2/Capable Habitat: forested land that has the capability of becoming suitable nesting marbled murrelet habitat, generally includes forest stand age 0 to 60 years (Trask & Associates, 2013).
4 Project components considered in calculation of habitat "Removed": Pacific Connector construction right-of-way, temporary extra work areas, aboveground facilities, permanent and temporary access roads (PAR, TAR), pipe storage yards, and hydrostatic locations.
5 Acres identified as UCSAs have been incorporated into the 100-meter indirect effects. Indirect Effects considers habitat within 100-meters of habitat removal as measured from the edge of habitat removal/edge of right-of-way/TEWA.
6 UCSAs would not be cleared of trees during construction and will not affect nesting structures or characteristics. These areas would be used to store forest slash, stumps and dead and downed log materials that would be removed and scattered across the right-of-way after construction during restoration and are considered as temporary insignificant understory habitat effects.
7 30-foot Maintenance Corridor will be kept in a shrub/sapling state for the life of the project.

Summarized from table Q-5 in appendix Q.

[1] Suitable Habitat: generally late-seral forested stands that provide or are presumed to provide nesting structures for marbled murrelet based on modeling and other available GIS data.
[2] Recruitment Habitat: forested land not currently suitable for marbled murrelet nesting that may be capable of becoming suitable marbled murrelet habitat within the next 25 years (FWS, 2006e; BLM, 1995a and b); generally forested stands 60 years or greater (Trask & Associates, 2013).
[3] Capable Habitat: forested land that has the capability of becoming suitable nesting marbled murrelet habitat, generally includes forest stand age 0 to 60 years (Trask & Associates, 2013).
[4] Unmapped LSRs include MAMU occupied stands that occur on matrix lands (included in BLM and Forest Service LUA coverage, as well as occupied murrelet stands within the project area that occur on matrix lands but were not included in the LUA coverage) and BLM delineated known northern spotted owl activity center.
[5] Project components considered in calculation of habitat "Removed": Pacific Connector construction right-of-way, temporary extra work areas, aboveground facilities, permanent and temporary access roads (PAR, TAR), pipe storage yards, and hydrostatic locations.
[6] Acres identified as UCSAs have been incorporated into the 100-meter indirect effects. Indirect Effects considers habitat within 100-meters of habitat removal as measured from the edge of habitat removal/edge of right-of-way/TEWA.
[7] UCSAs would not be cleared of trees during construction and will not affect nesting structures or characteristics. These areas would be used to store forest slash, stumps and dead and downed log materials that would be removed and scattered across the right-of-way after construction during restoration and are considered as temporary insignificant understory habitat effects.
[8] 30-foot Maintenance Corridor will be kept in a shrub/sapling state for the life of the project; all other habitat outside of the 30-foot maintenance corridor will be revegetated.

Summarized from table Q-7 in appendix Q. Non-Capable habitat (not forested and not capable of becoming suitable habitat, or deciduous forest) that occurs in NWFP LSRs and unmapped LSRs is included in table Q-7 in appendix Q.

**Table 4.3.3-17**
**Summary of Habitat Affected in Marbled Murrelet Designated Critical Habitat Unit OR-06-d from the Proposed Action**

| Critical Habitat Unit | Land Ownership | NWFP Land Use Allocation | Total acres of PCE1 that will be removed [1] | Total acres of PCE2/Recruitment removed [2] | Total acres of PCE2/Capable [3] | Length of pipeline through CHU OR-06-d (miles) | Additional Comments |
|---|---|---|---|---|---|---|---|
| OR-06-d | Coos Bay BLM | LSR | 1.03 | 0.0 | 14.38 | 0.96 | 1st crossing (MPs 41.33-42.01): pipeline routed through mostly regenerating (capable) and mid-seral (recruitment) forest, with a portion crossing through the edge of an old-growth/occupied (suitable) stand; crosses corner of critical habitat section. Follows or occurs within an existing road for a small portion.<br><br>2nd crossing (MPs 43.17-43.50): route mostly parallels a road through regenerating (capable) forest. |
| OR-06-d | Roseburg BLM | LSR / Unmapped LSR | 3.08 | 4.63 | 5.47 | 0.85 | 3rd crossing (MPs 46.91-47.17) – Weaver Ridge reroute: crosses mosaic of old-growth (suitable) and regenerating (capable) forest; parallels a road for approximately 0.06 mile.<br><br>4th crossing (MPs 52.61-52.94): crosses mid-seral (recruitment) and regenerating (capable) forest; crosses corner of critical habitat section.<br><br>5th crossing (MPs 53.10-53.36): mostly follows a road located between late successional (suitable) and regenerating (capable) stands. |
| OR-06-d | Roseburg BLM | Connectivity | 0.0 | 0.66 | 2.58 | 0.33 | 5th crossing (MPs 53.36-53.69): follows a road between regenerating (capable) and late successional (suitable) stands. |

[1] PCE 1 = suitable habitat
[2] PCE 2 = recruitment habitat
[3] PCE 2 = capable habitat, which includes early mid-seral forest, as well as clearcut and regenerating coniferous forest.

In addition to direct loss of critical habitat and effects to PCEs due to construction of the Project, the project's indirect effects to MAMU that were discussed above (fragmentation, edge, and effects to interior forest) indirectly affect designated critical habitats and PCEs. Edge effects and effects to interior forest may induce changes to forest characteristics later in time and would indirectly affect PCEs. Such effects may induce changes at individual nest trees and/or trees with potential nest platforms (PCE 1). Long-term effects on edges and interiors of recruitment habitat (PCE 2) are less well defined and over time, edge effects will diminish as edges evolve from "hard" to "soft" after revegetation occurs in the construction right-of-way, and in particular, trees are planted outside of the 30-foot maintenance corridor (see for example, Peery and Henry, 2010).

Long-term effects from removal of interior forest within critical habitat, NWFP LSRs, and unmapped LSRs by the Pacific Connector pipeline could occur from clearing MAMU habitat. Table 4.3.3-15 and table 4.3.3-16 identify the distance that MAMU habitat is crossed by the proposed project within and outside of interior habitat, summarizes the acreage of MAMU habitat directly removed and indirectly affected within 100 meters of the PCGP Project (habitat removal) by Marbled Murrelet Inland Zones 1 and 2, and landowner within critical habitat units and NWFP LSRs and unmapped LSRs, respectively. Tables Q-5 and Q-6 in appendix Q provide detailed effects to MAMU Habitat within critical habitat unit OR-06-d and NWFP LSRs and unmapped LSRs, respectively, including MAMU habitat affected within and outside of MAMU SHUs and interior forest. Most indirect effects to forested habitat within 100 meters of habitat removal occur in MAMU habitat that has been previously affected by existing edge, such as roads, waterbodies, early seral forest, and nonforested habitat.

**Cumulative Effects**

FWS and NMFS describe cumulative effects (50 CFR § 402.02) as the result of future actions by state or private entities, not involving federal actions, but reasonably certain to occur in the action area considered in this biological assessment. Future federal actions that are unrelated to the proposed action are not considered here because they require separate consultation pursuant to section 7 of the ESA. The Pacific Connector pipeline would not be operational until at least 2017. Consequently, the foreseeable future required for cumulative effects analysis would actually occur before implementation of the proposed action, not after its implementation, which is more often the case.

Cumulative effects to marbled murrelets would be generated by timber harvesting and other sources of habitat losses on non-federal lands in the foreseeable future. Areas of marbled murrelet habitat-capable land have been monitored as a component of the Northwest Forest Plan (NWFP). Habitat-capable lands are capable of supporting forest structure with the potential to provide murrelet nesting habitat (Raphael et al. 2011). In Oregon, the evaluation of habitat-capable land was limited to Marbled Murrelet Zone 1 (of the NWFP) and did not include any analysis of habitat within Marbled Murrelet Zone 2.

In 2012, there were 1,428 acres of suitable habitat and 4,088 acres of recruitment habitat on non-federal lands within the Terrestrial Nesting Analysis Area (see table 4.3.3-2 in Section 4.3.3.2, above). Recruitment habitat and suitable habitat, used here, are considered equivalent to habitat Class 3 (moderately high likelihood of suitability) and habitat Class 4 (highest likelihood of suitability), respectively. Those two habitat classes were included in modeling changes in marbled murrelet habitat availability from 1996 (baseline conditions) to 2006 (Raphael et al. 2011).

Within Marbled Murrelet Zone 1, which coincides with the Coast Range physiographic province, there were 421.5 thousand acres of Class 3 and Class 4 habitats in 1996; by 2006 there were 377.9 thousand acres in those habitat classes on non-federal lands (see Table 9 in Raphael et al. 2011). There was a net loss of 43.6 thousand acres of Class 3 and Class 4 habitats (-10.3 percent), declining by 10.3 percent during the 10-year period (Table 9 in Raphael et al. 2011), and used here as an annual loss of suitable and recruitment habitats at 1.03 percent per year. That rate of decline on non-federal lands is assumed to be constant over time within the Terrestrial Nesting Analysis Area. Areas of suitable and recruitment habitats present in 2012 would be expected to decline at that annual rate. With an additional net loss in 2017, there would be 1,354 acres of suitable habitat and 3,877 acres of recruitment habitat within the analysis area on non-federal land by the time the PCGP project is expected to be implemented in 2017.

The Project would remove 8.41 acres of suitable habitat and 89.22 acres of recruitment habitat on non-federal (state and private) lands in Marbled Murrelet Zone 1 by 2017 (see table 4.3.3-10 in Section 4.3.3.3, above). The amount of suitable habitat removed would be 0.62 percent of the suitable habitat remaining on non-federal lands (1,354 acres) in the analysis area by 2017. Likewise, the amount of recruitment habitat removed would be 2.30 percent of the habitat remaining on non-federal lands (3,877 acres) in the analysis area by 2017. When compared to the estimated amount of suitable and recruitment habitat on non-federal land within the analysis area, the PCGP project would affect a total of 97.63 acres, which would be 1.87 percent of the total suitable and recruitment habitat available within the foreseeable future in 2017.

Although Raphael et al. (2011) limited their evaluation of habitat-capable land to Marbled Murrelet Zone 1 (of the NWFP), the same analysis was included, as described above, for Zone 2 using the annual loss of 1.03 percent which is included in table 4.3.3-18.

## Table 4.3.3-18
## Estimates for Losses of Marbled Murrelet Suitable and Recruitment Habitat on Non-Federal Land within the Terrestrial Nesting Analysis Area by 2017, with PCGP Project-Related Effects on Non-Federal Land Compared to Cumulative Effects

| Marbled Murrelet Inland Zone | Marbled Murrelet Habitat Areas on Non-Federal Land in Analysis Area in 2012 [1] | | | Loss of Marbled Murrelet Habitat Between 1996 and 2006 [2] | | Marbled Murrelet Habitat on Non-federal Land in Analysis Area Expected in 2017 | | | Marbled Murrelet Habitat Removed by PCGP on Non-federal Land in Analysis Area in 2017 [3] | | | Percent of Marbled Murrelet Habitat in Analysis Area Expected in 2017 to be Affected by PCGP | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | Suitable Habitat (acres) | Recruitment Habitat (acres) | Total Habitat (acres) | Percent Change from 1996 | Percent Change per Year | Suitable Habitat (acres) | Recruitment Habitat (acres) | Total Habitat (acres) | Suitable Habitat (acres) | Recruitment Habitat (acres) | Total Habitat (acres) | Suitable Habitat | Recruitment Habitat | Total Habitat |
| Zone 1 | 1,428 | 4,088 | 5,516 | -10.3% | -1.03% | 1,354 | 3,877 | 5,231 | 8.41 | 89.22 | 97.63 | 0.62% | 2.30% | 1.87% |
| Zone 2 | 22 | 3,883 | 3,905 | | | 21 | 3,682 | 3,703 | 0.06 | 129.65 | 129.71 | 0.29% | 3.52% | 3.50% |

[1] Data from table 4.3.3-2 in Section 4.3.3.2.
[2] Percent loss in Marbled Murrelet Zone 1 on Non-Federal Land from Table 9 in Raphael et al. 2011.
[3] Data from table 4.3.3-10 in Section 4.3.3.3.

#### 4.3.3.4 Conservation Measures

**Avoidance, Minimization, and Rehabilitation / Restoration:** Conservation measures have been proposed by Pacific Connector to minimize construction and operation impact to the Terrestrial Nesting Analysis Area. Those measures have been compiled in table 2C in appendix N. Specific conservation measures that would benefit MAMUs include those that:

- Minimize removal of forest by incorporating UCSAs into the Project design;
- Utilize two-year construction window to minimize the overall temporary extra work areas;
- Flag large diameter trees on edges of construction right-of-way or temporary work areas where feasible to save from clearing;
- Minimize soil erosion during and after construction;
- Ensure that all trash, food waste, and other items attractive to crows, jays, and other corvids will be contained and removed from the project area on a daily basis to minimize potential predation on murrelet nestlings;
- Use of logging methods to minimize damage to adjacent trees when clearing the right-of-way to reduce potential infestation from forest pathogens and insects; and
- Minimize potential for establishment of invasive vegetation and establish control of noxious weeds.

Pacific Connector has also proposed measures to rectify, repair, rehabilitate, and otherwise reduce impact to forested habitats once construction of the Pacific Connector pipeline is complete. Those measures have been compiled in table 3C in appendix N. Specific conservation measures that would benefit MAMUs include those that:

- Replant conifer species outside of the 30-foot wide maintenance corridor after construction, which will contribute to the reestablishment of native vegetation and soften the edge effect;
- Contribute to forest habitat structural diversity (e.g., snags and downed timber); and
- Minimize potential for increased human use of the reclaimed construction right-of-way and intrusion into undisturbed habitats.

Plans included in the appendices of Pacific Connector's POD will also minimize effects to marbled murrelet habitat and/or nesting murrelets. The Leave Tree Protection Plan describes the preconstruction surveys that will be completed to clearly mark the boundaries of the projects certificated working limits, and procedures to identify individual trees within and along the edges of the certificated work limits that can be conserved or left standing, as well as BMPs that would be employed to minimize damage to trees within UCSAs and protect trees not removed from the construction right-of-way (see Appendix P to the POD, available upon request). An Integrated Pest Management Plan (see Appendix N to the POD, available upon request) describes BMPs to address the control of noxious weeds, invasive plants, forest pathogens, and soil pests, as well as describes measures to minimize the potential spread of invasive species and potential adverse effects of control treatments. The Blasting Plan and Air Noise and Fugitive Dust Plans (see Appendices C and B to the POD, respectively – available upon request) provide mitigation measures and monitoring plans to minimize noise effects to nesting murrelets during construction of the PCGP Project.

Within known occupied stands, Pacific Connector has proposed the route within existing roads that traverse the stand or situated the right-of-way within existing edge (i.e., within clearcut or regenerating forest adjacent to a stand) to avoid or minimize habitat removal from the stand, where feasible. In other areas, Pacific Connector has rerouted the Original 2007 Route (FERC, 2009) to avoid removing habitat and further fragmenting suitable marbled murrelet stands – occupied, unoccupied, unsurveyed, and presumed occupied. Also, to minimize impacts to marbled murrelet stands and suitable nesting habitat, Pacific Connector has incorporated minor alignment adjustments or TEWA modifications into the proposed Project. Other major and minor route alternatives that further minimize effects to marbled murrelets and habitat have been considered and included into the Proposed Route which are discussed in the Marbled Murrelet and Northern Spotted Owl Avoidance and Minimization Plan, appendix V).

Pacific Connector initiated additional marbled murrelet surveys in spring 2013 within eight stands identified with suitable habitat, where surveys are permitted, to determine presence or absence of occupied marbled murrelet behavior. Where occupied marbled murrelet behavior was documented, measures similar to those applied to known occupied stands will be applied, if feasible, including: 1) reroute the pipeline to avoid occupied stands or suitable habitat, 2) incorporate minor route adjustment to reduce habitat removed, 3) modify or move temporary work areas, and 4) restrict the pipeline construction right-of-way to roads. Second year surveys will continue in two stands during the 2014 survey season, and if determined occupied, similar measures described above will be applied.

When Pacific Connector acquires survey access in stands identified to have potential nesting habitat (presumed occupied stands), where survey permission has been denied, Pacific Connector will evaluate the stands for trees with suitable nesting structures. If suitable nesting structures are identified and time permits for two years of surveys prior to beginning the proposed Project, Pacific Connector will survey those stands for occupied marbled murrelet behavior. When additional information on the status of these presumed occupied marbled murrelet stands is acquired, Pacific Connector will advise the FWS of their updated status, including whether they are determined to have suitable nesting structures, determined to be occupied or unlikely occupied, or determined to not be suitable habitat for nesting marbled murrelets.

Prior to timber clearing, Pacific Connector would apply a "Standards Rule Set" developed during a meeting in June 2008 with FWS and the cooperators to further minimize Project effects to MAMUs that would accomplish the following:

- identify potential nest trees that would be allowed to remain standing within TEWAs or edge of right-of-way;
- identify TEWAs to be reduced in size or eliminated to reduce removal of suitable habitat;
- identify any additional minor route adjustments that would not alter constructability but further reduce removal of suitable habitat;
- identify any previously unknown nest tree discovered and assure that it is properly protected by applying the appropriate seasonal limitations or daily timing restrictions associated with similar locations along the pipeline alignment; and
- EIs would be supported by qualified biologists to identify potential nest trees.

To avoid direct effects to MAMU, Pacific Connector will remove timber outside of the entire marbled murrelet breeding season (after September 15 but before March 31) within 300 feet of MAMU stands to ensure that murrelets and chicks are not felled. Additionally, to minimize disturbance within forested areas, Pacific Connector has designated nearly 129 acres (see table 4.3.3-10) of UCSAs within Marbled Murrelet Inland Zones 1 and 2 that will not be cleared of trees but be used to store forest slash, stumps, and dead and downed log materials during construction that will be scattered across the right-of-way after construction and during restoration. The UCSAs will be useful for the construction of the PCGP Project while not requiring removal of trees or understory vegetation, as well as allow the maintenance of suitable or potentially suitable and recruitment habitat function.

Construction of the proposed Project will occur within Marbled Murrelet Inland Zones 1 and 2, including within marbled murrelet occupied stands during the entire breeding season. Construction will occur after timber has been felled outside of the breeding season and will adhere to daily timing restrictions (DTRs, activity limited to 2 hours after sunrise and 2 hours before sunset) within 0.25 mile of marbled murrelet stands (occupied, presumed occupied, unoccupied) at least through the critical breeding season to minimize risk of disturbance to adult marbled murrelets entering and leaving the stand, as well as possible dispersal of juveniles. DTRs will continue to be applied to large transport helicopter use in the late breeding season within 0.25 mile of a MAMU stand if helicopter use is necessary.

During construction, Pacific Connector would ensure that the construction contracts include stipulations ensuring that all trash, food waste, debris, and other items attractive to crows, jays, and other corvids would be picked up and removed from the Project area on a daily basis during the breeding season to minimize potential predation of marbled murrelet nestlings. Pacific Connector's EI's would be responsible for overseeing that the construction contractor is adequately following these stipulations.

Following construction, affected forested lands (the construction right-of-way and TEWAs outside of the 30-foot maintenance right-of-way) would be replanted and allowed to return to the pre-construction condition, with tree species in the approximate proportion to those species removed. Tree establishment would be allowed to occur up to 15 feet on either side of the pipeline centerline. Over the long-term (200 to 250 years to become marbled murrelet suitable nesting habitat) revegetated areas outside of the 30-foot maintenance corridor may achieve tree structural characteristics comparable to trees that would be removed, had they not been affected. Over the short-term, replanting approximately 724 acres on the edge of the 30-foot maintenance corridor will provide a soft edge to adjacent forested habitat and minimize effects of edge, as well as reduce predator presence (see table 4.3.3-10).

**Compensatory Mitigation**: Since effects by the proposed action could not be fully mitigated on-site whether by avoidance, minimization, or restoration measures, Pacific Connector has developed a Compensatory Mitigation Plan (CMP) that provides a means to compensate for unavoidable impacts to listed species and their habitat, including marbled murrelets. The CMP combines agency-recommended projects to enhance existing forested and aquatic habitats, re-designation of allocated forest lands (NWFP), and acquisition of forested habitats to compensate for habitats affected by the project. The CMP includes opportunities for funding projects in southern Oregon that could be implemented by federal land managing agencies, state or local resources agencies, or conservation groups. Projects or actions that are being considered include permanent reclamation of existing disturbances within capable habitat, such as roads within LSRs that are no longer required for resource management. These mitigation funds would also be used to conduct noncommercial thinning treatments or other silvilcultural projects to create or accelerate development of old growth characteristics in trees elsewhere on federal land. Pacific

Connector also proposes to acquire easements or properties as conservation parcels within the range of the species that would preserve and protect potentially suitable and recruitment habitat as mitigation for Project impacts. These easements or parcels could be deeded to a federal agency or a conservation organization or trust.

The BLM and Forest Service have proposed a suite of off-site mitigation projects to address the effects of the PCGP Project on various resources within the project area and will ensure the Project can be consistent with the objectives of BLM Resource Management Plans and Forest Service Land and Resource Management Plans. The CMP provides the BLM and Forest Service mitigation summaries which describe the various offsite mitigation projects as a supplemental mitigation to address important issues or land management plan objectives that cannot be acceptably mitigated on-site (see Attachment 1 and Attachment 2 to the CMP, appendix O). A summary of BLM and Forest Service mitigation projects are provided in Table 1 of the CMP (see appendix O) Pacific Connector has assessed the BLM's mitigation projects in relation to the Project effects by watershed, along with the proposed mitigation projects proposed by the Forest Service, that have been approved in principle by Pacific Connector (see Attachment 4 to the CMP, appendix O). The BLM and Forest Service mitigation projects have also been reviewed with respect to the Project's responsibilities to mitigate for the potential effects to ESA listed species and their habitats. The BLM's and Forest Service's mitigation summaries list their proposed projects by watershed.

The following projects or actions, including those proposed by BLM and Forest Service, are also being considered as compensation in the CMP:

- decommissioning roads in LSRs that are identified by the BLM and Forest Service and are no longer required for management activities;
- acquiring title or easement to private lands in the range of the species that could be managed/preserved as late successional habitat;
- funding the conversion of matrix lands to LSR and enhancement of converted lands;
- funding non-commercial thinning treatments or other silvicultural projects to create or accelerate development of old growth characteristic elsewhere on federal land;
- funding to conduct silviculture (pre-commercial and commercial thinning) projects to reduce fuel load to minimize the risk of stand-replacing fires; and/or
- creating snags in adjacent habitat.

FWS has prepared Conservation Frameworks for the Pacific Connector Gas Pipeline Project that provides direction and methods to quantify and categorize the impact to marbled murrelets [and northern spotted owls] and their habitat (see appendix Z4) and means to offset the calculated impacts. In some instances, projects proposed by BLM and Forest Service would be considered applicable to offsetting the impact calculated and described, below.

The initial Framework (Trask & Associates, 2013) and subsequent revisions through personal communications provides guidance for categorizating effects to MAMU habitat into Severe Impact, High Impact, Moderate Impact, and Low Impact categories based on the amount and type of MAMU Habitat removed, as well as the area the habitat is removed within the MAMU SHU (see MAMU habitat impact categorization for each MAMU stand in appendix Z1). The Habitat Impact Category assigned to each MAMU SHU (appendix Z1) is then applied to acres of

MAMU habitat affected by the proposed Action (summarized in table 4.3.3-10 from table Q-3 in appendix Q). MAMU habitat affected outside of MAMU SHUs or within a MAMU SHU that were provided a "No Impact Category" in appendix Z1 are considered areas of "Low Impact", as well. Table 4.3.3-19, below provides a summary of MAMU habitat affected by Habitat Impact Category within and outside of interior forest. No MAMU stand was provided a "Severe Impact" category because Pacific Connector would remove suitable habitat outside of the breeding season, and it is also not expected that a MAMU nest tree would be removed. The FWS (Trask & Associates, 2013) recommends two primary actions to offset indirect impacts to MAMU habitats: land acquisition of like-to-like habitats affected by the Project (suitable, recruitment, and capable habitat) and/or silvicultural treatments for recruitment and capable habitat affected within MAMU SHUs. Following direction within the Habitat Conservation Framework (Trask & Associates, 2013), individual assessments included in appendix Z1 for each MAMU Stand (occupied, unoccupied, and presumed occupied) have been used to evaluate and determine the type and amount of mitigation recommended for impacts from the proposed action. The CMP identifies the amount of habitat acquisition proposed by Pacific Connector to offset effects of the proposed project on MAMU habitat (in consideration of NSO habitat overlap; see Section 1.6 in appendix O).

**Table 4.3.3-19**
**Summary of MAMU Habitat Removed from the Proposed Action by Habitat Impact Category**

| Habitat Impact Category[1] | Interior Forest[2] | Miles Crossed | MAMU Habitat Removed (acres) | | | |
|---|---|---|---|---|---|---|
| | | | Suitable[3] | Recruitment[4] | Capable[5] | Total Habitat Removed |
| High | Interior Forest | 3.3 | 30.91 | 3.82 | 8.51 | 43.24 |
| | Other | 7.2 | 26.18 | 30.87 | 55.07 | 112.12 |
| | High Impact Total | 10.5 | 57.09 | 34.69 | 63.58 | 155.36 |
| Moderate | Interior Forest | 0.2 | 0.00 | 1.36 | 0.37 | 1.73 |
| | Other | 1.5 | 0.59 | 3.94 | 21.21 | 25.74 |
| | Moderate Impact Total | 1.7 | 0.59 | 5.30 | 21.58 | 27.47 |
| Low | Interior Forest | 0 | 0.00 | 0.00 | 0.00 | 0.00 |
| | Other | 0 | 0.00 | 0.00 | 0.00 | 0.00 |
| | Low Impact Total | 0 | 0.00 | 0.00 | 0.00 | 0.00 |
| Outside MAMU SHU / No Impact | Interior Forest | 4.6 | 0.00 | 35.02 | 32.54 | 67.56 |
| | Other | 38.5 | 0.00 | 194.11 | 481.15 | 675.26 |
| | Outside SHU / No Impact Total | 43.1 | 0.00 | 229.13 | 513.69 | 742.82 |
| Overall Total | Interior Forest | 8.1 | 30.91 | 40.20 | 41.42 | 112.53 |
| | Other | 47.3 | 26.77 | 228.92 | 557.43 | 813.12 |
| | Overall Total | 55.4 | 57.68 | 269.12 | 598.85 | 925.65 |

[1] see Trask & Associates (2013) for Impact Categorization factors and appendix Z1 for individual Habitat Impact Category assessments for each MAMU SHU.
[2] Interior Forest: not affected by existing disturbance (i.e., roads, existing corridors) or adjacent landuse/vegetation type (i.e., agriculture, non-forest, early regenerating forest); Other Forest Type includes forested habitat that is currently affected by existing disturbance or adjacent landuse/vegetation types within 100 meters of stand/MAMU habitat type
[3] Suitable Habitat: generally late-seral forested stands that provide or are presumed to provide nesting structures for marbled murrelet based on modeling and other available GIS data.
[4] Recruitment Habitat: forested land not currently suitable for marbled murrelet nesting that may be capable of becoming suitable marbled murrelet habitat within the next 25 years (FWS, 2006e; BLM, 1995a and b); generally forested stands 60 years or greater (PC Trask & Associates, 2013).
[5] Capable Habitat: forested land that has the capability of becoming suitable nesting marbled murrelet habitat, generally includes forest stand age 0 to 60 years (Trask & Associates, 2013).

FWS provided additional guidance to Pacific Connector on January 24, 2014 to assess and mitigate direct effects (disruption and disturbance) to MAMU by the Proposed Action (Trask & Associates, 2014). This new guidance essentially decoupled the direct effects from the previous guidance provided to Pacific Connector in June 2013 (see Trask & Associates, 2013) and outlined a new method to categorize direct effects to MAMU stands into the following Disruption-Disturbance (D/D) Impact Categories: High Impact, Moderate Impact, Low Impact, Low Impact – no mitigation, and No Impact. The assessment considers the timing, types, and location of Project-related activities in relation to MAMU stands that could result in disturbance or disruption of nesting MAMU to assist in determining a D/D Impact Category for each Project activity for each MAMU stand. In many instances a MAMU stand is provided more than one D/D Impact Category because of different project effects and different locations of effects on the MAMU stand (i.e., construction effects and proposed use of existing access roads; see D/D Impact Categorization in appendix Z1). The FWS provides a method to calculate the acres of MAMU stand by D/D Impact Category within a disruption and/or disturbance distance (0.25 mile) of project activities, including use of access roads. Calculated D/D Impact Category acres for each individual MAMU Stand within 0.25 mile of project activities is included in appendix Z1, with a list of factors considered when determining if an activity would be considered a disruption, a disturbance, or have no effect on each MAMU stand. The resulting D/D Impact Category(ies) is also included for each stand in table Q2 in appendix Q. Table 4.3.3-20 summarizes the acres of MAMU stands (occupied, presumed occupied, and unoccupied) within 0.25 mile of proposed activities that would be categorized as Moderate Impact, Low Impact, and No Impact. No MAMU stand was assigned a "High" category because Pacific Connector would adhere to DTRs during the critical breeding period for construction and timber removal activities that occur within 0.25 mile of MAMU stands. The FWS (Trask & Associates, 2014) recommends actions to offset direct impacts to nesting MAMU based on the acres of habitat within 0.25 mile of project activities and D/D Imapct Category and recommended acreage "multiplier". Following direction within the D/D Conservation Framework (Trask and Associates, 2014), individual assessments included in appendix Z1 for each MAMU Stand (occupied, unoccupied, and presumed occupied) have been used to determine the amount of acres by D/D Impact Type that should be mitigated to offset impacts (see appendix O).

This CMP has been developed in close consultation with the Forest Service and BLM. Pacific Connector has been and will continue to be in consultation with the FWS during development of the CMP.

**Table 4.3.3-20**
**Summary of Acres of MAMU Stand within 0.25 mile of Project Activities that Could Disturb or Disrupt MAMU Behavior by D/D Impact Category**

| Status of Marbled Murrelet Stand | General Landowner | Number of MAMU Stands within 0.25 mile of Project Activities | | | | Disturbance / Disruption Impact Category and acres affected | | | |
|---|---|---|---|---|---|---|---|---|---|
| | | Disruption | Disturbance | None4 | Total Number of Stands | Moderate Impact | Low Impact | No Impact / Low Impact (no mitigation) | Total Acres |
| Occupied Stand | Federal | 0 | 30 | 0 | 45 | 538.59 | 2,475.49 | 32.84 | 3,046.92 |
| | Non-Federal | 0 | 1 | 0 | 1 | 5.92 | 36.32 | 0.00 | 42.23 |
| | Total | 14 | 31 | 0 | 46 | 544.51 | 2,511.80 | 32.84 | 3,089.15 |
| Presumed Occupied | Federal | 0 | 61 | 0 | 69 | 10.67 | 2,654.12 | 6.78 | 2,671.57 |
| | Non-Federal | 0 | 40 | 0 | 55 | 77.67 | 572.13 | 16.43 | 666.24 |
| | Total | 14 | 105 | 0 | 124 | 88.35 | 3,226.25 | 23.21 | 3,337.81 |
| Unoccupied | Federal | 2 | 1 | 0 | 3 | 210.88 | 203.49 | 0.00 | 414.38 |
| | Non-Federal | 0 | 0 | 0 | 0 | 0.00 | 0.00 | 0.00 | 0.00 |
| | Total | 2 | 1 | 0 | 3 | 210.89 | 203.49 | 0.00 | 414.38 |
| Total MAMU Range | Federal | 16 | 92 | 5 | 117 | 760.15 | 5,333.10 | 39.62 | 6,132.87 |
| | Non-Federal | 14 | 41 | 1 | 56 | 83.59 | 608.45 | 16.43 | 708.47 |
| | Total | 30 | 137 | 6 | 173 | 843.74 | 5,941.55 | 56.05 | 6,841.34 |

[1] Summarized from table Q-2 in appendix Q.
[2] Construction Activities include:
[3] Road use:
[4] None: 3 presumed occupied stands > 0.25 mile from project components, 1 occupied stand and 1 presumed occupied stand < 0.25 mile of roads but public road closer than other access road, and 1 presumed occupied stand just within 0.25 mile of project component but with existing ambient/background noise construction would not be detectible.

### 4.3.3.5 Determination of Effects

Listed Species

The Project **may affect** MAMUs because:

- Suitable habitat is available within the Terrestrial Nesting Analysis Area.
- Marbled Murrelets have been located within the Terrestrial Nesting Analysis Area during survey efforts for the proposed action.

The Project is **likely to adversely affect** MAMUs because:

- Disturbance associated with Project activities would occur within the critical breeding season and within 0.25 mile of known MAMU stands. Proposed actions which generate noise above local ambient levels might disturb MAMUs and interfere with essential nesting behaviors.
  - 79 MAMU stands (20 occupied, 56 presumed occupied, and 3 unoccupied) are within 0.25 mile of the proposed construction right-of-way that could be constructed during the breeding season.

- 161 MAMU stands (45 occupied, 113 presumed occupied, and 3 unoccupied) are within 0.25 mile of proposed access roads that could be used during the breeding season.

- Blasting activities may occur within 0.25 mile of MAMU stands between April 1 and September 30.
- Helicopter use within 0.25 mile of eleven MAMU Stands (7 occupied, 1 unoccupied, and 1 presumed occupied) during the breeding period (between April 1 and September 15) could occur and disturb MAMU adults and nestlings, as well as potentially blow nestlings out of the nest tree within seven MAMU Stands (5 occupied, 1 unoccupied, and 1 presumed occupied) from rotor wash.
- The proposed Project would remove and modify potential suitable nesting habitat and recruitment habitat within the range of the MAMU, which does not support the recovery of the species.

Critical Habitat

A **may affect** determination is warranted for MAMU critical habitat because:

- The Project occurs within designated MAMU critical habitat, and
- The Project would result in habitat impacts within designated critical habitat area.

A **likely to adversely affect** determination is warranted for MAMU critical habitat because:

- The proposed action could remove or degrade individual trees with potential nesting platforms or the nest platforms themselves, resulting in a significant decrease in the value of the trees for future nesting use (PCE1, or suitable or potentially suitable habitat).
- The proposed action could remove or degrade trees adjacent to trees with potential nesting platforms that provide habitat elements essential to the suitability of the potential nest tree or platform, such as providing cover from weather or predators (PCE 2, or recruitment/capable habitat).

### 4.3.4 Northern Spotted Owl

#### 4.3.4.1 Species Account and Critical Habitat

**Status**

The northern spotted owl (NSO) was listed by the FWS as threatened on June 26, 1990 (FWS, 1990), including populations in Oregon. The Final Rule cited declining populations due to loss and adverse modification of suitable habitat from timber harvest and natural catastrophes (wild fire, windthrow), as well as inadequate regulatory mechanisms to protect the owl or its habitat (FWS, 1990).

**Threats**

As of 1990, an estimated 60 percent of suitable NSO habitat present in the Pacific Northwest in 1800 had been eliminated with 90 percent of all remaining suitable habitat occurring on public lands (less than 5 percent of old growth habitats occurred on private, state or tribal lands in 1990). FWS (1990) indicated that given the current trends, remaining unprotected NSO habitat could be eliminated in 10 to 30 years. Since the inception of the NWFP in 1994 (1994 through 2007), NSO habitat on federal lands has decreased by 3.4 percent range wide (approximately

298,600 acres; most of the lost occurred within NWFP reserved allocations as a result of wildfires (approximately 203,900 acres) (Davis and Dugger, 2011). Further, the quality of 50 percent of total remaining NSO habitats was judged to be affected by reduction of individual stand size, fragmentation, and edge effects so that successful NSO reproduction was at risk (FWS, 1990). Continued logging practices were chiefly responsible for the loss and degradation of habitat, and public forest lands that are intensively managed for timber production generally are not able to achieve old-growth characteristics, which may require 200 years to develop (FWS, 1990). In the last two decades timber harvest on federal lands has been greatly reduced, but residual habitat loss and continued timber harvest on private lands across the range of the spotted owl continues to threaten this species (FWS, 2011c).

With decreased availability and scattered distribution of suitable habitats, NSO populations are becoming more isolated and at risk of ecological “bottlenecks” (FWS, 1990) that can lead to magnified deleterious effects from other, natural perturbations including fire (e.g., the 1933–1951 Tillamook burn), wind (e.g., the 1962 Columbus Day storm), and volcanic eruption (e.g., Mount St. Helens in 1980). Natural events and logging create a fragmented landscape that is utilized less by NSO than more intact landscapes (FWS, 1990). Further, fragmentation reduces potential metapopulation dynamic interactions between NSO-inhabited patches (extinction, colonization within patches), resulting in potential adverse genetic effects (FWS, 1990).

High levels of fragmentation, particularly fragmentation found on BLM lands interspersed with private lands forming a “checkerboard”, adversely affect adult survivorship and fecundity (FWS, 1990), which are the major drivers influencing population growth. Computed rates of annual population change from data available in 1990 indicated declining NSO populations, with a higher rate of decline in fragmented habitats (FWS, 1990).

In addition to the relationship of habitat quality and quantity to NSO population declines, predation by great horned owls was thought to adversely affect NSO, especially juveniles which would be more exposed and thus potentially more vulnerable in fragmented landscapes (FWS, 1990). In 1990, barred owls were recognized as a potential threat to NSO due to their aggressiveness and potential to displace NSO through competitive interactions (FWS, 1990).

Additional threats have emerged since the 1990 listing. By 2006, FWS (2007e) recognized that competition from barred owls was a significant “pressing” threat to NSO throughout its range. Threats from barred owls had developed within the context of habitat loss and diminished distribution of habitat by past logging activities and other catastrophic disturbances, as well as ongoing habitat losses from timber harvest, albeit reduced harvest levels since implementation of the NWFP (FWS, 2007e, FWS, 2008c). Hazards to NSO from barred owl include competition for resources and displacement from suitable habitat (Kelley et al., 2003; Kelley and Forsman, 2004) and to a lesser degree than thought in the 1990 listing, hybridization with NSOs (Courtney et al., 2004; Kelley and Forsman, 2004).

Since the Final Rule in 1990, demographic analyses (FWS, 2004) indicated that some NSO populations were declining at a higher rate than initially estimated (e.g., at Mount Rainier and the Olympic Peninsula in Washington), while analyses of other populations indicated they were stationary (including Tyee, Klamath, and South Cascades in Oregon).

Evidence also indicated that anticipated genetic consequences of small or isolated populations had not occurred. However, genetic evidence did reveal some hybridization with barred owls (FWS, 2004), which had not been discovered in 1990. Continued habitat loss from natural disturbances and timber management, particularly in southern Oregon, was also documented in the 5-year review (FWS, 2004). Conservation plans developed since 1990 and evolution of forest characteristics through natural succession and/or management actions were expected to provide some long-term benefits to NSO habitats, though habitat restoration takes decades to be effective (FWS, 2004).

Another threat to NSO populations is loss of habitat from wildfires, especially within forests that demonstrate succession toward climax communities in the absence of fires (FWS, 2011c; Courtney et al., 2004). In drier portions of NSO range, such as the Eastern Oregon Cascades and Klamath Mountains provinces, wildfire has become more of a threat (FWS, 2011c and 2004). New potential threats to the NSO and its habitat include West Nile virus and tree diseases (see Section 3.3.1.3), respectively (FWS, 2006f). A probable future threat to NSO is the West Nile Virus because it has the potential to reduce population numbers beyond what was anticipated from other causes. To date no mortality of NSO has been recorded, but the first cases of the virus in other avian species were recently recorded in the range of the NSO (Lint, 2005). At this time West Nile virus is not considered a significant effect to spotted owls (FWS, 2011c). Effects of climate change on vegetation and NSO habitats, in addition to expanding incidence of diseases such West Nile Virus (FWS, 2004), are potential though poorly defined future threats (FWS, 2007e).

**Species Recovery**

<u>1992 Draft Recovery Plan (FWS, 1992b)</u>

The 1992 Draft Recovery Plan for the Northern Spotted Owl considered threats to NSO populations within the proposed Project area to include: low and declining populations, loss and fragmentation of habitat, poor population connectivity within each province and with adjacent provinces, and high levels of predators. As a result of these threats, the 1992 Draft Recovery Plan established 196 designated conservation areas (DCAs), of which 56 were considered category 1 DCAs (having the potential to support at least 20 NSO pairs), and the other 140 were considered category 2 DCAs (potential to support 1 to 19 NSO pairs). DCAs were derived from concepts presented by Thomas et al. (1990) in "A Conservation Strategy for the Northern Spotted Owl" that focused on the establishment of large habitat blocks that could support self-sustaining populations of 15 to 20 pairs and protected lands for dispersal of juveniles. The Recovery Plan also provided guidelines for federal lands outside of designated DCAs to be managed for NSO breeding and dispersal habitat (since identified by the 1994 NWFP as LSRs), as well as encouraged contributions from non-federal lands within the vicinity of federal lands (i.e., conservation easements) contributing to the recovery of the NSO to increase habitat for pairs and/or provide dispersal between DCAs.

<u>2008 Final Recovery Plan (FWS, 2008e)</u>

In April 2007, the FWS released a NSO draft recovery plan for public review, identifying criteria and actions needed to stop NSO decline, reduce threats, and return the species to a stable, well-distributed population in Washington, Oregon, and California over the next 30 years (FWS, 2007e). In May 2008, FWS approved the Final Recovery Plan for the Northern Spotted Owl. The recovery plan recommended specific actions that address the threat of the barred owl, as well as actions to maintain habitat for the recovery and long-term survival of the NSO including dry-forest landscape management strategies. The recovery plan built off strategies set forth in the 1992 Draft Recovery Plan for NSO (FWS, 1992b) and the NWFP (BLM and USFS, 1994), using a network of Managed Owl Conservation Areas (MOCAs) on federal lands and Conservation Support Areas (CSAs) on federal and non-federal lands where recovery actions and criteria would be targeted. MOCAs are larger tracts of lands within non-fire-dominated provinces that are expected to support a stable number of breeding pairs of NSOs over time and allow for movement of NSOs across the network. Within the drier forests of the Eastern Cascades Province, the recovery plan did not identify MOCAs or CSAs since it is expected that the rate of loss of older forests to stand-replacing wildfires would continue or increase in the coming years as the climate changes (Westerling et al., 2006 in FWS, 2008c). Rather, the recovery plan recommended treatments to older forests to reduce risks of fires and insect outbreaks even though the strategy could have short-term impacts on NSO habitat, but would achieve the long-term goal of creating more sustainable NSO habitat.

<u>2011 Revised Final Recovery Plan (FWS, 2011c)</u>

The Northern Spotted Owl Recovery Plan was revised in 2011 after the Court remanded the 2008 Recovery Plan; it builds extensively on the 1992 Draft Recovery Plan, the 1994 NWFP, and the 2008 Recovery Plan. The revised recovery plan recognizes the importance of addressing the barred owl threat, as well as the importance of maintaining and restoring high value habitat for the recovery and long-term survival of the spotted owl. It integrates an adaptive management approach to achieve results and focus on the most important actions for recovery. Four recovery criteria have been identified to serve as objective, measureable guidelines to assist in determining if the spotted owl has recovered and may be delisted: 1) stable population trend, 2) adequate population distribution, 3) continued maintenance and recruitment of spotted owl habitat, and 4) post-delisting monitoring. Thirty-three recovery actions have been included to guide activities needed to accomplish the four recovery criteria. In some instances, recovery actions are specific to physiographic provinces, which have been identified as recovery units within the 2011 Revised Recovery Plan to assist managers in measuring the objectives of the recovery criteria.

**Life History, Habitat Requirements, and Distribution**

The NSO is a medium-sized owl that occurs in coniferous or mixed coniferous-hardwood forests from southwestern British Columbia through western Washington, Oregon, and northern California south to San Francisco Bay (FWS, 1990). Although NSO habitat is variable over its range, to support NSO reproduction, a home range requires appropriate amounts of nesting, roosting, and foraging (NRF) habitat arrayed so that nesting pairs can survive, obtain resources, and breed successfully. NSOs primarily occur in old-growth and mature forests because these habitat types provide the structure and characteristics required for NRF, but they may also inhabit younger forests with the appropriate structural, vegetation, and prey characteristics, including:

- moderate to high canopy cover (60 to 80 percent);
- multi-layered, multi-species canopy dominated by large overstory trees (greater than 30 inches diameter at breast height (dbh);
- a high incidence of large trees with various deformities,
- numerous large snags;
- large accumulations of fallen trees and other woody debris on the ground; and
- sufficient open space below the canopy to fly (FWS, 1990).

High canopy closure is important to help NSOs thermoregulate and reduce potential predation (FWS, 1990 and 2007e). Dispersing NSOs, whether adults moving between blocks of suitable

NRF habitat (generally 15 miles for females and 9 miles for males; Forsman et al., 2002), or juveniles dispersing from natal areas (a range of 0.3 to 69 miles; Forsman et al., 2002), utilize a wider array of forest types and structure including more open and fragmented habitat. Although forest attributes needed for successful dispersal have not been thoroughly evaluated, they generally consist of conifer and mixed mature conifer-hardwood habitats with canopy cover greater than or equal to 40 percent and conifer trees averaging at least 11 inches dbh (FWS, 1992b). Dispersal habitat may occur in nesting, roosting, or foraging habitat, but it lacks the optimal structural characteristics needed for nesting. Northern spotted owls have been reported to occur in the following forest types: Douglas-fir and western hemlock in the coastal forests of Washington and Oregon, Pacific silver fir on the west slope of the Cascades in Washington and Oregon, mixed conifer stands including Douglas-fir, grand fir, and ponderosa pine on the east slope of the Cascades, dry Douglas-fir and mixed conifer in southern interior Oregon, and Douglas-fir, mixed-conifer, and coastal redwood or mixed conifer-hardwood habitat types in California (FWS, 1992b; Forsman et al., 1984). The NSO has been reported from a variety of elevations, from 70 feet on the Olympic Peninsula in Washington to more than 6,000 feet in California (FWS, 1990).

NSOs remain on their home range throughout the year. As a result, NSO have large home ranges that provide all the habitat components and prey necessary for the survival and successful reproduction of a territorial pair. Home ranges vary in size by physiographic province, forest type, and heterogeneity but generally increase in size from south to north where habitat quality decreases and/or becomes more fragmented (Courtney et al., 2004; FWS, 1992b; Forsman et al., 1984). Courtney et al. (2004) determined that the home range size of NSOs appeared to be influenced by a variety of factors including proportion of mature and old-growth forest within the home range, forest fragmentation, and the availability of dominant prey species (larger home ranges where flying squirrels dominated the diet compared to home ranges where wood rats dominated the diet). Within the range of the NSO, home ranges typically encompass an area within a radius around the nest site as follows: 1.8 miles within the Washington Cascades, 2.2 miles within the Olympic Peninsula, 1.2 miles within the Oregon Cascades, 1.5 miles along the Oregon Coast Range, and 1.3 miles within the Klamath Province (FWS, 1992b).

Home ranges contain three distinct use areas: 1) the nest patch, which research has shown to be an important attribute for site selection by NSOs and includes approximately 70 acres of usually contiguous forest (300 meter radius around an activity center; FWS et al., 2008), 2) the core area, which is used most intensively by a nesting pair and varies considerably in size across the geographic range, but on average encompasses approximately 500 acres around the nest site (1/2 mile radius around the activity center), and is generally made up of mostly mature/old-growth forest (FWS, 2007e; Courtney et al., 2004), and 3) the remainder of the home range which is used for foraging and roosting and is essential to the year-round survival of the resident pair (FWS, 2007e).

Spotted owls are primarily nocturnal, foraging between dusk and dawn, with peak activity occurring two hours after sunset and two hours prior to sunrise (Delaney et al., 1999; Forsman et al., 1984). However, if prey is easily available near their day roosts, NSOs would take advantage of the opportunity, a behavior that is used to determine reproductive status in NSO survey protocol.

**Population Status**

Demographic data collected from nine study areas throughout the NWFP area in Washington, California, and Oregon have been used to monitor NSO populations in their geographical range from 1985 through 2008, of which five sites occur in Oregon (Anthony et al., 2006; Davis et al., 2011). The primary objectives of these studies were to estimate fecundity, apparent survival, and annual rate of change, and to determine if there were any temporal trends in these population parameters. Three of the study sites in Oregon, Tyee, Klamath, and southern Oregon Cascades, are located within and/or adjacent to the Project area. The proposed action is located within the Klamath and South Cascades study areas in Douglas County (approximately Pacific Connector MP 94.13 to MP 98.9) and in Jackson and Klamath counties (approximately Pacific Connector MP 153.87 to MP 172.25). Forests on these study sites were mostly characterized by mixtures of Douglas-fir and western hemlock or by mixed-conifer associations of Douglas-fir, grand fir, western white pine, and ponderosa pine (Anthony et al., 2006). Estimates of fecundity, apparent survival rates, and population change for five study sites within Oregon are included in table 4.3.4-1 (Forsman et al., 2011; Davis et al., 2011).

**Table 4.3.4-1**
**Estimates of Fecundity, Apparent Survival Rates and Population Change for the Five Northern Spotted Owl Demographic Study Sites on Federally-Managed Lands in Oregon [1]**

| | | Fecundity [2] | | Apparent Survival [2] | | Population Change | | |

4 Trends based on data collected between 1988 – 2008
5 Trends based on data collected between 1991 – 2008
6 Although study sites appeared stationary throughout the study period, there was some suggestion that populations were declining in the last three years of the study.

Within Oregon, apparent adult survival rates are declining on all but the Klamath study area; most declines have occurred primarily in the last 10 years on the other four study sites. Effects of barred owls have been attributed to the spotted owl survival rate, but varied by study site: decreased survival was associated with barred owls in the Coast Ranges and H.J. Andrews study sites, whereas, in the Klamath study area, evidence was negligible. In Oregon, increased fecundity was associated with higher annual estimates of the amount of suitable habitat. Overall, demographic declines in some study sites were attributed to the increased numbers of barred owls and loss of habitat (Forsman et al., 2011; Davis et al., 2011).

A general discussion of NSO population trends was included in a biological assessment for the Roseburg BLM District (BLM, 2008b), which revealed a consistent declining trend among NSO pairs throughout Oregon. In the Tyee Density Study Area, the number of non-juvenile NSOs detected dropped from 146 in 2005 to 129 in 2006. By 2007, the number of non-juveniles in this study area had dropped to 119, the lowest since the population had been studied. The proportion of sites occupied by a pair of NSOs in the Klamath demography study area also declined, from 64 percent in 2002 to 52 percent in 2007.

BLM (2008b) hypothesized that potential NSO inbreeding and other genetic problems due to small population sizes could occur. However, BLM (2008b) cited studies that concluded there was no indication of reduced genetic variation or past bottlenecks in Washington, Oregon, or California.

**Critical Habitat**

Critical habitat for the NSO was originally designated on January 15, 1992 and included approximately 6.9 million acres in California, Oregon, and Washington, of which 3.3 million acres occurred in Oregon (FWS, 1992b). The 1992 designation was revised in 2008 (FWS, 2008d), and more recently in 2012 (FWS, 2012a). The 2012 final rule (FWS, 2012a) designates approximately 9.6 million acres within 11 critical habitat units (CHU) and 60 critical habitat subunits in California, Oregon, and Washington. Eight CHU and 58 subunits are identified in Oregon on a little more than 4.5 million acres. The FWS (2012a) relied on recovery criteria set forth in the Revised Recovery Plan for the NSO (FWS, 2011c) to ensure that designated CHUs met the following criteria: 1) ensures sufficient habitat to support stable, healthy populations across the range and within each critical habitat unit, 2) ensures distribution of northern spotted owl populations across the range of habitat conditions used by the species, and 3) incorporates uncertainty, including potential effects of barred owls, climate change, and wildfire disturbance risk.

The FWS (1992b) determined that the physical and biological habitat features (primary constituent elements – PCEs) that are essential for the recovery of the spotted owl are forested lands used or potentially used for nesting, roosting, foraging, and dispersal. Recently, FWS (2012a) revised its 1992 designation of critical habitat that provided more specificity to PCEs for the owl. Based on more current information on the life history, biology, and ecology of the species, the revised PCEs are (FWS, 2012a):

1. Forest types that may be in early-, mid-, or late-seral stages and that support northern spotted owls across its geographical range, primarily: sitka spruce, western hemlock, grand fir, Pacific silver fir, Douglas-fir, white fir, Shasta red fir, redwood/Douglas-fir (in coastal California and southwestern Oregon), and the moist end of the ponderosa pine coniferous forest zones. This PCE must occur in concert with at least one of the following PCEs.
2. Forested habitat (see PCE1) that provides for nesting and roosting, and could provide for foraging. Nesting and roosting habitat provides structural features for nesting, protection from adverse weather conditions, and cover to reduce predation risks for adults and young. Across the owl's range, habitat requirements are nearly identical and are associated with a high incidence of large trees with various deformities (large cavities, broken tops, mistletoe infections) or large snags suitable for nest placement. Patches of nesting habitat, in combination with roosting habitat, must be sufficiently large and

contiguous to maintain NSO core areas and home ranges, and must be proximate to foraging habitat.

3. Habitat that provides for foraging, which varies widely across the NSO range. It can consist of nesting and roosting habitat, and provide for dispersal, but its primary function is to provide a food supply for survival and reproduction. Foraging habitat is closely tied to the prey base and in some cases can include more open and fragmented forests, especially in the southern portion of the owl's range. NSO feed primarily on small mammals, especially northern flying squirrels and wood rats in southwestern Oregon (citations in Anthony et al., 2006).
4. Habitat that supports dispersal of spotted owls, which could provide nesting, roosting, and foraging habitat, but could also be composed of other forest types between larger blocks of nesting, roosting, and foraging habitat. Dispersal habitat must, at a minimum, provide stands with adequate tree size and canopy cover to provide protection from avian predators and at least minimal foraging opportunities. It is essential to maintaining genetic and demographic connections among populations across the range of the species.

Because not all life history functions require all the PCEs, not all proposed revised critical habitat would contain all four PCEs described above. Some CHUs contain all PCEs and support multiple life processes, while other units contain only one or two (FWS, 2012a). All CHUs have had or have presence of NSO.

Activities that disturb or remove the primary constituent elements within designated CHUs might adversely modify the owls' critical habitat. These activities could include actions that would reduce the canopy closure of a timber stand, reduce the average dbh of trees in the stand, appreciably modify the multi-layered stand structure, reduce the availability of nesting structures and sites, reduce the suitability of the landscape to provide for safe movement, or reduce the abundance or availability of prey species (FWS, 1992b).

<u>NWFP Late Successional Reserves</u>

Additional habitat protection for the NSO was established when the Forest Service and BLM adopted the Northwest Forest Plan (NWFP) in 1994. The NWFP (Forest Service and BLM 1994) was designed to protect habitat for NSO and other species associated with late-successional forests while allowing a reduced amount of commercial logging on federal lands. Large amounts of federal land within the range of NSO were allocated for riparian and late successional reserves; the primary objective for these lands was to maintain or restore habitat for NSO and other fish and wildlife species. Riparian Reserves and other NWFP land use allocations provide connectivity between LSRs and federally designated critical habitat. Additionally the NWFP states that sites occupied by marbled murrelets and known owl activity centers (100-acre areas identified by BLM and Forest Service) that are within Matrix lands are considered "unmapped LSRs" and managed as lands allocated as LSRs by the NWFP. A good portion of the federally designated critical habitat overlaps with LSR land allocations; however, some lands do not and therefore afford additional habitat protection for listed species.

#### 4.3.4.2 Environmental Baseline

<u>Provincial Analysis Area</u>

The proposed action is located within four Physiographic Provinces: Oregon Coast Range, Oregon Klamath Mountains, West Oregon Cascades, and East Oregon Cascades. NSO home ranges vary across provinces as a result of habitat heterogeneity and type, and prey availability (Courtney et al., 2004). NSO home ranges vary by province, using the following NSO home range radii: 1.5 miles within the Coast Range Physiographic Province, 1.3 miles within the Klamath Mountains Physiographic Province, and 1.2 miles within the West and East Cascades Physiographic Provinces. Described below are two components to the action area within which Project-related activities can affect NSOs; one for habitat removal or modification and a second for disturbance/disruption of NSO during the breeding season. The two components have been combined together to consider all components of the Provincial Analysis Area (see figure 4.3-13).

Habitat Removal or Modification

The Habitat Removal or Modification Analysis Area applies to all proposed action components that have the potential to remove or modify habitat, including construction of the Port's Multi-slip Terminal, LNG facilities, and Pacific Connector pipeline and aboveground facilities. Also, the Provincial Analysis Area includes a 100-meter (328 feet) wide buffer along the edge of the area of habitat impact (e.g., edge of right-of-way or edge of new roadway corridor). In addition to the 100-meter buffer, the Provincial Analysis Area includes any NSO Home Range with an activity center located between the outer edge of the 100-meter wide buffer of the proposed action components out to the distance equal to the applicable NSO physiographic home range radius: 1.5 miles, 1.3 miles, or 1.2 miles of the proposed Project.

Disturbance/Disruption

Harassment that could occur from proposed construction, including blasting (greater than 2 pounds) and/or large transport helicopter use by the proposed action is expected within 0.25-mile. A 0.25-mile analysis area would be considered for construction and timber removal activities, as well as existing roads that have been identified for access to the proposed action to account for disturbance from noise generated from traffic or road improvements.

**Species Presence**

NSO populations consist of resident owls (adult and subadult) that defend a territory vocally, and non-territorial owls (adult, subadult, and juvenile owls) that generally move through habitats in search of vacant territories or available mates and rarely vocalize. Surveys to determine if potential suitable NSO habitat is occupied are accomplished by imitating NSO calls to elicit a response, generally from the territorial owls. This is usually more effective at night, as NSOs will defend their territory more readily at night (Hobbs et al., 2004; Courtney et al., 2004; Forsman, 1983). Generally sites identified at night would be visited the following day to determine status (i.e., pair, nesting, resident single). Reproduction information for territorial owls is obtained by feeding an individual adult owl live mice to determine if it is a member of a nesting pair or not, based on the owl's behavior (Lint, 2001; FWS, 1992b). FWS (2012e) recommends conducting at least six visits a year for two years to determine site occupancy and potential reproductive success, although protocol suggests that this information can be gathered during 6 visits to a site in one year if noise disturbance is only expected from a project. Previous northern spotted owl survey protocol (FWS, 1992c) recommended 3 visits per year over a two year period.

To determine species presence and/or absence within the Provincial Analysis Area, Pacific Connector obtained historical and current northern spotted owl locations from BLM Districts and National Forests crossed by the PCGP Project, as well as information collected from the demographic studies occurring within the PCGP Project area (various GIS data provided to Pacific Connector – BLM, 2006 and 2012; Forest Service, 2006 and 2012; FWS, 2008d). Additionally, Pacific Connector contracted Siskiyou BioSurvey, Inc (SBS – Eagle Point, Oregon) to conduct two years of surveys in 2007 and 2008 to determine species presence within 2009 FERC FEIS construction right-of-way. For analyses within the BA, Pacific Connector will assume all owl sites (known, best location, and PCGP assumed) are occupied.

Pacific Connector Spotted Owl Surveys (2007 and 2008)

To determine nesting NSO presence and/or absence, as well as nesting status (if possible) within the analysis area, NSO surveys were conducted by Pacific Connector between March 15 and August 31 in 2007 and 2008 as defined by the *Protocol for Surveying Proposed Management Activities that May Impact Northern Spotted Owls* (FWS, 1992c). Surveys were conducted by SBS and were carried out within suitable NSO habitat and outside of ongoing NSO demographic and monitoring survey efforts. In general, surveys were conducted within 0.5 mile of the proposed construction right-of-way where suitable NSO habitat would be removed by the Project. Otherwise, surveys were conducted within 0.25 mile of the proposed construction right-of-way if suitable habitat is present, but would not be removed (as advised by Smith et al., 2007). In areas that were identified as requiring blasting and/or timber removal and pipeline construction by helicopter, surveys within suitable NSO habitat were conducted 1 mile from the proposed pipeline alignment in 2008 (Smith et al. 2007; Wille et al., 2006).

The 0.25-mile disturbance and the 0.5-mile habitat alteration survey areas followed the 1992 FWS 2-year survey protocol (3 visits per year) in 2007 and 2008. Surveys conducted out to 1 mile from blasting (greater than 2 pounds) and/or large transport helicopter disturbance areas in 2008 followed the 1-year survey protocol (6 visits per year). Surveys conducted within the Project area took extra precautions to reduce negative effects of barred owls on NSO, following guidance provided by the FWS in March 2007, which dictate that if a barred owl responds to a NSO call, stop calling for the NSO. This guidance is similar to the direction provided in the 2012 revised and updated survey protocol (FWS, 2012e). To further reduce NSO harassment from multiple survey efforts, Pacific Connector did not conduct surveys where other survey efforts by agency biologists were ongoing, including demographic and monitoring studies in the Roseburg BLM District (approximately MP 46.8 through MP 100.7), South Cascades demographic study conducted in Jackson and Klamath counties (MP 155.2 through MP 170.7), and a NSO monitoring study area in Lakeview BLM District.

Within the defined survey area for 2007, approximately 28,774 acres were identified as suitable NSO habitat and were organized into 61 separate survey areas. Of that acreage, 8,562 acres identified were located on private lands but permission to survey was granted on only 3,713 acres was granted (access was denied for 4,849 acres). Overall, 83 percent or approximately 23,925 acres were surveyed in 2007 following the 2-year survey protocol. In 2008, an additional 32,221 acres were identified as potential suitable NSO habitat within 1 mile of areas that may require blasting (greater than 2 pounds) and large transport helicopter use. Of the 58,652 acres identified as suitable NSO habitat, permission to survey was granted for 47,679 acres (81 percent), and these were surveyed in 2008. New habitat identified followed the 1-year survey protocol whereas habitat surveyed in 2007 followed the 2-year protocol. Some areas where survey permission had been denied are covered in the call effective zone, but it cannot be assumed that these properties were surveyed since follow-up surveys could not be conducted. The call effective zone was created by SBS by initially applying a buffer of 1,980 feet to all calling station points to represent the effective auditory distance. Buffers were then assessed to determine variations from this distance based on topography. Where ridgelines appear significant enough to impede sound, the buffers were reduced accordingly. In four instances, the buffer was increased to one-half mile because the calling stations were located along major ridgelines with calling projected into smoothly dropping terrain. A 1,000-foot buffer was also applied to transects to represent the effective daytime continuous calling distance for daytime follow-up surveys.

NSO surveys conducted in 2007 detected NSO 115 times in 29 of the 61 survey areas established in the 2009 FERC FEIS project area. Twelve NSO pairs and one resident single (located at least three times on separate survey visits) were detected. No nest sites were located in 2007; however, at one site fledglings were observed with their parents, suggesting a nest location in the vicinity. During 2008 surveys, NSO were detected 190 times and were found in 26 of the 54 survey areas established, including survey areas established within 1-mile of proposed blasting (greater than 2 pounds) and large transport helicopter activities. NSO pairs were detected at 20 locations and two nests were located. Resident singles were identified at six sites. Approximate activity centers were drawn around the pairs and resident singles documented in 2007 and/or 2008 based on detection date and time, the age and sex of owls observed, the owls' behavior, and occasionally the habitat of a detection location. Seven NSO pairs documented within the 2009 FERC FEIS project area were assumed to be NSO activity sites previously documented and/or monitored by other agencies, and seven pairs were adopted as new activity sites within agency management areas considering activity documented during 2007 and/or 2008 survey results, including two areas that were previously identified as "predicted" owl sites by FWS (Thrailkill, 2008). NSO pairs or resident singles that were not associated with previous known NSO activity centers or were not adopted by agencies as new activity sites are considered PCGP "best location" activity centers for analysis within this BA.

Although survey design was not intended to locate or census barred owls, this species was documented 36 times in 14 survey areas in 2007, and 115 times in 14 survey areas in 2008, including 8 pairs.

For full description and information on NSO surveys and detections, see the 2007–2008 Northern Spotted Owl Survey Report included under separate cover with the June 2013 FERC Certificate application for the Pacific Connector.

Northern Spotted Owl Activity Sites Considered for Analysis

In 2008, Pacific Connector received a Northern Spotted Owl Occupancy Map (NSOOM) from FWS that included both historical and recent NSO sites provided by BLM Districts and National Forests within the proposed Project area that were combined with survey data collected for the PCGP Project by SBS in 2007/2008. Additionally, the NSOOM provided areas of potential northern spotted owl nests sites modeled or "predicted" to occur on the landscape based on current NSO occupancy and available NSO habitat (see Appendix 1 in Appendix A of Trapper Timber Sale Biological Opinion). Agency biologists reviewed the data and revised NSO activity centers considered for the PCGP Project based on local knowledge prior to providing the final data to Pacific Connector. The objective of the collaborative process was to generate a clean but complete NSO map that could be used for analyses purposes for the proposed Pacific Connector pipeline. Also, the objective was to take a conservative approach so that analysis considered the "worst case scenario." Therefore, recent survey efforts by Pacific Connector, local habitat knowledge, alternate nest sites, and barred owl activity were taken into consideration when finalizing the best location of owl activity to analyze. Some areas where owl activity was less certain, such as where resident single or pair activity was identified by SBS that may be associated with other known activity sites but not enough information was available (i.e., no band color collected), were included for analysis (i.e., PCGP best location sites). If an alternate nest site was closer to the PCGP Project, the alternate site was considered rather than the site with the most recent activity for a more conservative analysis. Consultations, discussions, and resolutions of specific sites within the proposed Project area provided for 2008 are included in table S-1 in appendix S.

To revise the 2008 NSOOM and account for new data and new survey efforts since 2008, Pacific Connector requested and obtained new NSO data from each of the BLM Districts and National Forests crossed, including demographic study data in March 2013. Using the same methodology that was applied to the 2008 NSOOM, a revised NSOOM was created for this current BA. The NSOOM methodology is intended to facilitate a reasonable basis for estimating potentially occupied NSO habitat within the proposed analysis area, especially where surveys have not been conducted or are incomplete as per FWS survey protocol, or barred owl presence may have negatively affected the response of NSOs during calling surveys. Table S-2 in appendix S provides summary of additional discussions and resolutions specific to the 2013 NSOOM use for analyses in this BA. This revised NSOOM was used in the September 2013 APDBA.

In June 2013, the use of the Owl Estimation Model (OEM) that produced "predicted" owls was challenged in federal district court. As a result of this challenge and other complaints, FWS, BLM, and Forest Service have requested that the use of "predicted owls" utilizing the OEM no longer be included in this BA analysis. The 2010 BA and the APDBA submitted in September 2013 included predicted owls utlilizing the OEM. Pacific Connector used the predicted owl sites to produce a more conservative analysis for habitat effects and disturbance disruption effects by the Project, as described above. As a result of the recent court activity and agency requests, Pacific Connector has removed 17 predicted owls created using the OEM from the analysis in this BA that were considered in the September 2013 APDBA. However, in order for Pacific Connector to continue with a conservative analysis approach for spotted owls (similar to Pacific Connector's approach for marbled murrelets – presumed occupied stands), Pacific Connector identified nine areas (PCGP assumed sites) within 1.2 to 1.5 miles of proposed Project disturbance (Cascades to Coast Range physiographic province home range radii distances) that could potentially support NSO pairs. PCGP assumed sites were established in areas that were either surveyed in 2007/2008 with NSO presence but no pair or resident single determined, or an area that could support a NSO pair based on suitable habitat available in an assumed nest patch/core area that is located farther than the average physiographic distance from a known or best location NSO site (> 2,084 meters in Coast Range, > 2,078 meters or 2,596 acres in Klamath Mountains, > 2,333 meters in West Cascades, and > 2,446 meters in East Cascades); see FWS et al, 2008. Pacific Connector took into consideration the general habitat characteristics of known NSO sites in the vicinity of potential "assumed" locations, since available NRF habitat within a PCGP assumed site often did not meet the FWS-recommended NRF threshold of more than 40 percent and more than 50 percent NRF in the home range and core area, respectively. Past predicted owl sites were also reviewed for consideration because PCGP survey efforts had targeted those areas; in five instances, PCGP assumed sites were established in the vicinity of previously "mapped" / "predicted" owl sites based on survey efforts or the amount of available high NRF/NRF that was also contiguous, interior forest. PCGP assumed sites have been placed in contiguous high NRF/NRF habitat at least 100 meters from the edge of the stand resulting in the site being placed in interior forest. These areas are PCGP assumed NSO sites and have been provided a site ID PCGP A-1 through PCGP A-9. No PCGP assumed sites were established between MPs 1.47R and 32.47 because this area consists of checkerboard BLM/private landownership where commercial timber harvest is prevalent and surveys conducted for the PCGP Project in areas of higher suitable habitat did not document NSO. Thus, PCGP eliminated OEM predicited owls from this BA but includes PCGP assumed sites based on best professional judgement of potentially available habitat.

Approximately 98 northern spotted owl home ranges – known current/historic (72), best location (17), and PCGP-assumed (9) occur within the vicinity of the proposed action, including existing access roads identified for use for construction and operation of the project, pipe yards, and rock storage areas. Ninety (90) home ranges are crossed by the proposed action and one (1) home range is within 100 meters of the proposed action, and an additional seven home ranges occur within 0.25 mile of existing access roads only and could be affected by use of roads (see table 4.3.4-2). Table 4.3.4-2 provides a summary of northern spotted owl home ranges, core areas, and nest patches (known, best location, or PCGP assumed) that intersect the proposed PCGP Project and/or proposed access roads within each physiographic province. Table Q-7 in appendix Q provides additional details for each NSO Home Range included in the Provincial Analysis Area, including available NSO habitat (high NRF, NRF, dispersal only, and capable) within each Home Range pre-action.

FWS et al. (2008) consider core areas with 50 percent or greater NRF habitat and home ranges with at least 40 percent NRF habitat to be necessary to maintain NSO life history function. Based on FWS et al. (2008) guidelines 35 spotted owl sites identified within the analysis area are above the threshold of available NRF habitat within both their core area (greater than 50 percent) and home range (greater than 40 percent): 29 of 72 (40 percent) known NSO sites and 6 of 17 (35 percent) best location sites. The remaining 63 spotted owl activity centers (43 known 11 best location, and nine PCGP assumed) are below NRF thresholds for the core area and/or home range. Table 4.3.4-3 provides a summary of the current habitat condition by Physiographic Province and owl status (known, best location, or PCGP assumed) of the 98 NSO sites within the provincial analysis area. Note that calculations of habitat conditions for each owl site in table 4.3.4-3 considered suitable habitat located on both federal and non-federal lands. The amount of NRF habitat currently available for each NSO within each habitat type (nest patch, core area, and home range) can be reviewed in table Q-7 in appendix Q. Amount of NRF habitat in table Q-7 in appendix Q is specific to each habitat type in its entirety; acres provided for the home range include acres that also occur within the core area and nest patch, and acres included in the core area also include acres within the nest patch. Table Q-7 in appendix Q provides the amount of suitable habitat for each individual owl in federal and non-federal lands and the habitat condition determined pre-action for each NSO home range. For a description of how NSO habitat was determined, see habitat section below.

## Table 4.3.4-2
## Summary of Known, Best Location, and PCGP Assumed Northern Spotted Owl Home Ranges, Core Areas, and Nest Patches Crossed by the PCGP Project, including Access Roads

| NSO Status | Number of NSO Activity Centers | Number of Home Ranges Crossed | | Number of Core Areas Crossed | | Number of Nest Patches Crossed | |
|---|---|---|---|---|---|---|---|
| | | Habitat Affected [1] | Access Roads [2] | Habitat Affected [1] | Access Roads [2] | Habitat Affected [1] | Access Roads [2] |
| **Coast Range Physiographic Province – 1.5 mile home range radius** | | | | | | | |
| Known Sites | 13 | 9 | 13 | 3 | 11 | 1 | 5 |
| Best Location Sites [3] | 1 | 1 | 1 | 0 | 1 | 0 | 0 |
| PCGP Assumed Sites | 4 | 4 | 4 | 2 | 3 | 0 | 1 |
| *Total* | *18* | *14* | *18* | *5* | *15* | *1* | *6* |
| **Klamath Mountains Physiographic Province – 1.3 mile home range radius** | | | | | | | |
| Known Sites | 33 | 33 | 33 | 13 | 21 | 1 | 6 |
| Best Location Sites [3] | 10 | 10 | 10 | 5 | 7 | 3 | 4 |
| PCGP Assumed Sites | 4 | 3 | 4 | 2 | 2 | 1 | 1 |
| *Total* | *47* | *46* | *47* | *20* | *30* | *5* | *11* |
| **West Cascades Physiographic Province – 1.2 mile home range radius** | | | | | | | |
| Known Sites | 21 | 19 | 21 | 5 | 12 | 1 | 7 |
| Best Location Sites [3] | 6 | 6 | 6 | 3 | 5 | 1 | 2 |
| PCGP Assumed Sites | 1 | 1 | 1 | 1 | 1 | 0 | 0 |
| *Total* | *28* | *26* | *28* | *9* | *18* | *2* | *9* |
| **East Cascades Physiographic Province – 1.2 mile home range radius** | | | | | | | |
| Known Sites | 5 | 5 | 4 | 1 | 2 | 1 | 0 |
| Best Location Sites [3] | 0 | 0 | 0 | 0 | 0 | 0 | 0 |
| PCGP Assumed Sites | 0 | 0 | 0 | 0 | 0 | 0 | 0 |
| *Total* | *5* | *5* | *4* | *1* | *2* | *1* | *0* |
| **All Physiographic Provinces Crossed** | | | | | | | |
| Known Sites | 72 | 66 | 71 | 22 | 46 | 4 | 18 |
| Best Location Sites [3] | 17 | 17 | 17 | 8 | 13 | 4 | 6 |
| PCGP Assumed Sites | 9 | 8 | 9 | 5 | 6 | 1 | 2 |
| **Total** | **98** | **91** | **97** | **35** | **65** | **9** | **26** |

[1] Habitat Affected considers all proposed disturbance, including uncleared storage areas (UCSAs), pipeyards, and rock sources.
[2] Access roads considered does not include paved roads that are used regularly by the public (i.e., County Roads, State Highways). Home ranges are included if the activity center is within 0.25 mile of a proposed access road.
[3] Best Location Sites – areas identified with pair activity during PCGP survey efforts in 2007 and/or 2008 but the nest was not located; SBS and local agency biologists determined best potential nest site based on survey data and available habitat.
[4] PCGP Assumed Sites - area identifed by Pacific Connector that may provide habitat for NSO pair.

**Table 4.3.4-3**
**Status of the Northern Spotted Owl and its Habitat within the Provincial Analysis Area [1]**

| Suitable NRF Habitat Condition within Owl Home Ranges [2] | Owl Status [3] | Physiographic Province: Coast Range | Klamath Mountains | West Cascades | East Cascades | Total |
|---|---|---|---|---|---|---|
| Home Range > 40% AND Core Area > 50% | Known | 1 | 14 | 10 | 4 | 29 |
| | Best Location | 0 | 3 | 3 | 0 | 6 |
| | PCGP Assumed | 0 | 0 | 0 | 0 | 0 |
| | *Total* | *1* | *17* | *13* | *4* | *35* |
| Home Range > 40% AND Core Area < 50% | Known | 0 | 3 | 4 | 0 | 7 |
| | Best Location | 0 | 1 | 2 | 0 | 3 |
| | PCGP Assumed | 0 | 0 | 0 | 0 | 0 |
| | *Total* | *0* | *4* | *6* | *0* | *10* |
| Home Range < 40% AND Core Area > 50% | Known | 2 | 2 | 2 | 0 | 6 |

| | *Total* | *18* | *47* | *28* | *5* | *98* |

[1] For detailed NRF/High NRF habitat available for each individual NSO and its habitat type (nest patch, core area, home range), refer to "pre-action" suitable habitat acres in table Q-7 in appendix Q.
[2] FWS et al. (2008) consider core areas with 50 percent or greater suitable NRF habitat and home ranges with at least 40 percent suitable NRF habitat to be necessary to maintain NSO life history function.
[3] Owl Status: 1) Known sites represent NSO activity sites provided by BLM and Forest Service biologists within the provincial analysis area; 2) Best Location sites represent pairs or resident singles documented by Pacific Connector during surveys in 2007 and 2008 with no nest site/activity center located, and; 3) PCGP Assumed sites include an area identifed by Pacific Connector that may provide habitat for NSO activity center.

Pacific Connector requested guidance from FWS in November 2012 to determine what additional surveys for NSO should be conducted for the proposed action, considering the revised survey protocol that was finalized in February 2010 (see FWS, 2010d) and previous surveys conducted in 2007 and 2008. FWS (McCorkle, 2012; appendix S – ROC) stated that additional full protocol NSO surveys across the entire project are not necessary, but recommended additional pre-construction "spot check" surveys with at least 3 site visits occur to confirm occupancy status, and to inform additional opportunities to fine-tune timing or distance buffers around active NSO activity centers. Pacific Connector will conduct additional "spot check" surveys within the analysis area (defined above) one year prior to scheduled timber removal in NRF habitat that is within 0.25 mile of the construction right-of-way in NSO home ranges to attempt to detect spotted owls that may have recently established territories in the project area (see "spot check" surveys in the revised NSO survey protocol; FWS, 2010). Surveys would not occur where annual monitoring survey efforts are on-going in the proposed action area to minimize NSO harassment. Reproductive follow-up surveys would occur at approximately 10 activity sites (five known, four best location, and one PCGP assumed site) that are within 0.25 mile of the construction right-of-way the following year prior to pipeline construction to determine if documented nest sites and/or pairs are active. The follow-up surveys would either consist of two visits before May 1 at least one week apart or one survey after May 1 as described by the revised NSO survey protocol (FWS, 2010d).

**Habitat**

FWS has identified four categories of northern spotted owl habitat that should be used to assess impacts to spotted owls and habitat for the proposed action (Trask & Associates, 2012): highly suitable NRF (high NRF), NRF, dispersal habitat, and capable habitat. High NRF is considered habitat that is characterized by large trees (> 32 dbh), high canopy cover (>60 percent), and multistoried with sufficient down wood and snags to support prey species (Trask & Associates, 2012). Other habitat definitions include (Trask & Associates, 2013; FWS; 2012a; North et al., 1999): 1) suitable NRF that consists of conifer-dominated stands older than 80 years, and are multi-storied in structure with large overstory trees (20-30 inch dbh), moderate to high canopy closure greater than 60 percent, and sufficient snags and down wood but does not meet the definition of High NRF; 2) dispersal habitat that is comprised of conifer and mixed mature conifer-hardwood habitats with a canopy cover greater than or equal to 40 percent in moist forests and greater than 30 percent in dry forests, and conifer trees greater than or equal to 11 inches average diameter-breast-at-height; and 3) capable habitat that is forested habitat that could provide NSO suitable NRF in the future (including recently harvested stands – i.e., clearcut) but currently does not provide the structures described above for NSO High NRF, NRF, or dispersal habitat. Non-capable habitat has been defined as areas that will never provide habitat for NRF or dispersal habitat, such as agriculture fields, grasslands, rivers, rock outcroppings, roads, etc. (FWS, 2006f).

In the previous analysis conducted for the 2009 FERC FEIS, Pacific Connector used the BioMapper Habitat Model created by the Forest Service Northwest Research Station and used in the 10-year Monitoring Report (see Lint, 2005) as the foundation to determine suitable habitat within the PCGP Project area. Davis et al. (2011) determined that the BioMapper model overestimated owl habitat suitability in portions of the range, including pine-dominated forests of the eastern Cascades, and young stands in the Coast Range and western Cascades. Additionally in the previous filing, spotted owl dispersal habitat was determined through a query of a Gradient Nearest Neighbor raster data set (developed by Landscape Ecology, Modeling, Mapping, & Analysis, www.fsl.orst.edu/elemma) for areas where conifers had a dbh of 11 or greater and the canopy cover of the stand was 40 percent or greater. Capable habitat was considered all forested habitat not included in the modeled NRF or dispersal habitats. Since the previous 2009 FERC FEIS analysis (FERC, 2009), improved northern spotted owl habitat models have been developed to monitor status and trends of the northern spotted owl populations and habitat within the past 15 years in the NWFP area; the habitat suitability models represent northern spotted owl habitat as of 2006 in Oregon (see Davis et al., 2011). These models have been used to determine high NRF, NRF, dispersal, and capable habitat within the proposed action project area, in conjunction with the vegetation GIS coverage that was delineated for the PCGP Project that classified forested habitat by type and age classes (clear-cut – 0 to 5 years, regenerating forest – 5 to 40 years, mid-seral – 40 to 80 years, late successional – 80 to 175 years, and old-growth – greater than 175 years; see discussion in Vegetation, Section 3.3.1.1 in Pacific Connector's FERC Certificate application).

To determine the four recommended NSO habitat categories (see Trask & Associates, 2013) within the proposed action project area, including all home ranges that intersected the proposed project area and existing access roads, Pacific Connector used two habitat suitability models developed for the 15-year NSO monitoring reports available online (http://reo.gov/monitoring/data-maps/nso-data-maps.shtml): 1) Northern Spotted Owl Nesting/Roosting Habitat Suitability – 2006/2007 (nwwfp_nso_15yr) that models unsuitable, marginal, suitable, and highly suitable habitat; and 2) Northern Spotted Owl Habitat Map – 2006/2007 (nwfp_hab_15yr) that models nonforest, forested but not dispersal, dispersal habitat, and nesting/roosting habitat. The two files were combined and created 16 habitat combinations. Pacific Connector used a conservative approach and let the higher habitat category trump the lower (see table 4.3.4-4).

**Table 4.3.4-4**
**Matrix of Northern Spotted Owl Habitat Modeling Using Two Models Developed by the Pacific Northwest Research Center [1]**

| Habitat Suitability (nwfp_nso_15yr) | Habitat Map (nwfp_hab_15yr) | PCGP NSO Habitat Model [2] |
|---|---|---|
| Unsuitable | Nonforest | Not Habitat |
| Unsuitable | Forested, but not dispersal habitat | Capable |
| Unsuitable | Dispersal habitat | Dispersal |
| Unsuitable | Nesting/roosting habitat | NRF |
| Marginal | Nonforest | Capable |
| Marginal | Dispersal habitat | Dispersal Habitat |
| Marginal | Forested, but not dispersal habitat | Capable Habitat |
| Marginal | Nesting/roosting habitat | NRF |
| Suitable | Nonforest | NRF |
| Suitable | Forested, but not dispersal habitat | NRF |
| Suitable | Dispersal habitat | NRF |
| Suitable | Nesting/roosting habitat | NRF |
| Highly suitable | Nonforest | High NRF |
| Highly suitable | Forested, but not dispersal habitat | High NRF |
| Highly suitable | Dispersal habitat | High NRF |
| Highly suitable | Nesting/roosting habitat | High Suitable (NRF) |

[1] Habitat models [Northern Spotted Owl Nesting/Roosting Habitat Suitability – 2006/2007 (nwwfp_nso_15yr) and Northern Spotted Owl Habitat Map – 2006/2007 (nwfp_hab_15yr) ] available online: http://reo.gov/monitoring/data-maps/nso-data-maps.shtml.
[2] NSO habitat classifications are based on direction provided in the FWS NSO and MAMU conservation framework (Trask & Associates, 2013).

Next, two habitat modeling methods were used to determine habitat within the vicinity of the proposed action (approximately 300 meters from proposed habitat removal) and beyond 300 meters using the vegetation file that was delineated for the PCGP Project that incorporates forest age class and the resulting habitat model (see table 4.3.4-4). Two methods were considered because vegetation delineation within 300 meters of the proposed action, particularly in the affected area, was delineated at a finer scale using 2012 aerial photography and has been reviewed by local agency biologists, whereas beyond 300 meters, vegetation mapping generally relied on available data (i.e., BLM Forest Operation Inventory (FOI) coverage, late successional GNN coverage) and included areas that had not been refined using aerial photography or visited by Pacific Connector. Within 300 meters of the proposed action, NSO habitat was initially delineated considering the following age classes and forest type: clearcut and regenerating forest was considered "capable"; mid-seral coniferous and mixed forest lands, as well as deciduous forests were considered "dispersal only"; and late successional coniferous and old-growth forest were considered nesting, roosting, and foraging (NRF) habitat. The developed model (see table 4.3.4-4) was used to designate areas of "high NRF" where 40 percent or more of modeled high NRF pixels were included in delineated old-growth and late successional forest (NRF) stands (within the range of the marbled murrelet, this corresponded well to occupied murrelet stands that would be expected to have old-growth characteristics). Outside of the 300 meters, the resulting model (see table 4.3.4-4) was generally used to determine northern spotted owl habitat (high NRF, NRF, dispersal, and capable) and should represent the changing forest characteristics across the four physiographic provinces better than applying age class methodology, as within the 300 meters of the Project. Within both modeled areas, 2012 aerial photography was used to delineate obvious young stands (i.e., clearcuts or early regenerating forest) and identify the habitat as capable (in many instances, high NRF and NRF were modeled in clearcuts).

These methods, along with a hybrid method that has been discarded, were presented to FWS at a meeting in March 2013, generally to discuss and compare the difference in modeling results. Within 300 meters of the Project Area, the habitat modeling generally maps more areas as high NRF, NRF, and dispersal habitat than the merged models presented in (see table 4.3.4-4) and used beyond 300 meters; this is a result of "stands" rather than 25m X 25m modeled pixels being used to identify northern spotted owl habitat. The model outside of the 300 meters tends to identify more forested stands as capable, rather than dispersal. Pacific Connector conducted the analysis based on practical application of conceptual models proposed by FWS.

The resulting NSO Habitat file described above should provide a good approximation of the northern spotted owl habitat (high NRF, NRF, dispersal only, and capable) within the proposed action area that will be affected by construction of the PCGP Project. The model was used to determine the amount of high NRF, NRF, dispersal, and capable habitat within the Physiographic analysis area by Physiographic Province and jurisdiction (see table 4.3.4-5). Figures 2, 3, and 4 in appendix Q provide an overview of NSO habitat within the Project analysis area in relation to spotted owl home ranges, NSO critical habitat, and NWFP LSRs. Table Q-7 in appendix Q identify the amount of NSO Habitat (high NRF, NRF, dispersal only, and capable habitat) available within each NSO Home Range.

Both federal and non-federal land occurs within the defined Provincial Analysis Area, and based on acres of high NRF and NRF habitat available within each (see table 4.3.4-5), it is apparent that federally-managed lands provide substantially more suitable NRF habitat than non-federal lands. Therefore, it can be expected that non-federal land within the Provincial Analysis Area plays a minor role in supporting NSOs and aiding in their recovery. Overall, federal lands within the Provincial Analysis Area provide approximately 48 percent suitable NRF (including High NRF) habitat (see table 4.3.4-5), which meets the criterion that FWS et al. (2007) consider necessary to maintain NSO life history function within owl home ranges. Also note, the majority of available NRF occurs within NSO home ranges. If physiographic provinces are reviewed individually, less than 40 percent of suitable NRF is available within each physiographic province; however, on federal lands each individual physiographic province, as well as collectively provide more than 40 percent NRF habitat which above the recommended threshold (Coast Range provides 40.7 percent NRF, Klamath Mountains 54.4 percent NRF, West Cascades 46.1 percent NRF, and East Cascades 53.3 percent NRF).

[1] Landowner is summarized by Federal (BLM Districts and National Forests) and Non-Federal (Private, State, Corps of Engineers, and Bureau of Indian Affairs Land).
[2] Total acres available within the entire analysis area, including non-capable habitat not identified in this table.
[3] High NRF (Trask & Associates, 2013): forested habitat characterized by large trees (> 32 dbh), high canopy cover (>60 percent), and multistoried with sufficient down wood and snags to support prey species.
[4] NRF (Trask & Associates, 2013; FWS, 2012a; North et al., 1999): conifer-dominated forested habitat greater than 80 years that does not meet the definition of High NRF but has multi-storied structure with large overstory trees (20-30 inch dbh), moderate to high canopy closure greater than 60 percent, and sufficient snags and down wood.
[5] Dispersal ONLY (FWS, 2012a): an average tree diameter of 11 inches dbh or greater; conifer overstory trees; canopy closure greater than 40 percent in moist forests and greater than 30 percent in dry forests; open space beneath the canopy to all for NSO to fly; High NRF and NRF provide dispersal habitat, as well.
[6] Capable Habitat (Trask & Associates, 2013): habitat that is forested or could become forested (i.e., recently harvested timberlands) that do not provide dispersal or NRF characteristics.

Discussion at the Task Force - ESA Consultation Subgroup meeting on April 2, 2008, indicated that NSO dispersal habitat could be considered adequate if at least 50 percent of the analysis area (in the Project's case, the defined Provincial Analysis Area) consists of dispersal habitat. Within the Provincial Analysis Area dispersal habitat is comprised of dispersal only habitat, as well as high NRF and NRF. Calculating the high NRF, NRF, and dispersal habitat within each physiographic province from table 4.3.4-5, the following acres of dispersal habitat are available within each province: 36,368 acres (41.0 percent) in the Coast Range, 60,324 acres (48.9 percent) in Klamath Mountains, 37,375 acres (50.9 percent) in West Cascades, and 9,382 acres (38.6 percent) in East Cascades. Only West Cascades physiographic province within the Provincial Analysis Area provides adequate levels of dispersal habitat (greater than 50 percent), although habitat in Klamath Mountains physiographic province is close.

**Critical Habitat**

Four federally-designated CHUs occur within the provincial analysis area (FWS, 2012a): Oregon Coast Ranges – OCR (Unit 2) totaling 859,864 acres and six subunits, East Cascades South – ECS (Unit 8) totaling 368,381 acres and three subunits, Klamath West – KLW (Unit 9) totaling 1,197,389 acres and 9 subunits, and Klamath East – KLE (Unit 10) totaling 1,052,731 acres and seven subunits. Eight subunits occur within the provincial analysis area (OCR-6, ECS-1, KLW-1, KLE-1, KLE-2, KLE-3, KLE-4, and KLE-5). All subunits are expected to function primarily for demographic support to the overall population, as well as connectivity between subunits and CHUs. Special management consideration or protection required for each subunit is to address threats from current and past timber harvest and competition from barred owls, as well as losses due to wildfire and the effects on vegetation from fire exclusion (with the exception of OCR-6).

- OCR (Unit 2): forest is dominated by western hemlock, Sitka spruce, and Douglas-fir. NSO nesting habitat tends to be limited to stands providing very large trees with cavities or deformities because Douglas-fir dwarf mistletoe is unusual in this region. Woodrats comprise an increasing proportion of the diet. One subunit occurs in the provincial analysis area: OCR-6.
    - OCR-6: consists of approximately 81,900 acres in Coos and Douglas Counties, Oregon and comprises lands managed by the BLM. 97 percent of the area was used by NSO at the time of listing.
- KLW (Unit 9): forest is a highly diverse mix of mesic forest communities such as Pacific Douglas-fir, Douglas-fir tanoak, and mixed evergreen forest interspersed with more xeric forest types; tanoak is a dominant factor. Douglas-fir dwarf mistletoe is uncommon and seldom used for nesting platforms by NSO. Prey is diverse, but dominated by woodrats and flying squirrels. One subunit occurs in the provincial analysis area: KLW-1.
    - KLW-1: consists of approximately 147,326 acres in Douglas, Josephine, Curry, and Coos Counties, Oregon and managed by the State of Oregon and BLM. 96 percent of the area was used by NSO at the time of listing.
- KLE (Unit 10): forest is a mixed-conifer/evergreen hardwood forest type and grades into the western hemlock forest. High summer temperatures and a mosaic of open forest conditions and Oregon white oak woodlands influence NSO distribution in this region. Dwarf mistletoe provides an important component of nesting habitat, enabling NSO to occasionally nest within stands of relatively younger, small trees. Five subunits occur in the provincial analysis area: KLE-1, KLE-2, KLE-3, KLE-4, and KLE-5.

- KLE-1: consists of 242, 338 acres in Jackson and Douglas Counties, Oregon and managed by Forest Service and BLM. 84 percent of the area was used by NSO at the time of listing.
- KLE-2: consists of 101,942 acres in Josephine and Douglas Counties, Oregon and is managed by BLM and the Forest Service. 92 percent of the area was used by NSO at the time of listing.
- KLE-3: consists of 111,410 acres in Jackson, Josephine, and Douglas Counties, Oregon and is managed by Forest Service and BLM. 97 percent of the area was used by NSO at the time of listing.
- KLE-4: consists of 254,442 acres in Jackson, Klamath, and Douglas Counties, Oregon and is managed by the Forest Service and BLM. 81 percent of the area was used by NSO at the time of listing.
- KLE-5: consists of 38,283 acres in Jackson County, Oregon and is managed by the BLM and Forest Service. 86 percent of the area was used by NSO at the time of listing.

- ECS (Unit 8): ponderosa pine is dominant at mid-to-lower elevations, with a narrow band of Douglas-fir and white fir at middle elevations providing the majority of NSO habitat. Dwarf mistletoe provides an important component of nesting habitat, enabling NSO to nest within stands of relatively younger smaller trees. One subunit occurs in the provincial analysis area: ECS-1.
    - ECS-1: consists of approximately 127,801 acres in Klamath, Jackson, and Douglas Counties, Oregon and comprises lands managed by the BLM and Forest Service. 78 percent of the area was used by NSO at the time of listing.

The current status of NSO habitat (high NRF, NRF, dispersal only, and capable) within designated CHUs and subunits located in the Project analysis area is shown in table 4.3.4-6. The baseline information shows that not all designated critical habitat is currently functioning as suitable NRF habitat. However, table 4.3.4-6 also provides the number of owls that are known to occur in the CHUs located in the analysis area (provided to Pacific Connector by FWS, BLM, and USFS. Given that suitable habitat acres within all affected CHUs currently support NRF habitat at levels that are adequate to support pairs of nesting NSOs, these CHUs are considered to be functional with respect to their recovery roles.

Of the 72 known, 17 best location, and 9 PCGP assumed NSO activity centers within the analysis area, 57 activity sites occur in Critical Habitat Units (43 known, 10 best location, 4 PCGP assumed). Table 4.3.4-7, below summarizes the number of activity sites analyzed within this BA that occur within each critical habitat subunit, and the condition of the home range (see table Q-7 in appendix Q). Just over half the activity centers (32 of 63) have suitable NSO habitat above the recommended level of 50 percent suitable NRF habitat in the core area and 40 percent suitable NRF habitat in the home range to support nesting and NSO survival.

## Table 4.3.4-6
## Summary of NSO High NRF, NRF, Dispersal Only, and Capable Habitat in Critical Habitat Subunits Available within the Provincial Analysis Area

| CHU and Subunit | Total Acres in CHU | Total Acres in Analysis Area | % Subunit within Analysis Area | Number of Known Owls [1] | High NRF in CHU [2] | | NRF in CHU [3] | | Dispersal Only in CHU [4] | | Capable in CHU [5] | | Total NSO Habitat in CHU [6] | |

| Overall CHU Total | 1,105,442 | 91,016 | 8 | 535 | 21,014 | 1.9 | 28,596 | 2.6 | 12,466 | 1.1 | 27,129 | 2.5 | 89,205 | 8.1 |

[1] Number of Known Owls in entire CHU Subunit: known owl sites obtained from known owl locations provided by BLM (2006, 2013), Forest Service (2006, 2013), and FWS (Thrailkill, 2008) and 2007/2008 surveys conducted by Pacific Connector.

[2] High NRF (Trask & Associates, 2013): forested habitat that is characterized by large trees (> 32 dbh), high canopy cover (>60 percent), and multistoried with sufficient down wood and snags to support prey species.

[3] NRF (Trask & Associates, 2013; FWS, 2012; North et al., 1999): conifer-dominated forested habitat greater than 80 years that does not meet the definition of High NRF but has multi-storied structure with large overstory trees (20-30 inch dbh), moderate to high canopy closure greater than 60 percent, and sufficient snags and down wood.

[4] Dispersal ONLY (FWS, 2012a): an average tree diameter of 11 inches dbh or greater; conifer overstory trees; canopy closure greater than 40 percent in moist forests and greater than 30 percent in dry forests; open space beneath the canopy to all for NSO to fly; High NRF and NRF provide dispersal habitat, as well.

[5] Capable Habitat (Trask & Associates, 2013): habitat that is forested or could become forested (i.e., recently harvested timberlands) that do not provide dispersal or NRF characteristics.

[6] Total NSO Habitat within CHU Subunits that occur within the Provincial Analysis Area; does not include non-capable habitat.

[7] Percent total: percent of habitat available in entire critical habitat unit, not just the Provincial Analysis Area.

NWFP Late Successional Reserves

NWFP designated LSR Units occur within the Provincial Analysis Area: RO 261, RO 223, RO 227, and RO 224 (not affected by the proposed project). LSR RO 261, a large LSR complex (70,611 acres) and provides 5,178 acres of high NRF/NRF habitat within the Provincial Analysis Area. LSR RO 223 is also a large LSR complex (66,173 total acres) and provides 11,993 acres of high NRF/NRF habitat within the Provincial Analysis Area. Both LSR RO 261 and RO 223 are within BLM-managed checkerboard lands, with the exception of a portion of LSR RO 223 that occurs in a more contiguous configuration on Umpqua National Forest. LSR RO227 is the largest LSR complex crossed by the PCGP Project (101,600 acres). It provides 17,547 acres of high NRF/NRF within the Provincial Analysis Area. LSR RO 227 is located within Rogue River – Siskiyou National Forest and Fremont-Winema National Forest and is generally contiguous. Table 4.3.4-8, below provides a summary of NSO habitat that occurs within each LSR unit within the provincial analysis area.

Additionally, approximately 7,506 acres of unmapped LSRs occur within the provincial analysis area, including 4,490 acres of unmapped LSRs associated with occupied marbled murrelet stands and 3,016 acres of unmapped LSRs associated with known NSO activity centers (KOAC). Table 4.3.4-8 includes a summary of available habitat within unmapped LSRs.

Much of the LSRs (and unmapped LSRs) within the provincial analysis area overlap the FWS designated critical habitat units for NSO. The overlap of LSRs with federally designated NSO critical habitat affords a greater degree of protection to the NSO and its critical habitat as the NWFP protections for LSRs are automatically imposed on those LSR acres that are found within a CHU. Thus, NSOs located within these land allocations also benefit from increased protection.

Areas of Concern (AOCs)

Two AOCs have been identified in Oregon, of which one, the Rogue/Umpqua AOC, is located within the proposed analysis area in the Coast Range, Klamath Mountains, and West Cascades physiographic provinces. AOCs were identified as areas where NSO dispersal opportunities were limited because of the available forested habitat, land use allocations identified by the NWFP (BLM and USFS 1994), and the checkerboard land ownership pattern. The Rogue/Umpqua AOC is located in the northern portion of the Klamath Mountains physiographic province and provides a link between federally-designated CHUs Oregon Coast Ranges (Unit 2), Klamath West (Unit 9), and Klamath East (Unit 10). The northern portion of the Rogue/Umpqua AOC is located between Pacific Connector MP 28.13 and MP 62.48, and MP 82.71 and MP 111.11. Approximately 15.2 percent of the Rogue/Umpqua AOC occurs within the provincial analysis area, of which 47.4 percent (60,784 acres) provides dispersal habitat (NRF, high NRF, and Dispersal only). Table 4.3.4-9 below provides acres of dispersal habitat available in the Rogue/Umpqua AOC by federal and non-federal lands within the three physiographic provinces in which it is located. The AOC incorporates a large area of the Provincial Analysis Area. Approximately 53 of the 98 NSO activity centers that are analyized for this project occur in the AOC (table 4.3.4-9).

[1] Unmapped LSRs consider MAMU occupied stands on NWFP matrix lands and KOAC.

[2] High NRF (Trask & Associates, 2013): forested habitat that is characterized by large trees (> 32 dbh), high canopy cover (>60 percent), and multistoried with sufficient down wood and snags to support prey species.

[3] NRF (Trask & Associates, 2013; FWS, 2012; North et al., 1999): conifer-dominated forested habitat greater than 80 years that does not meet the definition of High NRF but has multi-storied structure with large overstory trees (20-30 inch dbh), moderate to high canopy closure greater than 60 percent, and sufficient snags and down wood.

[4] Dispersal ONLY (FWS, 2012a): an average tree diameter of 11 inches dbh or greater; conifer overstory trees; canopy closure greater than 40 percent in moist forests and greater than 30 percent in dry forests; open space beneath the canopy to all for NSO to fly; High NRF and NRF provide dispersal habitat, as well.

[5] Capable Habitat (Trask & Associates, 2013): habitat that is forested or could become forested (i.e., recently harvested timberlands) that do not provide dispersal or NRF characteristics.

[6] Total NSO Habitat within NWFP LSRs and unmapped LSRs that occur within the Provincial Analysis Area; does not include non-capable habitat.

[7] Percent total: percent of habitat available in LSR units withint the Provincial Analysis Area.

### 4.3.4.3 Effects by the Proposed Action

#### Direct Effects

Project-related effects to NSOs would be caused by the action and occur at the same time and place, including the following within the provincial analysis area: 1) removal of a known nest tree during the entire breeding season (March 1 through September 30), and 2) human and noise disturbance due to right-of-way clearing and construction during the breeding period, including noise due to blasting and helicopter support during construction. These effects would extend over the short-term.

<u>Habitat Removal During Breeding Season</u>

Removal of habitat during the breeding season within a nest patch could result in the potential death of nestlings if the nest tree is felled. Removing habitat after the entire breeding season (after September 30) would eliminate any direct impact to individual NSOs or nestlings. Habitat removal within 0.25 mile of an activity center within the Project would occur after the entire breeding season (after September 30); therefore, no direct effect to NSOs through habitat removal is expected.

Noise and Visual

NSOs would be directly affected by noise and disturbance related to proximate human-related activities associated with timber removal, construction, and operation and maintenance of the Pacific Connector pipeline that would result in diminished reproductive success and survival (if behavior response to construction makes them more vulnerable to injury). Disturbance (both visual and noise) would include use of chainsaws and heavy equipment during vegetation clearing and pipeline construction, explosives to trench through rock, helicopters and/or small aircraft to inspect the pipeline once per year during the life of the Project, and brush control (i.e., mowing and cutting) within the permanent right-of-way every three to five years for the life of the Project. The term "disruption" was alluded to in the ESA, under the definition of "harassment" (50 CFR §§ 17.3) as:

> "an intentional or negligent act or omission which creates the likelihood of injury by annoying it (the organism) to such an extent as to significantly disrupt normal behavior patterns which include but are not limited to, breeding, feeding or sheltering".

The term "disturbance" was not included in the ESA but a reasonable working definition was provided by Leal (2006) and has been incorporated into this BA:

"any potential auditory or visual stimuli or deviation from ambient/baseline conditions [that] an individual bird, at a given site, is likely to detect and potentially react to."

Reactions of NSOs to close human presence in the canopy, and excessive noise levels in the immediate vicinity of owls are expected to include the following: 1) flushing from the nest site, which would leave eggs or young exposed to predation; 2) causing juveniles to prematurely fledge, which would increase juveniles' risk of predation; 3) interrupting foraging activities, which would result in the reduced fitness or even mortality of an individual; and/or 4) disrupting roosting activities which would cause a NSO to be displaced and possibly relocate. In the Northern Spotted Owl Status Review, none of these types of disturbance were considered a threat to the species (Courtney et al., 2004). However, at the individual level, based on anecdotal information and effects to other bird species (Wesemann and Rowe, 1987; Delaney et al., 1999; Delaney and Grubb, 2001; Swarthout and Steidl, 2001; FWS, 2003b; and FWS, 2005c), disturbance to NSOs could occur. Disturbance to owls is inversely related to stimulus distance and positively related to noise level, similar to results reported for bald eagles (Grubb and King, 1991), gyrfalcon (Platt, 1977), and other raptors (Awbrey and Bowles, 1990). For a significant disruption of NSO behavior to occur as a result of disturbance caused by an action, the disturbance and the NSO must be in close proximity to one another (FWS, 2003b; FWS, 2005c). Human presence on the ground is not expected to cause a significant disruption of behavior because NSOs do not seem to be startled by human presence (FWS, 2005c); however, increased human presence in an area that previously had minimal human presence may be an indirect effect of the proposed Project.

The available research and anecdotal accounts show that the effects of noise from a variety of sources elicit disturbance-responses from spotted owl subspecies (including Mexican spotted owls - MSO, northern spotted owls – NSO, and California spotted owls - CSO) but not disruption-responses such as flushing or flight that would be construed as interference with normal behavior patterns including but not limited to, breeding, feeding or sheltering. The following are brief summaries of available spotted owl research:

- All NSO foraged adjacent to roads and appeared undisturbed by the occasional passage of vehicles on narrow secondary gravel forest roads (Forsman et al., 1984).
- Male NSOs within 0.25 mile of a major logging road or timber harvest had higher fecal corticosterone levels than males farther away; no differences found for females related to distance from roads or timber harvest (Wasser et al., 1997).
- Proximity to roads (paved, improved surface, any type) was not correlated with fecal corticosterone in CSO (Tempel and Gutierrez, 2004).
- CSO exposure to chainsaw noise did not result in a detectable increase in fecal corticosterone level; CSO can tolerate low-intensity human sound in their environment without eliciting a physiological stress response (Tempel and Gutierrez, 2003).
- MSO nest occupancy <1 mile from firing sites was higher than nest occupancy > 1 mile away; MSO not affected by explosives but were affected by hikers (Hathcock et al., 2010).
- MSO response to military aircraft overflights (noise levels 78, 92 and 95 dB during sequential exposures) ranged from none to sudden head turning; behaviors during flights were no different than pre- and post-flight periods (Johnson and Reynolds, 2002).
- Relationships of NSO baseline physiology, nutritional stress, and reproductive success to exposures to high and low levels of routine OHV traffic (Hayward et al., 2011).
  - Male NSO show high fecal glucocorticoid (GC) response to OHV trials during incubation period.
  - Male NSO 50-800 m from loud roads show lower fecal GC response to motorcycle trials than males 50-800 m from quiet roads in July (fledging period).
  - Female NSO with good nutrition but no young show high fecal GC response to OHV trials.
  - Female NSO with good nutrition but no young show high fecal GC response to OHV trials.
  - Female NSO with 2 young and poor nutrition show low fecal GS response to OHV trials.
  - NSO close to roads had better nutrition but levels of fecal GC were not related to proximity to roads or noise.
  - NSO within 100 m of quiet roads fledged more young than NSO farther from roads; NSO within 100 m of noisy roads fledged fewer young.

NSOs disturbed at a roost site are presumably capable of moving away from disturbance without a significant disruption of behavior. Since NSOs are primarily nocturnal predators, projects that occur during the day are not likely to disrupt foraging behavior and the potential for effects is mainly associated with breeding behavior at an active nest site.

In the late breeding period, potential effects from Project activities decline because juvenile NSOs are increasingly more capable of moving as the nesting season progresses. Once capable of sustained flight, young owls are presumably able to distance themselves from disturbance and minimize their risk of predation. To ensure that more than 86 percent of juvenile NSOs in the Oregon Western Cascades Physiographic Province are able to move away from disturbances without increasing their risk of predation or harm, the critical nesting period is considered to be

March 1 through July 15. This is based on fledge data (Turner, 1999) and includes an additional two weeks to allow for development of flight skills. After July 15, most fledgling NSOs are assumed to be capable of sustained flight and can move away from harmful disturbances. The critical breeding period for the Oregon Western Cascades Physiographic Province is applied to the entire Provincial Analysis Area (March 1 through July 15), even though research has provided data that indicate NSOs fledge earlier in other Physiographic Provinces within the analysis area.

**Auditory and Visual Disturbance – FWS Guidance.** FWS (2003c and 2006e) indicated that the behaviors noted above may occur when 1) the project-generated sound level substantially exceeds existing ambient noise levels by 20 to 25 dB; 2) when the total sound level (project and ambient noise levels combined) exceeds 90 dB; or 3) when the visual proximity of human disturbance occurs within 130 feet of an active nest site. FWS concluded that noise and human presence can result in a significant disruption of breeding, feeding, and/or sheltering behavior of NSOs such that it creates the potential for injury to the individuals (i.e., incidental take in the form of harassment).

FWS (2006e) established distances within which sound levels and visual disturbance for various activities may result in injury or harassment of NSOs by significantly disrupting the normal behavior pattern of individuals or breeding pairs. Table 4.3.4-10 (Disruption Threshold Distance) provides the distances at which FWS (2003b and 2006e) indicate that NSOs could be disrupted or "harassed" by certain activities during the critical breeding period and late breeding period. In a previous Biological Opinion, FWS (FWS, 2006f) provides distances from a Project boundary within which NSOs could potentially be distracted, or "disturbed" from their normal activity. Those distances are often applied as seasonal buffers to minimize impacts of Projects on nesting NSOs (Disturbance Threshold Distance; table 4.3.4-10). The threshold disruption distances applied to NSO during the critical breeding period are either the same or extend farther (i.e., more conservative) than distances provided by FWS (2003b and 2006e; see Noise Evaluation in Appendix Z3). Other actions, including use of existing roads and large helicopters were added after 2006.

FWS (2003b and 2006e) reviewed available scientific literature on behavioral and physiological responses of different bird species to various noise sources. They determined that birds would likely detect noises that were ≥4 decibels or more above ambient noise levels. FWS (2006e) also opined that anthropogenic noise attenuating to within 25 dB above ambient sound level would be the threshold above which harassment to individual NSO is likely to occur. That determination, however, was based on one account of Mexican spotted owls responding to chainsaw noise (Delaney et al., 1999) and one account of a colonial nesting seabird (crested tern, Brown, 1990) responding to simulated aircraft noise. In both situations, the subject birds were exposed to human presence prior to exposure to noises and response to noises were not controlled for visual disturbances. Using those two studies however, FWS (2006e) subtracted the noise level that elicited a harassment-indicating behavior (flight or flushing) from the minimum ambient noise at the respective sites and decided that action-generated noise levels that are 25 dB above ambient levels will constitute the sound level threshold above which harassment is likely to occur (FWS, 2006e). From that exercise, FWS (2006e) decided that a noise level of 70 dB would be a disturbance threshold and noise ≥70 dB would be disruptive, based entirely on the responses of crested terns to simulated aircraft noise (Brown, 1990), as above. That conclusion appears to be arbitrary (WSDOT, 2011), has not been tested, and is not supported by field studies of NSO (see available research and anecdotal accounts, above). Consequently, Pacific Connector has not accepted or applied the FWS (2006e) sound threshold of 25 dB above ambient noise or noise ≥70 dB as a decibel level above which harassment is likely to occur.

Injury to individuals would occur if a threshold of 92 dBA occurs or is exceeded (FWS, 2003b). FWS (2006e) defined a "tolerance threshold" of 82 dB for marbled murrelets and northern spotted owls. The tolerance threshold assumes that respective nest sites become "intolerable" to the species and harassment occurs due to the total sound level the species must endure. However, no time duration component was associated with the tolerance threshold. FWS (2006e) did recognize that a tolerance threshold of 92 dB for aircraft (e.g., helicopters) would be applicable due to the usually slow onset of aircraft noise approaching spotted owls but they (FWS, 2006e) applied the threshold of 82 dB as a sound-related injury threshold level for spotted owls.

The FWS typically considers the disturbance threshold for general noise-generating activities within a 0.25-mile radius (125-acre area) of the activity during the critical breeding season (March 1 to July 15). For louder disturbance activities such as open air blasting using more than a 2 pound charge or large aircraft, FWS generally applies a 1.0 mile radius (2,176 acre area) around NSO sites during the entire breeding season (March 1 to September 30) to minimize disturbance to nesting NSO (FWS, 2003b; Smith et al., 2007; Wille et al., 2006). However, FWS suggested that if additional studies could demonstrate that use of larger blasts (greater than 2 pounds) and large helicopters with mitigation measures proposed for the Project attenuated to less than 92 dB, and preferably below 70 dB (disturbance threshold versus 92 dB disruption threshold) within a mile, to provide a report and additional data would be considered to reduce the threshold distances for those activities (Smith et al., 2007; Wille et al., 2006). Pacific Connector has adopted the FWS standard that northern spotted owls would detect project-related noise ≥4 dBA which would be a disturbance. Pacific Connector also adopted the FWS (2006e) threshold of 82 dB as a sound-related injury threshold level for northern spotted owls and a tolerance threshold of 92 dB for approaching aircraft. Based on evidence reviewed and summarized above, Pacific Connector has proposed and applied that project-related noise at levels between the two thresholds constitute a disturbance, not a disruption.

**Blasting and Helicopter Noise Levels.** Pacific Connector prepared a report (see appendix P) that analyzes the distances at which conventional blasting required for trenching within rock substrate for pipeline construction and transport helicopters attenuate to 92 dB. Appendix P shows empirical noise data evaluations for trench blasting and heavy transport helicopters and was used to determine the distances for which noise levels remain below 92 dB during construction operations with appropriate mitigation measures applied. Under the worst case conditions with common and appropriate mitigation measures applied to trench blasting operations, it is expected that blasting noise would attenuate to 92 dB within 200 feet of the source, and to 70 dB within 1,025 feet of the blast source in soft rock. Likewise, large transport helicopters would attenuate to 92 dB within 700 feet. The greater distance for helicopter use is due to the directional aspects of blade slap noise that is directed toward the ground.

Mitigation for helicopter noise includes operational restrictions, such as maintaining a high altitude and flight paths away from noise sensitive areas whenever possible. Analyses for NSOs in this biological assessment consider the distances for larger blasts and large helicopters to be more conservative than what the noise report suggests. Pacific Connector has suggested a disruption threshold distance for blasting greater than 92 dB but with mitigation measures applied to be the same disruption distance expected for smaller blasts (less than 92 dB) – 120 yards or 360 feet – more conservative than the noise report describes, and the disturbance threshold distance associated with large blasts to be expected within 0.25 mile of blasting activity (see table 4.3.4-10). It is expected that these distances be considered throughout the entire breeding season (March 1–September 30) because of the sudden onset of noise associated with blasting activities. Pacific Connector has suggested a disruption threshold distance for large/transport helicopter use with proposed mitigation to be slightly farther than the report suggests, considering disruption distance of 240 yards (720 feet) and a disturbance threshold distance of 0.25 mile (see table 4.3.4-10).

**Table 4.3.4-10**
**Threshold Distances Where Noise and Visual Disturbances are Unlikely to Occur to Nesting Northern Spotted Owls during the Breeding Season [1]**

| Activity | Disruption Threshold Distances From NSO Activity Centers | | Disturbance Threshold Distance From NSO Activity Centers | |
|---|---|---|---|---|
| | NSO Critical Breeding Season [2] | NSO Late Breeding Season [2] | NSO Critical Breeding Season [2] | NSO Late Breeding Season [2] |
| Existing Road Use [3] | 35 yards (105 feet) | No Disruption Anticipated | 0.25 mile | No Disturbance Anticipated |
| Chainsaws [4] | 45 yards (135 feet) | No Disruption Anticipated | 0.25 mile | No Disturbance Anticipated |
| Heavy equipment [3] | 35 yards (105 feet) | No Disruption Anticipated | 0.25 mile | No Disturbance Anticipated |
| Rock ditching equipment [4] | 120 yards (360 feet) | No Disruption Anticipated | 0.25 mile | No Disturbance Anticipated |
| Blasting – more than 2 pounds with mitigation measures | 120 yards (360 feet) | 120 yards (360 feet) | 0.25 mile | 0.25 mile |
| Small Helicopter/Airplanes | 120 yards (360 feet) | No Disruption Anticipated | 0.25 mile | No Disturbance Anticipated |
| Large/Transport Helicopters with mitigation measures [5] | 240 yards (720 feet) | 240 yards (720 feet) | 0.25 mile | 0.25 mile |

[1] Sources: FWS, 2003b, 2006f; PC Trask & Associates, 2013; Michael Minor & Associates, 2008 (see appendix P).
[2] Northern Spotted Owl breeding period is from March 1-September 30; critical breeding period is considered from March 1-July 15; late breeding season is considered from July 16-September 30.
[3] Heavy equipment includes: back trackhoes, side-booms, bulldozers, semi-trucks, pneumatic hammers.
[4] Rock ditching equipment includes: auger drill rig, mounted impact hammer (hoe ram), rock drill, and blasting (mitigated or less than 2 lbs; see figure 3.2-3.
[5] Transport helicopters proposed for this Project include: Boeing Chinook (CH-47) and Boeing Vertol 107-II (CH-46)

Even though FWS (2003b) provided some evidence suggesting that noise that builds gradually, such as a helicopter approaching from a distance, may result in less risks, and even though FWS does not anticipate effects from smaller aircraft use after the critical breeding period, for analysis within this assessment, Pacific Connector anticipated that use of large/transport helicopters may disrupt or disturb NSOs throughout the entire breeding season (March 1–September 30). In a memorandum provided to TetraTech, contractor to FERC (September 16, 2008), FWS indicated that if noise levels above 92 dB are recorded at 0.25 mile of the blasting activities, that blasting operations should cease until more effective mitigation measures can be employed.

**Noise Evaluation Procedure**. Pacific Connector has prepared a Noise Evaluation (see appendix Z3) to assist in evaluating noise effects of proposed activities for each NSO activity center analyzed within the Provincial Analysis Area, considering reviewed available scientific literature on behavioral and physiological responses of bird species to various noises, as well as the ambient noise level near each NSO activity center. The guidance provided in Table 4.3.4-10 was derived under forested situations and are not applicable to many of the field situations and habitats through which the PCGP Project passes. Also, available research and anecdotal reports do not support use of fixed distances between a noise source and northern spotted owl responses indicating disruption. Noise levels attenuate differently under various conditions which are not accounted for in the FWS guidance.

The noise evaluation estimates noise attenuation at each NSO nest site from the proposed project activities due to hard site (hard, smooth surfaces intervening between source and receptors) and soft site (irregular, vegetated surfaces) conditions, intervening tree cover, topography, and/or differential elevations allowing lines-of-sight between sources and receptors. This noise evaluation has been used as an adjustment factor of direct effects (disturbance and disruption) for individual NSO nest stands in the impact assessments located in appendix Z2 and included in table Q-8 in appendix Q.

**Disruption and Disturbance – Timber Clearing, Pipeline Construction, Existing Road Use.** Approximately 3.7 miles of timber clearing and construction will occur within 0.25 mile of 10 NSO activity centers (four known sites, four best location sites, and two PCGP assumed sites; see table 4.3.4-11). Pacific Connector has proposed to clear timber within 0.25 mile of NSO activity centers outside of the entire breeding season (between October 1 and February 28); therefore, noise, visual disturbance, and in some instances large helicopter use would not be expected to disturb or disrupt NSO breeding activities (see Habitat Removal during Breeding Season, above). However, due to construction constraints, safety of construction crew, and adherence to the in-service date, Pacific Connector would need to construct within 0.25 mile of activity centers during the breeding season. To minimize disturbance, though, Pacific Connector will construct within 0.25 mile of activity centers after the critical breeding season (after July 15). With the exception of helicopter activities that could occur within 0.25 mile of three NSO activity centers (2317B, PCGP 095.3, and assumed PCGP A-1) and potential blasting activities (greater than 2 pounds of explosives) that could occur within 0.25 mile of six NSO activity centers (two known sites, three best location sites, and one PCGP assumed site), acoustic and visual disturbances from the proposed action are not expected to disrupt NSO nesting and rearing activities because they would occur after the critical breeding season (see table 4.3.4-10). Table Q-8 in appendix Q provides distances from proposed project activities (timber clearing, construction activities, road use, operations/maintenance) and timing of those actions that are expected to occur within 0.25 mile of known, best location, and PCGP assumed NSO sites during timber removal, construction activities (including large transport helicopter use and blasting > 2 pounds of explosives), and access road use. Additionally, table Q-8 in appendix Q provides the expected direct effect (disruption, disturbance, no effect) and rationale for each known, best location, and PCGP assumed NSO site based on timing and distance from the Project activities for each proposed activity (based on disturbance distances from table 4.3.4-10), as well as site-specific analysis included in the Noise Evaluation (appendix Z3).

Informal consultations with FWS (June 5, 2008 meeting; see NSO and MAMU Avoidance Plan) identified disturbance from travel on existing roads to be less of an impact than other actions associated with the proposed Project, especially if farther than 35 yards (105 feet). Additionally, BLM does not consider disruption or disturbance effects to occur to MAMU from use of existing access roads throughout the entire breeding season (see Coos Bay FY2008-2013 Programmatic Consultation #13420-2008-F-0118). Based on available scientific literature, use of existing roads may be detectible by NSO within 0.25 mile but it is not expected that use of every existing road would disturb nesting northern spotted owls and use of existing roads would not significantly disrupt normal behavior patterns and lead to harassment under the ESA, described above (see also Pacific Connector's Noise Evaluation in appendix Z3). Therefore, Pacific Connector assumes that use of existing access roads (EARs), regardless of distance from road to activity center would be a potential disturbance to NSO and could result in temporary reduced habitat suitabilility, but would not disrupt breeding behaviors.

**Expected Disturbance Effects.** Impact assessments for each NSO activity center analyzed within this BA (see appendix Z2) identify how far a NSO activity center is in relation to proposed construction activities, including large transport helicopter use and blasting (greater than 2 pounds of explosives). The impact assessments also identify existing access roads within 0.25 mile of known, PCGP Assumed, or best location NSO sites, including distance from the access road(s) and expected road improvements within the nest patch or 0.25-mile buffer of the activity site. Each NSO activity center has a series of maps with the analysis that show the NSO home range in relation to the proposed actions and include a 0.25 mile spatial buffer around each activity center (see appendix Z2). Additionally, maps 1 - 50 in appendix Q show the locations of NSO activity centers in relation to different Project components and identify spatial buffers (360 feet and 0.25 mile buffers) associated with a NSO activity site. Table 4.3.4-11 summarizes the effects (disruption, disturbance, no effect) to known, best location, or PCGP assumed owl sites located within 0.25 mile of proposed project activities, including use of access roads within the Provincial Analysis Area affected (disturbed) by the proposed Project based on the timing of activities, distance from proposed activity to NSO activity center, and site-specific noise evaluations prepared for each NSO activity center (appendix Z3) (summarized from table Q-8 in appendix Q). Noise expected during each phase of pipeline construction as it relates to equipment associated with each phase is provided in table 3.1.3.3-2, and has been applied to each NSO activity center individually in the Noise Evaluation (appendix Z3). This analysis is conservative, assuming that each NSO activity site (known – historic and current location, best location sites – no known nest site, and PCGP assumed sites – no known nest site) is actively reproducing and if located within 0.25 mile of the project could be affected by project activities. Also, the closest alternate nest site was considered, although it may not have the most recent documented reproductive activity.

**Maintenance and Operation.** No activities associated with general maintenance and operations of the proposed action are expected to affect NSO sites. FERC requires that vegetation maintenance activities occur only between August 1 and April 15 of any year (see appendix C). To reduce impacts to nesting NSOs, Pacific Connector would maintain vegetation within the pipeline corridor after the entire breeding season within known, best location, and PCGP assumed nest patches and after the critical breeding season within a 0.25 mile of NSO activity centers. Routine clearing of vegetation greater than 6 feet in height within the 30-foot permanent right-of-way would not occur more frequently than every 3 years. A 10-foot corridor centered over the pipeline may be maintained annually in an herbaceous state to facilitate periodic corrosion and leak surveys. Pacific Connector would also require pilots conducting annual aerial inspection (small plane/helicopter) of the pipeline to adhere to the spatial restrictions recommended in the vicinity of known, best location, or PCGP assumed sites (no overflight within 1,300 feet agl during the critical breeding season [March 1 through July 15]); no effects from aerial pipeline inspection would be expected.

## Table 4.3.4-11
## Number of Northern Spotted Owl Sites within each Physiographic Province with Expected Disturbances from Noise and/or Visuals Associated with Activities Proposed within 0.25 mile of Activity Centers[1]

| Status of Northern Spotted Owl Site | Total Number of Owl Sites | Construction Activities and Road Use[2] | | Construction Activities Only[3] | | Road Use Only[4] | | None[5] |
|---|---|---|---|---|---|---|---|---|
| | | Disruption | Disturbance | Disruption | Disturbance | Disruption | Disturbance | |
| Known Site | 13 | 0 | 0 | 1 | 0 | 0 | 7 | 5 |
| Best Location | 1 | 0 | 0 | 0 | 0 | 0 | 0 | 1 |

| Overall Total | 98 | 2 | 5 | 1 | 2 | 0 | 30 | 58 |

[1] Summarized from table Q-8 in appendix Q.
[2] Construction Activities and Road use: both proposed activities occur within 0.25 mile of NSO activity center
[3] Construction Activities Only: includes general construction activities, blasting (> 2lbs explosives), and large transport helicopter use; no proposed road use within 0.25 mile of NSO activity centers
[4] Road use only: no construction activities proposed within 0.25 mile of NSO activity centers
[5] None: construction and proposed road use > 0.25 mile of NSO activity center

Helicopter Rotor Wash

Strong winds can adversely affect NSOs (FWS, 1990) by directly removing habitat from windthrow that could fragment forests and increase edge effects (risk of predation, microclimatological changes). Wind can also cause direct mortality by blowing chicks out of nests (FWS, 1992b). Helicopter drive rotors produce high velocity vortices (winds) that extend from the center of the helicopter outward in all directions. Vertical downwash of air (rotor wash) close enough to the ground produces surface winds that dissipate as they move away from the helicopter (sidewash). Induced winds caused by helicopter rotor wash may exceed hurricane force velocities and would be expected to adversely affect nesting NSOs in the area. Since induced rotor downwash and surface sidewash are functions of helicopter size, rotor surface area, helicopter weight, flight speed and height above ground (Teske et al., 1997; Gordon et al., 2005), effects to nesting birds can be minimized or avoided by routing helicopter flight paths and staging locations far enough away from nests so that locally induced winds would not adversely affect nests or nestlings.

Maximum induced surface velocities produced by downwash and sidewash from various helicopters were measured in the field to determine the decay function of rotor-produced vortices near ground level (Teske et al., 1997). Field studies included measurements on three helicopter models that might be utilized during construction of the Pacific Connector pipeline: 1) the twin-rotor CH-47 (civilian variant is the Boeing HH-47 Chinook) with rotor diameter 59.1 feet, 2) the single rotor CH-54 with a rotor diameter of 72 feet (civilian variant is the Sikorsky S-64 Skycrane), and 3) the twin-rotor CH-46 (civilian variant Boeing Vertol 107) with rotor diameter of 49.9 feet (Teske et al., 1997). Using parameters derived from the field trials, estimates of maximum induced surface velocities were made for each of the three helicopter models at varying heights above ground while flying at different ground speeds. In general, maximum induced surface velocities increase with rotor diameters, decrease with distance above ground, and decrease with faster ground speeds.

Results of modeling maximum induced surface velocities (model described in Teske et al., 1997) produced by a Chinook helicopter are shown in figure 4.3-14 for drop heights (heights above ground level at which the helicopter would discharge a payload of foam, water, or retardant during wild fire control) ranging from 10 to 320 feet while flying at ground speeds ranging from 5 to 25 miles per hour (mph). Included in figure 4.3-14 are four wind speed categories on the Beaufort Scale (NOAA: http://www.spc.noaa.gov/faq/tornado/beaufort.html) which was developed to describe damage associated with wind forces ranging from calm to hurricane forces. On the Beaufort Scale, induced surface winds of 9 to 11 mph produced by rotor wash would be equivalent to a “gentle breeze” during which leaves and small twigs would be constantly moving and light flags would be extended. Wind velocities of 19-24 mph are classified as a “fresh breeze” (small trees in leaf would sway). Wind velocities of 19 to 24 mph are classified as a “fresh breeze”; small trees in leaf would sway. Winds 39 to 46 mph are “gale” force strength – difficult to walk against while twigs and small branches would be blown off trees - and winds greater than 74 mph are classified as a “hurricane”.

Figure 4.3-14 shows the heights above ground that Chinook helicopters would produce maximum induced surface winds with velocities equivalent to a “fresh breeze” while traveling at ground speeds of 5, 10, 15, 20 or 25 mph. For example, if traveling at a ground speed of 5 mph, the Chinook would have to be approximately 185 feet above ground to produce a maximum induced surface velocity of 24 mph, equivalent to a "fresh breeze". If traveling at ground speed of 25 mph, the Chinook could be 75 feet above ground and still induce a maximum surface velocity of 24 mph.

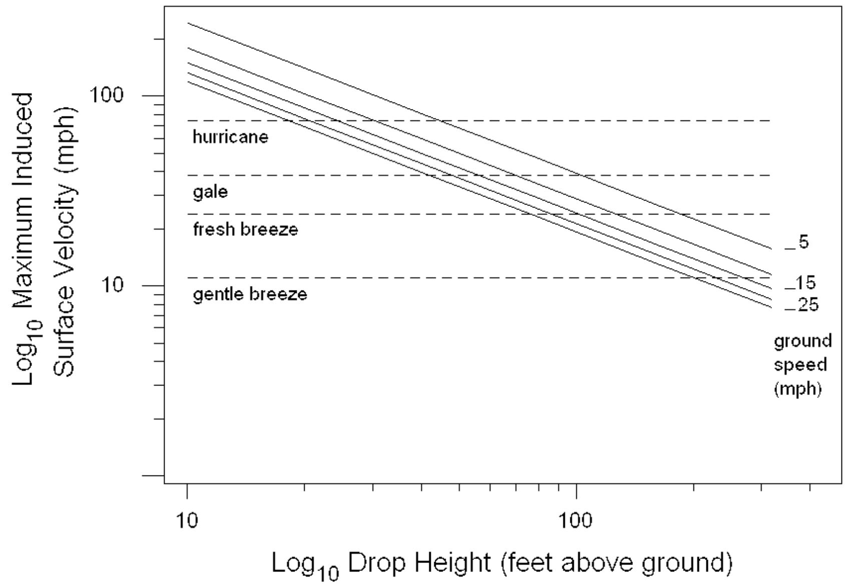

**Figure 4.3-14**
**Modeled Maximum Surface Velocities Induced by Chinook C-47 Helicopters while Flying at Ground Speeds From 5 to 25 mph at Heights From 10 to 320 feet Above Ground. (Modeled from data in Teske et al., 1997)**

In the Project area, wind speeds reported by the Western Regional Climate Center (available online at http://www.wrcc.dri.edu/htmlfiles/westwind.final.html#OREGON) at the North Bend airport averaged 10.2 mph in June, 11.2 mph in July and 9.9 mph in August, the three months with highest average wind velocities during the period from 1996 to 2006. During the same period, winds in Roseburg averaged 5.0 mph in June, 5.2 mph in July, and 4.4 mph in August. These data indicate that winds as strong as a fresh breeze (19-24 mph) would be expected along the Oregon Coast and most likely inland during the period when NSOs are nesting. We assume that induced winds the strength of a fresh breeze would not adversely affect young or nests. Incoming or outgoing Chinook helicopters flying at 5 mph while 185 feet above a tree with a nest would most likely produce winds with velocities less than a fresh breeze at the tree top because there would be no resistance by the ground to induce maximum sidewash vortices.

Similar results were produced by the Boeing Vertol 107 (see figure 4.3-15) even though it is smaller than the Chinook (rotor diameter 49.9 feet compared to 59.1 feet). The Vertol 107, flying at a ground speed of 5 mph, would have to be approximately 200 feet above ground to produce a maximum induced surface velocity of 24 mph, equivalent to a fresh breeze. If traveling at a ground speed of 25 mph, the Vertol 107 could be 82 feet above ground and still induce a maximum surface velocity of 24 mph. Overall, the Vertol 107 produces slightly greater maximum induced surface velocities than the Chinook CH-47 even though its maximum equipment weight is less than the Chinook.

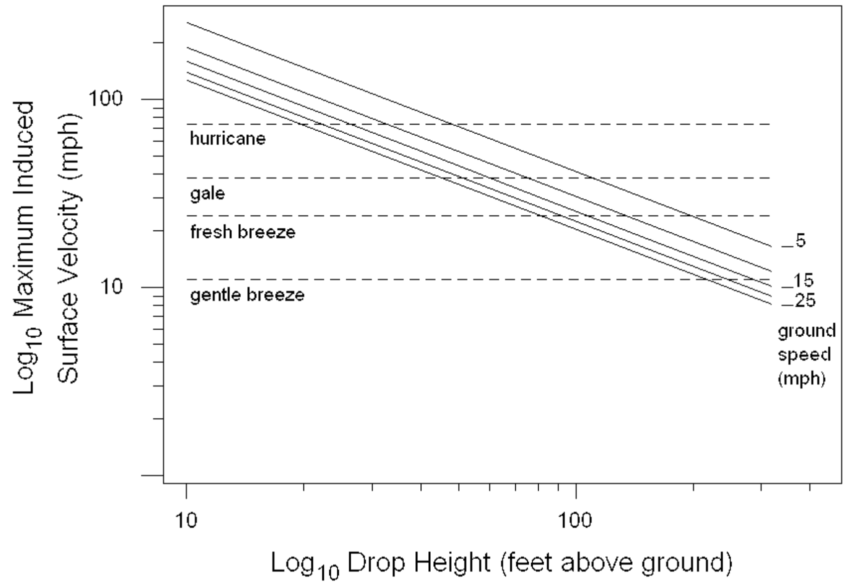

**Figure 4.3-15**
**Modeled Maximum Surface Velocities Induced by Boeing Vertol 107 Helicopters while Flying at Ground Speeds From 5 to 25 mph at Heights From 10 to 320 feet Above Ground (Modeled from data in Teske et al., 1997**

The single rotor S-64 Skycrane has the largest rotor diameter (72 feet diameter) of the three models. As modeled in figure 4.3-16, the Skycrane would produce greater maximum induced surface velocities while flying at the same ground speeds and same drop heights as the other two helicopter models.

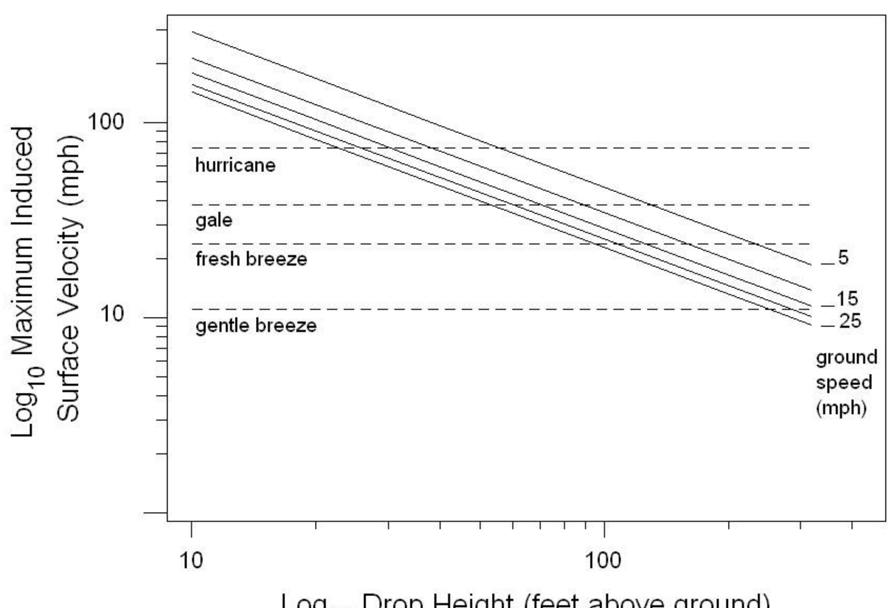

**Figure 4.3-16**
**Modeled Maximum Surface Velocities Induced by Skycrane S-64 Helicopters while Flying at Ground Speeds From 5 to 25 mph at Heights From 10 to 320 feet Above Ground. (Modeled from data in Teske et al., 1997**

Flying at a ground speed of 5 mph, the Skycrane would have to be approximately 233 feet above ground to produce a maximum induced surface velocity of 24 mph, equivalent to a fresh breeze. The Chinook and Vertol 107 helicopters would induce similar maximum surface velocities flying at heights of 185 feet and 200 feet above ground, respectively. If traveling at ground speed of 25 mph, the Skycrane could be 95 feet above ground to induce a maximum surface velocity of 24 mph.

Actual downwash and sidewash vortices produced by Chinook CH-47 and Skycrane (CH-54) helicopters were measured during field tests (Leese and Knight, 1974) while aircraft were hovering at 40–50 feet and 80–90 feet above ground level (agl) while under maximum loads of 36,000 pounds (CH-47) and 45,000 to 47,000 pounds (CH-54). The Vertol 107 (CH-46) was not included in the field tests.

With a 47,000-pound load, the single rotor CH-54 hovering at 40 feet agl produced a maximum sidewash velocity of 87 mph 50 feet away from the rotor hub. At 80 feet agl, the maximum sidewash was 74 mph, also measured at 50 feet from the hub though the gross weight was 45,000 pounds during that particular trial. Both maximum sidewash measurements were at heights of 0.3 feet above ground (Leese and Knight, 1974). Under the specified load conditions, the CH-54 produced a sidewash of 11 mph 170 feet away from the rotor hub while hovering at 40 feet agl and a sidewash of 9 mph 150 feet away from the hub while hovering at 80 feet agl. Maximum sidewash velocities of 74–87 mph that were associated with the CH-54 helicopter while it was hovering, are within the range of hurricane force winds on the Beaufort Scale while winds of 9–11 mph produced by rotor sidewash would be described as a “gentle breeze”. Sidewash velocities between 9 and 11 mph at distances 150 to 170 feet away from a CH-54 helicopter (Skycrane) would not create a risk of young NSOs being blown out of nests.

Downwash and sidewash velocities measured for the CH-47 helicopter (Chinook) were greater than 100 mph up to 70 feet horizontally from the rotor hub when it was hovering at 90 feet agl with maximum load of 36,000 pounds (Leese and Knight, 1974). The twin rotor CH-47 produced sidewash velocities as high as 56 mph 190 feet away from the rotor hub when it was hovering 90 feet agl. The Beaufort Scale classifies winds between 55 and 63 mph as a “storm”, with trees uprooted and structural damage likely. The strength of winds produced by the CH-47 is likely due to the interaction of descending air produced by the two rotors (Fabey, 2008); sidewash winds are generally strongest at 120 and 240 degrees (4 o’clock and 8 o’clock, respectively) relative to the helicopter’s heading (data in Leese and Knight, 1974).

Sidewash wind velocities produced by the CH-47 at various distances away from the rotor hub (Leese and Knight, 1974) were used to predict the distance at which the helicopter would be far enough away from adversely affecting NSO nests and young. The prediction is based on the sidewash wind velocities produced by the CH-47 averaged for wind measurements made 0.3 feet above ground at angles of 120 and 240 degrees while the helicopter was hovering 90 feet agl under a load of 36,000 pounds. The prediction is shown below in figure 4.3-17 in which a sidewash velocity of 0 mph would occur 293 feet away from the rotor hub. Due to the observed variation in sidewash winds at different distances away from the rotor hub (solid circles in figure 4.3-17), the upper 95 percent prediction interval on that predictive estimate of 0 mph at 293 feet from the hub would be 23.8 mph. A wind velocity of 23.8 mph is classified as a fresh breeze on the Beaufort Scale. One would be 95 percent certain that a stronger wind would not occur which could potentially adversely affect nesting NSOs.

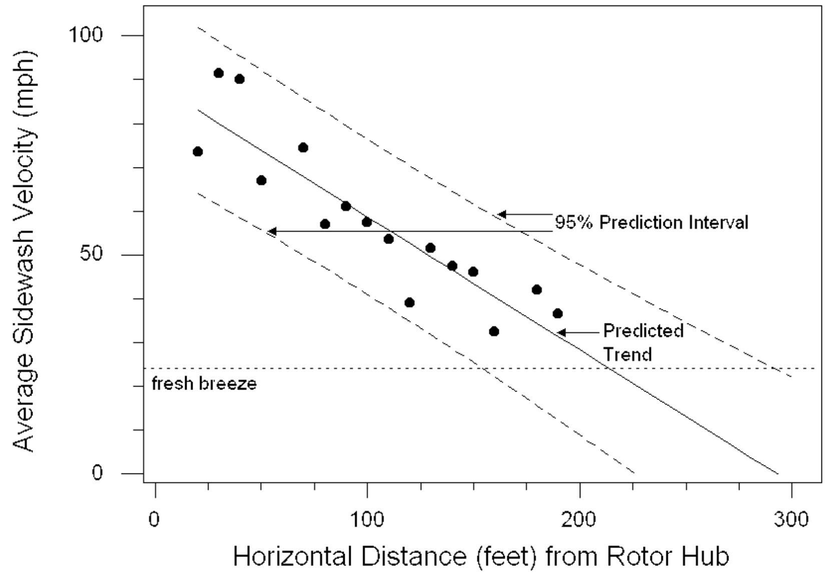

**Figure 4.3-17**
**Average Sidewash Wind Velocities Produced by the CH-47 at Varying Horizontal Distances from the Rotor Hub While Hovering 90 feet agl Under a Load of 36,000 pounds. The Observed Averages (solid circles) were used to Predict Sidewash Winds at Distances Out to 300 feet. (Source: Leese and Knight, 1974)**

These estimates clearly suggest that greater distances would be required to avoid adverse effects to NSOs if Chinook helicopters, rather than Skycranes, are employed for heavy lifting along remote sections of the Pacific Connector pipeline construction right-of-way. Based on the similarities of maximum induced surface velocities between Chinook and Vertol 107 helicopters, sidewash velocities induced while hovering are likely to be similar as well. However, if known NSO activity centers can be avoided by at least 200 feet above tree tops by heavy-lifting helicopters in transit and avoided horizontally by at least 300 feet while helicopters hover above staging sites, no adverse effects to the species would be expected due to rotor downwash and induced sidewash.

Three activity centers occur within 0.25 mile of proposed helicopter use (known 2317B, best location site PCGP 095.3, and assumed PCGP A-1), of which all sites could have helicopter activity within their nest patch (see table Q-8 in appendix Q, and individual NSO impact assessments, appendix Z2). Helicopter use for timber extraction within 0.25 mile of a NSO activity center would occur outside of the entire breeding season (between October 1 and February 28); no adverse effects from rotor wash of large helicopters are expected during timber extraction. Adverse effects to the three NSO activity centers could occur from rotor wash of large helicopters during pipe delivery for construction of the proposed action since it may be within 200 feet above nest trees and horizontally within 300 feet of nest trees; however, the nest site is unknown for each activity center, including known 2317B. Helicopter use would only occur after the critical breeding season (after July 15), minimizing risk to NSO.

Burning and Smoke

Effects on NSOs from smoke, whether by prescribed burning as a habitat enhancement procedure or by burning slash have not been studied. However, FWS et al. (2007) have declared (see Table 15, FWS et al., 2007) that "smoke can cause [spotted owl] adults to move off nest sites, therefore leaving eggs or young exposed to predation or resulting in lost feedings reducing the young's fitness."

According to BLM and Forest Service (2008, page 34), NSOs "are potentially affected by fire control activities and drifting smoke during burning. The threshold distance for disturbance from smoke is 0.25 mile for spotted owls," which would be subject to smoke-related disturbance during the critical breeding period (March 1 to July 15). Pacific Connector would not conduct slash burning during the critical breeding season within 0.25 mile of an occupied NSO activity center during the critical breeding season. No direct effect to NSOs due to slash burning is expected.

**Indirect Effects**

Project-related effects to NSOs which are caused by the action (induced by the action and by human presence and use increase) and are later in time or farther removed in distance, but are still reasonably foreseeable are indirect effects. Habitat loss and modification, whether to nesting, roosting or foraging habitats, due to forest clear-cutting has been the most significant factor causing declines of the NSO (FWS, 1992b). Habitat losses and habitat fragmentation have indirect impacts that can affect survival and reproduction of NSOs. Short-term impact is expected with UCSAs and is likely to last from the initiation of use until 1 to 5 years afterward. Long-term impact to NSOs and NSO habitat is expected to last at least 5 years or more.

Other indirect effects to NSOs that are often related to habitat loss or modification are increased predation, increased competition, and effects to prey utilized by NSOs. In addition, secondary effects (Comer, 1982) due to an increased human population base are expected, whether resulting from the requirements of the action itself (the workforce needed to construct or operate the Project) or as consequences of the action (need for ancillary goods, services, recreational opportunities resulting from the Project). Potential indirect or secondary effects by the proposed Project include increased recreation demand (including off-road vehicle use), increased habitat conversion, and habitat degradation by human intrusion and encroachment (Comer, 1982).

To determine effects to known, best location, and PCGP assumed owl home ranges within the Provincial Analysis Area, 14 NSO groups were created that included all known, best location, and PCGP assumed owls whose home ranges overlapped. Table 4.3.4-12 summarizes the number of owls by status (known, best location, and PCGP assumed) and physiographic province that occur within each owl group. The number of owls included in each group varied from one to 39 NSO activity centers (see table Q-7 in appendix Q for specific information on each northern spotted owl site included in each owl group). Owl groups have been used to identify the area of habitat being affected within and outside of NSO home ranges in the PCGP Project area.

**Table 4.3.4-12**

[1] Summarized from table Q-7 in appendix Q.
[2] Owl status: known (provided by BLM Districts, Forest Service, or FWS within the project area), PCGP assumed (area identifed by Pacific Connector that may provide habitat for NSO activity center), best location (no nest located during PCGP survey efforts but survey results determined best potential site for nest).

Habitat Removal and Modification

The decline of NSOs has been linked to the removal and degradation of available suitable NRF habitat. Appropriate vegetation and structural components are necessary to maintain suitable habitat, and the removal of these components can potentially have adverse effects on NSO populations. These effects could include displacement from traditional nesting areas, increased concentration of NSOs into smaller, fragmented areas of suitable habitat, and diminished reproductive success (FWS, 2006f).

In the Provincial Analysis Area, NSO habitat needs and home ranges vary based on physiographic provinces and forest type. In the Coast Range Physiographic Province (MP 1.47R to MP 52.21), the home range is assumed to be circular with a radius of 1.5 miles. Within the Klamath Mountains Physiographic Province (MP 52.21 to MP 122.61) the home range radius is

1.3 miles, and in the West Cascades (MP 122.61 to MP 167.71) and East Cascade Physiographic Provinces (MP 167.71 to MP 191.19) the home range radius is 1.2 miles (FWS, 1992d). Although differences exist in natural stand characteristics that influence provincial home range size, habitat loss and forest fragmentation caused by timber harvest effectively reduce habitat quality in the home range. A reduction in the amount of suitable habitat reduces NSO abundance and nesting success (Bart and Forsman, 1992; Bart, 1995), and recent studies have indicated that NSOs' home ranges are substantially larger in more heavily fragmented stands (Courtney et al., 2004).

The Pacific Connector pipeline would affect NSOs over the long-term by habitat removal and modifications. Table 4.3.4-13 summarizes effects to NSO habitat from construction and operation (30-foot maintenance corridor) of the proposed Project by physiographic province, land owner, and Project component (see table Q-9 in appendix Q for detailed information on habitat impact including amount removed/modified from CHUs, NWFP LSRs, and interior forest, by landowner within and outside of NSO groups). Habitat cleared outside of the 30-foot maintenance corridor would be revegetated and allowed to return to its pre-action state.

In total, the Project would remove approximately 565 acres of suitable NRF (high NRF and NRF) habitat during construction (see table 4.3.4-13; table Q-9 in appendix Q), of which approximately 145 acres would be permanently lost to the pipeline corridor and maintained free of vegetation for the life of the Project within the 30-foot maintenance corridor (table 4.3.4-13; table Q-9 in appendix Q). The other 420 acres of suitable NRF habitat cleared outside the 30-foot maintenance corridor would be revegetated and considered capable of becoming NRF habitat in approximately 80 years, although some of it may become functional foraging or roosting habitat prior to 80 years. Removal of 565 acres of NRF habitat across the four physiographic provinces crossed represents approximately 0.6 percent of the 89,562 acres of suitable NRF/high NRF habitat in the Provincial Analysis Area (see table 4.3.4-5, above). Additionally, 245 acres of suitable NRF habitat have been identified for use by the proposed Project as UCSAs, which would not have vegetation removed but may be used to store forest slash, stumps, and dead and downed log materials between existing trees during construction and before they are scattered across the right-of-way after construction during restoration (see table 4.3.4-13; table Q-9 in appendix Q). Use of the UCSAs would be a short-term modification of suitable NRF habitat, and habitat function should be maintained.

Approximately 1,256 acres of dispersal habitat (high NRF, NRF, and dispersal only habitat) would be removed by the proposed action, of which the majority would be removed within Klamath Mountains Physiographic Province. Removal of 1,256 acres of dispersal habitat within the four physiographic provinces crossed by the proposed Project represents approximately 0.9 percent of all total available dispersal habitat (143,449 acres) within the Provincial Analysis Area (see high NRF, NRF, and dispersal only habitat in table 4.3.4-5).

Discussion at the Task Force - ESA Consultation Subgroup meeting on April 2, 2008 indicated that NSO dispersal habitat could be considered adequate if at least 50 percent of the analysis area (in the Project's case, the defined provincial analysis area) consisted of dispersal habitat. Table 4.3.4-5 shows the amount of dispersal habitat available and its percentage in each physiographic province within the defined provincial analysis area. Only one physiographic province is currently above the recommended threshold of 50 percent available dispersal habitat – West Cascades (50.9 percent). Removal of 313.13 acres of dispersal habitat from the West Cascades Physiographic Province crossed would not cause the amount of available dispersal habitat within the defined Provincial Analysis Area to drop below the recommended 50 percent dispersal habitat threshold (approximately 37,062 acres or 50.4 percent available). The reduction of available dispersal habitat within the provinces crossed is not considered significant. Additionally, removal of dispersal habitat would not be in one locale, but would be removed along 193.3 miles of proposed pipeline in the range of the NSO. After the Project is completed, neither the temporary 95-foot-wide construction right-of-way and associated temporary extra work areas or the permanent 30-foot maintenance corridor should impede the movement of juveniles and adults.

Construction and permanent effects to habitat capable of becoming suitable NRF habitat (Capable Habitats) are also included in table 4.3.4-13. Approximately 1,022 acres of NSO capable habitat would be removed by construction of the proposed Project, of which 223 acres would remain in a permanent herbaceous/shrub state within the 30-foot operational corridor for the life of the Project. Approximately 743 acres of capable habitat removed on private lands is not expected to mature to provide suitable NRF or high NRF habitat for NSO based on review of research on timber harvest practices in Oregon (Zhou et al., 2005; Rasmussen et al., 2012). These studies noted that forest harvest practices on non-federal lands typically occur between 45 and 65 years of age.

If just considering habitat within the known, best location, or PCGP assumed home ranges of NSOs within the analysis area (see NSO Groups in table 4.3.4-13), approximately 431 acres of suitable NRF habitat (high NRF and NRF) would be removed and impacted over the long term; 221 acres would be impacted over the short-term by potential use of proposed UCSAs. This is approximately 76 percent of suitable NRF habitat removed or modified by the proposed Project. Table Q-10 in appendix Q provides a summary of suitable, dispersal, and capable habitat affected by the proposed Project within NSO groups by nest patch, core area, and home range. Suitable but unoccupied habitat removed outside of known, best location, or PCGP assumed home ranges may reduce the physical, geographical, and/or demographic connectivity between habitat and population reserves.

Davis et al., (2011) observed increased extinction rates of spotted owls in response to decreased amounts of old forest within the core area and higher colonization rates when old-forest habitat was less fragmented in the Southern Cascades Study Area, which is situated within the PCGP Project area on federal lands (see Population Status Section, above). The proposed action would affect NSO high NRF and NRF habitat within approximately 30 core areas (18 known sites, seven best location sites, and five PCGP assumed sites) mostly within the Klamath Mountains Physiographic Province (see table 4.3.4-14), potentially increasing habitat abandonment and/or barred owl competition and encroachment (see Davis et al., 2011). Table Q-7 in appendix Q identifies the location and distance of each spotted owl site center from construction of the PCGP Project, as well as identifies the current condition of each spotted owl nest site and the amount of habitat removed from the nest patch, core area, and home range for each NSO activity center, where applicable. It would be expected that spotted owl sites with less habitat available within their core area (i.e., Habitat Condition 2 or 4 in table Q-7 in appendix Q) would be affected more by habitat removal within their core area: four PCGP assumed sites, four best location sites, and nine known spotted owl sites (table 4.3.4-16, below).

1 General Location identifies areas within Northern Spotted Owl Groups (areas within NSO home ranges; see table Q-10 in appendix Q) and areas outside of NSO groups (outside of NSO home ranges).
2 High NRF (Trask & Associates, 2013): forested habitat that is characterized by large trees (> 32 dbh), high canopy cover (>60 percent), and multistoried with sufficient down wood and snags to support prey species.
3 NRF (Trask & Associates, 2013; FWS, 2012; North et al., 1999): conifer-dominated forested habitat greater than 80 years that does not meet the definition of High NRF but has multi-storied structure with large overstory trees (20-30 inch dbh), moderate to high canopy closure greater than 60 percent, and sufficient snags and down wood.
4 Dispersal ONLY (FWS, 2012a): an average tree diameter of 11 inches dbh or greater; conifer overstory trees; canopy closure greater than 40 percent in moist forests and greater than 30 percent in dry forests; open space beneath the canopy to all for NSO to fly; High NRF and NRF provide dispersal habitat, as well.
5 Capable Habitat (Trask & Associates, 2013): habitat that is forested or could become forested (i.e., recently harvested timberlands) that do not provide dispersal or NRF characteristics.
6 Noncapable Habitat: not forested and not capable of becoming forested.
7 Project components considered in calculation of habitat "Removed": Pacific Connector construction right-of-way, temporary extra work areas, aboveground facilities, permanent and temporary access roads (PAR, TAR), pipe storage yards, and hydrostatic locations.
8 UCSAs would not be cleared of trees during construction and will not affect nesting structures or characteristics. These areas would be used to store forest slash, stumps and dead and downed log materials that would be removed and scattered across the right-of-way after construction during restoration and are considered as temporary insignificant understory habitat effects.
9 30-foot Maintenance Corridor will be kept in a shrub/sapling state for the life of the project; all other habitat outside of the 30-foot maintenance corridor will be revegetated.

Note: More detailed information on BLM Districts and National Forests impacted, as well as critical habitat, NWFP late successional reserves, is located in table Q-9 in appendix Q.

[1] Nest patch: includes an area that is 300 meters from the site center (70 acres occur within a nest patch).
Core area: generally 502 acres occur within a core area.
Home range: generally 4,525 acres, 3,398 acres, and 2,895 acres occur within the Oregon Coast Range, Klamath Mountains, and Cascades NSO home ranges, respectively.
[2] High NRF (Trask & Associates, 2013): forested habitat that is characterized by large trees (> 32 dbh), high canopy cover (>60 percent), and multistoried with sufficient down wood and snags to support prey species.
[3] NRF (Trask & Associates, 2013; FWS, 2012; North et al., 1999): conifer-dominated forested habitat greater than 80 years that does not meet the definition of High NRF but has multi-storied structure with large overstory trees (20-30 inch dbh), moderate to high canopy closure greater than 60 percent, and sufficient snags and down wood.
[4] Dispersal ONLY (FWS, 2012a): an average tree diameter of 11 inches dbh or greater; conifer overstory trees; canopy closure greater than 40 percent in moist forests and greater than 30 percent in dry forests; open space beneath the canopy to all for NSO to fly; High NRF and NRF provide dispersal habitat, as well.
[5] Capable Habitat (Trask & Associates, 2013): habitat that is forested or could become forested (i.e., recently harvested timberlands) that do not provide dispersal or NRF characteristics.
[6] Noncapable Habitat: not forested and not capable of becoming forested.
[7] Project components considered in calculation of habitat "Removed": Pacific Connector construction right-of-way, temporary extra work areas, aboveground facilities, permanent and temporary access roads (PAR, TAR), pipe storage yards, and hydrostatic locations.
[8] UCSAs would not be cleared of trees during construction and will not affect nesting structures or characteristics. These areas would be used to store forest slash, stumps and dead and downed log materials that would be removed and scattered across the right-of-way after construction during restoration and are considered as temporary insignificant understory habitat effects.

NOTE: Summarized from table Q-10 in appendix Q.

There is a potential for temporary, indirect habitat loss occurring due to noise and human presence during the breeding season (i.e., within a 0.25 mile buffer around the proposed pipeline construction work space, access roads, etc.). Approximately 13,378 acres of suitable NRF habitat (high NRF and NRF) occur within 0.25 mile of the proposed action, of which 11,046 acres occur within NSO home ranges that could experience indirect and temporary loss of habitat due to associated noise disturbance within the NSO breeding season (March 1 through September 30; table 4.3.4-15). Within 0.25 mile of NSO activity centers, timber removal would occur outside of the entire breeding season beginning in October and construction activities would occur the following year after the critical breeding season (after July 15; see table Q-9 in appendix Q for specific timing within individual owl home ranges). Beyond 0.25 mile of NSO activity centers, timber removal and construction activities could occur during the entire NSO breeding season. Activity would not occur simultaneously within the 193.26 miles of the proposed Project that lies within the range of the NSO, and therefore, any temporary, indirect habitat loss would be less than estimated in table 4.3.4-15. Spot check surveys will be conducted within 0.25 mile of the proposed action one year prior to construction to determine if additional suitable habitat has become occupied and the above schedule will be adjusted, if necessary, further minimizing temporary, indirect habitat loss during the breeding season.

**Table 4.3.4-15**
**Amount (acres) of Nesting, Roosting, and Foraging Habitat (acres) Indirectly Impacted Due to Disturbance during the Breeding Season (March 1 through September 30)**

| Physiographic Province | Miles of Proposed Pipeline | Suitable NRF within 0.25 mile of Proposed Activities [1] | Suitable NRF within 0.25 mile of Proposed Activities within NSO Home Ranges [1] | Percent of NRF Habitat within NSO Home Ranges |
|---|---|---|---|---|
| Coast Range | 54.51 | 2,125 | 1,690 | 79.5 |
| Klamath Mountains | 71.02 | 6,650 | 5,814 | 87.4 |
| West Cascades | 44.88 | 3,806 | 3,035 | 79.7 |
| East Cascades | 22.85 | 796 | 507 | 63.7 |
| **Total** | **193.26** | **13,378** | **11,046** | **82.6** |
| [1] Suitable NRF Habitat includes both high NRF and NRF habitat within 0.25 mile of proposed habitat removal. | | | | |

Known, Best Location, or PCGP Assumed Owl Sites

There are 98 known, best location, or PCGP assumed owl home ranges that overlap the proposed Project. Of these, eight NSO home ranges would not have habitat removed or modified because they are only intersected by existing roads to be used to access the right-of-way or are within 100 meters of habitat removal. The effects of habitat changes to the other 90 known, best location, or PCGP assumed owls within the Provincial Analysis Area as a result of the proposed action were evaluated at three scales: the nest patch, the core area, and the home range. The pre-action and post-action habitat conditions are provided in table Q-7 in appendix Q for each NSO home range; the amount of NSO habitat is specific to each habitat type in its entirety; acres provided for the home range include acres that also occur within the core area and nest patch, and acres included in the core area also include acres within the nest patch. Also, amount of suitable NRF habitat removed within each owl habitat type does not consider overlap with neighboring owl sites.

Table 4.3.4-16 summarizes the number of NSO activity centers and acres of NSO habitat by physiographic province that would have NSO habitat removed from their nest patch, core area, and/or home range (summarized from table Q-7 in appendix Q). Spotted owls that are below the FWS recommended suitable habitat thresholds or are near those thresholds, either in the core area or home range, and would have suitable habitat removed could be impacted more by the Project than those above the recommended FWS suitable habitat thresholds (less than 50 percent and/or less than 40 percent available high NRF/NRF in their core area or home range, respectively). Table 4.3.4-16 tabulates the number of NSO home ranges/core areas that are below threshold, by physiographic province, that would have habitat removed and identifies the habitat use area (nest patch, core area, home range) that each owl would be affected. Generally, removal of habitat from home ranges already below threshold represents less than 0.2 percent of available suitable habitat within the owls' home range (see table Q-7 in appendix Q). Since removal of habitat represents such a small percentage of available suitable NRF habitat (high NRF and NRF) within the core area and/or home range, removal of habitat within owl site core areas and home ranges should not adversely impact those NSO pairs or resident singles. However, habitat removed in closer proximity to the nest site or nest patch may have a greater impact to the NSO pair or resident single.

NSOs with suitable habitat availability within their core area and/or home range below the FWS recommended threshold of suitable habitat (< 40 percent suitable habitat in home range, < 50 percent suitable habitat in core area) could be considered adversely affected, especially if habitat is removed during the breeding season within 0.25 mile of an activity center. Habitat would be removed from 90 home ranges (including 35 core areas) within the four physiographic provinces crossed, of which 56 home NSO activity centers are below the recommended habitat thresholds in the core area and/or home range. Habitat removal within 0.25 mile of 10 NSO activity centers (five known, four best location, and one PCGP assumed), of which six are below recommended NRF threshold, would occur outside of the entire breeding period (between October 1 and February 28); disturbance associated with these activities should not adversely affect spotted owls. If survey efforts prior to construction identify additional NSO activity within 0.25 mile, habitat removal will occur outside of the breeding seasion within 0.25 mile of those sites, as well.

Eight nest patches would be crossed by the proposed action; suitable NRF habitat (high NRF, NRF) would be removed from seven nest patches, of which five NSO home ranges have suitable habitat below the recommended NRF threshold in the core area and/or home range (see table 4.3.4-17). Timber would be removed outside the entire breeding season (after September 30 but before March 1) within each nest patch and 0.25 mile of that activity center; therefore, no direct impact to those NSOs is expected. Removal of habitat from the nest patches, however, could have an indirect, negative impact on those NSOs, especially in the five sites below recommended FWS NRF threshold for core area and/or home range. Four NSO sites represent pairs documented during 2008 survey efforts (best location sites); however, none of the sites had a nest tree identified. As a result, these nest patches represent a 300-meter radius around the "best location" as determined by the surveyors and local agency biologists based on detection date and time, individual owls (age and sex) present at particular detections, behavior of owls at a particular detection, and occasionally the habitat of a detection location. In discussions with various agency biologists (table S-1 in appendix S), it was thought that these sites were associated with other monitored pairs and that nesting at the "best location" sites was not occurring, but not enough information was available to be sure of this. Therefore, Pacific Connector continues to include these best location NSO pair sites for analyzing worst case scenarios. If additional surveys conducted prior to construction and timber clearing indicate that these are not active, Pacific Connector would revise the schedule accordingly. Table 4.3.4-17 provides details specific for each NSO nest patch crossed by the proposed Pacific Connector pipeline.

## Table 4.3.4-16
## Number of NSO Home Ranges, by Physiographic Province and Habitat Condition that Would Have NSO Habitat Removed by the Proposed Project[1]

[1] For detailed NRF/High NRF habitat available for each NSO and its habitat type (nest patch, core area, home range), refer to “pre-action” suitable habitat acres in table Q-7 in appendix Q.

[2] FWS et al. (2008) consider core areas with 50 percent or greater suitable NRF habitat and home ranges with at least 40 percent suitable NRF habitat to be necessary to maintain NSO life history function. Habitat condition for each NSO affected is summarized from table Q-7 in appendix Q.

[3] Owl Status: 1) Known sites represent NSO activity sites provided by BLM and Forest Service biologists within the provincial analysis area; 2) Best Location sites represent pairs or resident singles documented by Pacific Connector during surveys in 2007 and 2008 with no nest site/activity center located, and; 3) PCGP assumed sites respresents and area identifed by Pacific Connector that may provide habitat for NSO pair.

## Table 4.3.4-17
## Summary of NSO Nest Patches Crossed by the Proposed Action

| MSNO or Site ID | Site Name | Nest Patch Location (MP) | Landowner | Land Allocation | Available High NRF/NRF[1] (acres) | Length Crossed[2] (feet) | High NRF/NRF Affected[3] | | Pre-Action Habitat Condition[4] | Additional Description |
|---|---|---|---|---|---|---|---|---|---|---|
| | | | | | | | Area (acres) | Percent of Available NRF | | |
| **Coast Range Physiographic Province** | | | | | | | | | | |
| 2317B | Brewster Valley | 37.40-37.80 | Coos Bay BLM | Unmapped LSR | 63.79 | 2,096 | 4.89 | 7.7 | <40% Home Range, >50% Core | Coos Bay BLM provided a newly documented alternate NSO activity center to Pacific Connector in January 2014; this area had been surveyed in previous years by Coos Bay BLM and Pacific Connector and spotted owl activity was identified in area, but no nest location or pair was documented (see Raymond et al., 2012; SBS, 2008a). Project will bisect late successional forest through the nest patch and western portion of the core area of this site; resulting two lobes of suitable NRF stand crossed = 198.00 acres and 108.40 acres (located within MAMU Stand C3090; see table 4.3.3-13). |
| **Klamath Mountains Physiographic Province** | | | | | | | | | | |
| PCGP 064.2 | Kent Creek | 62.70-65.66 | Private | None | 7.81 | 1,091 | 0 | 0 | <40% Home Range, <50% Core Area | Project located in regenerating forest approximately 202 meters (663 feet) from best location site within strip of mid-seral forest adjacent to regenerating forest; one road travels through the nest patch; right-of-way would create additional fragmentation; will create edge within older regenerating interior forest for approximately 300 feet (600 feet of new edge in interior forest); approximately 360 feet of new edge in forest already affected by existing edge will also be created (720 feet). |
| PCGP 090.2 | Bland Mountain | 88.86-91.61 | Roseburg BLM | Matrix | 26.12 | 2,031 | 2.81 | 10.8 | <40% Home Range, <50% Core Area | Project located through middle of best location nest patch; best location site identifed adjacent to an existing access road that also bisects the nest patch; consultations within agencies (see table S-1 in appendix S) presume the nest site is not at this best location site; northern portion of the right-of-way traverses through old-growth for approximately 920 feet, including interior forest and bisects the stand. |
| PCGP 095.3 | Milo South | 93.82-97.04 | Roseburg BLM | LSR | 38.54 | 1,795 | 1.44 | 3.7 | <40% Home Range, > 50% Core | Project traverses through approximately 500 feet of old-growth forest, including approximately 240 feet of interior forest in best location nest patch; the remainder of project is adjacent to old-growth stand in early regenerating forest. |

[1] Available high NRF and NRF in the nest patch; see table Q-7 in appendix Q.
[2] Length is provided for pipeline across the nest patch.
[3] Acres of NRF (high NRF and NRF) affected within the nest patch, if NRF affected; see table Q-7 in appendix Q.
[4] FWS et al. (2008) considers NSO home ranges and core areas to provide suitable NRF if the available NRF is greater than 50 percent (Core Area) or is greater than 40 percent (Home Range).

Habitat Fragmentation

In addition to impact by surface disturbances, fragmentation of connected, contiguous habitat will occur. Fragmentation of NSO habitat is considered a cause for poor demographic performance, although the threat posed by fragmentation is still not fully understood (Courtney et al., 2004). FWS (2004) indicated that habitat fragmentation was the "aggregate of effects of historical habitat loss, continuing habitat loss due to uncharacteristic wildfire, and continuing timber harvest, albeit at reduced levels," and that habitat fragmentation remained a threat in the northern part of the NSO's range but was reduced in the southern part. It is assumed that these broad statements are referring to the amount of timber harvest still occurring. Courtney et al. (2004) indicated that typically a larger area is required for NSO home ranges in more fragmented habitats. Based on this assumption, the Provincial Home Range Radii provided in the 2010 Northern Spotted Owl Survey Protocol would be indicative of more fragmented habitats in the northern part of the NSO's range than in the southern portion (1.8 mile radius in the Washington Cascades, 2.2 miles on the Olympic Peninsula, 1.2 miles in the Oregon Cascades, 1.5 miles in the Oregon Coast Ranges, and 1.3 miles in Klamath Province).

Fragmentation includes increasing levels of edge between older forests and younger forest types. NSO fecundity has been positively related to forest edge (Franklin et al., 2000, Olson et al., 2004; Hayward et al., 2011) and FWS (2011c) has suggested that spotted owls evolved with natural disturbance processes (e.g., fire) that caused mosaics of forest age classes, edges included. While the size of old-growth patches was strongly related to nest site selection by NSO, extent of clearcut forest and indices of forest fragmentation were not (Meyer et al., 1998). Prey abundance and higher nutritional status have been related to forest edges (Franklin et al., 2000, Franklin and Gutierrez, 2002; Hayward et al., 2011), particularly the abundance of woodrats (Ward et al., 1998), and possibly flying squirrels (Rosenberg and Anthony, 1992). Reproductive output was found to be greater at sites with more edge between older forest (mature and old growth) and other adjacent vegetation, while reproductive output declined in areas with greater amounts of interior forest (Franklin et al., 2000). Alternatively, NSO survival increased with more interior forest and increased edge (Franklin et al., 2000). As reviewed by Franklin and Gutiérrez (2002), locations in which NSO have high reproduction and high survivorship (collectively, high fitness) are a balance between the amounts of interior forest and edges with older forest.

Alternatively, increased fragmentation can lead to decreased survivorship of NSOs by facilitating predation by great horned owls, northern goshawks, and other avian predators (Franklin et al., 2000; FWS, 2011). Competition with barred owls may also be facilitated by forest fragmentation, although the levels of competition are not straight forward (Dugger et al., 2011). With increased fragmentation, NSO have been found to expand their home range size (Schilling et al., 2013) which could lead to increased predation (larger areas equating to more time spent away from nests) and possibly increased competition (Dugger et al., 2011).

The Provincial Analysis Area has already been subjected to extensive fragmentation by past land uses including transportation corridors, timber harvest and associated activities (i.e., road construction), and urban development. The project will occur within approximately 195.00 miles across four physiographic provinces (MP 1.47R to MP 190.58), of which 103.4 miles occur within NSO home ranges. Within the four physiographic provinces crossed by the proposed action, the Pacific Connector pipeline would be located within or parallel to existing corridors for approximately 70.3 miles (36.1 percent of proposed action in the NSO range; see table Q-4 in appendix Q), thus minimizing fragmentation within approximately 76 home ranges and NSO habitat. Table Q-4 in appendix Q identifies the location of NSO home ranges (including nest patches and core areas) in relation to existing rights-of-ways and corridors. However, additional fragmentation will occur within high NRF and NRF habitat, as well as dispersal and capable habitat due to the proposed project. Depending on local conditions, fragmentation may not be an adverse impact to NSO home ranges if prey abundance ultimately increases, but on the otherhand, fragmentation could contribute to increased predation of NSO nests which would be detrimental. Measures in the CMP include financial support of a barred owl management program that is expected to off-set negative aspects of fragmentation.

**Habitat Edge**. Indirect effects from construction of the Pacific Connector pipeline are also expected within habitat adjacent to the PCGP construction right-of-way, including within interior forest within NSO high NRF, NRF, dispersal, and capable habitat. The conversion of large tracts of old-growth forest to small, isolated forest patches with large edge areas can create changes in microclimate, vegetation species, and predator-prey dynamics. In general, microclimates along edges differ from those in forest interiors. Two main physical factors affecting and creating an edge microclimate are sun and wind (Forman, 1995; Chen et al. 1995; Harper et al., 2005). Compared to the forest interior, areas near edges receive more direct solar radiation during the day, lose more long-wave radiation at night, have lower humidity, and receive less short-wave radiation. Such a change in humidity could affect migration and dispersal of flying insects, including tree parasites such as the Douglas-fir beetle (Chen et al., 1995) and promote expansions of infestations which can affect interior forest stand structure and formations of gaps in formerly closed stands (Furniss, 1979). Humidity, coupled with soil moisture and temperature, also affects decomposition of litter and coarse woody debris; rates of litter decomposition were higher near edges with a shallower organic layer (Chen et al., 1995). Decreased humidity may also affect distribution of fungi that are dependent on old-growth forest environments. Since the diets of northern flying squirrels mostly consist of fungi (Verts and Carraway, 1998), changes in interior forest microclimates could affect local abundance of prey utilized by NSOs.

Other physical factors affecting edge includes edge orientation (Chen et al., 1995). For example, the general orientation of the PCGP Project is from northwest to southeast. Therefore, edge effects will be most pronounced on the southwest-facing edges and weakest along the northeast-facing edges (see discussion in Chen et al., 1995). Harper et al. (2005) reported that the mean distance of edge influence could occur to approximately 328 feet (100 meters) and result in 1) tree mortality, damage, recruitment, growth rate, canopy foliage, understory foliage, and seedling mortality, 2) amounts of canopy trees, canopy cover, snags and logs, understory tree density, herbaceous cover, and shrub cover, and 3) stand composition metrics such as species, exotics, individual species and species diversity. In other younger coniferous forests or mixed forests with deciduous species, edge effects compared to interior forests have been much less pronounced (Heithecker and Halpern, 2007; Harper and MacDonald, 2002).

Old-growth and late seral forests are important to northern spotted owls as NRF habitat, but edges associated with those NRF habitats have been shown to increase NSO fitness in terms of fecundity and survivorship (see Franklin et al., 2000, Olson et al., 2004; Hayward et al., 2011). Annual survival of NSO on territories was positively associated both with amounts of interior old-growth forest and with length of edge between those forests and other vegetation types. Conversely, reproduction was negatively associated with interior forest, but positively associated with edge between mature and old-growth conifer forest and other vegetation types (Franklin et al., 2000). Similarly, Olson et al. (2004) found that a mixture of mid- and late succesional with young forest and nonforested habitats appear best NSO reproduction and survival. Roads create edges that affect interior forest biotic and microclimatological conditions, even narrow forest roads 40 feet wide (Baker and Dillon, 2000). Edges created by roads with low levels of traffic disturbance have been shown to have a positive effect on northern spotted owl nutrition and fecundity (Hayward et al., 2011), perhaps due to abundance of prey (wood rats) along edges, including those associated with roads. Edges may affect interior old growth forests, but not necessarily adversely affect NSO fitness.

To determine indirect effects to NSO habitat (high NRF, NRF, dispersal, capable) from construction of the PCGP Project, Pacific Connector assessed effects to NSO habitat within 100 meters (328 feet) of proposed habitat removal, including effects to interior forest. This distance is similar to 300 feet that during discussions within the Habitat Quality subtask force to analyze effects to interior forests (2007 and 2008), and used as an edge assessment (295 feet) by Davis et al. (2011) within the NWFP 15 Year Monitoring Report for northern spotted owl habitat. Existing edge, such as roads, waterbodies, early seral forest, and nonforested habitat were incorporated into the interior forest modeling (buffered by 100 meters) to identify habitat currently affected by existing edge. This assessment considers the indirect effects of the newly constructed right-of-way on NSO habitat within 100 meters of habitat removal, including interior forest.

**Interior Forest Habitat**. Indirect effects from construction of the Pacific Connector pipeline are also expected within habitat adjacent to the PCGP construction right-of-way, including within interior forest that the marbled murrelet relies on for nesting habitat. To determine indirect effects to northern spotted owl habitat (high NRF, NRF, dispersal only, capable) from construction of the PCGP Project, Pacific Connector assessed effects to NSO habitat within 100 meters (328 feet) of proposed habitat removal, including effects to interior forest. Table 4.3.4-18 identifies the distance that NSO habitat is crossed by the proposed project within and outside of interior forest habitat, summarizes the acreage of NSO habitat directly removed and indirectly affected within 100 meters of the PCGP Project (habitat removal) by physiographic province, landowner, and NSO Groups (summarized from table Q-9 in appendix Q).

Approximately 14,234 acres of NSO habitat (3,243 acres of high NRF/NRF habitat, 4,336 acres of dispersal only habitat, and 6,656 acres of capable habitat) occur within 100 meters of habitat removal, of which 2,967 acres (20.8 percent of NSO habitat indirectly affected) of interior NSO habitat would be indirectly affected (962 acres of high NRF/NRF habitat, 1,134 acres of dispersal only habitat, and 872 acres of capable habitat; table 4.3.4-18). The majority of NSO habitat indirectly affected occurs within NSO groups crossed by the PCGP Project: 8,078 acres (56.7 percent) of all NSO habitat within 100 meters of habitat removal, which includes 1,997 acres of interior NSO habitat and 6,207 acres of NSO habitat currently affected by existing edge. Table Q-9 in appendix Q identifies the acres of NSO habitat affected 100 meters from habitat removal by physiographic province and general landowner, including effects within critical habitat and LSR. Effects to NSO habitat adjacent to the construction right-of-way will decrease as the forested area (approximately 1,741 acres; see table 4.3.4-13) outside of the 30-foot maintenance corridor are replanted with trees and return to early regenerating stands.

Based on analyses summarized in table 4.3.4-18, we assume that at least 26.4 miles of interior forest will experience fragmentation as a result of the proposed project, creating at least 52.8

miles (26.4 miles x 2) of additional edge in NSO habitat; this considers interior forest crossed by the proposed project within older regenerating forest to old-growth forest. Additional fragmentation of approximately 50.9 miles within forest currently affected by existing disturbance ("other" forest in table 4.3.4-18) could be affected since approximately 36.1 percent (70.3 miles) of the project within the range of NSO occurs within or is adjacent/parallels existing disturbance (see co-locate table Q-4 in appendix Q; 121.2 miles minus 70.3 miles = 50.9 miles), creating approximately 101.8 miles of additional edge in forest already affected by existing disturbance. In addition to NSO habitat crossed and affected within the NSO range, approximately 47.2 miles of non-capable habitat will be crossed and will remove approximately 2,031.37 acres (see table 4.3.4-13 and table Q-9 in appendix Q). Table 4.3.4-18 and figure 4.3-18 provide examples of how indirect effects to NSO habitat, both within and outside of interior forest are considered within the range of the NSO.

<u>Predation</u>

Few empirical studies exist to confirm that habitat fragmentation contributes to increased levels of predation on NSOs (Courtney et al., 2004). Great horned owls are known and potential predators of NSO (Johnson, 1992; Gutierrez et al., 1995), particularly in the context of effects of forest fragmentation on predation response, since great horned owls appear closely associated with forest openings and clearcuts (Johnson, 1992; Laidig and Dobkin, 1995). However, after a review of available evidence including predation by great horned owls, Courtney et al. (2004, pages 8–30) conclude: "there appears to be no reasonable basis for regarding an effect of fragmentation on predation levels as a primary or significant effect on NSO populations. Absent new information, the indirect effects of fragmentation through predation remains an untested hypothesis." Also, the FWS 5-Year Review (2004) stated that indirect evidence from demography studies suggests that predation, particularly by great horned owls, is not a major influence on NSO populations as was originally considered in the 1990 ESA listing.

Table 4.3.4-14 and table 4.3.4-16 indicate that 90 home ranges will be affected from habitat removal by the proposed action and may experience additional fragmentation with construction of the PCGP Project, including 35 core areas and eight nest patches (see also table Q-7 in appendix Q). It is possible that the 45 NSO sites that are below recommended threshold of available NRF habitat in the core area and/or home range, and/or would have interior forest habitat removed could experience a greater increase of predation, as great horned owls have been identified throughout the provincial analysis area during surveys in 2007 and 2008 (see biological reports submitted as a stand alone document to the FERC Certificate Application). Table 4.3.4-19 summarizes the number of home ranges that would have interior forest habitat (late regenerating forest to old-growth) removed by the proposed action and could experience additional fragmentation.

**Table 4.3.4-18**

1 Landowner is summarized by Federal (BLM Districts and National Forests) and Non-Federal (Private, State, Corps of Engineers, and Bureau of Indian Affairs Land).
2 General Location identifies areas within Northern Spotted Owl Groups (areas within NSO home ranges; see table Q-10 in appendix Q) and areas outside of NSO groups (outside of NSO home ranges).
3 Interior Forest: further than 100 meters from existing disturbance (i.e., high-traveled roads, existing corridors) or adjacent landuse/vegetation type (i.e., agriculture, non-forest, early regenerating forest); Other Forest Type includes forested habitat that is currently affected by existing disturbance or adjacent landuse/vegetation types within 100 meters of forested stand.
4 High NRF (Trask & Associates, 2013): forested habitat that is characterized by large trees (> 32 dbh), high canopy cover (>60 percent), and multistoried with sufficient down wood and snags to support prey species.
5 NRF (Trask & Associates, 2013; FWS, 2012; North et al., 1999): conifer-dominated forested habitat greater than 80 years that does not meet the definition of High NRF but has multi-storied structure with large overstory trees (20-30 inch dbh), moderate to high canopy closure greater than 60 percent, and sufficient snags and down wood.
6 Dispersal ONLY (FWS, 2012): an average tree diameter of 11 inches dbh or greater; conifer overstory trees; canopy closure greater than 40 percent in moist forests and greater than 30 percent in dry forests; open space beneath the canopy to all for NSO to fly; High NRF and NRF provide dispersal habitat, as well.
7 Capable Habitat (Trask & Associates, 2013): habitat that is forested or could become forested (i.e., recently harvested timberlands) that do not provide dispersal or NRF characteristics.
8 Total habitat only considers forested NSO habitat within the range of the NSO; non-capable habitat affected in range of NSO is included in table Q-9 in appendix Q.
9 Project components considered in calculation of habitat "Removed": Pacific Connector construction right-of-way, temporary extra work areas, aboveground facilities, permanent and temporary access roads (PAR, TAR), pipe storage yards, and hydrostatic locations.
10 Indirect Effects considers habitat within 100 meters of habitat removal as measured from the edge of habitat removal/edge of right-of-way/TEWA.
11 Acres identified as UCSAs have been incorporated into the 300-foot indirect effects. UCSAs would not be cleared of trees during construction and will not affect nesting structures or characteristics. These areas would be used to store forest slash, stumps and dead and downed log materials that would be removed and scattered across the right-of-way after construction during restoration and are considered as temporary insignificant understory habitat effects.

Summarized from table Q-9 in appendix Q.

[1] For detailed NRF/High NRF habitat available for each individual NSO and its habitat type (nest patch, core area, home range), refer to "pre-action" suitable habitat acres in table Q-7 in appendix Q. Interior forest includes habitat from late regenerating to old-growth.
[2] FWS et al. (2008) consider core areas with 50 percent or greater suitable NRF habitat and home ranges with at least 40 percent suitable NRF habitat to be necessary to maintain NSO life history function.
[3] Owl Status: 1) Known sites represent NSO activity sites provided by BLM and Forest Service biologists within the provincial analysis area; 2) Best Location sites represent pairs or resident singles documented by Pacific Connector during surveys in 2007 and 2008 with no nest site/activity center located, and; 3) PCGP assumed sites considered for analysis in this BA.

<u>Competition</u>

Since the listing of the NSO, recent reviews have more specifically identified competition with the barred owl in the Coast Range and wildfire in the relatively dry East Cascades and Klamath Mountain provinces, as greater threats than previously considered (FWS, 2011b; Anthony et al., 2006; FWS, 2004; Courtney et al., 2004; Kelley et al., 2003).

Barred owls are known to use a wide variety of forest types, including early successional habitats, and some authors have suggested that timber harvest activities may favor the species. For instance, fragmentation of forest habitat may have created favorable conditions for survival and reproduction of barred owls. By contrast, NSOs appear to be more generally associated with old growth forest or forests that are structurally complex (Courtney et al., 2004). Therefore, timber harvest may have increased overlap of the two species' preferred and potential habitats which has led to increased competition. Hicks et al. (2001) attempted to examine that hypothesis in the northern part of the range by determining the amounts of different habitat types surrounding NSO territories that either have or have not been invaded by barred owls. They detected no effect of surrounding habitat on the probability of replacement by competitive barred owls. Also, under the Plum Creek Habitat Conservation Plan, harvest was deferred for areas of nesting, roosting and foraging habitat around 30 productive NSO sites. After six years, only 10 sites had NSO presence – the rate of decline is very similar to that seen at other areas where timber harvest occurred.

Although survey design was not intended to locate or census barred owls or barred owl pairs, during surveys for NSOs conducted along the Pacific Connector pipeline route, barred owls were documented 79 times in 14 survey areas in 2007 (4 pairs), and 115 times in 14 survey areas in 2008 (8 pairs). Of the 194 barred owls documented, 33 were dispersed along the pipeline right-of-way within the Coast Range, 74 were documented within Klamath Mountains mostly along the eastern portion of the province, 21 were located in West Cascades, and 66 documented sites were located within the western portion of East Cascades province, of which seven were located while surveying the original Buck Lake route (see table 4.3.4-20). Ray Davis (2008b), a biologist with the Umpqua National Forest, provided an analysis using partial data (only 36 barred owl sites) provided in December 2007, that demonstrated barred owls located within the Pacific Connector pipeline occurred more often in marginal NSO suitable nesting, roosting, foraging habitat than the NSOs documented during 2007 surveys, which were generally located within the more contiguous and suitable NRF habitat within the Project Area. Reduction of suitable NSO habitat may have an effect on the NSO by providing a competitive advantage for barred owls, since some research and preliminary modeling by Davis (2007) has demonstrated that barred owls have a wider breadth of habitat use than the NSO and are more often located in marginal habitat than the NSO (Courtney et al., 2004).

Barred owls were documented in 44 of the 98 NSO home ranges during 2007/2008 PCGP survey efforts (see superscript "B" next to Site Name in table Q-7 in appendix Q), including five nest patches (two known NSO – UMP 0408 and UMP 0401, and three best location sites (PCGP 084.6, PCGP 097.6, and PCGP 165.8). A summary of barred owl locations for each physiographic province in respect to NSO home ranges and available suitable NRF habitat (high NRF and NRF) greater or less than 40 percent is provided in table 4.3.4-20. Habitat below the 40 percent available NRF habitat in the home range could be considered "marginal" habitat. Approximately 36 percent of the barred owls documented within NSO home ranges were documented in "marginal" habitat, and 51 percent of barred owls documented were located in NSO home ranges with more suitable NRF available (see >40 percent suitable NRF Habitat; table 4.3.4-20).

**Table 4.3.4-20**
**Summary of Barred Owl Locations Documented During 2007 and 2008 Northern Spotted Owl Surveys**

| Barred Owls Documented in 2007/2008 | Coast Range | | Klamath Mountains | | West Cascades | | East Cascades | | Total NSO Range | |
|---|---|---|---|---|---|---|---|---|---|---|
| | # NSO Home Ranges | # of Barred Owls | # NSO Home Ranges | # of Barred Owls | # NSO Home Ranges | # of Barred Owls | # NSO Home Ranges | # of Barred Owls | # NSO Home Ranges | # of Barred Owls |
| Total Documented outside of NSO Home Ranges | N/A | 33 | N/A | 74 | N/A | 21 | N/A | 60 | N/A | 194 |
| Total Documented within < 40 percent suitable NRF Habitat | 8 | 26 | 8 | 12 | 1 | 2 | 1 | 7 | 18 | 69 |
| Total Documented within > 40 percent suitable NRF Habitat | 1 | 1 | 13 | 40 | 8 | 19 | 4 | 18 | 26 | 98 |
| Total Documented within NSO Home Ranges | 9 | 27 | 21 | 52 | 9 | 21 | 5 | 25 | 44 | 167 |

Table Q-7 in appendix Q provides a subscript “B” where barred owls were documented in the home range, core area, and/or nest patch.

It is conceivable that construction of the proposed pipeline may serve as a corridor for barred owl expansion, but this is speculative. Review of available literature did not indicate that linear transportation corridors increase barred owl presence/expansion. If inclusion of these additional barred owl locations indicates that barred owls do occur more often in marginal northern spotted owl habitat than northern spotted owls do, then focus should be on currently suitable northern spotted owl habitat (see Habitat Condition 1 in table Q-7 in appendix Q) being brought below FWS recommended thresholds by the proposed Project, and areas currently below thresholds that the proposed Project could further impact (see Habitat Conditions 2 through 4 in table Q-8 in appendix Q). With the exception of the Coast Range physiographic province, the majority of barred owls documented were located within northern spotted owl home ranges with adequate amounts of suitable habitat (greater than 40 percent suitable habitat available in home range and greater than 50 percent suitable habitat available in the core area).

Effects to Prey

Cleared areas would remove suitable habitat for arboreal prey species (flying squirrels, red tree voles), but could improve habitat for non-arboreal species (western red backed voles, deer mice) adjacent to cleared areas. NSOs seldom venture far into non-forested stands to hunt, although it is likely they would cross the corridor at night to forage on both sides of the right-of-way. Edges can be areas of high prey availability, but also increased vulnerability (Zabel et al., 1995). Prey animals could be more exposed in the disturbed area and may move away from edges in the short term. Some minor changes in prey availability could occur as cover is disturbed and animals redistribute within the understory. Disturbance might attract other predators such as other owls, hawks, and mammals. This could increase competition for NSOs in the treatment area, but the exposure of prey could also benefit NSOs.

Some disturbance of habitat could improve forage conditions in remaining stands on both sides of the corridor by bringing more light and resources into the stand, stimulating forbs, shrubs, and other prey food. Once the initial impact of disturbance recovers (6 months to two years), the understory habitat conditions for prey food would increase over the next few years, until shrubs and residual trees respond to again close in the stand.

**Critical Habitat**

The FWS (2012a) determined the physical and biological habitat features that support nesting, roosting, foraging, and dispersal activities for northern spotted owls and are essential to the conservation of this species include the following primary constituent elements (PCEs): PCE1 – forested habitat in a variety of seral stages that support the northern spotted owl across its geographical range; PCE2 – forested habitat that provides for nesting and roosting, and could provide for foraging; PCE3 – habitat the provides for foraging; and PCE4 – habitat that supports dispersal of spotted owls, which could provide nesting, roosting, and foraging habitat, but could also be composed of other forest types between larger blocks of nesting, roosting, and foraging habitat. Within this analysis, PCEs would be similar to northern spotted owl habitat mapped for the PCGP Project: PCE1 would be all forested habitat affected within the range of the northern spotted owl; PCE2 would include high NRF as well as NRF; PCE3 would include NRF and high NRF; and PCE4 would include dispersal only habitat, as well as high NRF and NRF that provide dispersal habitat for the spotted owl.

Activities that disturb or remove the PCEs within designated CHUs might adversely modify the owl's critical habitat. These activities may include actions that would reduce the canopy closure of a timber stand, reduce the average dbh of trees in the stand, appreciably modify the multi-layered stand structure, reduce the availability of nesting structures and sites, reduce the suitability of the landscape to provide for safe movement, or reduce the abundance or availability of prey species (FWS, 1992b).

In contrast, activities that would have no effect on critical habitat's primary constituent elements almost certainly would not adversely modify the critical habitat. However, even though an action may not adversely modify critical habitat, it may still affect northern spotted owls (e.g., through disturbance) and therefore be subject to consultation under the jeopardy standard of Section 7 of the ESA (FWS, 1992b).

Approximately 37.4 miles of the proposed pipeline route crosses seven designated critical habitat sub-units, of which 35.0 miles cross NSO habitat: ORC-6, KLE-1, KLE-2, KLE-3, KLE-4, KLE-5, and ECS-1 (see table 4.3.4-21). Table Q-11 in appendix Q provides the amount of high NRF, NRF, dispersal only, capable, and non-capable habitat within each critical habitat unit by landowner that would be removed and modified, which is summarized below in table 4.3.4-21. With the exception of CHU ECS-1, all CHU subunits occur completely within NSO home ranges, and partially within NWFP LSRs and unmapped LSRs (see table Q-9 in appendix Q for overlap of CHUs with NWFP LSRs and unmapped LSRs).

**Table 4.3.4-21**

[1] General Location identifies areas within Northern Spotted Owl Groups (areas within NSO home ranges; see table Q-10 in appendix Q) and areas outside of NSO groups (outside of NSO home ranges).
[2] High NRF (Trask & Associates, 2013): forested habitat that is characterized by large trees (> 32 dbh), high canopy cover (>60 percent), and multistoried with sufficient down wood and snags to support prey species.
[3] NRF (Trask & Associates, 2013; FWS, 2012a; North et al., 1999): conifer-dominated forested habitat greater than 80 years that does not meet the definition of High NRF but has multi-storied structure with large overstory trees (20-30 inch dbh), moderate to high canopy closure greater than 60 percent, and sufficient snags and down wood.
[4] Dispersal ONLY (FWS, 2012a): an average tree diameter of 11 inches dbh or greater; conifer overstory trees; canopy closure greater than 40 percent in moist forests and greater than 30 percent in dry forests; open space beneath the canopy to all for NSO to fly; High NRF and NRF provide dispersal habitat, as well.
[5] Capable Habitat (Trask & Associates, 2013): habitat that is forested or could become forested (i.e., recently harvested timberlands) that do not provide dispersal or NRF characteristics.
[6] Total habitat only considers forested NSO habitat within NSO critical habitat units; non-capable habitat affected NSO critical habitats is included in table Q-11 in appendix Q.
[7] Project components considered in calculation of habitat "Removed": Pacific Connector construction right-of-way, temporary extra work areas, aboveground facilities, permanent and temporary access roads (PAR, TAR), pipe storage yards, and hydrostatic locations.
[8] UCSAs would not be cleared of trees during construction and will not affect nesting structures or characteristics. These areas would be used to store forest slash, stumps and dead and downed log materials that would be removed and scattered across the right-of-way after construction during restoration and are considered as temporary insignificant understory habitat effects.
[9] Indirect Effects considers habitat within 100 meters of habitat removal as measured from the edge of habitat removal/edge of right-of-way/TEWA.
[10] 30-foot Maintenance Corridor will be kept in a shrub/sapling state for the life of the project; all other habitat outside of the 30-foot maintenance corridor will be revegetated.
Note: More detailed information on BLM Districts and National Forests impacted in critical habitat units is located in table Q-11 in appendix Q. Overlap with LSRs can be reviewed in table Q-9 in appendix Q.

Overall, the proposed Project would remove 558.29 acres of northern spotted owl habitat from critical habitat units, of which 487.92 acres is NSO habitat or capable of becoming NSO habitat (106.51 acres of high NRF, 144.40 acres of NRF, 68.29 acres of dispersal only habitat, and 168.70 acres of capable habitat), of which 126.78 acres (28.00 acres in high NRF, 40.38 acres in NRF, 16.93 acres in dispersal only habitat, and 41.47 acres in capable) would be kept within an early seral state within the 30-foot maintenance corridor for the life of the Project (see table 4.3.4-21). Over the long-term, 361.14 acres of northern spotted owl habitat within critical habitat units would return to its original state (outside of the 30-foot operational corridor) and begin functioning as dispersal only habitat (see table 4.3.4-21). Table Q-11 in appendix Q provides further detail of critical habitat units affected, including landowner by physiographic province within or outside of interior forest.

In addition to direct loss of critical habitat and effects to PCEs due to loss that were summarized in table 4.3.4-21, the project's indirect effects to NSO that were discussed above (fragmentation, edge, and effects to interior forest) indirectly affect designated critical habitats and PCEs. Edge effects and effects to interior forest may induce changes to forest characteristics later in time and would indirectly affect PCEs. In particular, creation of isolated forest patches with large edge areas can create changes in microclimate, vegetation species, and predator-prey dynamics. Two main physical factors affecting and creating an edge microclimate are sun and wind (Forman, 1995; Chen et al., 1995, Harper et al., 2005) which could directly affect characteristics of nesting trees and could decrease canopy cover and stand conditions for future NSO habitat components described in the PCEs.

Interior forest has been defined as 100 meters (328 feet) from any existing edge of a contiguous forested stand (50 feet from canopy covered roads), including edges created by adjacent regenerating stands approximately 10 to 20 years old (see Harper et al., 2005). However effects of strong wind may extend beyond that distance (see Chen et al., 1995). Such effects are dependent on local conditions such as orientation of an edge; the magnitudes of change in humidity with distance from an edge are most extreme with south-facing edges, compared to east- and west-facing edges (see Figure 6 in Chen et al., 1995). Such effects may induce changes within PCEs. Long-term effects on edges and interiors of NSO habitat are less well defined and over time, edge effects will diminish as edges evolve from "hard" to "soft" (see for example, Peery and Henry, 2010).

There is considerable overlap of forest habitat, including interior forest that is within NSO CHUs and within LSRs. Long-term effects from removal of forest within critical habitat, NWFP LSRs, and unmapped LSRs by the proposed project would be expected. Most indirect effects to forested habitat within 100 meters of habitat removal occur in NSO habitat that has been previously affected by existing edge, such as roads, waterbodies, early seral forest, and nonforested habitat. Table Q-9 in appendix Q provides a more detailed tabulation of indirect effects to interior forest habitat within NSO critical habitat units and NWFP LSRs/unmapped LSRs by landowner and physiographic province.

<u>NWFP Late-Successional Reserves</u>

Additional habitat protection for the northern spotted owl was established when late successional reserves (LSRs) were adopted in the NWFP. Within the Provincial Analysis Area, northern spotted owl critical habitat units overlap with LSRs to varying degrees (see table Q-9 in appendix Q). The Pacific Connector pipeline crosses 21.8 miles of three allocated LSRs: RO

223 (BLM Roseburg District and Umpqua National Forest), RO 227 (Rogue River-Siskiyou National Forest), and RO 261 (BLM Coos Bay District and Roseburg District); see table 4.3.4-22.

There are three northern spotted owl activity centers that have been delineated on lands administered by Roseburg BLM that occur within the proposed PCGP Project area but occur on Matrix lands: P2199, P0361, and P2294. These areas are considered "unmapped LSRs" and are managed similarly as NWFP LSRs, as well as the occupied marbled murrelet stands that occur on Matrix lands, discussed above. Although these sites were identified as 100 acre core areas, recent activity has not been at these sites. For example, site P2199 is located between MPs 53.36 and 54.08 and recent activity for MSNO 2199B is over 1.25 miles southeast of P2199. Site P0361 is located between MPs 82.97 and 83.30 (MSNO 0361A) is over 0.75 mile northwest of this known spotted owl activity center. Site P2294 is located between MP 85.96 and 86.18; activity at this site and others has been monitored in the Klamath demographic for more than 20 years. Most recent activity at this site (P2294) was in 1994; however, the site remains in its current protected status by Roseburg BLM. Table Q-12 in appendix Q differentiates between the acres of unmapped LSRs that are occupied marbled murrelet stands or known spotted owl activity centers delineated on NWFP Matrix lands.

Table 4.3.4-22 summarizes the impact to northern spotted owl high NRF, NRF, dispersal, and capable habitat within each NWFP LSR and unmapped LSRs impacted (habitat removed or affected within UCSAs) by the proposed Project. Overall, the proposed Project would remove 395.96 acres from NWFP allocated late-successional reserves and unmapped LSRs (table Q-12 in appendix Q), of which 342.66 acres is NSO habitat or capable of becoming NSO habitat (106.28 acres of high NRF, 84.05 acres of NRF, 32.12 acres of dispersal only habitat, and 120.21 acres of capable habitat). After construction, approximately 90.01 acres (29.43 acres of high NRF, 24.05 acres of NRF, 8.77 acres of dispersal only habitat, and 27.76 acres of capable habitat) would be kept within an early seral state within the 30-foot maintenance corridor for the life of the Project (see table 4.3.4-22). Over the long-term, 252.65 acres of forested habitat within LSRs and unmapped LSRs would return to its original state (outside of the 30-foot operational corridor) and begin functioning as dispersal only habitat (see table 4.3.4-22). Table Q-12 in appendix Q provides NSO habitat affected within NWFP LSRs and unmapped LSRs, by landowner and physiographic province within and outside of interior forest.

LSRs and unmapped LSRs cover approximately 71,254 acres within the Provincial Analysis Area and provide approximately 41,261 acres of high NRF and NRF habitat (see table 4.3.4-8). The proportional amount of available NRF habitat that would be removed (190.33 acres) within NWFP LSRs and unmapped LSRs in the Provincial Analysis Area is 0.5 percent, while 0.2 percent of available NRF would be affected in the short-term within UCSAs (83.40 acres).

## Table 4.3.4-22
## Summary of High NRF, NRF, Dispersal, and Capable NSO Habitat Impacted within NWFP Late-Successional Reserves (LSRs) and Unmapped LSRs, Including Area within and outside of NSO Groups

| Landuse Allocation | General Location[1] | Miles NSO Habitat Crossed | High NRF Habitat[2] | | | | NRF Habitat[3] | | | | Dispersal Only Habitat[4] | | | | Capable Habitat[5] | | | | Total Acres[6] | | | |

1 General Location identifies areas within Northern Spotted Owl Groups (areas within NSO home ranges; see Table Q10 in Appendix Q) and areas outside of NSO groups (outside of NSO home ranges).
2 High NRF (Trask & Associates, 2013): forested habitat that is characterized by large trees (> 32 dbh), high canopy cover (>60 percent), and multistoried with sufficient down wood and snags to support prey species.
3 NRF (Trask & Associates, 2013; FWS, 2012; North et al., 1999): conifer-dominated forested habitat greater than 80 years that does not meet the definition of High NRF but has multi-storied structure with large overstory trees (20-30 inch dbh), moderate to high canopy closure greater than 60 percent, and sufficient snags and down wood.
4 Dispersal ONLY (FWS, 2012): an average tree diameter of 11 inches dbh or greater; conifer overstory trees; canopy closure greater than 40 percent in moist forests and greater than 30 percent in dry forests; open space beneath the canopy to all for NSO to fly; High NRF and NRF provide dispersal habitat, as well.
5 Capable Habitat (Trask & Associates, 2013): habitat that is forested or could become forested (i.e., recently harvested timberlands) that do not provide dispersal or NRF characteristics.
6 Total habitat only considers forested NSO habitat within the range of the NSO; see table Q-12 in appendix Q for effects to non-capable habitat in NWFP LSRs and unmapped LSRs.
7 Project components considered in calculation of habitat "Removed": Pacific Connector construction right-of-way, temporary extra work areas, aboveground facilities, permanent and temporary access roads (PAR, TAR), pipe storage yards, and hydrostatic locations.
8 Indirect Effects considers habitat within 100 meters of habitat removal as measured from the edge of habitat removal/edge of right-of-way/TEWA.
9 Acres identified as UCSAs have been incorporated into the 100-meter indirect effects. UCSAs would not be cleared of trees during construction and will not affect nesting structures or characteristics. These areas would be used to store forest slash, stumps and dead and downed log materials that would be removed and scattered across the right-of-way after construction during restoration and are considered as temporary insignificant understory habitat effects.
10 30-foot Maintenance Corridor will be kept in a shrub/sapling state for the life of the project; all other habitat outside of the 30-foot maintenance corridor will be revegetated.

Note: More detailed information on BLM Districts and National Forests impacted in critical habitat units is located in table Q-12 in appendix Q. Overlap with CHUs can be reviewed in table Q-9 in appendix Q.

Areas of Concern (AOCs)

The proposed Project traverses the Rogue/Umpqua Area of Concern between MPs 28.13 and 62.48 and MPs 82.71 and 111.11. BLM (2008b) indicated that timber harvesting on private lands within these identified AOCs has reduced the overall dispersal habitat and would likely decline further as harvesting continues. Removal of forested habitat within this AOC may further limit the dispersal ability of NSOs; however, within this area, the pipeline has been routed generally along existing roads and so should minimize the amount of forested habitat removed and/or creation of additional corridors, as well as limit negative impacts to NSO dispersal (see appendix Q-4 in appendix Q).

Table 4.3.4-22 provides acres of dispersal habitat available within the Rogue/Umpqua AOC by federal and non-federal lands within the three physiographic provinces in which it is located, as well as dispersal habitat (high NRF, NRF, and dispersal only habitat) that would be removed or modified by the proposed Project. It is not anticipated that use of dispersal habitat (high NRF, NRF, and dispersal only habitat) within UCSAs would remove the function of the dispersal habitat. Within the Coast Range physiographic province, the removal of 104.3 acres of dispersal habitat within the Rogue/Umpqua AOC would result in a total loss of 0.2 percent of available dispersal habitat in the Coast Range Provincial Analysis Area (67,193 acres), and removal of approximately 295.0 acres of dispersal habitat within the Klamath Mountains physiographic province would result in a total loss of 0.5 percent of available dispersal habitat in the Klamath Mountains Provincial Analysis Area (58,357 acres; see table 4.3.4-9). No dispersal habitat would be impacted (removed or modified) within this AOC in the West Cascades physiographic province. Approximately 92.73 acres of total dispersal habitat would be left in a permanent herbaceous/shrub state along the 30-foot maintenance corridor but is not expected to limit dispersal of spotted owls. Over the life of the project, the 306.59 acres of dispersal habitat affected outside of the 30-foot maintenance corridor would be reforested/replanted and begin functioning as dispersal only habitat. Approximately 53 of the 98 NSO home ranges included within this BA would have dispersal habitat removed in the AOCs (table 4.3.4-9)

**Cumulative Effects**

FWS and NMFS describe cumulative effects (50 CFR § 402.02) as the result of future actions by state or private entities, not involving federal actions, but reasonably certain to occur in the action area considered in this biological assessment. Future federal actions that are unrelated to the proposed action are not considered here because they require separate consultation pursuant to section 7 of the ESA. The Pacific Connector pipeline would not be operational until at least 2017. Consequently, the foreseeable future required for cumulative effects analysis would actually occur before implementation of the proposed action, not after its implementation, which is more often the case.

[1] High NRF (Trask & Associates, 2013): forested habitat that is characterized by large trees (> 32 dbh), high canopy cover (>60 percent), and multistoried with sufficient down wood and snags to support prey species.

[2] NRF (Trask & Associates, 2013; FWS, 2012a; North et al., 1999): conifer-dominated forested habitat greater than 80 years that does not meet the definition of High NRF but has multi-storied structure with large overstory trees (20-30 inch dbh), moderate to high canopy closure greater than 60 percent, and sufficient snags and down wood.

[3] Dispersal ONLY (FWS, 2012a): an average tree diameter of 11 inches dbh or greater; conifer overstory trees; canopy closure greater than 40 percent in moist forests and greater than 30 percent in dry forests; open space beneath the canopy to all for NSO to fly; High NRF and NRF provide dispersal habitat, as well.

[4] Project components considered in calculation of habitat "Removed": Pacific Connector construction right-of-way, temporary extra work areas, aboveground facilities, permanent and temporary access roads (PAR, TAR), pipe storage yards, and hydrostatic locations.

[5] UCSAs would not be cleared of trees during construction and will not affect nesting structures or characteristics. These areas would be used to store forest slash, stumps and dead and downed log materials that would be removed and scattered across the right-of-way after construction during restoration and are considered as temporary insignificant understory habitat effects.

[6] 30-foot Maintenance Corridor will be kept in a shrub/sapling state for the life of the project; all other habitat outside of the 30-foot maintenance corridor will be revegetated.

Cumulative effects to NSO would be generated by timber harvesting and other sources of nesting, roosting, and or foraging (NRF) habitat losses on non-federal lands in the foreseeable future. High NRF is considered habitat that is characterized by large trees (> 32 dbh), high canopy cover (>60 percent), and multistoried with sufficient down wood and snags to support prey species (see Section 4.3.4.1, above). Suitable NRF consists of conifer-dominated stands older than 80 years, and are multi-storied in structure with large overstory trees (20-30 inch dbh), moderate to high canopy closure greater than 60 percent, and sufficient snags and down wood but does not meet the definition of High NRF. As defined, High NRF and NRF NSO habitats correspond with Late Successional-Old Growth (LSOG) forests.

Areas of LSOG forest have been monitored as a component of the Northwest Forest Plan (NWFP). In Oregon, LSOG was evaluated in 1996 (Moeur et al., 2005) and in 2006 (Moeur et al., 2011). Differences in areas of LSOG forests were described in the four physiographic provinces that coincide with the PCGP project that showed an overall decline of LSOG on all lands. Most of the losses in LSOG on federal lands were attributed to large fire events including the 2002 Biscuit Fire in the Klamath Mountains, the 2003 B&B Fire in the Western Cascades, and the 2003 B&B Fire and Davis Fire in the Eastern Cascades (Moeur et al, 2011). However, losses associated with wildfire were negligible on non-federal lands where most of the decline in LSOG was due to timber harvest, primarily concentrated in the Oregon Coast Range province (see Table 7 in Moeur et al., 2003)

In 2012, there were 6,298 acres of High NRF habitat and 10,852 acres of NRF habitat on non-federal lands within the Provincial Analysis Area (see table 4.3.4-5 in Section 4.3.4.2, above) in all four Physiographic Provinces, combined. From 1996 to 2006 there was an overall net loss of LSOG on non-federal lands within the Coast Range province (-17.1 percent), Klamath Mountains province (-6.7 percent), Western Cascades province (-10.8 percent), and Eastern Cascades province (-12.6 percent) provinces (see Table 7 in Moeur et al., 2011). Percent loss of LSOG on non-federal lands during the 10-year period was used as the basis for the annual loss of High NRF and NRF habitats, included in table 4.3.4-24. Those rates of decline on non-federal lands were assumed to be constant over time within the Provincial Analysis Area. Areas of High NRF and NRF habitats present in 2012 would be expected to decline at the annual rates of loss specific to each Physiographic Province with a net loss in 2017. Using the annual rates of LSOG loss, there would be an estimated 5,997 acres of High NRF and 10,348 acres of NRF habitats within the analysis area on non-federal land by the time the PCGP project is expected to be implemented in 2017 (see table 4.3.4-24).

The Project would remove 50.79 acres of High NRF habitat and 85.04 acres of NRF habitat on non-federal (state and private) lands (see table 4.3.4-13 in Section 4.3.4.3) in all four Physiographic Provinces, combined by 2017. The amount of High NRF habitat removed would be 0.85 percent of the High NRF habitat remaining on non-federal lands (5,997 acres) within all four provinces of the analysis area by 2017. Likewise, the amount of NRF habitat removed by the PCGP project would be 0.82 percent of the NRF habitat remaining on non-federal lands (10,348 acres) within all four provinces of the analysis area by 2017. When compared to the estimated amount of NSO habitat on non-federal land within the analysis area, the PCGP project would affect a total of 135.83 acres, which would be 0.83 percent of the total High NRF and NRF habitat available within the foreseeable future in 2017.

## Table 4.3.4-24
## Estimates for Losses of Northern Spotted Owl Nesting, Roosting, and Foraging Habitat on Non-Federal Land within the Provincial Analysis Area by 2017, with PCGP Project-Related Effects on Non-Federal Land in Relation to the Expected Cumulative Effects

| Physiographic Province | LSOG Area on Non-federal Land in Analysis Area in 2012 [1] | | | Loss of LSOG in Province, Between 1996 and 2006 [2] | | LSOG Area on Non-federal Land in Analysis Area Expected in 2017 | | | LSOG Removed by PCGP on Nonfederal Land in Analysis Area in 2017 [3] | | | Percent of LSOG in Analysis Area Expected in 2017 Likely to be Affected by PCGP | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | High NRF (acres) | NRF (acres) | Total LSOG (acres) | Percent Change from 1996 | Percent Change per Year | High NRF (acres) | NRF (acres) | Total LSOG (acres) | High NRF (acres) | NRF (acres) | Total LSOG (acres) | High NRF | NRF | Total LSOG |

[3] Data from table 4.3.4-13 in Section 4.3.4.3.

#### 4.3.4.4 Conservation Measures

**Avoidance, Minimization, and Rehabilitation / Restoration:** Conservation measures have been proposed by Pacific Connector to minimize construction and operation impact to northern spotted owl habitat within the Provincial Analysis Area. Those measures have been compiled in table 2C in appendix N. Specific conservation measures that would benefit northern spotted owls include those that:

- Minimize removal of forest by incorporating UCSAs into the Project design;
- Utilize two-year construction schedule to minimize the overall temporary extra work areas;
- Flag large diameter trees on edges of construction right-of-way or temporary work areas where feasible to save from clearing;
- Minimize soil erosion during and after construction;
- Ensure that all trash, food waste, and other items attractive to crows, jays, and other corvids will be contained and removed from the project area on a daily basis to minimize potential predation of spotted owl nestlings;
- Use logging methods to minimize damage to adjacent trees when clearing the right of way to reduce potential infestation from forest pathogens and insects;
- Minimize potential for establishment of invasive vegetation and establish control of noxious weeds; and
- Route the pipeline through previously disturbed lands near LSRs so that impacts to these areas are minimized.

Pacific Connector has also proposed measures to rectify, repair, and rehabilitate and otherwise reduce impact to forested habitats once construction of the Pacific Connector pipeline is complete. Those measures have been compiled in table 3C in appendix N. Specific conservation measures that would benefit NSOs include those that:

- Replant conifer species outside of the 30-foot wide maintenance corridor after construction, which will contribute to the reestablishment of native vegetation and soften the edge effect created from construction of the PCGP Project;
- Contribute to forest habitat structural diversity (e.g., snags and downed timber); and
- Minimize potential for increased human use of the reclaimed construction right-of-way and intrusion into undisturbed habitats.

Plans included in the appendices of Pacific Connector's POD will also minimize effects to northern spotted owl habitat and/or nesting spotted owls. The Leave Tree Protection Plan describes the preconstruction surveys that will be completed to clearly mark the boundaries of the projects certificated working limits, and procedures to identify individual trees within and along the edges of the certificated work limits that can be conserved or left standing, as well as BMPs that would be employed to minimize damage to trees within UCSAs and protect trees not removed from the construction right-of-way (see Appendix P to the POD, available upon request). An Integrated Pest Management Plan (see Appendix N to the POD, available upon request) describes BMPs to address the control of noxious weeds, invasive plants, forest pathogens, and soil pests, as well as describes measures to minimize the potential spread of invasive species and potential adverse effects of control treatments. The Blasting Plan and Air Noise and Fugitive Dust Plans (see Appendices C and B to the POD, respectively – available upon request) provide mitigation measures and monitoring plans to minimize noise effects to nesting spotted owls during construction of the PCGP Project.

During the project route selection and construction footprint design processes (i.e., placement and size of temporary extra work areas), Pacific Connector determined a pipeline alignment that would ensure the long-term safety and integrity of the proposed pipeline through geotechnical evaluations while attempting to minimize adverse impacts to northern spotted owl nest patches, core areas, critical habitat, LSRs, and otherwise potential suitable habitat. However, not all designated critical habitat, LSRs, suitable habitat, and known northern spotted owl nest patches and core areas could be avoided. Major and minor route alternatives have been considered and incorporated into the Proposed Route that minimize effects to northern spotted owl and habitat (see Resource Report 10/Sections 10.5 and 10.6 in the FERC Certificate application). Pacific Connector prepared an Avoidance and Minimization Plan for marbled murrelet and northern spotted owl (see appendix V) which identifies the additional measures that have been incorporated into the project design to reduce impacts to both marbled murrelets and northern spotted owls. This avoidance plan was developed through consultations with the FWS and the cooperating agencies (Interagency Habitat Quality Subgroup-Micro Siting Working Group, June 4, 2008). Application of measures outlined in the plan would minimize the impacts to suitable NSO habitat by 1) converting TEWAs to UCSAs to reduce the amount of suitable habitat removed by the Project, 2) moving TEWAs to avoid impacts to suitable habitat within core areas, and 3) moving the pipeline alignment to avoid NSO nest patches. A "Standard Rules Set" was developed during the meeting to further minimize effects to NSO nest patches, and this would be implemented prior to or concurrent with tree felling. The Standard Rules Set measures include:

- identify potential nest trees to be allowed to remain standing within TEWAs or edge of right-of-way;
- identify TEWAs to be reduced in size or eliminated to reduce removal of suitable habitat;
- identify any additional minor route adjustments that would not alter constructability but would further reduce removal of suitable habitat;
- identify any previously unknown nest trees discovered and assurance that they are properly protected by applying seasonal restrictions associated with similar locations along the Project alignment; and
- support of EIs by qualified biologists to identify habitat or potential nest trees.

Prior to timber clearing, Pacific Connector will have experienced biologists cruise northern spotted owl core areas and nest patches where high NRF and NRF habitat will be modified by PCGP construction and mark trees that currently have northern spotted owl nesting structures. Pacific Connector will avoid removal of those marked trees, if feasible. To further minimize impact to northern spotted owls, Pacific Connector will remove timber outside of the entire northern spotted owl breeding season (after September 30 and before February 28) within at least 0.25 mile of activity centers (known best location, and PCGP assumed sites) to ensure that nesting spotted owls and owlets are not felled. Additionally, to minimize disturbance within forested areas, Pacific Connector has designated nearly 638.6 acres (see table 4.3.4-13) of UCSAs within the range of northern spotted owls that will not be cleared of trees but be used to store forest slash, stumps, and dead and downed log materials during construction that will be scattered across the right-of-way after construction and during restoration. The UCSAs will be useful for the construction of the PCGP Project while not requiring removal of trees or understory vegetation, as well as allow the maintenance of high NRF, NRF, dispersal, and capable habitat function. Where feasible, Pacific Connector would leave large trees on the edges of the construction right-of-way and TEWAs throughout the Project area to benefit the northern spotted owl and other late-successional-dependent wildlife species.

Construction of the proposed Project will occur within range of the northern spotted owl during the breeding season; however, where activity centers (known, best location, PCGP assumed) occur within 0.25 mile of the proposed Project, construction will occur after the critical breeding period (after July 15). Construction within 0.25 mile of activity centers will occur after timber has been felled outside of the breeding season. During construction, Pacific Connector would ensure that the construction contracts include stipulations ensuring that all trash, food waste, debris, and other items attractive to crows, jays, and other corvids would be picked up and removed from the Project area on a daily basis during the breeding season to minimize potential predation of northern spotted owlets. Pacific Connector's EI's would be responsible for overseeing that the construction contractor is adequately following these stipulations.

Following construction, approximately 1,741 acres of affected forested lands (the construction right-of-way and temporary extra work areas outside of the 30-foot maintenance right-of-way; table 4.3.4-13) would be replanted and allowed to return to pre-construction condition with tree species in the approximate proportion to those species removed. Tree establishment would be allowed to occur up to within 15 feet on either side of the pipeline centerline. Over the long-term (80 years or more), revegetated areas outside of the 30-foot maintenance corridor may achieve tree structural characteristics comparable to trees that would be removed, had they not been affected, and could serve as northern spotted owl suitable habitat. Although nesting function may not be reestablished over the long-term, the habitat may provide structures suitable for foraging, roosting, and dispersal as it regrows.

One year prior to construction activities, Pacific Connector will conduct spot check surveys within 0.25 mile of Project activities in known, best location, and PCGP assumed NSO home ranges, where permitted, to supplement the full survey efforts conducted in 2007 and 2008, as recommended by FWS (see McCorkle, 2012; appendix S – ROC). These surveys would determine if the site is still occupied or has moved, attempt to locate the nest trees per protocol, determine if best location or PCGP assumed owl sites are occupied, adjust the construction schedule to apply seasonal constraints, if necessary, and apply minor route adjustments to further minimize impact, if feasible. The spot check surveys will include at least three night visits spaced a minimum of 7 days apart to confirm occupancy status (FWS, 2012a). If occupancy is documented within 0.25 mile of Project activities during spot check surveys, all construction activity within 0.25 mile of that proposed site would not occur until after the critical breeding period (after July 15), and timber clearing would occur in the fourth quarter of Year One outside of the breeding period. If spotted owls are not detected during spot-check surveys, construction of the PCGP Project could occur during the breeding season; however, spot checks should be repeated each year if construction activities during the critical breeding season are anticipated (FWS, 2012a).

**Compensatory Mitigation**: Since effects by the proposed action could not be fully mitigated on-site whether by avoidance, minimization, or restoration measures, Pacific Connector has developed a Compensatory Mitigation Plan (CMP) that provides a means to compensate for unavoidable impacts to listed species and their habitat, including northern spotted owls. The CMP combines agency-recommended projects to enhance existing forested and aquatic habitats, re-designation of allocated forest lands (NWFP), and acquisition of forested habitats to compensate for habitats affected by the project. The CMP includes opportunities for funding projects in southern Oregon that could be implemented by federal land managing agencies, state or local resources agencies, or conservation groups. Projects or actions that are being considered include permanent reclamation of existing disturbances within capable habitat, such as roads within LSRs that are no longer required for resource management. These mitigation funds would also be used to conduct noncommercial thinning treatments or other silvilcultural projects to create or accelerate development of old growth characteristics in trees elsewhere on federal land. Pacific Connector also proposes to acquire easements or properties as conservation parcels within the range of the species that would preserve and protect potentially suitable and recruitment habitat as mitigation for Project impacts. These easements or parcels could be deeded to a federal agency or a conservation organization or trust.

The BLM and Forest Service have proposed a suite of off-site mitigation projects to address the effects of the PCGP Project on various resources within the project area and will ensure the Project can be consistent with the objectives of BLM Resource Management Plans and Forest Service Land and Resource Management Plans. The CMP provides the BLM and Forest Service mitigation summaries which describe the various offsite mitigation projects as a supplemental mitigation to address important issues or land management plan objectives that cannot be acceptably mitigated on-site (Attachment 1 and Attachment 2 to the CMP, appendix O). A summary of BLM and Forest Service mitigation projects are provided in Table 1 of the CMP (see appendix O). Pacific Connector has assessed the BLM's mitigation projects in relation to the Project effects by watershed, along with the proposed mitigation projects proposed by the Forest Service, that have been approved in principle by Pacific Connector (see Attachment 4 to the CMP, appendix O). The BLM and Forest Service mitigation projects have also been reviewed with respect to the Project's responsibilities to mitigate for the potential effects to ESA listed species and their habitats. The BLM's and Forest Service's mitigation summaries list their proposed projects by watershed.

The following projects or actions, including those proposed by BLM and Forest Service are also being considered as compensation in the CMP:

- decommissioning roads in LSRs that are identified by the BLM and Forest Service and are no longer required for management activities;
- acquiring title or easement to private lands in the range of NSO that could be managed/preserved as late successional habitat;
- funding the conversion of matrix lands to LSR and enhancement of converted lands;
- funding non-commercial thinning treatments or other silvicultural projects to create or accelerate development of old growth characteristic elsewhere on federal land;
- funding to conduct silviculture (pre-commercial and commercial thinning) projects to reduce fuel load to minimize the risk of stand-replacing fires; and/or
- creating snags in adjacent habitat.

FWS has prepared Conservation Frameworks for the Pacific Connector Gas Pipeline Project that provides direction and methods to quantify and categorize the impact to northern spotted owls [and marbled murrelets] and their habitat (see appendix Z4) and means to offset the calculated impacts. In some instances, projects proposed by BLM and Forest Service would be considered applicable to offsetting the impact calculated and described, below.

The initial Framework (Trask & Associates, 2013) and subsequent revisions through personal communications provides guidance for categorizating effects to NSO habitat within home ranges into High Impact, Moderate Impact, and Low Impact categories based on the amount and type of NSO Habitat removed, as well as the area the habitat is removed within the habitat use type – home range, core area, and/or nest patch (see NSO habitat impact categorization for each NSO home range in appendix Z2). The Habitat Impact Category assigned to each NSO home range (appendix Z2) is then applied to acres of NSO habitat affected by the proposed Action (summarized in table 4.3.4-13 from table Q-9 in appendix Q). NSO habitat affected outside of NSO home ranges or within NSO home ranges that were provided a "No Impact Category" in appendix Z2 are considered areas of "Low Impact", as well. Table 4.3.4-25, below provides a summary of NSO habitat affected by Habitat Impact Category within and outside of interior forest. No NSO home range was provided a "Severe Impact" category because Pacific Connector would not remove a known nest site or activity center or cause a NSO home range to become nonfunctional (loss of the territory).

**Table 4.3.4-25**
**Summary of NSO Habitat Removed[1] from the Proposed Action by Habitat Impact Category**

| Habitat Impact Category[1] | Interior Forest[2] | Milse Crossed | NSO Habitat Removed (acres) | | | | |
|---|---|---|---|---|---|---|---|
| | | | High NRF[3] | NRF[4] | Dispersal Only[5] | Capable[6] | Total Habitat Removed |
| High | Interior Forest | 16.1 | 59.11 | 42.87 | 63.02 | 56.41 | 221.41 |
| | Other | 57.4 | 136.46 | 185.32 | 186.40 | 404.20 | 912.38 |
| High Impact Total | | 73.5 | 195.57 | 228.19 | 249.42 | 460.61 | 1,133.78 |
| Moderate | Interior Forest | 0.4 | 0.00 | 0.03 | 5.62 | 0.46 | 6.10 |
| | Other | 5.3 | 0.00 | 4.68 | 19.28 | 53.78 | 77.74 |
| Moderate Impact Total | | 5.7 | 0.00 | 4.71 | 24.89 | 54.24 | 83.84 |
| Low | Interior Forest | 1.3 | 0.00 | 0.00 | 2.60 | 13.59 | 16.19 |
| | Other | 5.0 | 0.00 | 2.76 | 24.81 | 58.29 | 85.85 |
| Low Impact Total | | 6.3 | 0.00 | 2.76 | 27.41 | 71.88 | 102.04 |
| Outside Home Range | Interior Forest | 8.6 | 3.05 | 30.59 | 69.66 | 19.24 | 122.53 |
| | Other | 53.4 | 18.06 | 81.87 | 320.13 | 416.40 | 836.46 |
| Outside Home Range Total | | 62.1 | 21.11 | 112.46 | 389.79 | 435.63 | 959.00 |
| Overall Total | Interior Forest | 26.4 | 62.16 | 73.49 | 140.89 | 89.69 | 366.23 |
| | Other | 121.1 | 154.52 | 274.62 | 550.62 | 932.67 | 1,912.43 |
| Overall Total | | 147.5 | 216.68 | 348.11 | 691.51 | 1,022.36 | 2,278.66 |

[1] see Trask & Associates (2013) for Impact Categorization factors and appendix Z2 for individual Habitat Impact Category assessments for each NSO Home Range.
[2] Interior Forest: not affected by existing disturbance (i.e., roads, existing corridors) or adjacent landuse/vegetation type (i.e., agriculture, non-forest, early regenerating forest); Other Forest Type includes forested habitat that is currently affected by existing disturbance or adjacent landuse/vegetation types within 100 meters of stand/MAMU habitat type
[3] High NRF (Trask & Associates, 2013): forested habitat that is characterized by large trees (> 32 dbh), high canopy cover (>60 percent), and multistoried with sufficient down wood and snags to support prey species.
[4] NRF (Trask & Associates, 2013; FWS, 2012; North et al., 1999): conifer-dominated forested habitat greater than 80 years that does not meet the definition of High NRF but has multi-storied structure with large overstory trees (20-30 inch dbh), moderate to high canopy closure greater than 60 percent, and sufficient snags and down wood.
[5] Dispersal ONLY (FWS, 2012): an average tree diameter of 11 inches dbh or greater; conifer overstory trees; canopy closure greater than 40 percent in moist forests and greater than 30 percent in dry forests; open space beneath the canopy to all for NSO to fly; High NRF and NRF provide dispersal habitat, as well.
[6] Capable Habitat (Trask & Associates, 2013): habitat that is forested or could become forested (i.e., recently harvested timberlands) that do not provide dispersal or NRF characteristics.

The FWS (Trask & Associates, 2013) recommends two primary actions to offset indirect impacts to NSO habitats: land acquisition of like-to-like habitats affected by the Project (high NRF, NRF, dispersal, and capable) and/or silvicultural treatments to offset effects to dispersal and capable habitat on federal lands. Following direction within the Habitat Conservation Framework (Trask & Associates, 2013), individual assessments included in appendix Z2 for each NSO home range (known, best location, and PCGP assumed) have been used to evaluate and determine the type and amount of mitigation recommended for impacts from the proposed action. The CMP identifies the amount of habitat acquisition proposed by Pacific Connector to offset effects of the proposed project on NSO habitat (in consideration of MAMU habitat overlap; see Section 1.6 in appendix O).

FWS provided additional guidance to Pacific Connector on January 24, 2014 to assess and mitigate direct effects (disruption and disturbance) to NSO by the Proposed Action (Trask & Associates, 2014). This new guidance essentially decoupled the direct effects from the previous guidance provided to Pacific Connector in June 2013 (see Trask & Associates, 2013) and outlined a new method to categorize direct effects to NSO pairs into the following Disruption-Disturbance (D/D) Impact Categories: High Impact, Moderate Impact, Low Impact, Low Impact – no mitigation, and No Impact. The assessment considers the timing, types, and location of Project-related activities in relation to NSO activity centers that could result in disturbance or disruption of NSO to assist in determining a D/D Impact Category for each Project activity for each NSO activity center. In many instances an NSO activity center could experience disturbance from more than one proposed activity (i.e., construction effects and proposed use of existing access roads; see D/D Impact Categorization in appendix Z2). Pacific Connector determined the D/D Impact Category for each NSO activity center within 0.25 mile of proposed project activities in appendix Z2, and included a list of factors considered when determining if an activity would be considered a disruption, a disturbance, or have no effect on each NSO activity center, including consideration of the site-specific noise evaluation for each NSO activity center. The resulting D/D Impact Category is also included for each NSO activity center in table Q-8 in appendix Q. The FWS (Trask & Associates, 2014 – appendix Z4) identified a couple of opportunities to offset the direct effects to NSO, including financial support of established programs that would assist in the recovery of the species (e.g., the barred owl control experimental program). Table 4.3.4-26 summarizes the number of NSO activity centers by D/D Impact Category and status of NSO activity center: Moderate Impact, Low Impact, and No Impact. No NSO activity center was assigned a “High” category because within 0.25 mile of an NSO activity center, Pacific Connector would remove timber outside of the entire breeding period and construct outside the critical breeding period (March 1 to July 15). Following direction within the D/D Conservation Framework (Trask and Associates, 2014), individual assessments included in appendix Z2 for each NSO home range (known, best location, and PCGP assumed) have been used to determine the funding necessary for barred owl mitigation to offset impacts (see appendix O).

**Table 4.3.4-26**
**Summary of NSO Activity Centers within the PCGP Project Area Assigned a D/D Impact Category**

| NSO Status | Disruption/Disturbance Impact Category | | | | Overall Total |
|---|---|---|---|---|---|
| | High | Moderate | Low | No/None | |
| Known | 0 | 1 | 25 | 46 | 72 |
| Best Location | 0 | 2 | 7 | 8 | 17 |
| PCGP Assumed | 0 | 0 | 5 | 4 | 9 |
| Total | 0 | 3 | 37 | 58 | 98 |

This CMP has been developed in close consultation with the Forest Service and BLM. Pacific Connector has been and will continue to be in consultation with the U.S. Fish and Wildlife Service (FWS) during development of the CMP.

#### 4.3.4.5 Determination of Effects

**Listed Species**

The Project **may affect** NSOs because:

- Suitable habitat is available within the Provincial Analysis Area.
- NSO pairs and resident singles have been located within the Provincial Analysis Area during survey efforts.

The Project is **likely to adversely affect** NSOs because:

- Noise from blasting and helicopter use within 0.25 mile of NSO sites during the late breeding season would occur and could increase the risk of predation to fledglings that are generally not as able to escape as adults during the latter part of the breeding season.
- The proposed action would remove high NRF and NRF habitat within the range of the NSO including effects to nest patches, core areas, and home ranges of known, best location, and PCGP assumed owls, some of which are currently below thresholds needed to sustain NSOs. Once suitable NRF habitat is reduced or modified in NSOs' home ranges, there is an increased likelihood that NSOs remaining in the Project area would be subject to:
  - displacement from nesting areas;
  - concentration into smaller, fragmented areas of suitable nesting habitat that may already be occupied;
  - increased interspecific (with barred owls) and intraspecific competition for suitable nest sites;
  - decreased survival due to increased predation and/or limited resource (forage) availability; and
  - diminished reproductive success for nesting pairs.
- The proposed Project would remove and modify high NRF, NRF, dispersal, and capable habitat for NSOs throughout the Project area, including removal of habitat within the home range of 90 NSOs, 56 of which are currently below sustainable threshold levels of suitable habitat for continued persistence in their home range and/or core area.

- The proposed Project would bring two NSO core areas below the 50 percent NRF threshold (one known NSO activity center and one best location activity center).

**Critical Habitat**

A **may affect** determination is warranted for NSO critical habitat because:

- The Project would occur within designated NSO critical habitat; and
- The Project would result in habitat impacts within designated critical habitat areas.

A **likely to adversely affect** determination is warranted for NSO critical habitat because:

- The proposed action would remove or potentially downgrade PCEs in critical habitat sub-units ORC-6, KLE-1, KLE-2, KLE-3, KLE-4, KLE-5, and ECS-1 as defined in the Final Rule designating critical habitat for the NSO (FWS, 2012).

### 4.3.5 Streaked Horned Lark

#### 4.3.5.1 Species Account and Critical Habitat

**Status**

The streaked horned lark (*Eremophila alpestris strigata*) was listed as threatened under the ESA in a final rule published Octorber 3, 2013 (FWS, 2013i). The species had been proposed for listing in October 2012 (FWS, 2012j).

**Threats**

Loss of nesting habitat in native prairies has lead to streaked horned larks nest on artificially maintained short grass areas adjacent to several airports in Washington and Oregon (FWS, 2013i). Maintenance mowing during the nesting period affects the species. Industrial developments in open areas has altered breeding and wintering habitat. Native grasslands have become isolated and intermingled with residential, municipal, and farm lands. In coastal areas, exotic beachgrasses have invaded dune habitats that were used for nesting by horned larks and have reduced nesting habitats in some area. In addition, predation of streaked horned lark nests has be a primary source of nest failure (FWS, 2010h). Predation can have a significant effect on small, declining, isolated populations. Those same population characteristics have contributed to overall loss of genetic diversity in the subspecies which may contribute lower fecundity. Other known or potential threats include climate change, unpredictable extreme weather events, aircraft and vehicle-related mortality (strikes), application of toxic herbicides and/or pesticides, and nest losses due to recreationists, especially along the coast (FWS, 2013i).

**Species Recovery**

No recovery information is available for the streaked horned lark.

**Life History, Habitat Requirements, and Distribution**

There are three subspecies of horned lark in Oregon (Marshall et al., 2006): the streaked horned lark, *E. a. strigata* (Willamette Valley, along the northern coast, from Multnomah County south to Lane County, and historically in the Rogue Valley of Jackson County), the subspecies *E. a. alpina* (breeds at higher elevations in the Washington Cascades), subspecies *E. a. merrilli* (breeds in intermountain valleys in Sherman, Wasco, Morrow, Klamath, and Lake counties), and subspecies *E. a. lamprochroma* (breeds in lowland shrub-steppe and agriculture in Lake, Harney, Umatilla, Wallowa, and Baker Counties). The subspecies also occurs on remnant prairies in the Puget Trough lowlands and along the outer coast of Washington (Stinson, 2005).

In Washington, horned larks on the outer coasts and on Columbia River islands occur year round while birds in the Puget lowlands are mostly migratory. Nests were initiated by early May and breeding completed by the end of July although clutch initiation along the coast may be earlier and later than inland (Pearson and Hopey, 2005). Clutch sizes ranged from 2 to 5 in coastal habitats, 2 to 4 in the Puget lowlands (Pearson and Hopey, 2005) with no significant difference between the two habitats. Nesting habitats include open grasslands, beaches and dredge spoils islands with sparse vegetation, and agricultural fields, preferring bare ground to vegetation several inches tall (Stinson, 2005). The same preferences are assumed for birds in Oregon: horned larks breed in the Willamette Valley and wintering flocks there may be a mixture of several subspecies (FWS, 2010). Wintering habitats used by migrating birds are also open; use of ocean beaches, dunes and airports have been described (Stinson, 2005).

**Population Status**

Estimates from 2010 were 330 streaked horned larks that bred at 12 sites in Washington and at least 500 birds in Oregon but there had been no comprehensive surveys conducted in the Willamette Valley. They appeared to be extirpated from British Columbia (FWS, 2010h). At the time of listing in 2013, streaked horned larks were declared extirpated from the northern Puget Trough, the Washington coast north of Grays Harbor, the Oregon coast, and the Rogue and Umpqua valleys in southwest Oregon (FWS, 2013i). The current rangewide population is estimated at 1,170 to 1610 birds with approximately 150-170 breeding in the Puget lowlands, 120 – 140 horned larks breeding on the Washington coast and Columbia River islands, and 900 – 1,300 streaked horned larks breeding in the Willamette Valley (FWS, 2013i).

**Critical Habitat**

Critical habitat was designated in a final rule (FWS, 2013j) at the same time streaked horned larks were listed as threatened. There are three critical habitat units in Washington and Oregon including the Washington Coast, islands in the Columbia River, and the Willamette Valley in which there are three subunits. Primary Constituent Elements for streaked horned lark critical habitat include (FWS, 2013j) areas having a minimum of 16 percent bare ground with sparse, low growing vegetation composed primarily of grasses and forbs ≤13 inches (33 cm) tall within the following site situations:

1. Large (300-acre (120-ha)), flat (with 0 to 5 percent slope) areas within a landscape context that provides visual access to open areas such as open water or fields, or
2. Areas smaller than described in (1), but provide visual access to open areas such as open water or fields.

All of the units designated as critical habitat are currently occupied by the streaked horned lark and contain the primary constituent elements to support the life-history needs of the subspecies (FWS, 2013j).

### 4.3.5.2 Environmental Baseline

**Analysis Area**

The same LNG terminal analysis area as described above for western snowy plovers (Section 4.3.2.2) would apply to streaked horned larks. The analysis area extends 1.7 miles beyond the perimeter of the LNG terminal project area to include sand dune and beach habitat on the North Spit and includes Horsfall Lake, old dredge spoils (eg., Menasha Spoils at Pony Slough), and portions of the Oregon Dunes National Recreational Area (see figure 4.3-2 in Section 4.3.2.2, western snowy plover).

**Species Presence**

The streaked horn lark was proposed for listing as threatened in Washington and Oregon (Benton, Clackamas, Clatsop, Columbia, Lane, Linn, Marion, Multnomah, Polk, Washington, and Yamhill Counties) in October 2012 with proposed critical habitat in Washington and Oregon (Clatsop, Columbia, Lane, Linn, Marion, Multnomah, Polk, and Yamhill Counties) (FWS, 2012). None of the counties crossed by the PCGP project were included in the sub-species range. FWS (2013a, citing Gabrielson and Jewett, 1940) noted there were historical records of nonbreeding horned larks in coastal counties of Clatsop, Tillamook, Coos and Curry counties from before 1940. However, Marshall et al. (2006) did not include southwestern Oregon within the range of *Eremophila alpestris* in the state.

Further investigations have revealed additional records of horned larks in the PCGP Project vicinity. In addition to the pre-1940 records noted by FWS (2013a), Contreras (1998) listed seven instances of horned larks within Coos County (Table 4.3.5-1), three of which were in near proximity to the JCEP site, including two on the Coos Bay North Spit and one at Horsfall Lake, approximately 0.9 mile north of the proposed LNG terminal. Based on the records in Table 4.3.5-1, Contreras (1998) described the horned lark in Coos County as a rare but regular fall and winter visitor found mainly on the outer coast.

**Table 4.3.5-1**
**Available Records of Horned Larks, *Eremohphilia alpestris*, in the Vicinity of Coos Bay (Contreras, 1998).**

| Observation Date | Location | Number |
|---|---|---|
| February 16-17 Before 1940 | unknown | unknown |
| Late November 1978 | North Spit Coos Bay | small flock |
| November 20 1979 | North Spit Coos Bay | one |
| December16 1979 | unknown | unknown |
| September 19 1981 | Bullard’s Beach Park | unknown |
| November 3 1985 | Bandon | one (with Lapland longspurs) |
| October 7 1987 | Horsfall Lake | six |
| November 20 1989 | unknown | unknown |

Horned larks were reported during Audubon Christmas Bird Counts (CBC) within the following CBC Count Circles (Audubon, 2013) nearest to the PCGP route:

1. Coos Bay: 6 in 2005, 18 in 2006.
2. Medford: 3 in 2000, 1 in 2002, and 4 in 2005.

3. Klamath Falls: 5 in 1996, 15 in 2000, 8 in 2002, 31 in 2007, and 1 in 2009.

None of the records identified by Contreras (1998) or reported in Audubon CBC Count Circles included any subspecies separation of *Eremophila alpestris*. Consequently, there is no way to determine if observations were of *E. a. strigata*, of *E. a. articola* (northeastern and eastern Oregon in winter), *E. a. merrilli* (east of the Oregon Cascades into northeastern California) or *E. a. lamprochroma* (eastern Oregon). Since *E. a. strigata* can be found in coastal dune habitats (FWS, 2010h), and birds in Coos County generally occurred as fall or winter migrants on Oregon's outer coast (Contreras, 1998), it is likely that observations in Coos County, including the records in the CBC Coos Bay count circle, were of *E. a. strigata*. Birds observed within the Medford CBC could have been *E. a. strigata* and/or *E. a. merrilli*. Birds observed within the Klamath Falls CBC could have been *E. a. merrilli* and/or *E. a. lamprochroma*. However, there no way of knowing which subspecies was observed at any of the locations.

In the winter, most streaked horned larks that breed in the south Puget Sound migrate south to the Willamette Valley or west to the Washington coast; streaked horned larks that breed on the Washington coast either remain on the coast or migrate south to the Willamette Valley (FWS, 2013i). Winter migrants from these populations may inhabit the Oregon coast, although there is no information to support that possibility. Streaked horned larks spend the winter in large groups of mixed subspecies of horned larks in the Willamette Valley at least as far south as Corvallis, and in smaller groups along the Washington coast and Columbia River (FWS, 2013i). Perhaps some of the horned larks seen in the project vicinity during fall and winter may have been streaked horned larks but there is no way to be certain.

**Habitat**

A focused field evaluation of the JCEP project site on the North Spit was conducted by SHN Consulting (SHN) staff on April 23, 2013, to assess the potential for streaked horned lark habitat to occur (see Resource Report 3, JCEP LNG Terminal Project). One small area, approximately 75 feet by 150 feet was noted at the proposed South Dunes Power Plant site; however, it is surrounded by the previous mill site industrial footprint and is not adjacent to open water. Along the utility corridor and access road between the South Dunes Power Plant and LNG Terminal sites, sparsely vegetated portions of the rolling (and at times steep) dunes in the area was noted; again, the sites were not adjacent to open water. Small pockets of potential habitat were also noted in the upper half of the slip site, but they are surrounded by and being encroached by European beachgrass, gorse, and Scotch broom. An additional area at the northwest tip of the Project site, immediately south of the Trans-Pacific Parkway, also provides sparsely vegetated sand habitat but is not adjacent to open water. These sites would be unsuitable habitat according to specific conditions described above as Primary Constituent Elements in critical habitat.

The "weedy fields between the shoreline and dunes on the Roseburg Forest Products facility" noted in previous surveys as potential habitat (LBJ, 2006) were scraped off approximately five years ago and planted with grass that has become dense. When the previous surveys were conducted in 2005 and 2006, the site was likely at the stage between unvegetated landscape and dense covering of grasses. That habitat no longer exists and the site would no longer be considered potential habitat for the streaked horned lark.

**Critical Habitat**

The PCGP Project does not coincide with any designated critical habitat units, the closest of which is the Willamette Valley Subunit 4-C at the William L. Finley National Wildlife Refuge, 80 miles north of the Project.

### 4.3.5.3 Effects by the Proposed Action

**Direct and Indirect Effects**

Winter migrants from northern populations may inhabit the Oregon coast, although there is no information to support that possibility. Since streaked horned larks spend the winter in large groups of mixed subspecies of horned larks in the Willamette Valley at least as far south as Corvallis (FWS, 2013i), some of the horned larks observed in the vicinity of Coos Bay, reported by Contreras (1998) and within the Coos Bay CBC Count Circle (Audubon, 2013) may have been streaked horned larks. Alternatively, none of those horned larks may have been *Eremophila alpestris strigata*.

Occurrence of the subspecies near the JCEP project might be limited to a few individuals during fall and winter, probably present during migrations some years, not others. No suitable habitats for migrating or wintering streaked horned larks would be affected by the Proposed Action. Construction of buildings associated with the LNG Terminal and South Dunes Power Plant would alter the open quality of the local landscape but there is no indication that horned larks occur at either location. Initial construction at the JCEP site could displace one or several streaked horned larks if any are present in the area coincidental with the activities. Continuing construction and operation of the LNG terminal would likely be avoided by any horned lark in the area.

If they occur, direct effects of the proposed action on streaked horned larks would be similar to those described above for western snowy plover. Direct effects could include increased noise associated with construction of the LNG terminal and operation activities associated with shipping although effects of noise on breeding or wintering streaked horned larks has not been described. The following were anticipated indirect effects to western snowy plovers by the proposed project: 1) increased human presence, and 2) increased predation of western snowy plovers due to increased human presence. In both types, effects were expected to lead to destruction of nests and/or disturbance of nesting plovers. Neither type would affect wintering streaked horned larks.

**Cumulative Effects**

Additional projects within the action area (estuarine analysis area and the LNG terminal Analysis Area) are anticipated as human population growth continues in the region. Associated road and commercial development, as well as maintenance and upgrading of existing infrastructure within the Estuary, are likely to occur in the foreseeable future. These were describe above, for western snowy plovers and are not repeated here. No specific state or private actions have been identified within the analysis area.

**Critical Habitat**

No critical habitat designated for the streaked horned lark would be affected by the Proposed Action.

#### 4.3.5.4 Conservation Measures

JCEP has committed to multiple conservation measures to offset any impact to western snowy plovers (see Section 4.3.2.4, above). Many of the measures target conservation of western snowy plover breeding and nesting habitat on the Coos Bay North Spit and would have limited or no conservation value to a migrating or wintering streaked horned lark, if one occurred. Removal or European beachgrass would probably have the greatest potential benefit. Other Best Management Practices described in Section 4.3.2.4 might benefit streaked horned larks, if one occurred.

#### 4.3.5.5 Determination of Effects

**Species Effects**

The Project **may affect** streaked horned larks because:

- Horned larks have been observed during fall and winter in the vicinity of the JCEP LNG terminal analysis area. It is possible that one or more of the horned larks reported was *Eremophila alpestris strigata*.
- However, use of the JCEP LNG terminal analysis area by streaked horned larks would be limited to infrequent occurrences. No suitable habitat is present at the project site.

The project is **not likely to adversely affect** streaked horned larks because:

- Birds in the vicinity of the project area could detect noise produced during construction and operation of the JCEP LNG terminal site but noise is not expected to cause any harm to streaked horned larks.
- Future presence of streaked horned lakes in the JCEP LNG terminal analysis area at the time of construction is extremely unlikely, considered to be discountable.

**Critical Habitat Effects**

No designated critical habitat for the streaked horned lark will be affected.

## 4.4 HERPETOFAUNA

### 4.4.1 Green Turtle

#### 4.4.1.1 Species Account and Critical Habitat

**Status**

Green turtles were listed as threatened, except for an endangered population nesting on the Pacific Coast of Mexico, under the ESA on July 28, 1978 (FWS, 1978).

**Threats**

The green turtle has long been susceptible to harvest of both eggs and adults. Harvesting is the most serious direct problem faced by the green turtle; however, it is assumed that direct take in the United States doesn't exist (NMFS and FWS, 1998a). As modernization and technology was adopted by native people of various island and coastal communities throughout the Pacific that harvested green turtles, traditional practices of restraint in the harvest of green turtles were abandoned (NMFS and FWS 1998a). The evidence for the human impact on green turtles is further strengthened by the fact that the only breeding sites of any significance that are left are found in those areas that are not inhabited by humans or are visited rarely for exploitation (NMFS and FWS, 1998a).

Although 26 different types of threats have been identified for green turtles, the threats vary depending upon the geographic area where the turtles are found. On the U.S. West Coast, three primary threats are identified including debris, boat collisions, and incidental capture of turtles from fishing operations (NMFS and FWS, 1998a). Other threats include environmental contaminants and dredging (NMFS and FWS, 1998a).

**Species Recovery**

Recovery plans for the East Pacific and Pacific green turtles were issued on May 22, 1998 (NMFS and FWS, 1998a). The recovery goal is to delist the species, and the plan listed the following necessary actions:

- Minimize boat collision mortalities, particularly within San Diego County, California.
- Minimize incidental mortalities of turtles by commercial fishing operations.
- Support the efforts of Mexico and the countries of Central America to census and protect nesting East Pacific green turtles, their eggs, and nesting beaches.
- Determine population size and status in U.S. waters through regular surveys.
- Identify stock home range(s) using DNA analysis.
- Identify and protect primary foraging areas in U.S. jurisdiction.

The stepdown outline in the recovery plan included the following recommendations:

- Protect and manage turtles on nesting beaches (no nesting in U.S. jurisdiction).
- Protect and manage nesting habitat.
- Protect and manage East Pacific green turtle populations in the marine habitat.
- Protect and manage marine habitat, including foraging habitats.
- Develop standards for the care and maintenance of sea turtles, including diet, water quality, tank size, and treatment of injury and disease.

- Establish a catalog of all captive sea turtles to enhance use for research and education.
- Designate rehabilitation facilities.
- Support existing international agreements and conventions to ensure that turtles in all life-stages are protected in foreign waters.
- Encourage ratification of CITES for all non-member Pacific countries, compliance with CITES requirements, and removal of sea turtle trade reservations held by member nations.
- Develop new international agreements to ensure that turtles in all life-stages are protected in foreign waters.
- Develop or continue to support informational displays in U.S. airports and ports of entry that have direct flights to Mexico and Latin America.

**Life History, Habitat Requirements, and Distribution**

The green turtle is found in warm tropical waters and, to a lesser extent, subtropical waters with temperatures above 20ºC (68ºF) (NMFS and FWS, 1998a). Many facets of the green turtle's life history and ecology remain unknown, including details of its residence in and use of the U.S. Pacific Coast. The Pacific green turtle nests on tropical beaches in Hawaii and other islands of the Pacific, while the East Pacific green turtle is a separate population of the same species, nesting primarily on the coast of Michoacan, Mexico and in the Galapagos Islands. The green turtle has a worldwide distribution in tropical and subtropical waters. Except during breeding migrations, green turtles tend to be found in shallow waters such as those inside reefs, bays, and inlets. The turtles are attracted to lagoons and shoals with an abundance of marine grass and algae. Seagrasses are the principal dietary component of juvenile and adult green turtles throughout the Caribbean region and degradation of seagrass beds has slowed recovery of green turtles due to reduced carrying capacity of seagrass meadows (NMFS, 1998b). Green turtles apparently have strong nesting site fidelity and migrate long distances between feeding grounds and nesting beaches.

The green sea turtle grows to a maximum size of about 4 feet and a weight of 440 pounds. Hatchling green turtles eat a variety of plants and animals, but adults are vegetarian, feeding on sea grass and algae. The nesting season varies with the locality and clutch size varies from 75 to 200 eggs (FWS, 2007g). Incubation of the eggs varies between 45 and 75 days. Age at sexual maturity is between 20 to 50 years (FWS, 2007g).

**Population Status**

The mean annual number of nesting green turtle females has declined by 48 to 67 percent over the last three generations, which was estimated from index nesting sites (Marine Turtle Specialist Group 2004). East Pacific green turtles are widely distributed in coast waters south of the United States, in Mexico and Central America where the main aggregations are along the west coast of Baja California, in the Sea of Cortez, along the coast of Oaxaca, and breeding ground s of Michoacan, Mexico (NMFS and FWS, 1998b). A small population (about 30 turtles in 1990) occurred in San Diego Bay, California, the northernmost resident population reported, although there is no known nesting by green turtles on the U.S. west coast (NMFS and FWS, 1998b).

**Critical Habitat**

Critical habitat was established for this species on Culebra Island, Puerto Rico on September 2, 1998 (NMFS, 1998b). No critical habitat for this species occurs on the U.S. West Coast or within the within the EEZ analysis area.

### 4.4.1.2 Environmental Baseline

**Analysis Area**

The analysis area applicable to green turtles is the EEZ, extending 200 nautical miles offshore from the Coos Bay Head and from San Diego to Cape Flattery, the same as described above for blue whales (see figure 4.2-1). Within the EEZ analysis area, effects to green turtles would be associated with LNG carriers inbound and outbound from the LNG terminal. ).

For reasons discussed for blue whales (see Section 4.2.1.4), LNG carriers are assumed to traverse the EEZ mostly perpendicularly - east and west - as they approach and depart from Coos Bay. Ships could also traverse the EEZ parallel to the U.S. West Coast if originating on or passing along the west coasts of Central or South America. The assumption of perpendicular transits is based on existing shipping traffic between Asia and the U.S. West Coast most of which travels a “Great Circle route” (Pacific States/British Columbia Oil Spill Task Force, 2002), and LNG imports for the LNG terminal are assumed to come from Australia and Southeast Asia.

**Species Presence**

Green sea turtles have been sighted from Baja California to southern Alaska, but most commonly occur from San Diego south (NMFS, 2007b). Green sea turtles primarily use three types of habitat: oceanic beaches (for nesting), convergence zones in the open ocean, and benthic feeding grounds in coastal areas (NMFS, 2007b). Reports of strandings suggest that the green turtle is a frequent visitor off the California coast. The northernmost stranding was reported in 1993 in Homer, Alaska, although it was speculated that this turtle may have died farther to the south and drifted north (NMFS, 1998b). Based on this data, green turtles are likely infrequent visitors to the Oregon coast, but may occasionally be found in the EEZ analysis area and within the LNG ship transit zone.

**Habitat**

Sightings offshore of the Pacific Coast have occurred but there are no known sea turtle nesting sites on the West Coast of the United States (NMFS and FWS, 1998a). The East Pacific green turtle was the most commonly observed hard-shelled sea turtle on the U.S. Pacific Coast (NMFS and FWS, 1998a) but most of the sightings (62 percent) were reported from northern Baja California and Southern California. The northernmost known resident population of East Pacific green turtles occurs in San Diego Bay, in the warm effluent of a power plant (NMFS and FWS, 1998a).

**Critical Habitat**

Critical habitat has been designated in the Caribbean, off Puerto Rico (NMFS, 1998b) but no critical habitat for this species occurs within the EEZ analysis area.

#### 4.4.1.3 Effects by the Proposed Action

**Direct and Indirect Effects**

Direct effects of the proposed action include injury and/or mortality due to ship strikes, underwater ship noise, and potential adverse effects from a ship release of LNG and fire at sea. Spills and/or released LNG could indirectly affect green turtles by impacting forage species. These effects are addressed below.

<u>Ship Strikes by LNG Carriers</u>

The proposed action would result in increased shipping traffic and may increase potential vessel strikes to green turtles within the EEZ analysis area. Boat collisions are listed as a major problem for green turtle recovery off the U.S. West Coast (NMFS, 1998b). Sea turtles can be injured or killed when struck by a boat, especially by an engaged propeller. Eighty percent of sea turtle deaths reported recently in San Diego Bay and Mission Bay, California were associated with evidence of boat collision. Experiments conducted with a small 20-foot aluminum boat used to approach green sea turtles at various speeds found that turtles could avoid the boat and collision more effectively at slow speeds than at fast speeds (Hazel et al., 2007). However, methods for reducing boat collisions are not included in recovery objectives, and based on their warm water requirements, green sea turtles are likely to only be occasional visitors to waters as far north as Oregon.

The proposed action is expected to increase traffic by 180 additional ship transits through the EEZ analysis area each year of operation. Given the low population and occurrence of the green turtles in Oregon coastal waters and current estimate of vessel traffic, the addition of 180 LNG carrier transits through the EEZ analysis area is not expected to result in measurable additional ship strike-related mortality or injury to green turtles. However, lack of ship-strike incidences to sea turtles in general or frequencies of collision preclude any estimate of effects to green turtles of additional vessel traffic due to LNG carriers. The possibility of ship strikes by LNG carriers paralleling the California coast may be higher because reports of strandings in California are more frequent. LNG carriers are expected to transit at least 50 nmi off the coast and so would be expected to avoid nearshore feeding areas used by green turtles.

<u>Underwater Noise</u>

Loggerhead sea turtles can detect sound and their hearing is most sensitive to lower frequencies below 1000 Hz (Bartol et al., 1999; Martin et al., 2012), within the same range of low frequencies generated by ships and sounds generated by large baleen whales (Würsig and Richardson, 2009). The same is assumed to be true of green sea turtles. However, studies have focused on sea turtle response to seismic operations (McCauley et al., 2000; Holst et al., 2006); turtles were observed to move away from the operations. Responses to ship noise have not been reported. Loggerhead and green turtles hear and respond to low frequency sound from seismic operations (increased swimming speed, increased activity, change in swimming direction, and avoidance) but their hearing threshold appears to be high. Based on available information, it is considered unlikely that sea turtles are more sensitive to seismic operations than cetaceans or some fish (Department of Fisheries and Oceans Canada, 2004).

Existing commercial vessels within the West Coast EEZ analysis area produce underwater noise levels that are comparable or exceed noise from the LNG tanker described by Hatch et al. (2008). Noise generated by various types of commercial ships (container ships, crude oil tankers, product tankers, bulk carriers, and others) were recently evaluated by McKenna et al. (2012). Underwater noise levels varied by ship type and also by vessel length, gross tonnage, vessel speed, and to some extent, vessel age (older vessels tended to be louder than newer vessels). With the existing levels of background shipping noise and the expected increase in shipping traffic by 2018, effects by project LNG tanker-related noise on green sea turtles are possible in the West Coast EEZ analysis area but the noise would be commensurate with existing noise levels and would not be expected to cause injury.

Releases and Fire at Sea

Characteristics of LNG released at sea were described in Section 4.2.1.3 for blue whales. At the water-vapor LNG pool interface, the cryogenically cooled LNG would begin to vaporize but, because of its relatively high density, the plume would remain at or close to the surface interface; methane is an asphyxiant but with low toxicity, at least to humans (Hightower et al., 2004). If a sea turtle surfaced to breathe at the LNG pool location, oxygen deficiency would occur with potential physiological effects, described for humans (ranging from impaired thinking to loss of consciousness with decreasing oxygen concentrations, see Table 39 in Hightower et al., 2004) but not for sea turtles. Because the estimated densities of sea turtles are believed to be low within the West Coast EEZ analysis area, the chance of an animal becoming asphyxiated by contact with a pool of LNG would extremely remote (see discussion about potential thermal injury, below).

Sandia National Laboratories modeled LNG spills from a standard LNG vessel (with capacity of 125,000 to 140,000 $m^3$) over water and potential injury to humans due to ignition of the fuel (Hightower et al., 2004). Thermal effects from a fire would vary, depending on the size of the LNG pool released. If one LNG tank is accidentally breached, due to collision with another ship, grounding, or ramming, the potential spill of LNG could form a pool with diameter of 685 feet. Ignition could cause a fire to burn for 20 minutes with severe thermal injuries extending to 820 feet away from the center of the pool (based on an exposure of 10 minutes and thermal flux of 37.5 $kW/m^2$) and second-degree skin burns on exposed skin (human) to a distance of 2,572 feet (based on an exposure of 10 minutes and thermal flux of 5 $kW/m^2$) from the center of the burning pool of LNG (see Table 41 in Hightower et al., 2004). Surfacing sea turtles within those distances would be assumed to experience severe burns or mild burns, based on similar thermal fluxes effects on humans although exposures for 10 minutes or more would be unlikely.

Expected densities of green sea turtles in the West Coast EEZ analysis area during 2018 are expected to be so low that the chance of a sea turtle surfacing in an area of pooled LNG or close enough to a fire to be injured is insignificant and discountable.

**Cumulative Effects**

FWS and NMFS describe cumulative effects (50 CFR § 402.02) as the result of future actions by state or private entities, not involving federal actions, but reasonably certain to occur in the action area considered in this BA. Future federal actions that are unrelated to the proposed action are not considered here because they require separate consultation pursuant to section 7 of the ESA.

As discussed above for blue whales, available information indicates that ship calls to the Port of Coos Bay have been declining since 2002. The observed declining linear trend in total annual vessel traffic over time is significant and, when used to forecast numbers of vessel calls to Coos Bay in the future, no vessels are predicted to enter Coos Bay in 2018 with between 0 and 17.6

vessels as reasonably foreseeable when the LNG terminal is expected to begin operation in 2018 (see figure 4.2-4 under blue whale). And as discussed above for blue whales, it appears that the background rate of spills off the Oregon coast by fishing vessels, recreation vessels, and other vessel types is generally low, a frequency that would be expected to continue into the foreseeable future.

The foreseeable cumulative effect of 90 LNG carriers per year with anticipated dry bulk vessel traffic in 2018 would be less than effects based on past levels of vessel traffic calls to the Port of Coos Bay which would have exceeded 90 vessels per year in 1992 given the current trend in figure 4.2-2. Consequently, cumulative effects to green turtles would likely be less than the estimate of direct effects discussed in the previous section. Those effects were judged to be insignificant and discountable.

The volume of annual vessel transits within the EEZ of California, Oregon, and Washington is related to numbers of vessel calls to ports in those states. Total annual calls for all vessels at ports in California, Oregon, and Washington (MARAD, 2013) were plotted above in figure 4.2-2 for 2002 through 2011. Unlike the trend analyzed for calls to Coos Bay (see figure 4.2-4 under blue whales) the observed linear trend in annual vessel traffic (port calls) along the U.S. West Coast was significantly increasing at a rate of 2.1 percent per year between 2002 and 2007. The increasing trend was interrupted by the global economic crisis in 2008 but data through 2011 indicate a return to the established increasing trend prior to 2008. The pre-2008 trend predicts 21,530 vessel calls to West Coast ports in 2018 (with 95% prediction intervals ranging from 17,360 to 25,710 vessel calls), the year the JCEP and PCGP projects are expect to be in service. Even with the uncertainty generated by available data, there is a reasonably foreseeable increasing trend, albeit imprecise, for vessel traffic volume in the future (by 2018) although unforeseen global events such as future economic crises could influence the prediticions. Cumulative effects of 90 LNG carriers per year to green sea turtles may be more or may be less than the estimate of direct effects discussed above.

**Critical Habitat**

No critical habitat would be affected by the proposed action.

#### 4.4.1.4 Conservation Measures

Measures to reduce ship speeds once inside the Coos Bay navigation channel to between 4 to 6 knots and within the EEZ when pods or large assemblages of cetaceans are observed near an underway ship would provide some protection to green turtles. However, it is highly unlikely that green turtles or other sea turtles would be seen from a LNG carrier. Nevertheless, the same Ship-Strike Reduction Plan, including marine mammal avoidance guidelines and LNG Management Plan to minimize risk of spills and releases at sea that were described in Section 4.2.1.4 (Blue Whale) apply to green turtles.

#### 4.4.1.5 Determination of Effects

**Species Effects**

The Project **may affect** green turtles because:

- Green turtles may occur within the EEZ analysis area during operation of the proposed action.

- The proposed action would increase shipping traffic (LNG carriers) within the EEZ analysis area.

However, the Project is **not likely to adversely affect** green turtles because:

- Whether or not green turtles have been struck by ships is unknown but is expected to be highly unlikely.
- The increase in annual ship traffic due to the proposed action is expected to cause an immeasurable increase for potential ship strikes to green turtles.
- Jordan Cove would provide a ship strike avoidance measures package to shippers delivering LNG cargo to the LNG terminal. The package consists of multiple measures to avoid striking marine mammals, which should also benefit sea turtles.
- LNG carriers approaching the Port of Coos Bay would be traveling slowly and escorted by tractor tugs from 50 nmi offshore to the Port.
- Noise produced by LNG carriers would contribute to overall noise within the EEZ en route to the Port of Coos Bay and effects of ship noise on green sea turtles could exceed NMFS interim noise exposure criteria for Level B single non-pulse noise but would not exceed existing background ship noise levels and would not cause injury.
- Accidental releases of LNG at sea would not cover an area large enough to coincide with expected green sea turtle presence (based on assumed densities). Ignited LNG would not extend far enough from the LNG pool to cause severe or mild thermal effects to green sea turtles if they emerged during a fire.

**Critical Habitat Effects**

No critical habitat has been designated or proposed for the green turtle.

### 4.4.2 Leatherback Turtle

#### 4.4.2.1 Species Account and Critical Habitat

**Status**

Leatherback turtles were listed as endangered under the Endangered Species Conservation Act on December 2, 1970 (FWS, 1970) and have been listed under the ESA since its implementation in 1973.

**Threats**

Egg collection was one of the primary reasons the leatherback turtles became endangered, along with harvest of female egg-laying turtles. NMFS and FWS (1998b) lists incidental take as the primary threat to leatherback turtles. This includes entanglement in nets and ingestion of marine debris.

Direct threats to leatherback turtles include harvesting. The primary threat to leatherback turtles on the U.S. West Coast continues to be incidental take in commercial fisheries operations (NMFS and FWS, 1998b). Other threats include injestion of debris, primarily plastics and plastic bags that are thought to be mistaken for jellyfish and eaten, leading to esophagus and stomach blockage and eventually death (Mrosovsky et al., 2009; Plotkin, 1995). These deaths, and the evidence for this type of death by this specific type of ingestion, appear to be on the rise (Plotkin, 1995). Threats at nesting grounds outside the United States still remain from collection of eggs and development along the coast. In addition, artificial light (during egg hatch viewing) causes confusion of newly hatched turtles that head in the direction of the light rather than out to sea (Plotkin, 1995; FWS, 2012f; NMFS and FWS, 1998b).

**Species Recovery**

A recovery plan was issued for the U.S. Pacific Coast population on May 22, 1998. The recovery goal (NMFS and FWS, 1998b) is to delist the species, and the plan listed the following necessary actions:

- Eliminate incidental take of leatherbacks in United States and international commercial fisheries.
- Support the efforts of Mexico and the countries of Central America to census and protect nesting leatherbacks, their eggs, and nesting beaches.
- Determine movement patterns, habitat needs, and primary foraging areas for the species throughout its range.
- Determine population size and status in U.S. waters through regular aerial or on-water surveys.
- Identify stock home ranges using DNA analysis.

The stepdown outline in the recovery plan included the following recommendations:

- Protect and manage turtles on nesting beaches.
- Protect and manage nesting habitat.
- Protect and manage leatherback turtle populations in the marine habitat.
- Protect and manage marine habitat, including foraging habitats.
- Support existing international agreements and conventions to ensure that turtles in all life-stages are protected in foreign waters.
- Encourage ratification of CITES for all non-member Pacific countries, compliance with CITES requirements, and removal of sea turtle trade reservations held by member nations.
- Develop new international agreements to ensure that turtles in all life-stages are protected in foreign waters.
- Develop or continue to support informational displays in airports that provide connecting legs for travelers to the areas where leatherbacks occur.

**Life History, Habitat Requirements, and Distribution**

The leatherback is the largest,most migratory, and widest range of all extant sea turtles (FWS, 2012f). Leatherback sea turtle nesting grounds are located around the world, with the largest remaining nesting assemblages found on the coasts of northern South America and West Africa. Adult leatherback sea turtles are capable of tolerating a wide range of water temperatures, and have been sighted as far north as the Gulf of Alaska (NMFS and FWS, 2007a). Their diet consists of soft-bodied prey, such as jellyfish and tunicates. Nesting occurs on sandy tropical beaches, with each female laying several clutches at intervals of 8 to 12 days. Mating occurs in the waters adjacent to nesting beaches within migration corridors. After nesting, female leatherbacks migrate from tropical waters to more temperate latitudes, which support high densities of jellyfish prey in the summer (NMFS and FWS, 1998b). Incubation of the eggs takes between 55 and 75 days, and hatching occurs at night. Sexual maturity is reached between 6 and 10 years (FWS, 2012f). No known nesting locations occur on the U.S. Pacific Coast.

NMFS (2012e) defined nine geographic areas along the west coast from Washington to Northern California that are occupied by leatherback turtles. Areas 2 and 3 include nearshore waters Point Arena in northern California to Cape Flattery Washington, extending offshore to the 2000 meter isobath. Area 2 (Cape Blanco to Cape Flattery) includes most of the Oregon coast and is a principal foraging area for leatherbacks. They feed on a variety of moon jellies brown sea nettles that are present in high densities associated with the Columbia River Plume and Heceta Bank, Oregon (NMFS, 2012c). Areas 4 and 5 extend offshore west of Areas 2 and 3 to EEZ. Jellyfish densities in those areas are unknown and likely serve as secondary foraging areas and area of passage to the primary foraging region in Area 2.

**Population Status**

Leatherbacks foraging off the coast of California nest on beaches in Indonesia, Papua New Guinea, and the Solomon Islands. Turtles foraging along the California coast are part of a distinct Western Pacific breeding stock (Harris et al., 2011). The same is assumed for leatherbacks foragiing along the Oregon and Washington coasts. Between 1984 and 2011, there was an overall significant decline of 78 percent in the number of leatherback turtle nests monitored in Papua Barat, Indonesia (Tapilatu et al., 2013). Approximately 75 percent of the total leatherbacks nesting in the the western Pacific nest at Papua Barat. In the Pacific, it is estimated that leatherback turtle populations have declined by 80 percent (NMFS 2007b).

**Critical Habitat**

Critical habitat was established for this species in the U.S. Virgin Islands on March 23, 1979 (NMFS, 1979). On January 5, 2010, NMFS proposed the designation of approximately 70,600 square miles within the EEZ as critical habitat for leatherback turtles (NMFS, 2010c). NMFS' final rule designated 16,910 square miles as critical habitat for leatherback turtles along the California coast from Point Arena to Point Arguello and 25,004 square miles along the Washington and Oregon coasts from Cape Blanco, Oregon to Cape Flattery, Washington (NMFS, 2011f).

Two PCEs were proposed (NMFS, 2010c): 1) occurrence of prey species, primarily jellyfish, of sufficient condition, distribution, diversity, and abundance to support individual as well as population growth, reproduction and development, and 2) migratory pathway conditions to allow for safe and timely passage and access to/from/within high use foraging areas (NMFS, 2010c). NMFS (2011c) eliminated the proposed migratory pathway PCE. In the final designation, there is only one PCE, occurrence of prey species, primarily scyphomedusae of the order Semaeostomeae (especially brown sea nettles, *Chrysaora fuscescens*) of sufficient condition, distribution, diversity, abundance and density necessary to support individual as well as population growth, reproduction, and development of leatherbacks.

Within those areas, the condition, distribution, diversity, and abundance of prey utilized by turtles may be affected by the same activities that may affect passage as well as effects from point pollution, pesticides, power plants, desalination plants, and LNG (NMFS, 2010c).

### 4.4.2.2 Environmental Baseline

**Analysis Area**

The analysis area applicable to leatherback turtles is the EEZ, extending 200 nautical miles offshore from the Coos Bay Head, the same as described above for green turtles and blue whales (see figure 4.2-1).

**Species Presence**

The leatherback sea turtle is the most common sea turtle in U.S. waters north of Mexico (NMFS and FWS, 1998b). Leatherbacks occur as far north as Alaska, and numerous sightings have been documented off the Oregon coast. Green et al. (1992) observed 16 Pacific leatherback turtles off the Oregon and Washington coasts, all of them north of a point due west of Pacific City, Tillamook County, Oregon. Sixty-two percent of the sightings occurred over the continental slope, with the remainder occurring over the continental shelf. Incidental catch of leatherback turtles has also occurred in gill-nets off the coasts of Washington, Oregon, and California. These data suggest that leatherback sea turtles migrate through and would be present in the EEZ analysis area.

**Habitat**

Adult leatherback turtles are highly migratory and available information indicates that eastern Pacific migratory corridors exist along the West Coast of the United States (NMFS and FWS, 1998b). The West Coast of the United States may represent some of the most important foraging habitat in the world for the leatherback turtle (NMFS and FWS, 1998b). The importance of the EEZ analysis area to leatherback turtles is unknown though they are expected to occur. Coastal upwelling of the California Current occurs along the Oregon Coast north of Cape Blanco. Peak numbers of leatherback turtles (July to September) occur in neritic zones when intermittent decrease of upwelling, allowing surface water temperatures to increase. Leatherback aggregate in the warm highly productive coastal areas to forage on preferred prey, scyphomedusae, the cnidarian jellies (NMFS, 2012c).

**Critical Habitat**

NMFS' final rule designated critical habitat within 25,004 square miles along the Washington and Oregon coasts from Cape Blanco, Oregon to Cape Flattery, Washington (NMFS, 2011c). NMFS (2011c) defined an area (Area 2) from Cape Blanco to Cape Flattery, including most of the Oregon coast, as a principal foraging area for leatherbacks. They feed on a variety of moon jellies and brown sea nettles that are present in high densities associated with the Columbia River Plume and Heceta Bank, Oregon (NMFS, 2012c). Based upon the best available scientific information, the features of Area 2 produce sufficient prey to provide for foraging by leatherback turtles that is essential to the conservation of the species, thus this area contains the prey PCE (NMFS, 2012b). Critical habitat extends to a water depth of 80 meters from the ocean surface and is delineated along the shoreline at the line of extreme low water offshore to the 2,000-meter depth contour. Critical habitat coincides with nearshore waters through which LNG carriers would transit to Coos Bay and the Jordan Cove terminal.

### 4.4.2.3 Effects by the Proposed Action

**Direct and Indirect Effects**

Direct effects of the proposed action include injury and/or mortality due to ship strikes, underwater ship noise, and potential adverse effects from a ship release of LNG and fire at sea. Spills and/or released LNG could indirectly affect leatherback turtles by impacting forage species. These effects are addressed below.

Ship Strikes by LNG Carriers

The proposed action would result in increased shipping traffic and may increase potential vessel strikes to leatherback sea turtles within the analysis area. However, the largest threat to leatherback turtles outside of their nesting grounds is entanglement in gill-nets and other incidental take. Boat collisions are not listed as a current threat to the recovery of leatherback populations (NMFS and FWS, 1998b). However, Harris et al. (2011) reported two of 19 leatherback turtles examined had multiple parallel lacerations in the carapaces that had healed but consistant with wounds from boat propellers. Risk of collision increases within increased vessel speed (Hazel et al., 2007), as discussed for green sea turtles, above. The risk was described for small craft but is unknown for large tankers.

The proposed action is expected to increase traffic by 180 additional ship transits through the EEZ analysis area each year of operation. Given the low population and occurrence of the leatherback turtles in Oregon coastal waters and current estimate of vessel traffic, the addition of 180 LNG carrier transits through the EEZ analysis area is not expected to result in measurable additional ship strike-related mortality or injury to leatherback turtles. However, lack of ship-strike incidences to sea turtles in general or frequencies of collision precludes any estimate of effects to leatherback turtles of additional vessel traffic due to LNG carriers. The possibility of ship strikes by LNG carriers paralleling the California coast may be higher because leatherback turtles are more common in California waters. LNG carriers are expected to transit ≥ 50 nmi off the coast and so would be expected to avoid most frequented areas on the continental slope.

Underwater Noise

Loggerhead sea turtles can detect sound and their hearing is most sensitive to lower frequencies below 1000 Hz (Bartol et al., 1999; Martin et al., 2012), within the same range of low frequencies generated by ships and sounds generated by large baleen whales (Würsig and Richardson, 2009). The same is assumed to be the case for leatherback turtles. However, studies have focused on sea turtle response to seismic operations (McCauley et al., 2000; Holst et al., 2006); turtles were observed to move away from the operations. Responses to ship noise have not been reported. Loggerhead and green turtles hear and respond to low frequency sound from seismic operations (increased swimming speed, increased activity, change in swimming direction, and avoidance) but their hearing threshold appears to be high. Based on available information, it is considered unlikely that sea turtles are more sensitive to seismic operations than cetaceans or some fish (Department of Fisheries and Oceans Canada, 2004).

Existing commercial vessels within the West Coast EEZ analysis area produce underwater noise levels that are comparable or exceed noise from the LNG tanker described by Hatch et al. (2008). Noise generated by various types of commercial ships (container ships, crude oil tankers, product tankers, bulk carriers, and others) were recently evaluated by McKenna et al. (2012). Underwater noise levels varied by ship type and also by vessel length, gross tonnage, vessel speed, and to some extent, vessel age (older vessels tended to be louder than newer vessels). With the existing levels of background shipping noise and the expected increase in shipping traffic by 2018, effects by project LNG tanker-related noise on leatherback sea turtles are possible in the West Coast EEZ analysis area but the noise would be commensurate with existing noise levels and would not be expected to cause injury.

Releases and Fire at Sea

Characteristics of LNG released at sea were described in Section 4.2.1.3 for blue whales. At the water-vapor LNG pool interface, the cryogenically cooled LNG would begin to vaporize but, because of its relatively high density, the plume would remain at or close to the surface interface; methane is an asphyxiant but with low toxicity, at least to humans (Hightower et al., 2004). If a sea turtle surfaced to breathe at the LNG pool location, oxygen deficiency would occur with potential physiological effects, described for humans (ranging from impaired thinking to loss of consciousness with decreasing oxygen concentrations, see Table 39 in Hightower et al., 2004) but not for sea turtles. Because the estimated densities of sea turtles are believed to be low within the West Coast EEZ analysis area, the chance of an animal becoming asphyxiated by contact with a pool of LNG would extremely remote (see discussion about potential thermal injury, below).

Sandia National Laboratories modeled LNG spills from a standard LNG vessel (with capacity of 125,000 to 140,000 $m^3$) over water and potential injury to humans due to ignition of the fuel (Hightower et al., 2004). Thermal effects from a fire would vary, depending on the size of the LNG pool released. If one LNG tank is accidentally breached, due to collision with another ship, grounding, or ramming, the potential spill of LNG could form a pool with diameter of 685 feet. Ignition could cause a fire to burn for 20 minutes with severe thermal injuries extending to 820 feet away from the center of the pool (based on an exposure of 10 minutes and thermal flux of 37.5 $kW/m^2$) and second-degree skin burns on exposed skin (human) to a distance of 2,572 feet (based on an exposure of 10 minutes and thermal flux of 5 $kW/m^2$) from the center of the burning pool of LNG (see Table 41 in Hightower et al., 2004). Surfacing sea turtles within those distances would be assumed to experience severe burns or mild burns, based on similar thermal fluxes effects on humans although exposures for 10 minutes or more would be unlikely.

Expected densities of leatherback sea turtles in the West Coast EEZ analysis area during 2018 are expected to be so low that the chance of a sea turtle surfacing in an area of pooled LNG or close enough to a fire to be injured is insignificant and discountable.

**Cumulative Effects**

FWS and NMFS describe cumulative effects (50 CFR § 402.02) as the result of future actions by state or private entities, not involving federal actions, but reasonably certain to occur in the action area considered in this Biological Assessment. Future federal actions that are unrelated to the proposed action are not considered here because they require separate consultation pursuant to section 7 of the ESA.

As discussed above for blue whales, available information indicates that ship calls to the Port of Coos Bay have been declining since 2002. The observed declining linear trend in total annual vessel traffic over time is significant and, when used to forecast numbers of vessel calls to Coos Bay in the future, no vessels are predicted to enter Coos Bay in 2018 with between 0 and 17.6 vessels as reasonably foreseeable when the LNG terminal is expected to begin operation in 2018 (see figure 4.2-4 under blue whale). And as discussed above for blue whales, it appears that the background rate of spills off the Oregon coast by fishing vessels, recreation vessels, and other vessel types is generally low, a frequency that would be expected to continue into the foreseeable future.

The foreseeable cumulative effect of 90 LNG carriers per year with anticipated dry bulk vessel traffic in 2018 would be less than effects based on past or present levels of vessel traffic calls to the Port of Coos Bay which would have exceeded 90 vessels per year in 1992 given the current trend in figure 4.2-2. Consequently, cumulative effects to leatherback turtles would likely be insignificant and discountable.

The volume of annual vessel transits within the EEZ of California, Oregon, and Washington is related to numbers of vessel calls to ports in those states. Total annual calls for all vessels at ports in California, Oregon, and Washington (MARAD, 2013) were plotted above in figure 4.2-2 for 2002 through 2011. Unlike the trend analyzed for calls to Coos Bay (see figure 4.2-4 under blue whale) the observed linear trend in annual vessel traffic (port calls) along the U.S. West Coast was significantly increasing at a rate of 2.1 percent per year between 2002 and 2007. The increasing trend was interrupted by the global economic crisis in 2008 but data through 2011 indicate a return to the established increasing trend prior to 2008. The pre-2008 trend predicts 21,530 vessel calls to West Coast ports in 2018 (with 95% prediction intervals ranging from 17,360 to 25,710 vessel calls), the year the JCEP and PCGP projects are expect to be in service. Even with the uncertainty generated by available data, there is a reasonably foreseeable increasing trend, albeit imprecise, for vessel traffic volume in the future (by 2018) although unforeseen global events such as future economic crises could influence the prediticions. Cumulative effects of 90 LNG carriers per year to leatherback turtles may be more or may be less than the estimate of direct effects discussed above.

**Critical Habitat**

Critical habitat has been designated within 25,004 square miles along the Washington and Oregon coasts from Cape Blanco, Oregon to Cape Flattery, Washington (NMFS, 2012c). NMFS (2012b) defined an area (Area 2) from Cape Blanco to Cape Flattery, including most of the Oregon coast, as a principal foraging area for leatherbacks. Critical habitat coincides with nearshore waters through which LNG carriers would transit to Coos Bay and the Jordan Cove terminal.

As discussed under Blue Whales, above, LNG carriers arriving from LNG source ports near the equator are assumed to traverse the EEZ perpendicular to the Oregon coastline. Those carriers would pass through critical habitat north of Cape Blanco, Oregon, described by NMFS (2012b). LNG carriers arriving from or passing Central and South America are expected to parallel the coast from California to Coos Bay and are assumed to follow a course 50 nmi offshore. Those carriers would pass through proposed critical habitat off the California coast from Point Arena, north of San Francisco Bay, south to Point Arguello which extends seaward approximately 100 nmi or more.

The proposed action could affect proposed critical habitat areas within the EEZ analysis area if a spill or release occurred from a LNG carrier. Spills could impact both leatherback turtles and their jellyfish prey. As discussed above, it appears that the background rate of spills off the Oregon Coast by fishing vessels, recreation vessels, and other vessel types is generally low. Any potential spills that could occur and that could affect the turtles or their prey would more likely be fuels or lubricants associated with the operation of the LNG carrier. These products are kept in relatively small quantities on ships and would not result in the types of effects associated with a spill from an oil tanker.

If an unignited LNG spill were to occur along the LNG carrier transit route where turtles and jellyfish were present, the LNG would float on the water until it vaporizes and would not have an adverse effect on the turtles or jellyfish, unless they came in direct contact with the LNG. Ignition of LNG would accelerate evaporation and methane would rise above sea level. Sea turtles surfacing to breathe could suffer hypoxia or anoxia.

There have been approximately 11 reportable LNG transport incidents between 1979 and 2006, worldwide. Because LNG has not been transported to the Pacific Northwest, no data are available. However, due to the double hull-construction of LNG carriers, none of the incidents that have occurred with LNG carriers have resulted in the loss of LNG cargo or other significant petroleum based spills.

#### 4.4.2.4 Conservation Measures

Measures to reduce ship speeds once inside the Coos Bay navigation channel to between 4 to 6 knots and within the EEZ when pods or large assemblages of cetaceans are observed near an underway ship would provide some protection to leatherback turtles. However, it is highly unlikely that leatherbacks or other sea turtles would be seen from a LNG carrier. Nevertheless, the same Ship-Strike Reduction Plan, including marine mammal avoidance guidelines and LNG Management Plan to minimize risk of spills and releases at sea that were described in Section 4.2.1.4 (blue whale) apply to leatherback turtles.

#### 4.4.2.5 Determination of Effects

**Species Effects**

The Project **may affect** leatherback turtles because:

- Leatherback turtles may occur within the EEZ analysis area during operation of the proposed action.
- The proposed action would increase shipping traffic (LNG carriers) within the EEZ analysis area.

However, the Project is **not likely to adversely affect** leatherback turtles because:

- Whether or not leatherback turtles have been struck by ships is unknown but is expected to be highly unlikely.
- The increase in annual ship traffic due to the proposed action is expected to cause an immeasurable increase for potential ship strikes to leatherback turtles.
- Jordan Cove would provide a ship strike avoidance measures package to shippers delivering LNG cargo to the LNG terminal. The package consists of multiple measures to avoid striking marine mammals, which should also benefit sea turtles.
- LNG carriers approaching the Port of Coos Bay would be traveling slowly and escorted by tractor tugs from 50 nmi offshore to the Port.
- Noise produced by LNG carriers would contribute to overall noise within the EEZ en route to the Port of Coos Bay and effects of ship noise on leatherback turtles could exceed NMFS interim noise exposure criteria for Level B single non-pulse noise but would not exceed existing background ship noise levels and would not cause injury.
- Accidental releases of LNG at sea would not cover an area large enough to coincide with expected leatherback turtle presence (based on assumed low densities). Ignited LNG

would not extend far enough from the LNG pool to cause severe or mild thermal effects to leatherback turtles if they emerged during a fire..

**Critical Habitat Effects**

The Project **may affect** proposed critical habitat for the leatherback turtle because:

- The EEZ analysis area to be used by LNG carriers includes coastal marine waters in California between Point Arena and Point Argello, California and between Cape Blanco, Oregon and Cape Flattery, Washington, both of which are included as designated critical habitat.

The Project is **not likely to adversely affect** proposed critical habitat for the leatherback turtle because:

- Spills or releases of LNG at sea would not cause the water column to cool to the point of affecting sea turtles in the water. Ignited LNG would affect species on the water but not sea turtles or jellyfish submerged in the water. The possibility that spills or releases at sea would affect passage of leatherback turtles and/or their prey is insignificant and discountable.

### 4.4.3 Olive Ridley Turtle

#### 4.4.3.1 Species Account and Critical Habitat

**Status**

Olive ridley turtles were listed as threatened, except for the breeding colony populations on the Pacific coast of Mexico, which were listed as endangered, under the ESA on July 28, 1978 (FWS 1978).

**Threats**

Direct threats to the species include the harvesting of sea turtles and their eggs and boat collisions (NMFS and FWS, 1998c). Olive ridley turtle eggs were collected at first by indigenous people and then for economic gain to sell in markets once the eggs were found to have commercial value (NMFS and FWS, 1998c). Another market was created that used olive ridley turtle leather that aided in the demise and ultimately the listing of the olive ridley turtle as threatened/endangered (NMFS and FWS, 1998c).

Natural disasters, debris entanglement and ingestion, and incidental take from domestic fisheries are listed as minor threats to olive ridley turtles (NMFS and FWS, 1998c). Primary threats to olive ridley turtles off the West Coast of the United States include incidental take from commercial fishing and boat collisions usually involving smaller boats (NMFS and FWS, 1998c). The more frequent occurrence of El Niño and general warming trends in the Pacific may be the reason that the zooplankton in the California Current are declining, resulting in the reduction of higher level vertebrates and other foods for the turtles to forage on (Plotkin, 1995).

**Species Recovery**

A recovery plan was issued in 1998. The recovery goal (NMFS and FWS, 1998c) is to delist the species, and the plan listed the following necessary actions:

- Minimize incidental mortalities of turtles by commercial fishing operations.

- Support the efforts of Mexico and the countries of Central America to census and protect nesting olive ridleys, their eggs, and nesting beaches.
- Identify stock home ranges using DNA analysis.

The stepdown outline in the recovery plan included the following recommendations:

- Protect and manage turtles on nesting beaches.
- Protect and manage nesting habitat.
- Protect and manage olive ridley populations in the marine habitat.
- Protect and manage marine habitat, including foraging habitats.
- Develop standards for the care and maintenance of sea turtles, including diet, water quality, tank size, and treatment of injury and disease.
- Establish a catalog of all captive sea turtles to enhance use for research and education.
- Designate rehabilitation facilities.
- Support existing international agreements and conventions to ensure that turtles in all life-stages are protected in foreign waters.
- Encourage ratification of CITES for all non-member Pacific countries, compliance with CITES requirements, and removal of sea turtle trade reservations held by member nations.
- Develop new international agreements to ensure that turtles in all life-stages are protected in foreign waters.
- Develop or continue to support informational displays in airports that provide connecting legs for travelers to the areas, which support olive ridleys.

**Life History, Habitat Requirements, and Distribution**

The olive ridley is primarily a pelagic sea turtle, but does occasionally inhabit coastal areas such as bays and estuaries. Olive ridleys undertake an annual migration from open-ocean foraging grounds to coastal breeding and nesting grounds. Olive ridley turtles are well known for their arribada behavior where hundreds to tens of thousands of ridley tutles emerge synchronously from the ocean over a few days to nest in close proximity (NMFS and FWS, 2007b).

Olive ridleys have been observed as far as 2,400 miles from shore. Adult turtles are small compared to other sea turtles, with an average weight of approximately 100 pounds. The olive ridley feeds on a variety of food items, including algae, lobster, crabs, tunicates, mollusks, shrimp, and fish. Females nest each year after reaching sexual maturity at about age 15. They nest one to three times per season, producing clutches of approximately 100 eggs each time. Incubation of the eggs generally takes between 50 and 60 days.

**Population Status**

The olive ridley is considered the most abundant sea turtle in the world, with an estimated 800,000 females nesting annually. However, there has been an estimated 50 percent reduction in population since the 1960s (Marine Turtle Specialist Group 2004 in NMFS 2007c). The eastern Pacific population that nests in El Salvador, Guatemala, Costa Rica, and Panama has declined since the 1970s. However, since Mexico banned harvest of nesting females and eggs, the nesting population at La Escobilla, Oaxaca, Mexico increased from 50,000 nests in 1988 to >1 million nests in 2000 (FWS, 2013h). At-sea estimates of density and abundance of olive ridley turtles were conducted along the Mexico and Central American coasts from 1992 to 2006. the yearly weighted average was 1.39 million in the eastern Pacific and consistent with increased nesting during prior to 2007 (NMFS and FWS, 2007b).

**Critical Habitat**

Critical habitat has not been designated for this species.

### 4.4.3.2 Environmental Baseline

**Analysis Area**

The analysis area applicable to olive ridley turtles is the EEZ, extending 200 nautical miles offshore from the Coos Bay Head, the same as described above for green sea turtles and blue whales (see figure 4.2-1).

**Species Presence**

At-sea occurrences in waters under U.S. jurisdiction are limited to the West Coast of the continental United States and Hawaii, where the species is rare, but possibly increasing. This species does not nest in the United States, but during feeding migrations, olive ridley turtles nesting in the East Pacific may disperse into waters off the Pacific west coast as far north as Oregon (FWS, 2013h). Olive ridleys have occasionally been killed by gill-nets and boat impacts as well as cold-stunning (or cold-stranding due to hypothermia by rapid decline of water temperatures) in Oregon and Washington (NMFS and FWS, 1998c). Based on sightings off the Oregon coast, olive ridley turtles may occasionally occur in the EEZ analysis area.

**Habitat**

Little is known about the abundance and distribution of olive ridley turtles in the northeastern Pacific. The olive ridley sea turtle strayed into Washington State waters on just a single documented occasion; the species is unlikely to occur along the Washington coast since ocean surface temperatures are apparently too low (Richardson, 1997). Important foraging grounds have not been identified although forage areas most likely exist along the coast of Baja California and Southern California (NMFS and FWS, 1998c). Less is known about the potential importance of Oregon waters and the EEZ analysis area to olive ridley turtles.

**Critical Habitat**

Critical habitat has not been designated for this species.

### 4.4.3.3 Effects by the Proposed Action

**Direct and Indirect Effects**

Direct effects of the proposed action include injury and/or mortality due to ship strikes, underwater ship noise, and potential adverse effects from an accidental ship release of LNG and at sea. Spills and/or released LNG could indirectly affect olive ridley turtles by impacting forage species. These effects are addressed below.

Ship Strikes by LNG Carriers

The proposed action would result in increased shipping traffic and may increase potential vessel strikes to olive ridley turtles within the analysis area. Boat collisions are listed as a moderate problem for olive ridley turtle recovery off the U.S. West Coast (NMFS and FWS, 1998c). Sea turtles can be injured or killed when struck by a boat, especially by an engaged propeller. Risk of collision with sea turtles increases within increased vessel speed (Hazel et al., 2007), as discussed for green sea turtles, above. However, methods for reducing boat collisions are not included in recovery objectives, and based on their warm water requirements, olive ridley sea turtles are likely only occasional visitors to waters as far north as Oregon.

The proposed action is expected to increase traffic by 180 additional ship transits through the EEZ analysis area each year of operation. Given the low population and occurrence of the olive ridley turtles in Oregon coastal waters and current estimate of vessel traffic, the addition of 180 LNG carrier transits through the EEZ analysis area is not expected to result in measurable additional ship strike-related mortality or injury to leatherback turtles. However, lack of ship-strike incidences to sea turtles in general or frequencies of collision precludes any estimate of effects to leatherback turtles of additional vessel traffic due to LNG carriers. The possibility of ship strikes by LNG carriers paralleling the California coast may be higher because olive ridley turtles are more common in California waters. LNG carrier are expected to transit ≥ 50 nmi off the coast and so would be expected to avoid most frequented areas on the continental slope.

Underwater Noise

Loggerhead sea turtles can detect sound and their hearing is most sensitive to lower frequencies below 1000 Hz (Bartol et al., 1999; Martin et al., 2012), within the same range of low frequencies generated by ships and sounds generated by large baleen whales (Würsig and Richardson, 2009). The same is assumed to be the case for olive ridley turtles. However, studies have focused on sea turtle response to seismic operations (McCauley et al., 2000; Holst et al., 2006); turtles were observed to move away from the operations. Responses to ship noise have not been reported. Loggerhead and green turtles hear and respond to low frequency sound from seismic operations (increased swimming speed, increased activity, change in swimming direction, and avoidance) but their hearing threshold appears to be high. Based on available information, it is considered unlikely that sea turtles are more sensitive to seismic operations than cetaceans or some fish (Department of Fisheries and Oceans Canada, 2004).

The proposed action is expected to increase traffic by 180 additional ship transits through the EEZ analysis area each year of operation. Given the low population and occurrence of the green turtles in Oregon coastal waters and current estimate of vessel traffic, the addition of 180 LNG carrier transits through the EEZ analysis area is not expected to result in measurable additional ship strike-related mortality or injury to olive ridley turtles. However, lack of ship-strike incidences to sea turtles in general or frequencies of collision preclude any estimate of effects to green turtles of additional vessel traffic due to LNG carriers. The possibility of ship strikes by LNG carriers paralleling the California coast may be higher because reports of strandings in California are more frequent. LNG carriers are expected to transit at least 50 nmi off the coast and so would be expected to avoid nearshore feeding areas used by olive ridley turtles.

Releases and Fire at Sea

Characteristics of LNG released at sea were described in Section 4.2.1.3 for blue whales. At the water-vapor LNG pool interface, the cryogenically cooled LNG would begin to vaporize but, because of its relatively high density, the plume would remain at or close to the surface interface; methane is an asphyxiant but with low toxicity, at least to humans (Hightower et al., 2004). If a sea turtle surfaced to breathe at the LNG pool location, oxygen deficiency would occur with potential physiological effects, described for humans (ranging from impaired thinking to loss of consciousness with decreasing oxygen concentrations, see Table 39 in Hightower et al., 2004) but not for sea turtles. Because the estimated densities of olive ridley turtles are believed to be low within the West Coast EEZ analysis area, the chance of an animal becoming asphyxiated by contact with a pool of LNG would extremely remote (see discussion about potential thermal injury, below).

Sandia National Laboratories modeled LNG spills from a standard LNG vessel (with capacity of 125,000 to 140,000 $m^3$) over water and potential injury to humans due to ignition of the fuel (Hightower et al., 2004). Thermal effects from a fire would vary, depending on the size of the LNG pool released. If one LNG tank is accidentally breached, due to collision with another ship, grounding, or ramming, the potential spill of LNG could form a pool with diameter of 685 feet. Ignition could cause a fire to burn for 20 minutes with severe thermal injuries extending to 820 feet away from the center of the pool (based on an exposure of 10 minutes and thermal flux of 37.5 $kW/m^2$) and second-degree skin burns on exposed skin (human) to a distance of 2,572 feet (based on an exposure of 10 minutes and thermal flux of 5 $kW/m^2$) from the center of the burning pool of LNG (see Table 41 in Hightower et al., 2004). Surfacing olive ridley turtles within those distances would be assumed to experience severe burns or mild burns, based on similar thermal fluxes effects on humans although exposures for 10 minutes or more would be unlikely.

Expected densities of olive ridley turtles in the West Coast EEZ analysis area during 2018 are expected to be so low that the chance of an olive ridley turtle surfacing in an area of pooled LNG or close enough to a fire to be injured is insignificant and discountable.

**Cumulative Effects**

FWS and NMFS describe cumulative effects (50 CFR § 402.02) as the result of future actions by state or private entities, not involving federal actions, but reasonably certain to occur in the action area considered in this BA. Future federal actions that are unrelated to the proposed action are not considered here because they require separate consultation pursuant to section 7 of the ESA.

As discussed above for blue whales, available information indicates that ship calls to the Port of Coos Bay have been declining since 2002. The observed declining linear trend in total annual vessel traffic over time is significant and, when used to forecast numbers of vessel calls to Coos Bay in the future, no vessels are predicted to enter Coos Bay in 2018 with between 0 and 17.6 vessels as reasonably foreseeable when the LNG terminal is expected to begin operation in 2018 (see figure 4.2-4 under blue whale). And as discussed above for blue whales, it appears that the background rate of spills off the Oregon coast by fishing vessels, recreation vessels, and other vessel types is generally low, a frequency that would be expected to continue into the foreseeable future.

The foreseeable cumulative effect of 90 LNG carriers per year with anticipated dry bulk vessel traffic in 2018 would be less than effects based on past or present levels of vessel traffic calls to the Port of Coos Bay which would have exceeded 90 vessels per year in 1992 given the current trend in figure 4.2-2 (under blue whale). Consequently, cumulative effects to olive ridley turtles would likely be insignificant and discountable.

The volume of annual vessel transits within the EEZ of California, Oregon, and Washington is related to numbers of vessel calls to ports in those states. Total annual calls for all vessels at ports in California, Oregon, and Washington (MARAD, 2013) were plotted above in figure 4.2-2 for 2002 through 2011. Unlike the trend analyzed for calls to Coos Bay (see figure 4.2-3) the observed linear trend in annual vessel traffic (port calls) along the U.S. West Coast was significantly increasing at a rate of 2.1 percent per year between 2002 and 2007. The increasing trend was interrupted by the global economic crisis in 2008 but data through 2011 indicate a return to the established increasing trend prior to 2008. The pre-2008 trend predicts 21,530 vessel calls to West Coast ports in 2018 (with 95% prediction intervals ranging from 17,360 to 25,710 vessel calls), the year the JCEP and PCGP projects are expect to be in service. Even with the uncertainty generated by available data, there is a reasonably foreseeable increasing trend, albeit imprecise, for vessel traffic volume in the future (by 2018) although unforeseen global events such as future economic crises could influence the prediticions. Cumulative effects of 90 LNG carriers per year to olive ridley turtles may be more or may be less than the estimate of direct effects discussed above.

**Critical Habitat**

No critical habitat would be affected by the proposed action; none has been designated.

#### 4.4.3.4 Conservation Measures

Measures to reduce ship speeds once inside the Coos Bay navigation channel to between 4 to 6 knots and within the EEZ when pods or large assemblages of cetaceans are observed near an underway ship would provide some protection to olive ridley turtles. However, it is highly unlikely that olive ridleys or other sea turtles would be seen from a LNG carrier. Nevertheless, the same Ship-Strike Reduction Plan, including marine mammal avoidance guidelines and LNG Management Plan to minimize risk of spills and releases at sea that were described in Section 4.2.1.4 (blue whale) apply to olive ridley turtles.

#### 4.4.3.5 Determination of Effects

**Species Effects**

The Project **may affect** olive ridley turtles because:

- Olive ridley turtles may occur within the EEZ analysis area during operation of the proposed action.
- The proposed action would increase shipping traffic (LNG carriers) within the EEZ analysis area.

However, the Project is **not likely to adversely affect** olive ridley turtles because:

- Whether or not olive ridley turtles have been struck by ships is unknown but is expected to be highly unlikely.
- The increase in annual ship traffic due to the proposed action is expected to cause an immeasurable increase for potential ship strikes to olive ridley turtles.
- Jordan Cove would provide a ship strike avoidance measures package to shippers delivering LNG cargo to the LNG terminal. The package consists of multiple measures to avoid striking marine mammals, which should also benefit sea turtles.
- LNG carriers approaching the Port of Coos Bay would be traveling slowly and escorted by tractor tugs from 50 nmi offshore to the Port.
- Noise produced by LNG carriers would contribute to overall noise within the EEZ en route to the Port of Coos Bay and effects of ship noise on olive ridley turtles could exceed NMFS

interim noise exposure criteria for Level B single non-pulse noise but would not exceed existing background ship noise levels and would not cause injury.

- Accidental releases of LNG at sea would not cover an area large enough to coincide with expected olive ridley turtle presence (based on assumed low densities). Ignited LNG would not extend far enough from the LNG pool to cause severe or mild thermal effects to olive ridley turtles if they emerged during a fire. .

### 4.4.4 Loggerhead Turtle

#### 4.4.4.1 Species Account and Critical Habitat

**Status**

Loggerhead turtles were listed as threatened under the ESA in 1978 (FWS, 1978). In 2007, NMFS and FWS completed a 5-year review in which the agencies determined that populations might be separated by ocean basins but more information was needed before applying distinct population segments (DPS) to the species under ESA while retaining its threatened status. Also in 2007, NMFS and FWS were petitiond to classify loggerhead turtles in the North Pacific as a DPS with endangered status with designated critical habitat. In Novermber 2007, NMFS and FWS released a notice of petition finding to list the loggerhead turtle population in the Pacific to be a DPS with endangered status. The finding stated that the petitioned action “may be warranted” (Conant et al., 2009). In 2011, NMFs (2011d) published a final rule in which the agencies determine loggerhead sea turtles are componsed of nine DPSs distributed worldwide; four DPSs are listed as threatened and five are listed as endangered. The North Pacific Ocean DPS is listed as endangered (NMFS, 2011d).

**Threats**

Direct threats to the loggerhead turtle include harvesting. There is no information about direct take of the loggerhead turtle, although is it assumed to be nonexistent in the Pacific Coast because of its rarity. Reasons for listing the loggerhead turtle include direct harvest in the Bahamas, Cuba, and Mexico as well as incidental capture of turtles in commercial fishing gear (NMFS, 2013b).

Two primary threats to loggerhead turtles include natural disasters and incidental take from commercial fishing operations (NMFS and FWS, 1998d). Minor threats to loggerhead turtles on the U.S. West Coast include natural disasters, environmental contaminants, debris entanglement and ingestion, and power plant entrapment (NMFS and FWS, 1998d). Threats (the degree of which are unknown) include predation, boat collision, and oil exploration and development (NMFS and FWS, 1998d). Dredging is listed as another important potential threat to loggerhead turtles, as they spend much of their time in continental shelf waters closer to shoreline looking for food (Plotkin, 1995).

**Species Recovery**

A recovery plan was issued on May 22, 1998 (NMFS and FWS, 1998d). The recovery goal is to delist the species, and the plan listed the following necessary actions:

- Reduce incidental capture of loggerheads by coastal and high seas commercial fishing operations.

- Establish bilateral agreements with Japan and Mexico to support their efforts to census and monitor loggerhead populations and to minimize impacts of coastal development and fisheries on loggerhead stocks.
- Identify stock home ranges using DNA analysis.
- Determine population size and status (in U.S. jurisdiction) through regular aerial or on-water surveys.
- Identify and protect primary foraging areas for the species.

The stepdown outline in the recovery plan included the following recommendations:

- Protect and manage turtles on nesting beaches.
- Protect and manage nesting habitat.
- Protect and manage loggerhead populations in the marine habitat.
- Protect and manage marine habitat, including foraging habitats.
- Develop standards for the care and maintenance of sea turtles, including diet, water quality, tank size, and treatment of injury and disease.
- Establish a catalog of all captive sea turtles to enhance use for research and education.
- Designate rehabilitation facilities.
- Support existing international agreements and conventions to ensure that turtles in all life-stages are protected in foreign waters.
- Encourage ratification of CITES for all non-member Pacific countries, compliance with CITES requirements, and removal of sea turtle trade reservations held by member nations.
- Develop new international agreements to ensure that turtles in all life-stages are protected in foreign waters.
- Develop or continue to support informational displays in airports and other ports of call that provide connecting legs for travelers to the area.

**Life History, Habitat Requirements, and Distribution**

Loggerhead turtles occur throughout temperate and tropical regions of the Atlantic, Pacific, and Indian Oceans. They are the most abundant sea turtle found in U.S. coastal waters, although they are much more prevalent on the Atlantic than Pacific Coasts, with major nesting areas being present in Florida. In the North Pacific, loggerhead nesting has only been documented in Japan but may also occur on beaches of the South China Sea (NMFS, 2011d). Turtles hatching on Japanese beaches enter the Kuroshio and North Pacific Currents and develop during migration; some reach the eastern Pacific and Baja California. Foraging areas have been documented off the coast of Baja California, Mexico (NMFS, 2011d). Evidence indicates that loggerhead turtles hatching in Japan remain in the North Pacific Basin for their entire life cycle, never crossing the equator into the South Pacific Basin (NMFS, 2011d).

Loggerheads reach sexual maturity at around 35 years of age. In the southeastern United States, mating occurs in late March to early June and females lay eggs between late April and early September. Females generally lay three to five nests per season. The eggs incubate approximately 2 months before hatching between late June and mid-November. Hatchlings move from their nest to the surf, swim and are swept through the surf zone, and continue swimming away from land for about one to several days. Post-hatchlings within this habitat are float-and-wait foragers feeding on a wide variety of floating food items. From these relatively nearshore habitats, juvenile turtles are swept into the open ocean by currents. Between the ages of seven and 12 years, oceanic juveniles migrate to nearshore coastal areas where they remain until reaching adulthood.

**Population Status**

In the United States, loggerhead turtles lay an estimated 68,000 to 90,000 eggs per year. There is no known nesting of loggerhead turtles on the U.S. Pacific Coast. Occasional cold-strandings occur in Washington and Oregon and incidental take by fisheries probably occurs (NMFS and FWS 1998d). In the eastern Pacific, loggerheads have been reported as far north as Alaska. In the U.S., occasional sightings are reported from the coasts of Washington and Oregon, but most records are of juveniles off the coast of California. The west coast of Mexico, including the Baja Peninsula, provides critically important developmental habitats for juvenile loggerheads. Records of females in the North Pacific Oceans DPS nesting on Japanese beaches indicate numbers increased from the late 1990s through 2005 but declined in 2006 and 2007 (Conant et al., 2009).

**Critical Habitat**

Critical habitat has not been designated for this species.

#### 4.4.4.2 Environmental Baseline

**Analysis Area**

The analysis area applicable to loggerhead turtles is the EEZ, extending 200 nautical miles offshore from the Coos Bay Head, the same as described above for green turtles and blue whales (see figure 4.2-1).

**Species Presence**

Loggerhead turtles sighted in U.S. Pacific Coast waters likely originate on Japanese nesting grounds (NMFS and FWS, 1998d). In the United States, occasional sightings are reported from the coasts of Washington and Oregon, but most records are of juveniles off the coast of California. Therefore, based on sightings and documented strandings, loggerhead turtles are likely at visitors to the EEZ analysis area, at least occasionally. The California/Oregon (CA/OR) drift gillnet fishery (for swordfish and thresher shark) was observed to incidentally capture 17 loggerheads (12 released alive, one injured, and four killed) from 1990 to 2000. Based on a worst-case scenario, NMFS estimated that a maximum of 33 loggerheads in a given year could be incidentally taken by the CA/OR drift gillnet fleet (Conant et al., 2009).

**Habitat**

The fact that juveniles are captured incidentally in longlines and driftnets in the pelagic Pacific indicates that the species’ range includes coastal and pelagic waters (NMFS and FWS, 1998d). The potential importance of Oregon waters and the EEZ analysis area to loggerhead turtles is unknown. Loggerheads are likely to move into the U.S. Pacific coast from Baja California as they follow preferred prey species, the pelagic red crab (Conant et al., 2009).

**Critical Habitat**

Critical habitat has not been established for this species.

### 4.4.4.3 Effects by the Proposed Action

### Direct and Indirect Effects

Direct effects of the proposed action include injury and/or mortality due to ship strikes, underwater ship noise, and potential adverse effects from an accidental ship release of LNG and fire at sea. Spills and/or released LNG could indirectly affect loggerhead turtles by impacting forage species. These effects are addressed, below.

Ship Strikes by LNG Carriers

The proposed action would result in increased shipping traffic and may increase potential vessel strikes to loggerhead sea turtles within the analysis area. However, the largest threat to loggerhead turtles outside of their nesting grounds is entanglement in gill-nets and other incidental take. Boat collisions are not listed as a current threat to the recovery of loggerhead populations (NMFS and FWS, 1998d). However, risk of collision with sea turtles increases within increased vessel speed (Hazel et al., 2007), as discussed for green sea turtles, above.

The proposed action is expected to increase traffic by 180 additional ship transits through the EEZ analysis area each year of operation. Given the low population and occurrence of the loggerhead turtles in Oregon coastal waters and current estimate of vessel traffic, the addition of 180 LNG carrier transits through the EEZ analysis area is not expected to result in measurable additional ship strike-related mortality or injury to leatherback turtles. However, lack of ship-strike incidences to sea turtles in general or frequencies of collision precludes any estimate of effects to leatherback turtles of additional vessel traffic due to LNG carriers. The possibility of ship strikes by LNG carriers paralleling the California coast may be higher because loggerhead turtles are more common in California waters. LNG carrier are expected to transit ≥ 50 nmi off the coast and so would be expected to avoid most frequented areas on the continental slope.

Underwater Noise

Loggerhead sea turtles can detect sound and their hearing is most sensitive to lower frequencies below 1000 Hz (Bartol et al., 1999; Martin et al., 2012), within the same range of low frequencies generated by ships and sounds generated by large baleen whales (Würsig and Richardson, 2009). However, studies have focused on sea turtle response to seismic operations (McCauley et al., 2000; Holst et al., 2006); turtles were observed to move away from the operations. Responses to ship noise have not been reported. Loggerhead and green turtles hear and respond to low frequency sound from seismic operations (increased swimming speed, increased activity, change in swimming direction, and avoidance) but their hearing threshold appears to be high. Based on available information, it is considered unlikely that sea turtles are more sensitive to seismic operations than cetaceans or some fish (Department of Fisheries and Oceans Canada, 2004).

Existing commercial vessels within the West Coast EEZ analysis area produce underwater noise levels that are comparable or exceed noise from the LNG tanker described by Hatch et al. (2008). Noise generated by various types of commercial ships (container ships, crude oil tankers, product tankers, bulk carriers, and others) were recently evaluated by McKenna et al. (2012). Underwater noise levels varied by ship type and also by vessel length, gross tonnage, vessel speed, and to some extent, vessel age (older vessels tended to be louder than newer vessels). With the existing levels of background shipping noise and the expected increase in shipping traffic by 2018, effects by project LNG tanker-related noise on loggerhead sea turtles are possible in the West Coast EEZ analysis area but the noise would be commensurate with existing noise levels and would not be expected to cause injury.

Releases and Fire at Sea

Characteristics of LNG released at sea were described in Section 4.2.1.3 for blue whales. At the water-vapor LNG pool interface, the cryogenically cooled LNG would begin to vaporize but, because of its relatively high density, the plume would remain at or close to the surface interface; methane is an asphyxiant but with low toxicity, at least to humans (Hightower et al., 2004). If a sea turtle surfaced to breathe at the LNG pool location, oxygen deficiency would occur with potential physiological effects, described for humans (ranging from impaired thinking to loss of consciousness with decreasing oxygen concentrations, see Table 39 in Hightower et al., 2004) but not for sea turtles. Because the estimated densities of loggerhead sea turtles are believed to be low within the West Coast EEZ analysis area, the chance of an animal becoming asphyxiated by contact with a pool of LNG would extremely remote (see discussion about potential thermal injury, below).

Sandia National Laboratories modeled LNG spills from a standard LNG vessel (with capacity of 125,000 to 140,000 $m^3$) over water and potential injury to humans due to ignition of the fuel (Hightower et al., 2004). Thermal effects from a fire would vary, depending on the size of the LNG pool released. If one LNG tank is accidentally breached, due to collision with another ship, grounding, or ramming, the potential spill of LNG could form a pool with diameter of 685 feet. Ignition could cause a fire to burn for 20 minutes with severe thermal injuries extending to 820 feet away from the center of the pool (based on an exposure of 10 minutes and thermal flux of 37.5 $kW/m^2$) and second-degree skin burns on exposed skin (human) to a distance of 2,572 feet (based on an exposure of 10 minutes and thermal flux of 5 $kW/m^2$) from the center of the burning pool of LNG (see Table 41 in Hightower et al., 2004). Surfacing loggerhead turtles within those distances would be assumed to experience severe burns or mild burns, based on similar thermal fluxes effects on humans although exposures for 10 minutes or more would be unlikely.

Expected densities of loggerhead turtles in the West Coast EEZ analysis area during 2018 are expected to be so low that the chance of a turtle surfacing in an area of pooled LNG or close enough to a fire to be injured is insignificant and discountable.

**Cumulative Effects**

FWS and NMFS describe cumulative effects (50 CFR § 402.02) as the result of future actions by state or private entities, not involving federal actions, but reasonably certain to occur in the action area considered in this BA. Future federal actions that are unrelated to the proposed action are not considered here because they require separate consultation pursuant to section 7 of the ESA.

As discussed above for blue whales, available information indicates that ship calls to the Port of Coos Bay have been declining since 2002. The observed declining linear trend in total annual vessel traffic over time is significant and, when used to forecast numbers of vessel calls to Coos Bay in the future, no vessels are predicted to enter Coos Bay in 2018 with between 0 and 17.6 vessels as reasonably foreseeable when the LNG terminal is expected to begin operation in 2018 (see figure 4.2-4 under blue whale). And as discussed above for blue whales, it appears that the background rate of spills off the Oregon coast by fishing vessels, recreation vessels, and other vessel types is generally low, a frequency that would be expected to continue into the foreseeable future.

The foreseeable cumulative effect of 90 LNG carriers per year with anticipated dry bulk vessel traffic in 2018 would be less than effects based on past or present levels of vessel traffic calls to the Port of Coos Bay which would have exceeded 90 vessels per year in 1992 given the current trend in figure 4.2-2 (under blue whale). Consequently, cumulative effects to loggerhead turtles would likely be insignificant and discountable.

The volume of annual vessel transits within the EEZ of California, Oregon, and Washington is related to numbers of vessel calls to ports in those states. Total annual calls for all vessels at ports in California, Oregon, and Washington (MARAD, 2013) were plotted above in figure 4.2-2 for 2002 through 2011. Unlike the trend analyzed for calls to Coos Bay (see figure 4.2-4) the observed linear trend in annual vessel traffic (port calls) along the U.S. West Coast was significantly increasing at a rate of 2.1 percent per year between 2002 and 2007. The increasing trend was interrupted by the global economic crisis in 2008 but data through 2011 indicate a return to the established increasing trend prior to 2008. The pre-2008 trend predicts 21,530 vessel calls to West Coast ports in 2018 (with 95% prediction intervals ranging from 17,360 to 25,710 vessel calls), the year the JCEP and PCGP projects are expect to be in service. Even with the uncertainty generated by available data, there is a reasonably foreseeable increasing trend, albeit imprecise, for vessel traffic volume in the future (by 2018) although unforeseen global events such as future economic crises could influence the predictions. Cumulative effects of 90 LNG carriers per year to loggerhead turtles may be more or may be less than the estimate of direct effects discussed above.

**Critical Habitat**

No critical habitat would be affected by the proposed action; none has been designated.

#### 4.4.4.4 Conservation Measures

Measures to reduce ship speeds once inside the Coos Bay navigation channel to between 4 to 6 knots and within the EEZ when pods or large assemblages of cetaceans are observed near an underway ship would provide some protection to loggerhead turtles. However, it is highly unlikely that loggerheads or other sea turtles would be seen from a LNG carrier. Nevertheless, the same Ship-Strike Reduction Plan, including marine mammal avoidance guidelines and LNG Management Plan to minimize risk of spills and releases at sea that were described in Section 4.2.1.4 (blue whale) apply to loggerhead turtles.

#### 4.4.4.5 Determination of Effects

**Species Effects**

The Project **may affect** loggerhead turtles because:

- Loggerhead turtles may occur within the EEZ analysis area during operation of the proposed action.
- The proposed action would increase shipping traffic (LNG carriers) within the EEZ analysis area.

However, the Project is **not likely to adversely affect** loggerhead turtles because:

- Whether or not loggerhead turtles have been struck by ships is unknown but is expected to be highly unlikely.
- The increase in annual ship traffic due to the proposed action is expected to cause an immeasurable increase for potential ship strikes to loggerhead turtles.
- Jordan Cove would provide a ship strike avoidance measures package to shippers delivering LNG cargo to the LNG terminal. The package consists of multiple measures to avoid striking marine mammals, which should also benefit sea turtles.
- LNG carriers approaching the Port of Coos Bay would be traveling slowly and escorted by tractor tugs from 50 nmi offshore to the Port.
- Noise produced by LNG carriers would contribute to overall noise within the EEZ en route to the Port of Coos Bay and effects of ship noise on loggerhead turtles could exceed NMFS interim noise exposure criteria for Level B single non-pulse noise but would not exceed existing background ship noise levels and would not cause injury.
- Accidental releases of LNG at sea would not cover an area large enough to coincide with expected loggerhead turtle presence (based on assumed low densities). Ignited LNG would not extend far enough from the LNG pool to cause severe or mild thermal effects to loggerhead turtles if they emerged during a fire.

**Critical Habitat Effects**

No critical habitat has been designated or proposed for the loggerhead turtle.

### 4.4.5 Oregon Spotted Frog

#### 4.4.5.1 Species Account and Critical Habitat

**Status**

The Oregon spotted frog (*Rana pretiosa*) was proposed for listing as threatened under the ESA in August 2013 (FWS, 2013e). The species had been petitioned for listing in May 2004 with a positive (warranted but precluded) 90-day finding issued in 2005 and had been a candidate species since then with Listing Priority of 2 (imminent with high magnitude of threat, see FWS, 2011d).

**Threats**

Oregon spotted frogs may be extirpated from as much as 90 percent of their historically documented range including all historical locations in California (FWS, 2013e). The species' wetland habitats have been lost from 30 to 85 percent across its range. Sources of loss include draining wetlands, water diversions, conversion of wetlands to agriculture and livestock grazing, developments adjacent to occupied habitats that alter seasonal hydrology (through creation of impervious surfaces), and occurrence of droughts which have become more frequent in parts of the species' range. Also, riverine functions that promote early successional wetland habitats have been altered including connectivity with floodplains. Beaver activities had contributed to historical mosaic of aquatic habitats and fires burning in summer influenced shallow water breeding habitats the following spring (FWS, 2013a). Introductions of exotic species, including reed canarygrass that degrades native wetland vegetation and nonnative predators including bullfrogs and warm water fish species have been and continue to threaten the species. Chytrid fungus infections have been documented Oregon spotted frog population in all of the sites sampled, including five sites located in the Klamath Basin (Pearl et al., 2009). Declines in various amphibian populations have been associated with fungal infections and may have contributed to the demise of Oregon spotted frog populations although some populations appear to be resistant (Padgett-Flohr and Hayes, 2011). There may be additional pathogens that affect Oregon spotted frogs (FWS, 2013a).

**Species Recovery**

The species has been proposed for listing and no recovery plan has been published. A Conservation Agreement to conserve Oregon spotted frogs in the Klamath Basin has been developed by the FWS, Forest Service, BLM (FWS et al., 2010) with the objectives to:

> "1) manage occupied habitat in a manner that sustains and/or restores its ability to support Oregon spotted frog populations; 2) stabilize or increase populations within the Klamath Basin; 3) reduce threats; and 4) increase distribution among available suitable habitats by restoring or creating habitat."

Implementing the conservation agreement has focused on bullfrog eradication program on Crane Creek since bullfrogs appeared in 2010 and controlling and reducing bullfrogs and analyzing the gut contents of bullfrogs at all life stages on BLM lands at Wood River. While the number of bullfrogs removed and seen at that site has decreased, bullfrog removal has also focused on areas outside the Oregon spotted frog. Despite these efforts, bullfrogs continue to persist in these Oregon spotted frog habitats in the Klamath Basin (FWS, 2013e).

**Life History, Habitat Requirements, and Distribution**

The current range of Oregon spotted frogs extends from the Fraser River sub-basin in southern British Columbia (Haycock, 2000) and adjacent areas in Whatcom County, Washington, south through the Puget Trough lowlands, through the Willamette Valley, southeast Oregon including Jackson and Klamath counties, and adjacent areas in the Pit River sub-basin of northern California (FWS, 2011d).

Spotted frogs inhabit perennial water bodies such as springs, ponds, lakes or slow moving streams and are usually associated with nonwoody, herbaceous wetland vegetation communities composed of sedges, rushes and grasses (Leonard et al., 1993). Several aspects of the Oregon spotted frog's life history have been proposed as contributing to the species' vulnerability to habitat alterations (FWS, 2011d): 1) communal egg laying at sites used year after year restricts the number of reproductive sites; 2) the species' warm water requirement results in habitat overlap with introduced warm water fish; 3) the active season warm water requirement may limit suitable habitat in the cool climates of the Pacific Northwest; 4) the species may be vulnerable to the potential loss or alteration of springs used for overwintering; and 5) changes that increase deep, permanent water components are likely to favor establishment of non-native bullfrogs and fish, both of which may be detrimental to Oregon spotted frogs.

In lower elevations of eastern and western Washington and Oregon, breeding occurs during February and March; at higher elevation breeding occurs in late May or early June (Leonard et al., 1993). Oregon spotted frogs typically oviposit communally; males may gather in large groups at a location and females lay eggs adjacent to or attached to other egg masses which are only partially submerged. These aggregations can contain eggs from 100 or more females in larger populations (FWS, 2011d). Spotted frog use traditional oviposition sites, year after year. Such sites may have limited availability because of unique characteristics and adults may have limited flexibility to switch sites if they become unsuitable. That possibility makes the Oregon spotted frog particularly vulnerable to habitat changes at oviposition sites (FWS, 2011d).

**Population Status**

Population estimates in most sub-basins inhabited by Oregon spotted frogs are insufficient to derive any trends (FWS, 2013e). The best available information indicates an undetermined population trend in Oregon but trends from the lower Fraser River in British Columbia and Middle Klickitat sub-basin in Washington indicate declining populations (FWS, 2013e).

There are 39 populations of Oregon spotted frog locations (sites) known, excluding those in British Columbia, with eight in Washington and 31 in Oregon (FWS, 2011d). Oregon spotted frogs have not been documented in recent surveys in California. In Oregon the species' extant distribution includes 23 sites in the Central Oregon Cascades (with the largest population of 500 to 2,500 breeding females at two sites) and nine sites in the Klamath Basin (FWS, 2011d). In 2005, personnel with the Forest Service surveyed 28 different sites in Lake, Klamath, and Jackson counties but no new Oregon spotted frogs were found. Data from the Klamath Basin data suggests that one population has declined since 2000, two populations appear stable, and five sites do not have enough data to determine trend, including the Buck Lake site. The Buck Lake site is isolated from all other Oregon spotted frog populations with little or no chance for genetic interchange or re-colonization; there is no hydrologic connectivity to other occupied habitats in the Klamath Basin (FWS, 2011d).

**Critical Habitat**

Critical habitat for the Oregon spotted frog was proposed in August 2013 (FWS, 2013f) at the same time that the species was proposed for listing as threatened under the ESA. The proposal includes critical habitat in Washington (Units 1 through 6) and in Oregon (Units 7 through 14). The Buck Lake site is within proposed critical habitat Unit 14: Upper Klamath, Oregon.

FWS (2013f) determine that the primary constituent elements specific to the Oregon spotted frog are:

1. Primary constituent element 1 (applicable to the following seasonal life stage periods - Nonbreeding (N), Breeding (B), Rearing (R), and Overwintering Habitat (O)) is <u>ephemeral or permanent bodies of freshwater</u>, including, but not limited to natural or manmade ponds, springs, lakes, slow-moving streams, or pools within or oxbows adjacent to streams, canals, and ditches, that have one or more of the following characteristics:
    - Inundated for a minimum of 4 months per year (B, R) (timing varies by elevation but may begin as early as February and last as long as September);
    - Inundated from October through March (O);
    - If ephemeral, areas are hydrologically connected by surface water flow to a permanent water body (e.g., pools, springs, ponds, lakes, streams, canals, or ditches) (B, R);
    - Shallow water areas (less than or equal to 30 centimeters (12 inches), or water of this depth over vegetation in deeper water (B, R);
    - Total surface area with less than 50 percent vegetative cover (N);
    - Gradual topographic gradient (less than 3 percent slope) from shallow water toward deeper, permanent water (B, R);

- Herbaceous wetland vegetation (i.e.,emergent, submergent, and floating leaved aquatic plants), or vegetation that can structurally mimic emergent wetland vegetation through manipulation (B, R);
- Shallow water areas with high solar exposure or low (short) canopy cover (B, R);
- An absence or low density of nonnative predators (B, R, N).

2. Primary constituent element 2 is aquatic movement corridors. Ephemeral or permanent bodies of fresh water that have one or more of the following characteristics:
    - Less than or equal to 5 kilometers (3.1 miles) linear distance from breeding areas;
    - Impediment free (including, but not limited to, hard barriers such as dams, biological barriers such as abundant predators, or lack of refugia from predators).
3. Primary constituent element 3 is refugia habitat. Nonbreeding, breeding, rearing, or overwintering habitat or aquatic movement corridors with habitat characteristics (e.g., dense vegetation and/or an abundance of woody debris) that provide refugia from predators (e.g., nonnative fish or bullfrogs).

#### 4.4.5.2 Environmental Baseline

**Analysis Area**

Similar to listed fish species, the analysis area for Oregon spotted frogs is the Spencer Creek riverine analysis area associated with Spencer Creek and Buck Lake which includes the water column and substrate of Spencer Creek to the extent downstream where water quality is adversely affected by turbidity generated during construction and sediment generated by runoff from the construction right-of-way. The associated riparian zone of Spencer Creek is included in the analysis area over the short-term during construction and in the long-term by operation.

Construction across Spencer Creek is expected to mobilize silt, assumed to be the predominant substrate particle at the crossing location. As discussed below, the downstream distance that silt particles would be expected to settle out of the water column during dam-and-pump construction is estimated to be 1,450 feet (based on assumptions and estimation procedures below). Consequently, the Spencer Creek riverine analysis area would extend 1,450 feet downstream from the point of pipeline construction, shown in figure 4.4-1.

**Species Presence**

Oregon spotted frogs inhabit Buck Lake. Spotted frogs were first documented in 1994 at Buck Lake in the Winema National Forest and adjacent private lands in a canal on the northwest edge of Buck Lake and on BLM lands within Tunnel Creek (USFS and BLM, 1995), inhabiting the channelized portion of the perennial stream that enters the Buck Lake basin from the southwest. These are the only sites in the Spencer Creek watershed likely to be inhabited by Oregon spotted frogs (USFS and BLM, 1995).

A mark-recapture study to assess the Oregon spotted frog population in Buck Lake was conducted between 1995 and 1997 by Marc Hayes. The study results provided a population estimate of about 519 adults (with a range of 0 to 1,499, derived from 95 percent confidence intervals) (Lerum, 2012). Demographic information from this study showed limited evidence of recruitment likely attributable to the presence of resident brook trout (FWS, 2011d). Observations of adult Oregon spotted frogs made between 1994 and 2001 ranged from 25 to 176, no adult frog were observed in 2005 or 2009 (FWS, 2011d; see figure 4.4-2). Since Hayes' study, various USFS, BLM, USFWS, and USGS personnel have sporadically resurveyed this population documenting continued presence through 2011 (Lerum, 2012). Since 2006, egg mass surveys have been conducted in addition to searches for adult frogs. Results are included in figure 4.4-2 and range from 6 egg masses in 2011 to 38 egg masses counted in 2010. However, the locations and search efforts varied from year to year, making inferences about trends based on egg masses counted inappropriate (Lerum, 2012).

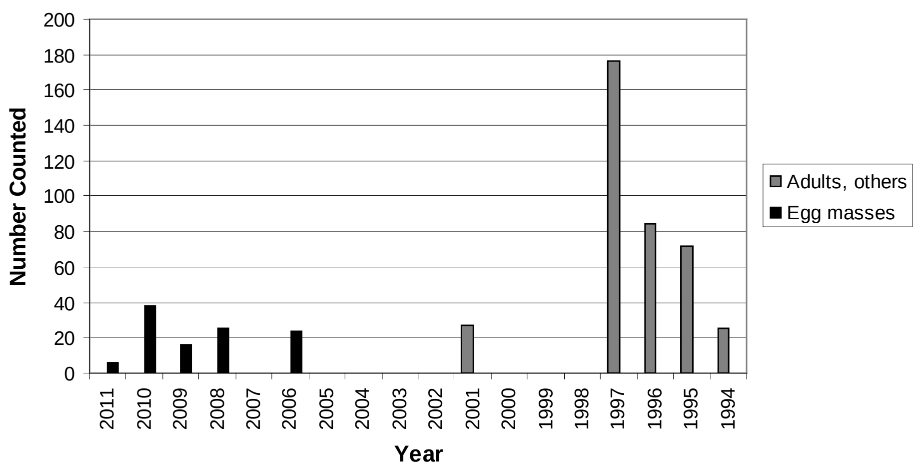

**Figure 4.4-2**
**Observations of Oregon Spotted Frog Adults (including juveniles and metamorphs) and Egg Masses at Buck Lake (Sources: FWS, 2011; Lerum, 2012)**

**Habitat**

Historically, Buck Lake was likely a large shallow marsh fed by springs and streams. Two perennial streams, Spencer Creek and Tunnel Creek, flow into Buck Lake but the basin is currently a meadow with drainage ditches, and at least two impounded areas fed by springs (Lerum, 2012). ORBIC (2012) has mapped Oregon spotted frog habitat at Buck Lake to include Spencer Creek from its inflow at the lake to approximately 6,100 feet upstream to where Spencer Creek passes through a culvert beneath Clover Creek Road. That segment of Spencer Creek is almost equally subdivided into Buck Marsh, closest to the highway, and Buck Meadow, closest to Buck Lake (Lerum, 2012). Spencer Creek flows through Buck Marsh and Buck Meadow on US Forest Service lands; Buck Marsh is fed by several springs with evidence of beaver activities and Buck Meadow is a pasture that often floods in the spring but does not stay flooded long enough to provide spotted frog breeding habitat. Further, soils are dense, possibly compacted by past heavy livestock use, provide little water infiltration and riparian vegetation is sparse and likely would not support beaver occupancy (Lerum, 2012). Neither Buck Marsh nor Buck Meadow currently provides habitat for Oregon spotted frogs (Lerum, 2012).

Some winters Spencer Creek freezes and flows cease. It is unknown if the site could provide overwintering habitat. It is not known exactly where Oregon spotted frogs in the Buck Lake complex overwinter. Underwater video cameras installed in 2010 and 2011 did not detect Oregon spotted frogs at suspected overwintering sites until March when frogs began to move to breeding sites (Lerum, 2012).

Lerum (2012) reported a Level II stream survey of Spencer Creek flowing through Buck Marsh and Buck Meadow conducted by the Forest Service on June 28, 2010 (USFS, 2011 cited in Lerum, 2012). Spencer Creek characteristics in this area (Reach 5) were summarized as: “Reach 5 was determined to be a Rosgen E6 stream channel type due to its gradient and silt dominated substrate. A large portion (3500’) of reach 5 was determined to be a marsh. The average wetted width (Rosgen E channel only) is 6.4 feet. The reach averages 19 pools per mile with residual pool depth of 1.2 feet. Stream banks are 98% stable and 2% unstable with sections of unstable bank along both sides of the stream. The reach had 6 pieces of LWD per mile (0 large/medium and 6 small pieces per size class). The stream side vegetation was dominated by grass forbs with an overstory of grass forbs. There are some isolated pockets of lodgepole pine. The stream runs through a very large valley dominated by marshland. A channel begins to take shape at the end of the valley up to the road crossing. There are active beaver dams in the marsh. Unidentified fish were observed throughout the reach.”

Typical Rosgen E6 channels (Wildland Hydrology, 1994):

- are slightly entrenched (entrenchment ratio >2.2);
- have very low width to depth ratios (ratio <12);
- have high sinuosity (>1.5);
- have water surface slope gradients <2 percent;
- channel substrate particles are predominantly silt and clay.

In 2002, lower Spencer Creek was listed by the Oregon Department of Environmental Quality (303(d) List, ODEQ, 2002) as impaired due to sediment based on the formation of appreciable bottom or sludge deposits. However, there are no estimates of ambient turbidity in Spencer Creek (USFS and BLM, 1995) although intense cattle grazing on Buck Lake has contributed to elevated sediment in the creek, probably downstream from Buck Lake. Within the watershed, the principal causes of stream sedimentation are bank erosion and delivery of sediment from roads and stream crossings (BLM, 2008).

There are no long-term discharge data for Spencer Creek. Flows were measured downstream from Buck Lake from 1992 to 1998 during which annual peak flows were from 150 to 200 cfs and summer base flows were 20 cfs, with a minimum of 5 cfs following a dry winter (BLM, 2008c). Peak flows in the middle portion of the Spencer Creek watershed were caused by snowmelt and rain-on-snow events.

### Critical Habitat

Proposed critical habitat Unit 14 includes seasonally wetted areas adjacent to the western edge of Buck Lake encompassing Spencer Creek, three unnamed springs, and Tunnel Creek, shown in figure 4.4-1. Buck Marsh and Buck Meadow are not included in the proposed critical habitat. The proposed critical habitat is approximately 6,400 feet downstream from where the proposed pipeline would cross Spencer Creek. There are 185.7 acres within proposed Unit 14 at Buck Lake, 38.23 acres are managed by the BLM, 0.17 acre is on the Fremont-Winema National Forest, and 147.30 acres are privately owned. Another area, Keene Creek in Jackson County, is also included in Unit 14 but is separated by approximately 14.5 miles from the proposed critical habitat at Buck Lake. According to FWS (2013f, page 53551), "all of the essential physical or biological features are found within the unit, but are impacted by woody vegetation succession, nonnative predators, lack of beaver, and hydrological changes. The essential features within this unit may require special management considerations or protection to ensure maintenance or improvement of the existing nonbreeding, breeding, rearing, and overwintering habitat; aquatic movement corridors, or refugia habitat, and to address any changes that could affect these features."

### 4.4.5.3 Effects by the Proposed Action

### Direct and Indirect Effects

Construction of the PCGP Project could directly and/or indirectly affect Oregon spotted frog and proposed critical habitat through one or more of the following pathways:

- Interference with key life history functions.
- Acoustic shock from blasting pipe trench through bedrock streambeds or use of a track hoe or impact hammer if frogs are proximate to the construction site.
- Turbidity generated during pipeline construction across waterbodies can adversely affect Oregon spotted frogs and aquatic habitats.
- Introduction and/or re-distribution of nonnative aquatic species and pathogens.
- Accidental release of fuels and entry of other petroleum products into surface waters can adversely affect spotted frogs and other aquatic organisms.
- Application of herbicides to control noxious weeds near waterbodies may adversely affect Oregon spotted frogs.

<u>Timing</u>

State guidelines (ODFW, 2008) would allow instream construction across Spencer Creek (a tributary to the Klamath River below Keno) from July 1 through September 30. Construction during that period would avoid any downstream effects to egg masses or spotted frogs during metamorphosis in Buck Lake.

<u>Acoustic Shock</u>

The base material where the pipeline is proposed to cross Spencer Creek is described as igneous rock and locally tuffaceous rock with local valley fill. There is a high potential for blasting to construct the pipeline trench across Spencer Creek if volcanic rocks cannot be excavated to the appropriate depth (GeoEngineers, 2013a). Effects of underwater blasting on frogs is generally unknown although effects on frogs' lungs are expected to be similar to effects on fish with swim bladders, and would cause mortality (Keevin and Hempen, 1997). Effects of underwater blasts on coho salmon are discussed below in Section 4.5.3.3. The analysis in that section identified straight line distances through rock and other materials for a single shot explosive charge, of given weight, to dissipate to an overpressure standard of 2.7 psi, the threshold for non-lethal pressure for anadromous fish, and assumed to be applicable to frogs. Pacific Connector may opt to blast across stream locations where consolidated rock makes traditional trenching methods unfeasible.

Typical trench blasting scenarios use multiple 1- to 2-pound charges separated by an 8-milisecond delay to excavate the trench. With use of 1- to 2-pound charges in rock, the set back distance (at which 2.7 psi would occur) from the blast trench to the aquatic habitat is between 34 and 49 feet (see Table 3, in Alaska Department of Fish and Game, 1991). Blasting would be conducted within dry streambanks isolated from the water column, most likely using dam-and-pump construction to bypass water around the dry workspace. Since no Oregon spotted frogs are expected in the vicinity of the Spencer Creek construction right-of-way, blasting is not expected to affect any animals. Native fish (eg, redband trout) are likely to be present, however. The same mitigation measures and fish salvage measures that have been described for coho salmon would be employed at Spencer Creek.

Suspended Sediment

Suspended sediments (turbidity) directly affect survival and growth of salmonids and other fish species, interferes with gill function, and adversely affects substrate for fish egg development (reviewed and compiled by Newcombe and Jensen, 1996 and Bash et al., 2001). Effects of turbidity on frogs have not been extensively reported. However, sedimentation and turbidity in wetlands accessible to cattle were reported to be 3.5 times greater than in wetlands that were not accessible; cattle increased turbidity by trampling vegetation, disturbing sediment, and defecation. In part due to increased turbidity, the relative abundances for larvae of two frog species were less in the cattle-accessed wetlands (Schmutzer et al., 2008). In another situation, road construction was found to cause sedimentation in previously unaffected streams. When compared to adjacent, unaffected streams, densities of three amphibian species were significantly lower in the streams impacted by sediment (Welsh and Ollivier, 1998). As summarized by Henley et al. (2000), sedimentation can reduce food availability, water and environmental quality, and habitats used by aquatic organisms resulting in decreased plant, zooplankton, and insect abundance and biomass that would affect aquatic food chains and consequently would affect frogs during different life stages.

Although background levels of suspended sediment in Spencer Creek are unknown (USFS and BLM, 1995), construction of the PCGP Project would probably mobilize particles into the water column, primarily silt which is the predominant substrate material in Spencer Creek (see above and Lerum, 2012). The distance downstream that silt particles would be transported can be estimated with the following equation (Trow Equation, see Harper and Trettel, 2002):

$$\mathbf{L = (D\ V_A) / V_S}$$

where **L** is the transported distance downstream (in feet); **D** is the average depth of stream flow (in feet), $\mathbf{V_S}$ is the particle size-specific settling velocity (in inches or feet per second), and $\mathbf{V_A}$ is the average streamflow velocity (in feet per second). The settling velocity ($\mathbf{V_S}$) for medium silt is 0.009 inch per second or 0.00075 feet per second (see the Wentworth Grain Size Chart, USGS, 2003). The average depth of streamflow within Spencer Creek at the time of construction is unknown but, using the average wetted width of 6.4 feet (see above and Lerum, 2012) and a low width to depth ratio of 10 (for Rosgen E6 channels the width to depth ratios are <12), the average depth is estimated to be 0.64 feet (8 inches).

Assuming a rectangular channel cross section, the cross-sectional area is **A** = 4.1 square feet (ft$^2$). The estimated cross-sectional area (**A**) can be used in Manning's Formula (Limerinos, 1970; Arcement and Schneider, 1989) to estimate **Q**, the stream discharge rate (cubic feet per second, or cfs) and ultimately to estimate $\mathbf{V_A}$ , the average streamflow velocity. Manning's Formula is:

$$\mathbf{Q = A\ (\mathit{k}/n)\ (R^{2/3})\ (S^{1/2})}$$

with estimated **A** = 4.1 ft$^2$, **R** is the hydraulic radius (in feet, where **R** = **A/P**, and **P** is the wetted perimeter in feet), **S** is the slope of channel (vertical feet per horizontal feet), the constant ***k*** equals 1.486 if English units are used but ***k*** equals 1 with metric units, and **n** is Manning's roughness coefficient (Manning's **n**).

For Spencer Creek, the wetted perimeter **P** = (2 x 0.64 feet) + 6.4 feet = 7.68 feet so that the hydraulic radius **R** = 0.53 feet, the slope of channel **S** = 0.015 (or 1.5 percent, for Rosgen E6 channels the water surface slope gradient is <2 percent). Manning's **n** was estimated at **n** = 0.070, based on a natural stream channel with sluggish reaches, weedy, and with deep pools (Chow, 1959).

With these parameters estimated, the solution for Manning's Equation is **Q** = 6.98 cfs. With the estimate for **Q**, and **A** = 4.1 ft$^2$, the estimated stream velocity is $\mathbf{V_A}$ = **Q** / **A** = 1.7 feet per second.

Solving the Trow Equation (above) using the following values: **D** = 0.64 feet, $\mathbf{V_S}$ = 0.00075 feet per second, and $\mathbf{V_A}$ = 1.7 feet per second, the estimated distance downstream (**L**) that silt particles would settle out of the water column would be **L** = 1,453 feet from the location where the PCGP project crosses Spencer Creek. That distance will fall within Buck Marsh. Currently, there are no Oregon spotted frogs inhabiting Buck Marsh although the presence of beaver activity and spring flooding could provide suitable breeding habitat (Lerum, 2012). Based on current information however, sediment mobilized during construction is not expected to reach habitats occupied by frogs in Buck Lake.

<u>Introduction of Non-Native Species and Disease</u>

Non-indigenous aquatic species (NAS) are aquatic species that degrade aquatic ecosystem function and benefits, in some cases completely altering aquatic systems by displacing native species, degrading water quality, altering trophic dynamics, and restricting beneficial uses (Hanson and Sytsma, 2001). FWS (2013g) identified warm water non-native fish (bullhead, fathead minnows), and cold water non-native brook trout that had been introduced to Buck Lake, although bullfrogs were absent. Non-native fish may limit numbers of juvenile frogs by predating larvae and/or juveniles. Bullfrogs also may act as direct predators on larval and juvenile frogs but bullfrogs are not known to occur on federal land in the Buck Lake complex (Lerum, 2012). Although unlikely, introduction of bull frogs and/or other warm water predaceous fish species due to the Proposed Action could occur through hydrostatic test water discharge.

Oregon spotted frogs in Buck Lake are infected with the fungal pathogen *Batrachochytrium dendrobatidis* (Bd) which causes chytridiomycosis (Pearl et al., 2009; FWS, 2013c). However, Oregon spotted frogs experimentally infected with the chytrid pathogen were able to clear the infections with no mortality suggesting some resistance to Bd (Padgett-Flohr and Hayes, 2011). The fungus may infect other nonamphibian hosts (eg, crayfish), persisting in freshwater ecosystems that are uninhabited by frogs but infected hosts may transmit the disease to uninfected frogs (McMahon et al., 2013)

The water mold *Saprolegnia* has been suggested as one possible cause of amphibian declines in the Pacific Northwest which destructs developing Oregon spotted frog egg masses (FWS, 2013a). Water-molds of the genus *Saprolegnia* have been identified in Oregon spotted frog populations in the Klamath Basin (Lerum, 2012). Mortality may be caused by parasitic infections by the trematode *Ribeiroia ondatrae* which are transmitted through aquatic snails (genus *Planorbella*), an intermediate host. The infections cause limb malformations in amphibians. Human manipulation of upland areas adjacent to amphibian breeding areas and direct manipulation of the breeding areas can affect the prevalence of *Planorbella* snails and the infection rate of *Ribeiroia ondatrae* (FWS, 2013e). Increased prevalence of trematodes and risks of parasitism to frogs may occur if water runoff from areas of heavy livestock use causes eutrophication, algal blooms, and increased snail abundance of in frog habitats (Johnson et al., 2007). The trematode has not been documented in the Buck Lake frog population (FWS, 2013g).

The risk of introducing *Saprolegnia*, *Ribeiroia ondatrae*, and/or other pathogens into Buck Lake during pipeline construction appears to be low. Pathogens might be brought to the Spencer Creek construction site if attached to machinery or if introduced by hydrostatic water discharged at a test header. The closest hydrostatic discharge location to Spencer Creek (MP 171.06) is 2 miles away at MP 173.10; at that site, 1,041,111 gallons (3.20 acre feet) of test water are proposed to be discharged on the construction right-of-way. Although the discharge site is 2,060 feet away and uphill from Buck Lake, the Clover Creek Road intervenes and would block any flow toward the lake.

Pacific Connector has developed BMPs to avoid the potential spread of the aquatic invasive species and pathogens of concern (see Hydrostatic Testing Plan – appendix U). If determined to be feasible for hydrostatic testing requirements, all water used in hydrostatic testing would be returned to its withdrawal source location after use; however, cascading water from one test section to another to minimize water withdrawal requirements may make it impractical to release water within the same watershed where the water was withdrawn. If it is not possible to return the water to the same water basin from where it was withdrawn, various water treatment methods would be used to disinfect water that would be transferred across water basin boundaries including screening/filtering, chlorine treatment, and discharge to upland sites. After hydrostatic test water withdrawal, all equipment used in the withdrawal process would be cleaned and sanitized to prevent the potential spread of aquatic invasives and pathogens from the use of this equipment in other waterbody sources (see appendix U).

Fuel and Chemical Spills

Oregon spotted frog habitat in the Buck Lake complex could be adversely affected if petroleum products were accidentally discharged into aquatic environments. Such materials are toxic to algae, invertebrates, fish and amphibians. Of the products likely to be present during pipeline construction, data compiled from a wide range of sources indicate that diesel fuels and lubricating oils are considerably more toxic to aquatic organisms than other, more volatile products (gasoline) or heavier crude oil (Markarian et al., 1994). Release of diesel fuel in freshwater habitats significantly reduced aquatic invertebrate densities and species richness at least 3 miles downstream but invertebrate densities recovered within a year (Lytle and

Peckarsky, 2001). Impacts to aquatic habitats that primarily affect aquatic substrates – hence spawning, incubating and rearing habitats – can remain for much longer periods (Markarian et al., 1994).

Construction equipment used to construct the pipeline across waterbodies can potentially release hydraulic fluid that include a variety of compounds those common of which are mineral oil-based, organophosphate esters, and polyalphaolefins (U.S. Department of Health and Human Services, 1997). Release from machinery can occur through faulty seals, hoses, sumps and reservoirs, or general system failure. Components of mineral oil and polyalpaolefins do appear to bioaccumulate in animals whereas larger molecular constituents in organophosphate esters can concentrate in fish, primarily partitioning in fat tissue (U.S. Department of Health and Human Services, 1997). In general, toxicity of organophosphate esters is greater than either mineral oil or polyalphaolefin-based hydraulic fluids for inhalation, oral, and dermal for humans but toxicities have not been clearly described for aquatic invertebrates, fish, or amphibians and would be dependent on specific chemical components (U.S. Department of Health and Human Services, 1997).

Inadvertent spills of fluids used during construction, such as fuels and lubricants, could contaminate wetland soils and vegetation. To minimize the potential for spills and any impacts from such spills, Pacific Connector's Spill Prevention, Containment, and Countermeasures Plan (SPCC Plan – see appendix L) will be implemented. In general, hazardous materials, chemicals, fuels, lubricating oils, and concrete-coating activities will be not be stored, nor will refueling operations be conducted within 150 feet of a wetland or waterbody in accordance with FERC's Wetland and Waterbody Procedures (see appendix C) and the SPCC Plan (see appendix L).

<u>Herbicide Application</u>

Following construction, Pacific Connector will implement a Noxious Weed Control Plan in part through the application of herbicides. Herbicides have the potential to cause toxic effects to different salmonid life stages and to other aquatic species, causing direct impacts, if used improperly. When herbicides are properly used according to label restrictions and BMPs to control noxious weeds, there is little to no chance of causing injury or mortality to fish or other aquatic organisms; the impact may be avoided or indirect.

Pacific Connector has developed an Integrated Pest Management Plan (IPM) in consultation with the Oregon Department of Agriculture, BLM and Forest Service (see Appendix I to the POD, available upon request) to address the control of noxious weeds and invasive plants across the project. The BMPs will minimize the potential spread of invasive species and minimize the potential adverse effects of control treatments.

According to the Pacific Northwest Weed Management Handbook (see Peachey et al., 2007), herbicides used in forests to control brush and weed-trees could include one of the following: 2,4-D, glyphosate, imazapyr, picloram, and ticlopyr which are applied during spring or fall dormancy although triclopyr or 2,4-D was not approved use by the Fremont-Winema National Forest (NF). Clopyralid may be used during summer to control thistles, other composites, and legumes while not damaging conifers. Only herbicides which are approved for use within treated lands (private, state, or federal) would be used. Chronic, long-term, elevated but sublethal toxic effects can lead to skin or eye irritation, headache, nausea, and possibly birth defects, genetic disorders, paralysis, cancer, and death (Tu et al., 2001). In general, most impact to waterbodies occurs from direct overspray or drift of herbicides (aerial applications) as well as leaching through soils into groundwater or as they are carried by surface/subsurface runoff (Tu et al., 2001). The ester form of herbicides is more toxic to fish and other aquatic species than salt or acid forms because esters are readily adsorbed through skin and gills. Esters are also water insoluble so that they are not diluted in waterbodies (Tu et al., 2001).

Herbicides potentially used during the project will breakdown over various periods of time, marked by the average half-life (the time it takes for the herbicide concentration to decline by 50% due to microbial metabolism –dependent on the microbial population, environmental pH, soil moisture and temperature - mineralization, and/or photolysis:

- 2,4-D – averages 10 day half-life in soils, less than 10 days in water. Salt formulations with low toxicity are registered for use against aquatic weeds, Acute exposure of 2,4-D to leopard frog tadpoles reduces their activity and feeding does not appear to be a particularly strong threat to larvae (Ryan et al., 2005).
- Glyphosate - ranges from several weeks to years, but averages two months. In water, glyphosate is rapidly dissipated through adsorption to suspended and bottom sediments, and has a half-life of 12 days to ten weeks. Toxicity of glyphosate-based pesticides to amphibians varies with developmental stage because there is some evidence that some formulations may interfere with metamorphosis (Howe et al., 2004).
- Imazapyr – ranges from 1 to 5 months in soil. In aqueous solutions with photodegradation the half-life may be 2 days. It has low toxicity to fish and algae and other submerged vegetation are not affected. Adverse effects to terrestrial and aquatic animals appear to be unlikely (Durkin and Follansbee, 2004).
- Toxicity of picloram and triclopyr on amphibians is not well understood (Durkin and Follansbee, 2003) although triclopyr applied to amphibian habitats could adversely affect them (Antunes-Kenyon and Kennedy, 2004).

The potential for adverse effects to Oregon spotted frogs and other aquatic species by these herbicides appear to be extremely remote, especially since application would be at least 100 feet from wetlands and waterbodies unless allowed by the appropriate agency. Pacific Connector will not use aerial herbicide applications and will not use herbicides for general brush/tree control within the 30-foot maintained easement. Given low toxicities and short half-lives in soil and water, expected effects of the other herbicides to amphibians would be discountable and insignificant.

Where weed control is necessary along the construction right-of-way, Pacific Connector's first priority will be to employ hand and mechanical methods (pulling, mowing, biological, disking, etc.) applicable to the species to prevent the spread of potential weed infestations, where feasible. To determine if an herbicide is to be used over other control methods, Pacific Connector will base the decision on weed characteristics and integrated weed management principles (Forest Service, 2005). If herbicides are used to control noxious weed infestations, they would be used when they are the most appropriate treatment method. Spot treatments and the use of selective herbicides would be utilized to minimize impact to native or non-target species. Pacific Connector will employ a state or federally-licensed herbicide applicator to ensure that the appropriate herbicides are utilized for the targeted weed species during its proper phenological period and at the specified rate. The applicator will ensure that the herbicides and any adjuvants[1] are used according to the labeling restrictions, and warnings, following all applicable laws and conforming to the appropriate land managing agency decision documents. The applicator will also ensure that the herbicides that are used are registered for their intended use. Permits or approvals for the use of herbicides and adjuvants on federal lands would be obtained prior to use/treatment, as detailed in the IPM (see Appendix I to the POD, available upon request).

**Cumulative Effects**

FWS and NMFS describe cumulative effects (50 CFR § 402.02) as the result of future actions by state or private entities, not involving federal actions, but reasonably certain to occur in the action area considered in this biological assessment. Future federal actions that are unrelated to the proposed action are not considered here because they require separate consultation pursuant to section 7 of the ESA. One hundred percent of the Spencer Creek riverine analysis area is within the Fremont-Winema National Forest. Consequently, there would be no private actions that would affect the PCGP riverine analysis area in the foreseeable future.

**Critical Habitat**

Proposed critical habitat for the Oregon spotted frog does not coincide with the Spencer Creek riverine analysis area. None of the three primary constituent elements identified for the proposed critical habitat Unit 14 in Buck Lake would be affected downstream from the riverine analysis area.

#### 4.4.5.4 Conservation Measures

Conservation measures have been proposed by Pacific Connector to minimize construction and operation impact to waterbodies and riparian zones. Those measures have been compiled in table 2C in appendix N and would apply to Oregon spotted frogs.

#### 4.4.5.5 Determination of Effects

**Listed Species**

The Project **may affect** Oregon spotted frogs because:

- The project will cross Spencer Creek which is hydrologically connected to Buck Lake which is occupied by the frog.

Because Oregon spotted frog are proposed for listing the Project **will not jeopardize the continued existence** of Oregon spotted frogs because:

- Buck Lake is approximately 6,400 feet downstream from where the pipeline would cross Spencer Creek. Suspended sediment generated by the Proposed Action is expected to remain in the water column for 1,450 feet downstream from the construction site. Suspended sediment in Spencer Creek would pass through Buck Marsh but Oregon spotted frogs do not currently inhabit Buck Marsh.
- If the Oregon spotted frogs does occur in Buck Marsh at the time of pipeline construction, conservation measures will limit potential effects due to acoustic shock, introduction of non-native species and/or disease, fuel and chemical spills, and

[1] Adjuvant(s) are substances added to the pesticide formulation to enhance the toxicity of the active ingredient or to make the active ingredient easier to handle.

herbicides. Future presence of Oregon spotted frogs in the Spencer Creek riverine analysis area at the time of construction is extremely unlikely, considered to be discountable.

**Critical Habitat**

Because critical habitat has been proposed for the Oregon spotted frog, the Project will **not adversely modify** the proposed critical habitat for Oregon spotted frogs in Unit 14.

## 4.5 FISH

### 4.5.1 North American Green Sturgeon (Southern Distinct Population Segment)

#### 4.5.1.1 Species Account and Critical Habitat

**Status**

On January 29, 2003 (NMFS, 2003), NMFS determined that the North American Green Sturgeon is comprised of two DPS's that qualify as species under the ESA: 1) a northern DPS consisting of populations in coastal watersheds northward of and including the Eel River in California; and 2) a southern DPS consisting of coastal and Central Valley populations south of the Eel River, with the only known spawning population in the Sacramento River. At that time however, neither DPS was listed because of the uncertainty about the population structure and status.

In April 2006, NMFS listed the Southern DPS as threatened under ESA within California, including spawning population of green sturgeon south of the Eel River, principally the Sacramento River green sturgeon spawning population (NMFS, 2006f). The Pacific Northern DPS, which includes coastal spawning populations from the Eel River north to the Klamath and Rogue Rivers, remains unlisted but is a Species of Concern (NMFS, 2007d).

**Threats**

The southern DPS was proposed for listing as threatened in 2005 (NMFS, 2005b) because 1) the majority of spawning adults were concentrated in one spawning river (Sacramento River), 2) threats since the first status review (see NMFS, 2002) have not been adequately addressed, 3) new evidence of loss of spawning habitat in the upper Sacramento and Feather Rivers, and 4) data showing a negative trend in juvenile green sturgeon abundance. One factor that was not considered a primary factor causing the decline of the Southern DPS, but likely poses a threat to the Southern DPS, was past and present commercial and recreational fishing, primarily ocean and estuarine bycatch of green sturgeon in the Oregon and Washington white sturgeon and salmonid fisheries; however, recent fishing regulations have reduced the risk for Southern DPS in Oregon and Washington (NMFS, 2006f). Actions that may negatively affect the Southern green sturgeon DPS include water diversion for human use, point and non-point source discharge of persistent contaminants, contaminated waste disposal, water quality standards, and fishery management practices (NMFS, 2006f).

The principal threat to the southern DPS green sturgeon remains as limited spawning habitat in the Sacramento River, California. Multiple dams on the river prevent adult migration to former spawning sites. Also, flow rates in the river and Delta have been affected by water diversions for agricultural, municipal and industrial uses and insufficient flow rates in the Sacramento River system are likely a significant threat to green sturgeon (NMFS, 2006f). In particular, entrainment of juveniles in water diversion structures has been identified though may not be as much as a problem as thought earlier (NMFS, 2005b). Other adverse effects within the Sacramento River system include elevated water temperatures and contamination from toxic materials (e.g., bioaccumulation of PCBs and selenium). Past and present commercial and recreational fishing may also affect green sturgeons including incidental catches (bycatch) by salmon fisheries in Oregon and Washington (NMFS, 2006e).

**Species Recovery**

No recovery plan has been drafted.

**Life History, Habitat Requirements, and Distribution**

Green sturgeons spawn in deep pools in large, turbulent river mainstems, generally from March through July with peak spawning from mid-April to mid-June Moyle, 2002). Adults migrate to/from spawning grounds during the spring and fall, consecutively, and juvenile migration occurs from April through November (Rien et al., 2001). Northern DPS green sturgeons enter the Rogue River during March through June to spawn. Spawning appears to be related to water temperature ($8.8^{o}$ to $16.4^{o}$C or $48^{o}$ to $62^{o}$F) but low flows probably dictate how far upstream sturgeon are able to migrate to potential spawning habitat (Erickson and Webb, 2007).

Little is known about sturgeon feeding, but some studies have found that adults and juveniles feed on benthic invertebrates including shrimp, mollusks, amphipods, and even small fish (Moyle, 2002). They are thought to spend most of their lives in nearshore oceanic waters, bays, and estuaries (NMFS, 2007d).

Green sturgeon move into estuaries of non-natal rivers to feed (Beamis and Kynard, 1997). They occupy large estuaries during the summer and early fall in the Pacific Northwest. Green sturgeons enter Washington estuaries during summer when water temperatures are more than $4^{o}$F warmer than adjacent coastal waters (Moser and Lindley, 2007). Green sturgeon abundance peaks during October in the Columbia River estuary, based on commercial catches. In Washington, (Willapa Bay and Grays Harbor) green sturgeons appear to be present from June until October (Moser and Lindley, 2007). Sturgeons in the Southern DPS that originate in the Sacramento River have been found in to be relatively extensive Washington estuaries and Columbia River. In the lower Columbia River (river mile 0 to 35), between 77 and 88 percent of the green sturgeons collected originated from the Southern DPS (Israel and May, 2007).

Data from tagged green sturgeons occurring offshore from the Klamath River in California suggests they are from the northern and southern DPS. Tagged green sturgeons that utilize the lower Klamath River have been observed in Grays Harbor, Washington (McCovey, 2007), approximately 400 nmi north of the Klamath River. There are no records of tagged green sturgeon occurring within Coos Bay which is approximately 125 nmi from the Klamath River estuary.

**Population Status**

It has been reported that there are no good data on current population of the green sturgeon (NMFS, 2007d). ODFW evaluated the presence of green sturgeon in coastal tributaries through 2005 and provided summaries of harvests of green sturgeon in California, Oregon, and Washington commercial and sport fisheries (Farr and Kern, 2005). Although many factors contribute to annual catch of sturgeons in the three states whether in coastal, estuarine, or riverine habitats, the overall declining trend since 1985 (see figure 4.5-1) is probably indicative of the species' declining population.

There are confirmed records of green sturgeon in the Umpqua River, captured above the zone of tidal influences. In 2000, two juvenile green sturgeons were regurgitated from a smallmouth bass caught in the Umpqua River (river kilometer 134) and in 1979, a green sturgeon nearly 2 meters long was caught at river kilometer 164 (NMFS, 2005b). In addition, a possible juvenile green sturgeon was captured at Big Butte Creek, near Lost Creek Dam on the Rogue River (NMFS, 2005b). From 2000 to 2004, 249 green sturgeons were captured in the Rogue River and 33 fish were capture while 2 sturgeons that had been tagged were recaptured in the Umpqua River (Farr and Kern, 2005). However, there is no indication to which DPS any of those reported green sturgeons belonged.

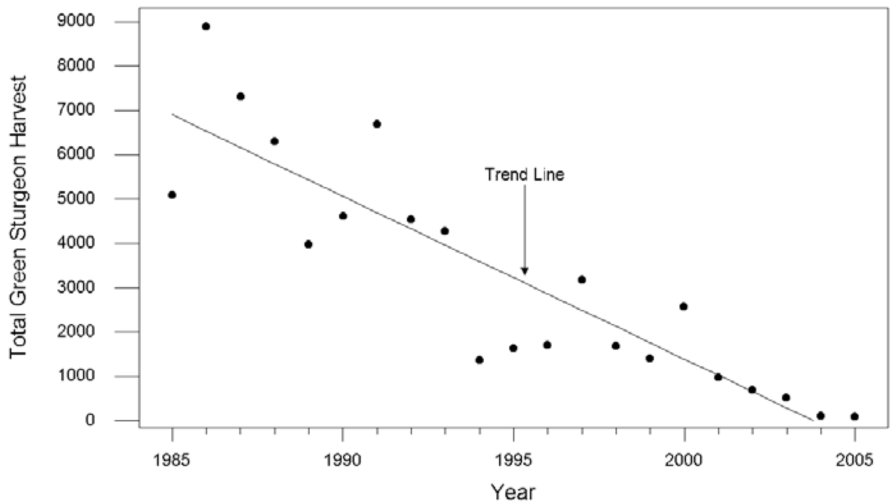

**Figure 4.5-1**

**Total Harvest of Green Sturgeon in California, Oregon, and Washington Commercial and Sport Fisheries from 1985 yo 2005. The linear relationship is significant ($r^2$ = 0.786, P<0.001). Source: Farr and Kern, 2005.**

## Critical Habitat

During reviews prior to designating critical habitat, NMFS (2008b) determined that subadult and adult Southern DPS green sturgeon inhabited certain estuaries along the coast of northern California, Oregon, and Washington during summer and inhabited coastal marine waters from central California to British Columbia. NMFS (2008b) noted large numbers of adult and subadult green sturgeons used Coos Bay as summer habitat, used by Southern DPS green sturgeons tagged in San Pablo Bay, a northern extension of San Francisco Bay. Based on that information, NMFS (2009b) designated critical habitat for the Southern DPS of North American green sturgeon to include all tidally influenced area of Coos Bay up to the elevation of mean higher high water, including the head of tide endpoint in the Coos River, Catching Slough, Stock Slough, Monkey Gulch, and Haynes Inlet, all of which are crossed by the PCGP Project. Critical habitat has also been designated in the Coos River, Boone Creek, Catching Slough, Monkey Gulch, Stock Slough, and Haynes Inlet, also crossed by the pipeline but critical habitat is limited to reaches downstream of tide gates near the mouths of those waterbodies.

PCEs have been identified for critical habitats including: 1) freshwater riverine systems, 2) estuarine habitats, and 3) nearshore coastal marine area. The fresh water riverine component includes the Upper and Lower Sacramento River, Lower Feather River, Lower Yuba River, and several bypasses in the Sacramento-San Joaquin Delta, all of which are in California.

The PCGP Project has potential to affect estuarine PCEs within Haynes Inlet in Coos Bay and coastal tributaries when occupied by subadult and adult green sturgeon (NMFS, 2009b). NMFS (2008b) determined that the Coos Bay estuary provided food resources, water flow, water quality, and migratory corridors to support migration and possibly feeding by subadult and adult green sturgeon. Estuarine PCEs include:

1. Food resources. Abundant prey items within estuarine habitats and substrates for juvenile, subadult, and adult life stages.
2. Water flow. Within bays and estuaries adjacent to the Sacramento River (i.e., the Sacramento-San Joaquin Delta and the Suisun, San Pablo, and San Francisco bays), sufficient flow into the bay and estuary to allow adults to successfully orient to the incoming flow and migrate upstream to spawning grounds.
3. Water quality. Water quality, including temperature, salinity, oxygen content, and other chemical characteristics, necessary for normal behavior, growth, and viability of all life stages.
4. Migratory corridor. A migratory pathway necessary for the safe and timely passage of Southern DPS fish within estuarine habitats and between estuarine and riverine or marine habitats.
5. Depth. A diversity of depths necessary for shelter, foraging, and migration of juvenile, subadult, and adult life stages.
6. Sediment quality. Sediment quality (i.e., chemical characteristics) necessary for normal behavior, growth, and viability of all life stages.

NMFS (2009b) identified coastal marine water depths within 110 meters (360 feet, or 60 fathoms) as occupied areas necessary to critical habitat, including coastal waters segments from San Francisco Bay to Humboldt Bay, California and from Humboldt Bay to Coos Bay. Migratory corridors, water quality and food resources are PCEs associated with coastal marine habitat components of critical habitat (NMFS, 2009b).

The specific PCEs in coastal marine areas include:

1. A migratory pathway necessary for the safe and timely passage of Southern DPS fish within marine and between estuarine and marine habitats without human-induced impediments, either physical, chemical, or biological, that would affect the migratory behavior of the fish such that its survival or the overall viability of the species is compromised.
2. Coastal marine waters with adequate dissolved oxygen levels and acceptably low levels of contaminants (*e.g.,* pesticides, PAH heavy metals that may disrupt the normal behavior, growth, and viability of subadult and adult green sturgeon).
3. Abundant prey items for subadults and adults, which may include benthic invertebrates and fish.

### 4.5.1.2 Environmental Baseline

#### Analysis Area

Two analysis areas are applicable to green sturgeons in the Southern DPS. First is the estuarine analysis area which includes: 1) the waters of Coos Bay in which construction-related effects to approximately 3.1 miles downstream from the proposed LNG terminal to a point 2.2 miles upstream from that site which includes the former Weyerhaeuser linerboard mill (distances were estimated for potential worst-case dispersion of turbidity, as provided by Moffatt and Nichol, 2006), 2) the 2.80-mile within-estuary route of the Pacific Connector pipeline after leaving the Weyerhauser Cove Pipe Yard at MP 1.7, crossing Haynes Inlet to where the pipeline emerges from the estuary at MP 4.1, and 3) accessible freshwater tributaries to Coos Bay that would be crossed by the PCGP project below the head-of-tide influence with potential use by green sturgeon (see figure 4.3-6 under section 4.3.3.2 marbled murrelet).

In addition, the proposed action could affect the green sturgeons within the EEZ analysis area which extends 200 nmi offshore. Within the analysis area, effects to green sturgeons within coastal marine waters up to 110 meters deep would be associated with LNG tankers, are assumed to transect the EEZ perpendicularly - east and west - as they approach and depart from Coos Bay or paralleling the West Coast – south and north (see figure 4.2-1 and the discussion above under Section 4.2.1.3 blue whale).

**Species Presence**

It is likely that the North American green sturgeon (both the unlisted Northern DPS and threatened Southern DPS) occur within Coos Bay and its adjacent waterbodies, such as the Coos River, since green sturgeon have been taken in almost all of the Oregon coastal estuaries from the Chetco River to Nehalem Bay (Environmental Protection Information Center et al., 2001) and genetic studies indicate that both Northern DPS and Southern DPS occur in the Columbia River (Israel et al., 2004).

There are historical records of green sturgeons caught in the Coos Bay commercial fishery (ranging from 67 to nearly 2,000 pounds of fish annually) between 1923 and 1949. Further, ODFW has records of green sturgeon caught off Cooson Point, Hays Slough, at the confluence of the Millicoma and Coos Rivers, in Davis Slough, and South Coos River (Farr and Kern, 2005). If their presence in Coos Bay is similar to occurrences on other large estuaries in Oregon and Washington, including the Columbia River, Willapa Bay and Grays Harbor, then a relatively high proportion of green sturgeons may be from the Southern DPS, perhaps as high as 77 to 88 percent similar to occurrence in the lower Columbia River (Israel and May, 2007).

Green sturgeon movements within the 100 meter isobath during migration along the West Coast were monitored using pinger-tags and hydrophone arrays. Although data are limited, tagged sturgeons moved from Seal Rock, Lincoln County, on the Oregon coast north of Coos Bay, south to Monterey Bay, California at the rate of 2 km per day and from Seal Rock north to Brooks Peninsula, B.C. at the rate of 4.2 km per day (Lindley et al., 2008). Migrating green sturgeons were documented along the Oregon coast (Seal Rock) mostly between October and June (Lindley et al., 2008).

**Habitat**

Coos Bay is known to support a small population of green sturgeon; however, natural reproduction in the estuary is considered low (Wagoner et al., 1990). The Coos River system is not considered to provide suitable spawning habitat for green sturgeon (Whisler et al., 1999). However, historical records of the American shad gill-net fishery in the Isthmus Slough indicate that green sturgeon were incidentally captured nearly every year from 1980 to 1992 (Farr and Rien, 2002). ODFW reported that many of these fish were probably younger than three years old based on their size, and suggested that the Coos Bay system may provide spawning or at least rearing habitat for juveniles (Cummings and Schwartz 1971; ODFW, 2006b). Green sturgeons may utilize both shallow and deep water habitats within the estuarine analysis area though there is no information relating individuals' occurrence to DPS membership.

Coastal bays and estuaries provide habitats that support juvenile rearing and growth through the time when they enter coastal marine habitats (NMFS, 2009b). Since no spawning occurs in freshwater tributaries to Coos Bay, the estuary most likely provides feeding and migratory habitat for adult and possibly subadult green sturgeons. Based on food habit studies in several Washington estuaries, adult and subadult green sturgeon fed on a variety of invertebrates (crangonid shrimp, burrowing thalassinidean shrimp - primarily burrowing ghost shrimp (*Neotrypaea californiensis*) and possibly other related species, amphipods, clams, and juvenile Dungeness crab (*Cancer magister*) as well as vertebrates including anchovies, sand lance (*Ammodytes hexapterus*), lingcod (*Ophiodon elongatus*), and other fish (NMFS, 2009b).

Presence of potential forage species within the vicinity of the Coos Bay Navigation Channel (Miller et al., 1990) was discussed above for Oregon Coast coho salmon. Total benthic invertebrate densities in Coos Bay were found to be lower than densities observed in the Umpqua River Estuary and the Columbia River Estuary (Bottom et al., 1985; Miller et al., 1989; Durkin and Emmett, 1980). Benthic studies conducted by NMFS within and in the vicinity of Coos Bay found that the amphipod, *Corophium salmonis*, occurred in much lower densities than other Oregon estuaries (Miller et al., 1990; Bottom et al., 1985; Miller et al., 1989; Durkin and Emmett, 1980). Previous studies in Coos Bay have found that *Corophium* spp. were abundant in intertidal areas and constituted an important diet element for juvenile Chinook salmon and striped bass (USDI, 1971).

Green sturgeons utilize West Coast estuaries during summer months when estuarine water temperatures exceed ocean coastal temperatures, perhaps optimizing their growth potentials by foraging in relatively warm, saline estuarine water (Moser and Lindley, 2007). The Oregon Department of Environmental Quality (ODEQ) periodically monitored water temperatures in Coos Bay at Marker #23 (near Henderson Marsh) from 1957 to 2005 (ODEQ, 2006), located just downstream from the Project site. Although the data are not continuous, they provide a general range of water temperatures in close proximity to the Project site. Temperatures collected during the period of record ranged from 5°C to 13°C (41°F to 55°F) in the winter to 9°C to 20°C (48°F to 68°F) in the summer (ODEQ, 2006).

Dissolved oxygen (DO) in lower Coos Bay is generally higher in the winter and lower in the summer. During winter, DO ranged from 8.9 to 10.4 mg/L and averaged 9.4 mg/L. During summer, DO ranged from 6.0 to 9.6 mg/L and averaged 7.4 mg/L (ODEQ, 2006). Arneson (1976) also sampled DO in the bay and reported that DO concentrations were slightly higher in December and March than in June and September. Lower DO levels in the summer are associated with lower freshwater inputs but would be a "properly functioning" habitat indicator, overall. Lower DO levels Coos Bay during the summer are associated with lower freshwater inputs.

**Critical Habitat**

NMFS (2009b) designated critical habitat for the Southern DPS of North American green sturgeon to include all tidally influenced areas of Coos Bay up to the elevation of mean higher high water, including the head of tide endpoints in the Coos River, Boone Creek, Catching Slough, Monkey Gulch, Stock Slough, and Haynes Inlet, all of which are crossed by the PCGP Project.

The Coos Bay estuary provides several primary constituent elements including food resources, migratory corridors (passage) between estuarine and marine habitats, sediment quality and water quality (NMFS, 2009b), all necessary to support various green sturgeon life stages. Similarly, coastal marine waters between Coos Bay and San Francisco Bay provide food, passage, and water quality as PCEs.

NMFS (2008b) determined that the Coos Bay estuary provided food resources, water flow, water quality, and migratory corridors to support migration and possibly feeding by subadult and adult green sturgeon. Shallow water habitats near the Project site have been mapped as habitat for *Corophium* spp. by Coos County Planning Department (1979). Ghost shrimp more commonly inhabit tide flats closer to the ocean and in Coos Bay, ghost shrimp may be further inland because of predation by the Pacific staghorn sculpin (Hornig et al., 1989; Posey 1986). Those species as well as bivalve mollusks (softshell, butter, littleneck, cockle, gaper piddocks and mussels) may provide food for migratory green sturgeon within the estuarine and near-shore EEZ analysis areas.

NMFS (2009b) has noted that subadults and adults feeding in bays and estuaries may be exposed to contaminants that may affect growth and reproduction. Such effects due to bioaccumulation of pesticides and other contaminants have been documented in white sturgeons that also inhabit West Coast estuaries (NMFS, 2009b). Sediments within the proposed dredge prism for the access channel were sampled to determine whether they meet Dredged Material Evaluation Framework (DMEF) guidelines, as identified for the Lower Columbia River Management Area, for in-water disposal (SHN Consulting Engineers and Geologists, Inc. 2006). An analysis of grain size distribution and total volatile solids composition was initially performed to determine if the sediments require further testing for chemical analysis. All of the samples were primarily composed of medium to fine grained sand and had a very low percentage of total volatile solids (SHN, 2006). Since none of the samples exceeded 20 percent fines or 5 percent total volatile solids, no further chemical testing was required and the sediments were deemed suitable for in-water disposal, according to DMEF guidelines. These findings indicate that resuspension of sediments associated with the dredging for the access channel should not result in significant increases the bioavailability of contaminants to fish and fish food organisms within the Project action area.

This conclusion is further supported by previous sediment evaluations conducted for Coos Bay channel maintenance and improvement dredging. Most recently in 2004, the COE performed sediment sampling and characterization at various stations along the Coos Bay Navigation Channel (COE, 2005). Throughout the entire sampling area, only low levels of sediment contaminants were identified, with all levels well below their respective DMEF screening levels. One of the sampling stations (0915CB-BC-10) was located approximately 0.4 mile downstream of the Project site. The 2004 sediment sampling effort found only low levels of chemical contaminants, with all levels below their respective DMEF screening levels. None of the samples contained DDT or its derivative by-products (DDE, DDD) at levels that could cause adverse effects to fish resources. No evidence for bioaccumulation of contaminants in potential prey species has been found.

Lower Coos Bay provides unobstructed migratory access for juvenile and adult salmonids, discussed above, and similarly assumed to be unobstructed for green sturgeons. Within the estuarine analysis area and lower riverine analysis area entering Coos Bay, access for migrating fish species is uninhibited, and is considered “properly functioning.”

#### 4.5.1.3 Effects by the Proposed Action

Coastal marine waters within depths of 110 meters (360 feet or 60 fathoms or fm) were identified as occupied areas necessary to critical habitat, including coastal waters segments from San Francisco Bay to Humboldt Bay, California and from Humboldt Bay to Coos Bay (NMFS, 2009b). As discussed for blue whales in section 4.2.1.3 above, LNG carriers traveling within the EEZ parallel to the coasts of California and Oregon are expected to transit 50 nmi off shore.

**Direct Effects – Estuarine Analysis Area**

Project-related effects to the Southern DPS of green sturgeon would be caused by the action and occur at the same time and place, including the following direct impacts within the estuarine analysis area: 1) turbidity effects from dredging the slip and access channel, 2) turbidity effects from LNG vessel propeller wash and ship wake, 3) turbidity effects from constructing the Pacific Connector pipeline within the estuary, 4) stranding sturgeons by LNG vessel propeller wash and ship wake, 5) introduction of exotic, invasive species from ballast water, 6) entrainment and impingement of sturgeons in LNG carriers' intake port, 7) estuary water cooling during LNG carrier cargo loading, 8) potential effects by effects by operational lighting, and 9) acoustic effects to sturgeon during LNG terminal construction.

<u>Timing</u>

In-water construction of the JCE and PCGP Project within the Coos Bay estuary is planned from October 1 through February 15 following ODFW's recommendation. Because no spawning occurs in freshwater tributaries to Coos Bay, the estuary most likely provides feeding and migratory habitat for adult and possibly subadult green sturgeons. Adults migrate to/from spawning grounds during the spring and fall, consecutively, and juvenile migration occurs from April through November (Rien et al., 2001). Green sturgeon move into estuaries of non-natal rivers to feed (Beamis and Kynard, 1997) and occupy large estuaries during the summer and early fall in the Pacific Northwest. Green sturgeon abundance peaks during October in the Columbia River estuary, but the same may not be true of green sturgeon abundance in Coos Bay. Nevertheless, Southern DPS of green sturgeon could be present within the estuary coincidental with in-water construction for the JCE and PCGP Project and within designated critical habitat offshore within the EEZ. Principal direct impact during in-water construction would most likely be related to turbidity generated by construction of the slip, dredging the access channel, and construction of Pacific Connector's pipeline across Haynes Inlet.

<u>Turbidity Effects –Slip and Access Channel</u>

Construction of the LNG terminal slip will require the excavation and dredging of approximately 4.3 million cubic yards (cy) of material (2.3 million cy excavated and 2.0 million cy dredged) and the construction of the access channel will require the dredging of 1.3 million cy for a total of approximately 5.6 million cy. The slip will be dredged to a depth of minus 45 feet (NAVD88). Volume estimates include two feet of over depth dredging. The 5.6 million cy will be used beneficially for the Project in raising both the LNG Terminal site and the nonjurisdictional South Dunes Power Plant site to elevations above the tsunami inundation zone. A total of 1.9 million cy will be placed on the LNG Terminal site, while the remaining 3.7 million cy will be placed on the power plant site.

The majority of the dredging for the slip will be conducted in isolation from the waters of Coos Bay. While the future slip area is being excavated and dredged, a berm (with a 3H:1V slope to the slip and a natural grade to the channel) will be maintained to provide complete separation of the excavation and dredging activities from the bay, resulting in no turbidity being released to the waters of Coos Bay.

Dredging of the berm separating the portion of slip from the bay and the access channel will result in temporary siltation and sedimentation impacts similar to those that currently occur during maintenance dredging activities. The dredging activity will occur only during the in-water work window established by ODFW.

On average, the USACE removes approximately 550,000 cy from the bar, 200,000 cy from Channel Mile (CM) 2-12 and 150,000 cy from CM 12-15 each year. In comparison, approximately 500,000 cy will be removed in the water during the removal of the berm and dredging of the access channel. Since the duration of the dredging in the bay will be 4-6 months and only during the in-water work window from October 1 to February 15 (ODFW, 2008), the minimal amount of turbidity created will be relatively short term and localized. Turbidity modeling demonstrated that turbidity levels dropped to near background levels beyond 200 meters (660 feet) of the dredging activity.

Turbidity was modeled for the new construction and maintenance dredging operations based on the anticipated geotechnical and environmental conditions for this project using the United States Army Corps of Engineers (USACE) DREDGE model and two dimensional numerical model Mike21 (developed by Danish Hydraulic Institute). Re-suspension of sediments during dredging operations can be a significant source of turbidity; however, through proper operational controls and potentially the use of physical barriers, this source can be controlled. Turbidity generation is a factor of the dredge type, dredging practices, sediment characteristics, and environmental conditions at the site (e.g., currents). From the results of the DREDGE model for the open "clamshell" dredge, during construction stage the maximum modeled suspended sediment concentrations (primarily sand) were less than 6,000 mg/l at the dredge location rapidly decreasing with distance to less than 50 mg/l at 200 m (approximately 660 feet). For the hydraulic cutterhead dredge the TSS levels were significantly lower with maximum of 500 mg/l in the vicinity of the dredge. The TSS concentrations reduce rapidly to maximum of 14 mg/l by a distance of 60 meters (200 ft).

During the maintenance dredging period, the dredged material is expected to be primarily fines (mud, clay, silt). Concentration predicted with the DREDGE model for the open "clamshell" dredge were lower than during the construction stage with the maximum of 830 mg/l in vicinity of the dredge and decreasing to 125 mg/l at 200 m (approximately 660 feet). The results from the Mike21 simulations show that distribution of the generated plume depends on location of the dredge in the channel and basin area. For dredging with an open "clamshell" dredge in the channel the generated sediment plume (concentration higher than 150 mg/l) can move up to 1.2–1.9 miles from the dredging location at highest ebb or flood currents; however, the duration of such entrainment is limited by not more than a two hour period and the time average concentrations do not exceed natural ambient concentrations (10–30 mg/l) outside the dredging area. During maintenance dredging with an open "clamshell" dredge, the maximum concentrations in the generated plume do not exceed 50 mg/l. Based on these results it is not anticipated that turbidity generation at the dredging site will be a significant issue.

Turbidity Effects –Propeller Wash and Ship Wake

Propeller wash from LNG vessels and tug boat propellers associated with the Project, as well as ship wakes breaking on shore, could cause increased erosion along the shoreline and re-suspend the eroded material within the water column. This may affect the diversity and health of the benthic community regarding food availability and feeding conditions for foraging and migrating fish species. At high concentrations, suspended sediments can affect oxygen exchange over the gills, resulting in weakened individuals or mortality. However, ship wakes associated with the operation of the slip are not expected to result in significant bank erosion or effects due to the low speed at which carriers would traverse the lower bay when approaching or departing the slip and the limited number of trips (approximately 90 round trips per year).

The possible impacts on the shoreline along the navigation route to and from the LNG Terminal from the pressure fields generated by passing deep-draft vessels and vessel wakes generated by assisting tug boats were analyzed (see Resource Report 2 and Volume 2 of the C&H Technical Report in Appendix H.2 for JCEP LNG Terminal Project).

The results of the analysis show that hydrodynamic effects from pressure field velocities measured along the sensitive shoreline from existing deep-draft vessels exceed the pressure field velocities that may be generated by future LNG carriers. The reason for this is that the USCG has mandated that all LNG carriers be escorted by a minimum of two tractor tugs each with 80 tonne bollard pull capacity. The use of these tugs allows the LNG carrier to transit at a lower speed than the existing vessels which transit without tug assist. Vessel velocity, rather than its size has a much greater impact on the amplitude of the pressure wave. The conclusion of this finding is that the potential impact from the proposed LNG carrier on coastal processes at the sensitive shoreline would be smaller than that from the existing deep-draft vessels.

Vessel wake effects have been studied using the 2-D spectral wave model SWAN (SWAN) for waves/wakes generation and propagation and empirical formulation for evaluation of swash sediment transport. The potential vessel wake impact at the sensitive areas was determined by comparing swash sediment transport for Post-Project Conditions relative to Existing Conditions. The possible impact on sensitive shoreline from increased vessel wake energy along the navigation route to the Project was evaluated using calculations of swash sediment transport. Swash sediment transport indicates the potential for shoreline response to waves/wakes energy delivered to the shoreline itself.

Swash sediment transport at the sensitive areas for Existing Conditions was assumed to be formed from two different contributing factors:

- Swash sediment transport generated by wind waves.
- Swash sediment transport generated by present traffic of tug-boat wakes.

Swash sediment transport at the sensitive areas for Post-Project Conditions was assumed to be formed from three different contributing factors:

- Swash sediment transport generated by wind waves.
- Swash sediment transport generated by present traffic of tug-boat wakes.
- Swash sediment transport generated by future traffic of tug-boat wakes.

SWAN was applied to generate wind-waves and propagate them to the sensitive shorelines from different directions at various tide elevations. A total of 1,080 modeling scenarios, combinations of wind speed, directions, and tide elevations were simulated with SWAN.

The results of the swash transport calculations show a small increase in wake-generated swash sediment transport at the areas of interest due to LNG carriers. The results show that the increase in swash sediment transport from combined inbound and outbound carrier traffic would not exceed six percent at Pigeon Point, eight percent at Clam Island, and five percent at the Airport sensitive shorelines. The total sediment transport for future inbound and outbound LNG carrier traffic will be less than eight percent of the existing and future wind-wave swash sediment transport. The estimated increase in swash sediment transport due to the LNG carrier traffic is a small fraction of the swash sediment transport due to the natural wind-wave conditions. This increase most likely would not be detected in a general balance of swash sediment transport due to yearly variability of wind-wave conditions and swash sediment transport.

Turbidity Effects – Pipeline Construction

Pacific Connector will construct the proposed pipeline across Haynes Inlet between October 1 and February 15, the in-water construction period recommended by ODFW (2008a). It is unlikely that green sturgeon would be present in the Coos Bay estuary during pipeline construction across Haynes Inlet. Construction would increase turbidity in the immediate vicinity of the construction right-of-way across Haynes Inlet but eulachon, if present, would be expected to avoid local turbid conditions. Natural turbidity in the Coos Bay estuary was judged to be higher at upper bay locations, away from water influx from the ocean (Moffatt and Nichol, 2006). Turbidity measured at the Charleston Bridge, near the entrance to Coos Bay varied from 3.7 to 18.1 NTU (5.7 to 45.7 mg/L) but sometimes exceeded 200 NTU. Modeled turbidity due to dredging in Coos Bay suggests a very narrow range of elevated suspended sediment (>100 mg/L) during low tidal velocity extending a few hundred feet from the dredge, while during typical tidal cycle values were as high as 50 mg/L from 0.2 to 0.3 mile away from the dredge. Moderately low values of 25 to 50 mg/L may extend out to about 3.5 miles depending on flow, sediment, and equipment used (Moffatt and Nichol, 2006). Expected turbidity levels during pipeline construction would be elevated but within ambient levels and would not be likely to affect eulachon, if present.

Trench excavation to install the pipeline in the bay would bury, displace, or injure benthic organisms (e.g. worms, clams starfish and vegetation). Mobile organisms like crabs, shrimp, and fish would move away from the trenching activities. Short-term impacts would occur to other benthic taxa in Coos Bay that include ribbon worms (Nemertinea), various burrowing segmented worms (Polychaeta), small crustaceans including amphipods, Dungeness crab, echinoderms, clams (i.e., *Macoma* sp.), and coral/anemone polyps (Anthoszoa) (Miller et al., 1990). However, benthic communities on mud substrates in Coos Bay that were disturbed by previous dredging activities recovered to pre-dredging levels in four weeks (Newell et al., 1998). Some impacts may be long-term if important habitat elements are affected, such as the effects of turbidity on eelgrass growth (Martin and Tyrrel, 2002

Construction of the pipeline across the Coos Bay estuary will utilize a wet-open cut method. The current pipeline route in the bay will cross 2.5 miles and disturb approximately 75.6 acres of subtidal (33.2 acres), mud/sandflat (36.2 acres and 1.2 acres of estuarine wetlands) habitats. Ellis Ecological Services, Inc. (2013) conducted a survey of eelgrass beds within Coos Bay along the pipeline route. Based on the survey of the route in 2013, there were about 5.0 acres of eelgrass beds that will be directly affected by the construction right-of-way (including temporary extra work areas - TEWAs). Eelgrass beds were placed into three categories based on density: low, medium, and high. From that survey, most of the area affected would be low density, and none were categorized as high-density eelgrass. Approximately 0.1 percent of the total eelgrass beds present in Coos Bay would be directly disturbed from pipeline construction across Haynes Inlet (Ellis Ecological Services, 2013).

On the chance that a sturgeon might be present, construction related effects would be due to local increases in turbidity. In that instance, the water quality PCE could be affected over the short term within critical habitat and disruption to intertidal and sub-tidal substrates could affect the food resources PCE for sturgeon critical habitat. However, sediment concentrations from pipeline trenching in Haynes Inlet would be similar to winter background levels for much of the construction period and few fish would be near the highest plume concentration due to active avoidance.

The pipeline will cross the Coos River using a HDD and will cross Catching Slough using a conventional bore. Other waterbodies within critical habitat will be crossed by dry-open cut construction between July 1 and September 15, the recommended in-water construction dates for Boone Creek, Catching Slough, Monkey Gulch, and Stock Slough (ODFW, 2008). Sediment released during dry open-cut construction is generally restricted to short-term peaks associated with installation and removal of isolation (temporary dams) and bypass structures (flume pipe, pump intake and exit conduit). Reid et al. (2004) evaluated sediment generated during dry open-cut construction and found that total suspended sediment (TSS) concentrations at flumed dry open-cut pipeline crossing was only 3.7 percent of TSS concentrations generated during wet open-cut construction. Likewise, TSS produced during dam-and-pump dry open-cut construction was 0.85 percent of the TSS produced during wet open-cut.

Turbidity and increased suspended sediment would be generated during pipeline construction across the Coos Bay estuary. While the exact duration of pipeline construction in the bay is unknown it would be completed during one season (i.e., less than the 4.5-month in-water work window). "Wet" crossing construction or open cutting (trench excavation, pipe installation, and backfilling the trench through flowing water) produces the highest downstream (or relative tidal flow direction) sediment loads of any construction technique (Mutrie and Scott, 1984; Reid and Anderson, 1999; Reid et al., 2004). Estuarine environments often have moderately elevated suspended sediment concentrations (i.e. >15 mg/L) and they are very productive (Gregory and Northcote, 1993). The amount of sediment produced by open cutting depends on multiple characteristics at the construction site including depth and width of the waterbody (effects mixing of the sediment plume in the water column), current velocity and local turbulence at the site and downstream, concentrations of suspended sediment initially at the site and at some distance downstream, particle diameter, specific weight, and settling velocity of the excavated and backfilled materials (Ritter, 1984; Reid et al., 2004). Based on sediment transport modeling, dispersal of the exposed and disturbed sediments will be very minor in intertidal areas of Haynes Inlet due to the low water velocities and sediment composition in that area and turbidity is not expected to adversely affect green sturgeon.

Stormwater Discharge at LNG Terminal

Stormwater discharge has the potential to contain chemicals toxic to green sturgeon. However the NPDES permit that the applicant would obtain requires discharges to not modify state water quality standards of the receiving water. The stormwater permit application states "The permit registrant must not cause a violation of instream water quality standards." Since the water quality standards are designed to protect aquatic resources, including green sturgeon, the applicant is to insure the standards are not exceeded, and therefore not cause adverse harm to the aquatic resources. So issuance of the permit by the state should insure that aquatic resources are protected. However, it is known that stormwater runoff often does result in chemical concentration values at the point of discharge in excess of EPA water quality criteria (WDOE, 2009). The general characteristics of the stormwater system and levels of some discharge items are presented below.

The proposed stormwater management system is designed to direct any flow that does not come into contact with any equipment containing potential contaminants (grease or lubrication oil) to the multi-user slip. Stormwater collected from non-LNG containing paved and curbed areas of the facility would be collected into an Oily Water Collection Sump. Primarily, these localized drains are located around equipment to contain grease and/or lubrication oil. The oily water from the collection sump overflows to the Oily Water Separator Package which is equipped with plate type separation devices to remove any oil and grease washed down from the facility equipment. Recovered oil and grease is held in the sump and periodically pumped directly to storage drums for disposal. The water would be kept in a holding area in the fire water pond where it would be tested for compliance with Oregon water quality standards to ensure that the water discharged meets the water quality criteria for the receiving water body, which have been established to be protective of fish. Water from the holding area would be released to the fire water pond and would be discharged via the NPDES permitted discharge point to the ocean.

The proposed oil and grease treatment system is designed to limit discharges of oil and grease to no more than 15 mg/l daily maximum. This system design would ultimately need approval from the State to obtain the NPDES permit. The treatment system function is an additional level of protection for inadvertent spills that come into contact with stormwater. The facility is not designed to intentionally mix oil and grease with stormwater and there are no continuous discharges of oil and grease from the LNG terminal. Discharges from the LNG terminal that could contain oil and grease would only occur during stormwater events. Only in the event of a significant spill or leak from a piece of equipment that occurred during a stormwater event would the concentration of oil and grease in the stormwater discharged from the LNG terminal approach the 15 mg/l daily maximum. Based on information available in the literature, it would appear that the 15 mg/l is below the limit where adverse effects occur on fish species. In 96-hour tests of acute toxicity, the LC50 (lethal concentration for 50 percent of the subjects) for juvenile coho salmon exposed to diesel fuel ranged between 2,186 and 3,017 mg/l (1 mg/L = 1 ppm) (World Health Organization, 1996). Water accommodated fractions (standardized preparation of water systems with dissolved oil components for toxicity studies) prepared from oils higher in aromatics (e.g. the middle distillates including Fuel Oil No. 2, kerosene, and diesel) are generally more toxic than those prepared from crude oils and gasoline (e.g. Anderson et al., 1974; Rice et al., 1976; Markarian et al., 1994). Consequently, LC50's for crude oil would most likely be higher than those, above, for diesel fuel. Discharges of most water containing oil products would be limited to the ocean discharge, where rapid dilution would occur, and further reducing potential effects.

The exact levels of other runoff chemicals can not be predicted at this time. However Washington State, in a review of all of their permitted monitored stormwater discharge facilities, found that copper and zinc, two chemicals commonly of concern to aquatic organisms, were relatively high often exceeding benchmark standards (WDOE, 2009). They noted that the sources of metals pollution include oils and lubricants from motor vehicles, tire dust, brake pad dust, raw material and products, and exposed galvanized metal surfaces on buildings, fences, and equipment (WDOE, 2009). It is likely many of these components would be present at the project site. In the Washington study across all stormwater discharges zinc levels exceeded benchmark values more than 50% of the time, while copper exceed the benchmark values in the range of 20 to 50 percent of the time. White sturgeon, and presumably green sturgeon, are sensitive to both copper and zinc in fairly low concentrations during embryonic, larval and development through fry life stages (Vardy et al., 2011). However, only adult and sub-adult green sturgeon would potentially be exposed to metal components in stormwater discharge and exposure effects to adults are unlikely.

Stranding from Ship Wake and Propeller Wash

Fish stranding can occur when fish become caught in a vessel's wake and are deposited on shore by the wave generated by the vessel wake. Stranding typically results in mortality unless another wave carries the fish back into the water. A series of interlinked factors act together to produce stranding during vessel traffic and may include water surface elevations, with low tides more likely to result in strandings than high tide; beach slope, with strandings more likely on low gradients than high; wake characteristics influenced by vessel size, hull form, depth underwater (draught), and speed; and biological factors, such as numbers of small fish present near the shoreline and whether fish are strong swimmers or not. Size of juvenile green sturgeons that have been reported caught in the Coos Bay esturary in the 1950s through the 1990s have varied from 40 cm to over 100 cm (15.7 to >39.4 inches) fork length or total length (Farr and Kern, 2005). The sizes of green sturgeon expected in the estuary are considerably larger than sizes of juvenile chinook salmon (<9 cm) stranded by ship wakes in the Columbia River (Pearson et al., 2006) and may not be susceptible to stranding by ship wake.

Ship wakes produced by deep-draft vessels traveling at speeds greater than the estimates for LNG carrier speeds have been observed to cause occasional stranding of juvenile salmon (Pearson et al., 2006); however, no strandings were observed as a result of vessels traveling at speeds under 9 knots (10.4 mph). The hull geometry of the LNG carriers is such that bow wakes are minimized, especially at the slower speeds of 4 to 6 knots that would occur during most of the transit route through Coos Bay. Therefore, the LNG carriers would be traveling at speeds less than that observed (Pearson et al., 2006) to cause stranding. In models and research conducted by the JCEP, wave heights produced by LNG carrier traffic would not exceed that of normal conditions in Coos Bay and overall waves would contribute to a small portion of the total waves that occur in the bay. In addition, the LNG carriers would be arriving and leaving at high tide, which is a period when gently sloping beaches are mostly covered and less likely dewatered from waves. Considering that LNG marine traffic would enter and leave at high slack tide, have low vessel speeds, and wave height would be in normal range, it appears unlikely that the Project would contribute o stranding of green sturgeons within Coos Bay.

Exotic, Invasive Species

NMFS (2005b) identified effects by exotic species as a risk to green sturgeons in the Southern DPS. For example, exotic species are concerns because of replacement of food items; the exotic clam *Potamocorbula amurensis*, was introduced to the Sacramento-San Joaquin River and Delta systems (California) in ship ballast water from Asia in 1988 and become the most common food of white sturgeon. The clam was also found in the only green sturgeon so far examined and is known to bioaccumulate selenium (Linville et al., 2002), a toxic metal potentially causing teratogenesis or abnormal embryonic developmental (Lemly, 1996). Further, rapid expansion of the exotic clam caused changes in the primary productivity and benthic community dynamics of portions of San Francisco Bay (Werner and Hollibaygh, 1993; Nichols et al., 1990).

Loaded with water from the surrounding ports and coastal waters throughout the world, ships can carry a diverse assemblage of marine organisms in ballast water that may be foreign and exotic to the ship's port of destination. The transfer of water from port-to-port can result in aquatic biological invasions. Invasive species threaten to outcompete and exclude native species and the overall health of an ecosystem, causing algal blooms and hypoxic conditions and affecting all trophic levels resulting in a decline in biodiversity.

Ballast water from ships' precedent ports would be emptied and exchanged with ocean seawater approximately 200 nmi offshore, at the outer edge of the EEZ. The ballast water exchange (BWE) process is mandatory under the National Ballast Water Management Program – originally established by Nonindigenous Aquatic Nuisance Prevention and Control Act of 1990 and further amended by National Invasive Species Act of 1996 and National Aquatic Invasive Species Act of 2003 – amended in 2005 and again in 2007. On March 23, 2012, the USCG issued its Rule regarding Standards for Living Organisms in Ships' Ballast Water Management Discharged in U.S. Waters, which amends the existing regulations and creates a standard for the allowable concentration of living organisms in ballast water discharged in U.S. waters consistent with the International Maritime Organization's International Convention for the Control and Management of Ship's Ballast Water and Sediments (BWM Conventions). This Rule will require all vessels equipped with ballast tanks bound for (or departing) U.S. ports to utilize at least one Ballast Water Management method described in the Rule (77 FR 17254). The most likely convention given the advanced technologies used by LNG carriers will involve a complete BWE in an area 200 nautical miles from any shore prior to discharging ballast water.

LNG ships will discharge ballast concurrently with the LNG cargo loading at the LNG terminal. The amount of ballast water discharged must, at a minimum, be adequate to maintain the LNG ship in a positive stability condition and with an adequate operating draft while the LNG cargo is loaded. The ballast water discharged at the terminal will be that from 200 miles out in the open sea as occurred as part of the mandated BWE process to eliminate or minimize risks of introducing exotic, invasive species.

Entrainment and Impingement

LNG carriers would re-circulate water while loading LNG at the berth and the amount of cooling water to be re-circulated is a function of the propulsion system for the vessels. Once the LNG fleet has been identified, cooling water flow rates and the amount of water required can be further addressed. It is likely that some organisms small enough to pass through the screens covering the carrier's intake port will be drawn in with the cooling water and will be lost from the population in the slip area; however, it is anticipated that the effect associated with the intake of cooling water will be minimal. Juvenile fish would need to be present in the slip area near the carrier's intake screens and be small enough to fit through the sea chests which are covered with screens composed of 4.5 mm thick bars spaced 24 mm apart and located approximately 32 feet below the water line, or 5.6 feet from the keel of the LNG carrier. The intake velocities for cooling water are low enough that it is not anticipated that any larger organisms (fish, marine mammals, or invertebrates) would be impinged on the intake screen. Generally the total water intake would occur over a 24-hour period during each loading period, about 90 times per year.

The LNG ships will also re-circulate water for engine cooling while loading LNG at the berth. The power requirements for loading LNG in the export mode are less than those for unloading LNG in the import mode because the LNG carrier does not have to use on board LNG pumps to handle LNG cargo; hence both the LNG carrier engine requirement and the required amount of cooling water flow are reduced. The amount of cooling water to be re-circulated is a function of the propulsion system of the LNG ship and, once the LNG ship fleet has been identified, the issue of cooling water circulation requirements can be further addressed. For purposes of this analysis, typical cooling water flow rates were used. Cooling water flows while at the berth are approximately 1,300 $m^3$/hr (343,421 gallons per hour or 5,723 gpm). For a 148,000 $m^3$ ship this would total approximately 4.3 million gallons while loading LNG cargo. In the event that a 217,000 $m^3$ ship is used, the amount of water required would be on the order of six million gallons. The intake port for this cooling water is approximately the same size and at the same location as the ballast water intake port, 3.5 to 4.2 square meters covered by a screen with 4.5 mm bars, spaced every 25 mm and approximately 32 feet below the water line, or 5.6 feet from the keel of the LNG ship. The velocity across this port is approximately 0.28 ft/sec with a temperature differential of three degrees centigrade. It is likely that some organisms that are small enough to pass through the screens covering the ship's intake port will be drawn in with the cooling water and will be lost from the population in the slip area. It is anticipated that the effect associated with the intake of cooling water will be minimal. The intake velocities for the cooling water are low enough that it is not anticipated that any larger organisms (fish, marine mammals and reptiles or amphibians) will be impinged on the intake screen.

Water Cooling

The LNG ships will also re-circulate water for engine cooling while loading LNG at the berth. The engines will be running to provide power for standard hotelling activities as well as running the ballast water pumps. The activities that will require LNG carrier power and the assumptions used to develop the cooling water flow requirements are as follows:

- Hotelling operations require the generation of 1.9 MW of power during the entire time that the LNG carrier remains in the slip. The vessel is anticipated to be within the slip for a total of 17.5 hours.
- A typical auxiliary power unit for an LNG carrier is the Wartsila 34DF. This is a dual fuel (liquid and natural gas) unit that is a complete primary driver/generator package capable of being sized upwards to 6.9 MW output. Fuel to power conversion is 7,700 kilojoules (kJ) per kilowatt-hour (kWh) (kJ/kWh) (7,305 British thermal units (Btu) per kWh (Btu/kWh)). This system has an overall fuel to power efficiency of 46.7 percent, thereby resulting in the rejection of 3,893 Btu of heat into the cooling water for each kWh of power generated.

- All calculations that follow are based upon the transfer of 148,000 $m^3$ of LNG from the LNG storage tanks to the LNG carrier. The 148,000 $m^3$ carrier is set as the basis because it represents the largest vessel authorized to call on the LNG Terminal.

The total gross waste heat discharged into the slip from the cooling water stream will be due primarily from the hotelling operations (including the power required to run the ballast water discharge pumps) as the shore side LNG pumps will be used to transfer the LNG from the LNG storage tanks to the LNG carrier. The hotelling operations were assumed to be as follows:

- Hotelling Operations -17.5 total hours x 1,900 kW x 3,983 Btu/kWh = 132.5 million Btu (MMBtu). The total amount of heat discharged into the slip during each vessel call is approximately 132.5 MMBtu.

Because of the extreme differential of the temperature of the cargo in the LNG carrier (-260$^{o}$F) and that of the surrounding air and water (nominally 45$^{o}$F) there is a constant uptake of heat by the LNG carrier from its surroundings. This heat uptake is manifested by the amount of LNG cargo that changes state from liquid to vapor on a daily basis. The typical LNG carrier sees 0.25 percent of its liquid cargo converted to the gaseous state each 24 hours. In this process 219 Btu of heat is absorbed for each pound of LNG converted to vapor. This results in a total of 53 MMBtu absorbed by a typical 148,0000 $m^3$ LNG carrier during the 17.5 hours it is within the slip. Given the distribution of vessel surfaces between those surfaces in contact with water as opposed to those surfaces in contact with air it is reasonable to assume that 50 percent or more of the heat take up by the vessel is extracted from the water. This assumption is further reinforced by the fact that the heat transfer coefficient between water and steel is significantly higher than the heat transfer coefficient between air and steel. Applying this allocation of heat absorption sources results in having 26.5 MMBtu being removed from the slip by the LNG vessel during its stay. Thus a portion of the 132.5 MMBtu of thermal energy discharged into the slip from the cooling water is offset by the uptake of 26 MMBtu by the LNG vessel itself, resulting in a net heat input to the slip of 106.5 MMBtu per 148,000 $m^3$ LNG carrier call.

Analysis and numerical modeling were performed to identify potential impacts of LNG carrier cooling water discharge on water quality in the slip and adjacent area of Coos Bay. The modeling was initially performed with two different numerical models: the 3-D UM3 model and the DKHW model. The models simulate hydrodynamic mixing processes of submerged discharges and predict temperature fields and dispersion of non-conserved substances in ambient water bodies. Cooling water numerical modeling requires input of steady-state flow velocity in the modeling domain. The results of tidal flowing modeling using the SELFE model showed that ambient current velocities inside the LNG Terminal area vary, depending on tidal stage. Peak current speeds in the berth only exceed approximately 0.32 ft/sec less than two percent of the time. Therefore, for cooling water modeling, two steady state ambient flow velocities were assumed and used further in the analysis: high velocity = 0.32 ft/sec and typical velocity = 0.16 ft/sec.

The following conservative assumptions were used in the analysis. The assumptions are conservative in that a steam powered ship was used. The steam powered ships tend to be older than the newer more modern dual fuel diesel electric ships that require lower quantities of cooling water.

- LNG carriers are steam-powered with a cargo capacity of 148,000 $m^3$.

- Maximum pump capacity for main condenser cooling is 10,000 $m^3$/hr (44,030 gpm) and maximum pump capacity for LNG carrier's equipment cooling is 3,000 $m^3$/hr (13,209 gpm). Total capacity being used at a given time is typically in the range of 6,300 $m^3$/hr (27,739 gpm). For the analysis, 6,300 $m^3$/hr (27,739 gpm) was used.
- Diameter of the horizontal discharge port is 1.1 meters (3.6 feet).
- Depth of discharge port below still water is 10.0 meters (32.8 feet).
- Maximum heating of cooling water at time of discharge is 3 ºC (5.4 ºF) above ambient temperature.

Results of the modeling showed that for typical ambient flow conditions at a distance of 50 feet from the discharge point (LNG carrier sea chest), temperatures will not exceed 0.3 ºC (0.54 ºF) above the ambient temperature. This difference will decrease with further distance.

<u>Effects of Operational Lighting</u>

Localized changes in light regime have been shown to affect fish species behavior in a variety of ways (Valdimarsson et al., 1997; Tabor et al., 2004, Nightingale and Simenstad, 2001). Disorientation may cause delays in migration, while avoidance responses may cause diversion of migratory routes into deeper, less protected waters. In some cases, increased light may attract both predators and potential prey species (Simenstad et al. 1999; Valdimarsson et al. 1997; Tabor et al. 2004).

Lighting at the LNG Terminal and onshore facilities would likely include a mixture of low-power fluorescent lighting and higher intensity security lighting that would primarily be located on shore, in and adjacent to the slip. When an LNG carrier is not in the berth, the lighting would be reduced to that required for security. It would be focused upon the structures and not be in proximity to the water so as to serve as an attractant or deterrent to fish species. When an LNG carrier is at the berth, it would physically block the lighting on the berth from the slip waters and, due to its proximity to the slip wall, would block the fish from getting too close to the lighting on the berth. Lighting used would be similar to that already in place at other Coos Bay facilities.

Lighting on the tug dock would be low intensity lighting for safety, providing sufficient light for personnel movements on the trestle out to the tug berth and for movement on the berth itself. There is no intention to provide lighting near the water line or high intensity lighting that would be associated with activities other than the simple berthing of the tugs at this location. The reduced lighting levels near the water would reduce or eliminate any behavioral effects to fish in the Project vicinity. Increased lighting from facility operations are not expected to significantly affect green sturgeon, Southern DPS.

<u>Acoustic Effects</u>

Underwater noise may affect green sturgeon. Prior to the excavation work starting for the LNG carrier slip, an open cell sheet pile bulkhead and retaining wall will be installed. The sheetpile system will serve as a retaining wall for the shoreline on the east side and support the LNG ship loading dock and associated berthing and mooring facilities. The open cell sheet pile wall system consists of face sheetpiles for retaining the soils as well as tailwalls for anchorage of the retaining wall. All sheetpiles and tailwalls will be driven from the land while the slip construction activities are isolated from Coos Bay.

Underwater noise may be generated by driving sheet piles on land (dry piles) since some noise propagates through ground and sediments (especially through harder substrates such as rock and clay), and may transfer to the water column somewhere else (known as sound flanking). Sound in the water column would be at a lower level than at the source (Washington State Department of Transportation, 2011a) since most sound energy does not travel through water but through the sediment. There would be minimal chance that driving pilings on land could physically injure fish from the impact of percussive sound pressure in the same was as driving piles in water (see Popper, et al. 2006).

**Direct Effects – EEZ Analysis Area**

Project-related effects to the Southern DPS of green sturgeon would be caused by the action and occur at the same time and place, including the following direct impacts within the within the EEZ analysis area could include: 1) sediment discharge at Site F, 2) acoustic effects to sturgeon from LNG ships transiting the EEZ, and 3) spills and releases of LNG at sea.

Turbidity at Site F

Discharge of the maintenance dredging at Site F, about 1.6 miles off the mouth of Coos Bay, would generate a turbidity plume that could affect green sturgeon within the EEZ analysis area. Site F is about 2,700 acres and ranges from 25 to 150 feet deep. Approximately 37,700 cy is the total maintenance dredging volume expected at year 1 and 34,600 cy is the total maintenance dredging volume expected at year 10. In the first 10 years, an approximate total of 360,000 cy would be removed and in the next 10 years approximately 330,000 cy would be removed for an approximate total of 690,000 cy in comparison to the earlier prediction of 1.75 million cy. This is a substantial reduction in volume which in turn will reduce the demand for disposal space at Site F. The original estimate for the frequency of dredging was every two years. Now, with the additional information from the modeling, the recommended future maintenance dredging requirements are approximately 115,000 cy would need to be dredged every three years for the first 9-12 years (10 years approximately) and after 10 years it would be safe to reduce the volume of dredging to some values in the range of 115,000 to 160,000 cy with a frequency of five years between dredging events.

Turbidity generated from discharge at Site F would be rapidly dissipated and may cause some short-term avoidance of the area by green sturgeon during discharge. But there is the possibility that young sturgeon (about 2 feet in length) if they were present directly under the sediment discharge from the barge or ship would be unable to dart out of the plume of sediment and become trapped in the sediment during active discharge. Potential adverse effects would occur to smaller subadults if they were present within the area.

Acoustic Effects

Underwater noise may affect green sturgeon. LNG carriers transiting the EEZ would produce underwater noise. Underwater noise levels are expected to vary by ship type and also by vessel length, gross tonnage, vessel speed, and to some extent, vessel age - older vessels tended to be louder than newer vessels (see discussion in Section 4.2.1.3 for blue whales). Based on the general trend for higher underwater noise generated by larger vessels (McKenna et al., 2012), it is possible for many of the LNG carriers that would utilize the Jordan Cove terminal to generate more noise than the LNG tanker built in 2003 with 138,028 $m^3$ capacity reported by Hatch et al. (2008) that produced sound levels (with 1 standard error) of 182 ± 2 dB re: 1 µPa @ 1 meter.

State agencies in Washington, Oregon, and California, along with federal agencies have developed interim noise exposure threshold criteria for pile driving effects on fish (Washington

State Department of Transportation, 2011a; Popper et al., 2006). Interim noise exposure threshold criteria for pile driving effects on fish (Washington State Department of Transportation, 2011a) include 1) a cumulative sound exposure level ($SEL_{cum}$) of 187 dB re 1 $\mu Pa^2$ s for fishes more than 2 grams, 2) a $SEL_{cum}$ of 183 dB re 1 $\mu Pa^2$ s for fishes less than 2 grams, and 3) a single-strike peak level ($SPL_{peak}$) of 206 dB re 1 μPa for all sizes of fishes (Washington State Department of Transportation, 2011a). $SEL_{cum}$ is the cumulative sound pressure squared, integrated over time, and normalized to one second. $SEL_{cum}$ is calculated as SEL (single strike at 10 meters from the pile) + 10 Log(number of strikes). Although ship noises reported by Hatch et al. (2008) and McKenna et al. (2013) are not directly equivalent to pile driving noise, or the interim noise exposure criteria, any LNG carrier noise generated in the EEZ would be below thresholds for adverse effects to fish, including sturgeons. Noise from LNG carriers would likely increase the background noise within the EEZ, and which is occurring globally (Slabbekoorn et al., 2010). Sturgeons in the EEZ might detect noise from LNG carriers but are not expected to be adversely affected by the projected since vessel traffic due to LNG carries is expected to add to the projected vessel traffic in 2017-2018 by 1.2 percent increase in shipping in coastal Oregon and Washington over the 2017-2018 estimates (see discussion in Section 4.2.1.3 for blue whales). Neither underwater noise generated during construction nor ship noises from LNG carriers transiting the EEZ are expected to adversely affect green sturgeon, Southern DPS.

Release and Fire at Sea

Oil or LNG spills at sea or offshore are unlikely to harm green sturgeon. The low amount of petroleum product on LNG vessels and low chance of LNG spill or fish contacting a spill greatly reduce chance of impacts in the marine environment from spills. Based on the double hulled construction of LNG carriers and the outstanding operating and safety record of LNG carriers, the probability of any incidents that could result in the loss of LNG cargo are extremely low. Any potential spills that could occur and that could affect the green sturgeon would more likely be fuels or lubricants associated with the operation of the LNG carrier. These products are kept in relatively small quantities on ships and would not result in the types of effects associated with a spill from an oil tanker.

Characteristics of LNG released at sea were described in Section 4.2.1.3 for blue whales and Section 4.3.3.3 for marbled murrelets. At the water-vapor LNG pool interface, the cryogenically cooled LNG would begin to vaporize but, because of its relatively high density, the plume would remain at or close to the surface interface (Hightower et al., 2004). The cooling effects of the LNG plume on submerged green sturgeons are unknown but are expected to be localized at the surface. Similarly, effects of a fire on prey species would likely be very limited to the ocean – LNG pool interface. Neither the LNG pool nor an ensuing fire would be expected to adversely affect green sturgeon.

LNG carriers have been operating commercially since 1959. Since then there have been more than 38,000 LNG carrier voyages, covering more than 60 million miles and transported a total of 1.5 billion cubic meters of LNG. Currently, approximately 352 LNG carriers safely transport more than 51,975,000 million cubic meters of LNG annually to ports around the world (Lloyd's, 2013). There have been approximately 11 reportable incidents between 1979 and 2006, worldwide. Because LNG has not been transported to the Pacific Northwest, no data are available. However, due to the double hulls of LNG carriers, none of the incidents that have occurred with LNG carriers have resulted in the loss of LNG cargo or other significant petroleum-based spills.

### Indirect Effects – Estuarine Analysis Area

Project-related effects to the Southern DPS of green sturgeon would be caused by the action (induced by the action as human presence and use increase), and are later in time or farther removed in distance, but are still reasonably foreseeable include the following indirect effects: 1) localized reduction of benthic and epibenthic invertebrates, 2) removal of eelgrass, and 3) shading the water surface by overhead structures.

Habitat Effects –Slip and Access Channel

Benthic and epibenthic invertebrates that presently inhabit shallow intertidal and subtidal regions within the boundaries of the proposed access channel dredging area would be removed with the dredged material. Ghost shrimp and sand shrimp (adults, juveniles and larvae), amphipods, clams, Dungeness crab, and various fish species are important prey for green sturgeon. Therefore, the loss of invertebrates and vertebrates at the access channel would result in a reduction in fish food available to green sturgeon in those areas affected by the Project.

As noted above, benthic communities in Coos Bay inhabiting mud substrates recovered to pre-dredging conditions in four weeks (Newell et al., 1998). Although the substrate proposed for maintenance dredging in the access channel and berth would largely be sand and silt, it is anticipated that recovery would occur within a similar time frame, resulting in only short-term effects to the benthic community and potential food resources for green sturgeon.

Habitat Effects – Pacific Connector pipeline

Construction of the pipeline across the Haynes Inlet of Coos Bay estuary would span 2.45 miles and disturb approximately 0.068 mile of eelgrass or 2.8 percent of that amount, most of which classified as low-density eelgrass beds. Eelgrass can be adversely affected by turbidity because the depth and distribution of eelgrass is strongly associated with water clarity and depth of light penetration (Dennison and Orth, 1993; Thom et al., 1998) as well as nutrient availability (Short et al., 1995), salinity, and water temperatures (Thom et al., 2003). Construction of the pipeline across the estuary is planned from October 1 through February 15 following ODFW's recommendation. During most of that period, eelgrass in Coos Bay would be dormant, coinciding with low temperatures and short photoperiods (Fonseca et al., 1998).

Shading Effects

Shading from over-water structures reduces the amount of light available to phytoplankton and aquatic macrophytes. However, the area where shading LNG terminal facilities would occur is intended for industrial uses and not the creation of new habitat. The general habitat in the slip's region would not be conducive for many marine resources because of depth and steep rip/raped armored banks, so relatively few resources would likely utilize this newly created area. The water areas within the slip are being created from upland areas and therefore shading of currently un-shaded habitat would occur, and no net loss in productivity due to shading would occur. Project components that potentially could shade the new open water created by the construction of the slip include:

- At the proposed slip, the access gangway to the LNG facility is narrow and well above the water surface and would have open mesh grating. Shade produced by the gangway is expected to be biologically insignificant.

- The unloading platform for the LNG facility is 60 feet wide and would be located at an elevation of +30 feet NAVD88. Because the platform is located offshore in deep water, no shading of shallow water habitat would occur.
- The tug dock is the only structure to be built over open water portion of the newly developed slip and it is 400 feet long by 12 feet wide. Shading would be minimized by open mesh grating, which is now commonly used on piers to reduce effects to marine resources from shading.
- The tug dock would be connected from shore by a narrow gangway. The dock would be 12 feet in width and located at +12 feet NAVD88. This too would have open mesh grating to reduce shading. Consequently, shading impacts would be small and probably insignificant.

Temporary underwater shading would also occur beneath the 1.3-mile long hydraulic slurry line to the Port's sand stockpile area. The slurry line would be floating offshore and would provide some shadow. It would be 20-inch diameter pipe and would total 0.3 acres of shade. It would be installed only during the in-water work window and would be used for a 4- to 6-month period, total. The pipe would be fused together on shore and would need minimal number of lines back to the onshore anchors. The anchor lines would not be the small size that one would find in a net, rather large enough to avoid potential entanglements.

Most fish, including coho salmon, have developed countershading as an adaptation to avoid predation (Moyle and Cech 2000) from above (dark dorsal surface blends with bottom substrate) and from below (light ventral surface blends with light from the surface). Fish within a shaded area would be more easily detected by a predator, especially from below because light colored ventral surfaces would stand out against a shaded water surface. Predation potential, based on some observed fish behavior, is a concern (Nightingale and Simenstad, 2001). However actual increased occurrence in predator numbers from even substantial overwater structures has rarely been documented. Additionally review of many marina and pier studies have not documented actual increased predation at these facilities (Nightingale and Simenstad, 2001). For example, marine marina studies have found no documentation of increased concentrations of juvenile salmonid predators and some predators such as birds may be of lower abundance than under natural shoreline conditions (Cardwell et al., 1980, and Heiser and Finn, 1970, as cited in NMFS, 2005c). The extent to which any of these predators affect juvenile green sturgeon in shaded areas created by the proposed action is unknown. But the actions taken (open mesh grating of all structures) should reduce the probability of this occurring.

**Cumulative Effects**

Additional projects within the action area (estuarine analysis area and the Port-terminal analysis area) are anticipated as human population growth continues in the region. Associated road and commercial development, as well as maintenance and upgrading of existing infrastructure within the Estuary, are likely to occur in the foreseeable future. For example, the Port of Coos Bay owns and operates the Charleston Marina, the Charleston Marina RV Park, and Charleston Shipyard. As a component of the Port's economic development, the focus of the Charleston Marina Master Plan is to develop commercial fishing and seafood processing, recreational fishing and boating, tourism, and growth in the retail and commercial sectors. Other, similar economic developments in the region could occur and, if they did, could contribute to the region's human population growth which could be detrimental to Southern DPS green sturgeon within and around the Coos Bay estuary.

A standard of “reasonably certain to occur” is clarified as “those actions that are likely to occur, bearing in mind the economic, administrative, or legal hurdles which remain to be cleared.” Further, NMFS provides that “speculative actions that are factored into the cumulative effects analysis add needless complexity into the consultation process…” (51 FR 19933). No specific state or private actions have been identified within the action area that meets this standard. Further, activities described above are somewhat speculative in nature and cannot be quantified here. Therefore, a logical conclusion is that there would be no cumulative effects to green sturgeon associated with the proposed action.

Within the action area and estuarine analysis area, gradual habitat and water quality improvements may also occur over time as federal, state and private conservation and habitat enhancement efforts are implemented. There are a number of potential federally permitted projects (e.g. repair of the entrance jetties and widening and deepening of the lower portion of the Coos Bay navigation channel) that could result in cumulative effects. However, since these projects would require federal permits, their impacts would be evaluated through the federal permitting process when and if they occur. As discussed above for blue whales, available information indicates that ship calls to the Port of Coos Bay have been declining since 2002. The observed declining linear trend in total annual vessel traffic over time is significant and, when used to forecast numbers of total vessel calls to Coos Bay in the future, no vessels are predicted to enter Coos Bay in 2018 with between 0 and 17.6 vessels as reasonably foreseeable when the LNG terminal is expected to begin operation in 2018 (see figure 4.2-4). And as discussed above for blue whales, it appears that the background rate of spills off the Oregon coast by fishing vessels, recreation vessels, and other vessel types is generally low, a frequency that would be expected to continue.

The foreseeable cumulative effect of 90 LNG carriers per year with anticipated total vessel traffic in 2018 would be less than effects based on past or present levels of vessel traffic calls to the Port of Coos Bay. Consequently, cumulative effects to green sturgeon would likely be less than the estimate of direct effects discussed in the previous section. Those effects were judged to be insignificant and discountable.

The volume of annual vessel transits within the EEZ of California, Oregon, and Washington is related to numbers of vessel calls to ports in those states. Total annual calls for all vessels at ports in California, Oregon, and Washington (MARAD, 2013) were plotted above in figure 4.2-2 for 2002 through 2011. Unlike the trend analyzed for calls to Coos Bay (see figure 4.2-4) the observed linear trend in annual vessel traffic (port calls) along the U.S. West Coast was significantly increasing at a rate of 2.1 percent per year between 2002 and 2007. The increasing trend was interrupted by the global economic crisis in 2008 but data through 2011 indicate a return to the established increasing trend prior to 2008. The pre-2008 trend predicts 21,530 vessel calls to West Coast ports in 2018 (with 95% prediction intervals ranging from 17,360 to 25,710 vessel calls), the year the JCEP and PCGP projects are expect to be in service. Even with the uncertainty generated by available data, there is a reasonably foreseeable increasing trend, albeit imprecise, for vessel traffic volume in the future (by 2017) although unforeseen global events such as future economic crises could influence the predictions. Cumulative effects of 90 LNG carriers per year to green sturgeon may be more or may be less than the estimate of direct effects discussed above.

Releases of diesel fuel and/or gasoline by commercial and recreational vessels are possible. According to annual reports published by the Pacific States/British Columbia Oil Spill Task

Force (2002), ODEQ reported 34 spills from fishing vessels or other harbor craft in 2002, 38 spills in 2003, and 7 spills from fishing vessels plus spills from 27 other vessel types in 2004. Those relatively consistent incidences apparently increased in 2005 with 18 spills from fishing vessels, 20 from recreational vessels, and 27 spills by other vessel types. By contrast in 2006, there were 3 spills from fishing vessels, 6 spills from recreational vessels, and only 6 spills from other vessel types. Though not known, it appears that the background rate of spills off the Oregon coast (incidence of spills in proportion to total vessel operation) by fishing vessels, recreation vessels, and other vessel types is generally low. Based on existing information, future rates of off-shore releases are also expected to be low and potential for green sturgeon to be affected by contamination by oil and other pollutants is not expected to increase above existing levels.

**Critical Habitat**

Coos Bay has been included in estuarine critical habitat for the species. The Coos Bay estuary provides several primary constituent elements including food resources, migratory corridors (passage) between estuarine and marine habitats, sediment quality and water quality (NMFS, 2009b), all necessary to support various green sturgeon life stages. Similarly, coastal marine waters 110 m (60 fm) deep or less, between Coos Bay and San Francisco Bay provide food, passage, and water quality as PCEs. Within Coos Bay, NMFS (2009b) noted that inwater construction or alterations, point and non-point source pollution, and LNG projects could affect PCEs within the Coos Bay estuary portion of designated critical habitat. Project-related effects to Southern DPS green sturgeon within the Coos Bay estuary are likely to be similar to those discussed above including the following: 1) turbidity effects to forage/prey species and habitat by dredging the access channel, 2) turbidity effects to forage/prey species and habitat by construction of the Pacific Connector pipeline and disposal at Site F, 3) shading effects on marine plants, 4) introduction of exotic species, and 5) ship wake.

LNG carriers traveling within the EEZ parallel to the coasts of California and Oregon are expected to transit 50 nmi off shore. Ships entering and exiting Coos Bay and San Francisco Bay would coincide with depths of <110 m (<60 fm) for approximately 9 nmi (Coos Bay) to 23 nmi (San Francisco Bay), but depths off either approach are highly variable. During transits however, barges maintaining a course 12 nmi off the coastline would be in waters deeper than 110 m (60 fm) except for an approximate 18 nmi-long segment south of Point St. George near Crescent City, California. Effects to water quality within coastal marine waters could occur by loss of LNG cargo but the chances of spills are very small and, for most of the EEZ analysis area, would not coincide with proposed coastal marine critical habitat.

Site F is within coastal marine critical habitat for Southern DPS green sturgeon. It is assumed that the existing approved permit would remain valid for discharge at Site F or that the COE and EPA would be coordinating with NMFS to have their operating permits modified to allow for the continued disposal of dredge material at these sites.

### 4.5.1.4 Conservation Measures

Unavoidable effects to North American green sturgeon, Southern DPS include removal of eelgrass by the LNG slip and access channel and the construction dock and temporary eelgrass effects from the PCGP within Haynes Inlet of the Coos Bay Estuary. The Estuary is included as designated critical habitat for the North American green sturgeon, Southern DPS.

The estuarine effects associated with Jordan Cove include 2.5 acres of eelgrass, 3.37 of shallow subtidal, 9.65 acres of intertidal, 0.20 acre of salt marsh, and 15.4 acres if deep subtidal. The estuarine effects will result from construction of the barge berth, slip and access channel, Trans Pacific Parkway/Highway 101 intersection improvements, power plant, and North Point Workforce Housing. Effects will be offset by wetland restoration mitigation at a former golf course. This area is now known as the Kentuck wetland mitigation site. The loss of the 2.5 acres of eelgrass by construction and operation of the LNG terminal will be mitigated at an offsite proposed eelgrass mitigation location south of the west end of the Southwest Oregon Regional Airport; at this site approximately 7.50 acres of new eelgrass habitat will be created. Alternative eelgrass mitigation sites are currently being evaluated, with one of those areas being in Jordan Cove.

The interim loss of the 13.02 acres of unvegetated mud flat (intertidal and shallow subtidal habitats) would be restored at a 3:1 ratio. Restoration would occur at the Kentuck Slough golf course, east of North Bend, where a portion of the golf course would be converted to intertidal and mudflat habitat to offset the estuarine impacts. Conversion would require removing existing levees and removing tide gates, actions that will reestablish tidal connections between former intertidal habitat within the golf course and Kentuck Slough. The Proponents also propose wetland mitigation to offset the effects on freshwater wetlands associated with the development of the LNG terminal site, power plant site, and utility corridor and access road between the LNG terminal and power plant (see attachment 9 to appendix O).

The 5.0 acres of eelgrass temporarily affected by the pipeline would be restored onsite at a 1:1 ratio (see attachment 7 to appendix O).

#### 4.5.1.5 Determination of Effects

**Species Effects**

The Project **may affect** green sturgeon (Southern DPS) because:

- Adult and/or subadult green sturgeons may occur within the estuarine analysis area during construction and operation of the proposed action;
- Adult and/or subadult green sturgeons may occur within the EEZ analysis area during operation of the proposed action;
- The proposed action may affect potential food resources and water quality during the short-term construction period and biennial maintenance dredging within the estuarine and nearshore marine analysis area;
- The discharge at Site F may directly entrap small subadults during biennial dredge and discharge at this marine location;
- The proposed action may affect water quality during the long-term operation period within the EEZ analysis area.

Some project components are **likely to adversely affect** southern green sturgeon, including:

- Bottom disturbance from project construction and biennial maintenance dredging may reduce benthic food supply within Coos Bay and at Site F;
- Discharge of dredge spoils biennially at Site F may trap small subadults that are present during biennial sediment discharge to this site.

**Critical Habitat Effects**

The Project **may affect** critical habitat for the green sturgeon (Southern DPS) because:

- The estuarine analysis area includes the Coos Bay estuary which is included as estuarine critical habitat;
- The EEZ analysis area includes coastal marine waters 110 meters (60 fm) deep or less, between Monterey Bay and Coos Bay and between Coos Bay and Strait of Juan de Fuca, which have been included as Nearshore Marine critical habitat.

While several project actions are not likely to cause adverse effects to critical habitat, some effects from project components **are likely to adversely affect** critical habitat for southern green sturgeon because:

- Bottom disturbance from project construction and biennial maintenance dredging may disrupt local food supply and habitat usability within Coos Bay;
- Discharge of dredge spoils at Site F may also reduce local food sources and have repeated short term reduction of usability during discharge from elevated turbidity.

## 4.5.2 Pacific Eulachon (Southern Distinct Population Segment)

### 4.5.2.1 Species Account and Critical Habitat

**Status**

NMFS was petitioned on July 16, 1999 to list and designate critical habitat under the ESA for Columbia River populations of Pacific eulachon (Columbia River smelt) in 1999. NMFS (1999a) found that although eulachon catches within the Columbia River basin had recently declined, substantial scientific information was lacking to support the petition (NMFS 1999a). In 2007, the Cowlitz Indian Tribe petitioned NMFS to list the eulachon population south of the U.S./Washington-Canada Border as threatened or endangered under the ESA (Cowlitz Indian Tribe, 2007). The NMFS found that the 2007 petition did provide sufficient information to warrant delineation of a Distinct Population Segment (DPS) for the eulachon south of the U.S./Washington-Canada Border and that this population had substantially declined in abundance (NMFS, 2009c).

NMFS listed the eulachon (Columbia River smelt), Southern DPS, as threatened in 2010 (NMFS, 2010d). The Southern DPS includes eulachon spawning in rivers from California into British Columbia (NMFS, 2008c).

**Threats**

Five primary threats to the eulachon included 1) climate change impacts on ocean conditions, 2) climate change impacts on freshwater habitat, 3) eulachon by-catch in offshore shrimp fisheries, 4) dams and water diversions in the Klamath and Columbia Rivers, and 5) predation in the Fraser and British Columbia coastal rivers (NMFS, 2008c).

The most serious threat recognized throughout the four subareas is climate change impacts on ocean conditions. This is closely followed by climate change impacts on freshwater habitat and eulachon by-catch in offshore shrimp fisheries. Additional threats cited include dams and water diversions in the Klamath and Columbia Rivers and predation in the Fraser and British Columbia coastal rivers (NMFS, 2008c).

**Species Recovery**

No recovery plan has been published but NMFS recently produced a Recovery Outline, Eulachon Southern DPS (NMFS, 2013b). The preliminary recovery strategy includes research and monitoring actions that include but are not limited to the following: 1) estimating long-term spawner abundance, 2) survival of larval eulachon, 3) evaluating importance of the tidal freshwater, estuary, plume, and nearshore ocean environments to the viability and recovery of eulachon in the Klamath, Columbia, and Fraser Rivers, 4) determining the significance of plume and ocean conditions that affect eulachon survival, 5) developing a marine abundance survey for eulachon and correlation with riverine abundance estimates, 6) determining the significance of climate-related impacts on ocean conditions that affect eulachon survival, and 7) determining the significance of water quality degradation by potential contaminants on eulachon recovery potential). Preliminary management recovery actions include: 1) maintaining a conservative fisheries program, 2) regulating catch size for the pink shrimp fisheries, 3) enhancing flows and water quality in the Columbia River to improve eulachon survival in plume and nearshore ocean environments, 4) maintain dredging and disposal BMPs on the Columbia River Navigation Channel Operations and Maintenance Dredging Program, 6) continue removal of Klamath River dams, monitor eulachon by-catch rates in trawl fisheries, and 7) establish better inter- and intra-agency coordination regarding scientific research conducted on eulachon.

**Life History, Habitat Requirements, and Distribution**

Pacific eulachon are an anadromous smelt and are endemic to the northeastern Pacific Ocean. They range from northern California to southwest and south-central Alaska and into the southeastern Bering Sea (NMFS, 2013b). Adult eulachon usually spend three to five years in saltwater before returning to fresh water to spawn from late winter though early summer (NMFS, 2009c). Eulachon generally spawn at night in rivers that are glacier-fed and/or have peak spring freshets, and it has been suggested that imprinting is confined to an estuary not a specific individual spawning river (Hay and McCarter, 2000). The typical spawning temperature is from $4^{o}$ to $10^{o}$ C in the Columbia River and tributaries and from $0^{o}$ to $2^{o}$ C in the Nass River (NMFS, 2009c).

Spawning time is mostly likely dependent on geographic location, with those individuals in the southern part of the range spawning earlier than their northern counterparts. Eulachon spawn earlier in southern portions of their range than in rivers to the north. River-entry and spawning begins as early as December and January in the Columbia River system (NMFS, 2008c). Reports have indicated spawning beginning in January in rivers of the Copper River Delta of Alaska and in May in North California. Within coastal British Columbia, the typical pattern is reversed, with spawning occurring as early as February in the Nass River and the latest spawning occurring in April and May in the Fraser River. Data also supports the evidence of waves or runs of eulachon spawning in some basins (Hay and McCarter, 2000). Most eulachon adults die after spawning.

Eulachon spawn earlier in southern portions of their range than in rivers to the north. River-entry and spawning begins as early as December and January in the Columbia River system (NMFS, 2008c). Most eulachon adults die after spawning. Euchalon sexes must synchronize their activities closely because eulachon sperm remain viable for only a short time, estimated to be minutes (Hay and McCarter, 2000). Eggs are fertilized in the water column, sink, and adhere to the river bottom typically in areas of gravel and coarse sand. Eulachon eggs hatch in 20 to 40 days, with incubation time dependent on water temperature. After leaving estuarine rearing areas, juvenile eulachon move from shallow near shore areas to deeper areas over the continental shelf. Larvae and young juveniles become widely distributed in coastal waters, with fish found mostly at depths up to 15 m (50 feet) but sometimes as deep as 182 m (600 feet) (Hay and McCarter, 2000).

Unlike other group spawners, the sexes must synchronize their activities closely because eulachon sperm remain viable for only a short time, estimated to be minutes (Hay and McCarter 2000). Eggs are fertilized in the water column, sink, and adhere to the river bottom typically in areas of gravel and coarse sand. Eulachon eggs hatch in 20 to 40 days, with incubation time dependent on water temperature. Shortly after hatching, the larvae are carried downstream and dispersed by estuarine and ocean currents (NMFS, 2009c).

After leaving estuarine rearing areas, juvenile eulachon move from shallow near shore areas to deeper areas over the continental shelf. Larvae and young juveniles become widely distributed in coastal waters, with fish found mostly at depths up to 15 m but sometimes as deep as 182 m (Hay and McCarter, 2000). There is currently little information available about eulachon movements in near shore marine areas and the open ocean.

Eulachon larvae and post-larvae eat phytoplankton, copepods and their eggs, mysids, barnacle larvae, worm larvae, and other eulachon larvae (NMFS, 2009c). Adults and juveniles commonly forage at moderate depths (15 to 182 m) in inshore waters, feeding on zooplankton, primarily eating crustaceans (Hay and McCarter, 2000). With their high lipid content and massing during spawning runs, eulachon are an important part of the Pacific coastal food web. Eulachon are prey to numerous fish, avian species, marine mammals, and terrestrial mammals (NMFS, 2009c).

Historically, the eulachon distributions correspond closely with the EPA's Coastal Range Ecoregion which extends from the Olympic Peninsula through the Coast Range and down to the Klamath Mountains and the San Francisco Bay Area. Streams within this region exhibit two distinct annual flow patterns: 1) streams draining coastal watersheds, where winter rain storms are common, have high flow periods coinciding with these storms; 2) streams draining more interior areas, such as the Columbia and Cowlitz Rivers, have a distinct spring freshet period coinciding with snow melt. Eulachon production is highest in these latter systems (NMFS. 2009c).

**Population Status**

The Columbia River has historically shown the largest returns of spawning population throughout the eulachon's range. A review of records has shown that eulachon spawning runs from California to southeastern Alaska have declined in the past 20 years, with a significant trend observed since the mid 1990s (Hay and McCarter 2000). From 1938 to 1992, the median commercial catch of eulachon in the Columbia River was approximately 1.9 million pounds. From 1993 to 2006, the median catch had declined to approximately 43,000 pounds, representing a 97.7 percent reduction in catch from the prior period. Despite a short increasing trend noted for the Columbia River from 2001-2003, recent catches remain lower than the historical median (Cowlitz Indian Tribe, 2007).

Similar trends were noted by the Cowlitz Indian Tribe for tributaries of the Columbia River in Oregon and Washington, as well as Fraser River; a rapid decline in the mid-1990s, increasing returns during 2001-2003, and a recent decline to low levels (NMFS, 2008c). The 2007 petition noted that the eulachon is most likely extirpated or nearly so in the Klamath River, Mad River, Redwood Creek, and Sacramento River (Cowlitz Indian Tribe 2007; NMFS, 2008c).

### Critical Habitat

Critical habitat for Pacific eulachon was designated in 2011 (NMFS, 2011e). Critical habitat for eulachon includes freshwater creeks and rivers and their associated estuaries comprising approximately 335 miles of habitat within in 16 specific estuarine and freshwater areas in California, Oregon, and Washington. Essential to the conservation of the species are physical and biological features of freshwater spawning and incubation sites include water flow, water quality, water temperatures, suitable substrate for spawning and incubation, and migratory access for adults and juveniles. The physical and biological features of freshwater migration corridors include water flow, water quality and water temperatures to support larval and adult mobility; abundant prey items to support larval feeding (NMFS, 2011e).

Activities that may affect the physical and biological features essential to the southern DPS of eulachon include: 1) dams and water diversions; 2) dredging and disposal of dredged material; 3) inwater construction or alterations; 4) pollution and runoff from point and non-point sources; 5) tidal, wind, or wave energy projects; 6) port and shipping terminals; and 7) habitat restoration projects (NMFS, 2011h). These activities may have an effect on one or more of the essential physical and biological features by altering alteration of one or more of the following: 1) stream hydrology, 2) water level and flow, 3) water temperature, 4) dissolved oxygen, 5) erosion and sediment input/transport, 6) physical habitat structure, 7) vegetation, 8) soils, 9) nutrients and chemicals, 10) fish passage, and 11) estuarine/marine prey resources (NMFS, 2011e).

## 4.5.2.2 Environmental Baseline

### Analysis Area

Two analysis areas are applicable to effects determinations for eulachon in the Southern DPS. The Estuarine analysis area includes 1) operational activities by LNG ships entering and existing Coos Bay, 2) construction-related effects to approximately 3.1 miles downstream from the proposed slip and LNG terminal to a point 2.2 miles upstream from that site (distances were estimated for potential worst-case dispersion of turbidity, as provided by Moffatt and Nichol, 2006), and 3) the crossing of the Haynes Inlet portion of Coos Bay by the Pacific Connector Pipeline (see figure 4.3-6 under section 4.3.3.2 marbled murrelet). Euchalon occur within marine waters off-shore and within the EEZ analysis area where they could be affected by 1) spills and accidental releases, and 2) discharge of sediment at Site F (see figure 4.2-1 and the discussion above under section 4.2.1.3 blue whale).

### Species Presence

Although Coos Bay is within the historic range of the eulachon, south of the Columbia River mouth, eulachon have been identified in very few coastal streams (Cowlitz Indian Tribe, 2007). Adults are found rarely in Coos Bay (NMFS, 1999a) and spawning runs have not been documented for the Coos River. The BRT review of status of eulachon also concluded that their presence in Coos Bay was "rare" (NMFS, 2008c). Observations of adult eulachon have been reported from the Umpqua and Rogue rivers, Oregon (Emmett et al., 1991).

### Habitat

Coos Bay is known to occasionally support adult populations of eulachon (NMFS, 1999a). When present, eulachon may utilize both shallow and deep water habitats within the estuary. Eulachon were captured in beach seine hauls in the Coos River estuary, June through September (NMFS, 2008c).

### Critical Habitat

Small numbers of eulachon have been observed in a few coastal rivers and creeks in Oregon, including historical accounts of their occurrence in the Siuslaw River, Coos Bay, and Rogue River estuaries (NMFS, 2008c). Critical habitat has been designated within the Lower Umpqua River. Eulachon apparently spawn and migrate within the lower Umpqua River from the mouth upstream to below the confluence with Mill Creek (NMFS, 2011e). No critical habitat has been designated within the Coos Bay Estuary or within the EEZ analysis area.

## 4.5.2.3 Effects by the Proposed Action

Some of the Project effects to Pacific eulachon, Southern DPS would be similar to those described above for North American green sturgeon.

### Direct Effects – Estuarine Analysis Area

Project-related effects to the Southern DPS of Pacific eulachon would be caused by the action and occur at the same time and place, including the following direct impacts within the estuarine analysis area: 1) turbidity effects from dredging the slip and access channel, 2) turbidity effects from LNG vessel propeller wash and ship wake, 3) turbidity effects from constructing the Pacific Connector pipeline within the estuary, 4) stranding eulachon by LNG vessel propeller wash and ship wake, 5) introduction of exotic, invasive species from ballast water, 6) entrainment and impingement of eulachon in LNG carriers' intake port, 7) estuary water cooling during LNG carrier cargo loading, 8) potential effects by effects by operational lighting, and 9) acoustic effects to eulachon during LNG terminal construction.

Timing

In-water construction of the JCE and PCGP Project within the Coos Bay estuary is planned from October 1 through February 15 following ODFW's recommendation. Because no spawning occurs in freshwater tributaries to Coos Bay, the estuary most likely provides incidentally occupied habitats for eulachon. Seasonal presence of eulachon in the estuary has not been definitively documented but fish have been reported captured in the estuary from June through September (NMFS, 2008c). If those reports are indicative of their seasonal occurrence, in-water construction would not coincide with eulachon presence.

Turbidity

Turbidity could be generated during dredging, by LNG propeller wash and ship wake, and during construction of the PGCP Project across Haynes Inlet (see discussion of direct impacts to green sturgeon within the estuarine analysis area, above). If present during in-water construction work and coincidental with LNG carriers, eulachon would be expected to avoid the LNG ships in the channel by using the shallow areas of the channel that the LNG ships are not able to use. Given the deep and shallow water habitats available, there is a low likelihood that there would be a significant impact on eulachon in Coos Bay, should they occur. The effects of ship traffic on spawning runs is not one of the threats listed by the NMFS for the eulachon, which further supports the low likelihood of adverse impacts that would be due to the Project.

Other Effects within the Estuarine Analysis Area.

Stranding of eulachon is by ship wake is possible but unlikely. The size of eulachon expected in the estuary would be 20 to 30 cm (Moyle, 2002), considerably larger than sizes of juvenile chinook salmon (<9 cm) stranded by ship wakes in the Columbia River (Pearson et al., 2006) and may not be susceptible to stranding by ship wake. Other direct impact to eulachon within the estuarine analysis area, are not expected to be adverse effects, similar to the discussions for green sturgeons in relation to introductions of exotic, invasive species from ballast water, entrainment and impingement of eulachon in LNG carriers' intake port, effects of estuary water cooling during LNG carrier cargo loading, potential effects by effects by operational lighting, or acoustic effects to eulachon during LNG terminal construction.

**Direct Effects – EEZ Analysis Area**

Project-related effects to the Southern DPS of green sturgeon would be caused by the action and occur at the same time and place, including the following direct impacts within the within the EEZ analysis area could include: 1) sediment discharge at Site F, and 2) spills and releases of LNG at sea.

Turbidity at Site F

Discharge of the maintenance dredging at Site F, about 1.6 miles off the mouth of Coos Bay, would generate a turbidity plume that could affect green sturgeon within the EEZ analysis area. Turbidity generated from discharge at Site F would be rapidly dissipated and may cause some short-term avoidance of the area by eulachon during discharge. There is the possibility that eulachon if they were present directly under the sediment discharge from the barge or ship would be unable to dart out of the plume of sediment and become trapped in the sediment during active discharge.

Release and Fire at Sea

Characteristics of LNG released at sea were described in Section 4.2.1.3 for blue whales and Section 4.3.3.3 for marbled murrelets. At the water-vapor LNG pool interface, the cryogenically cooled LNG would begin to vaporize but, because of its relatively high density, the plume would remain at or close to the surface interface (Hightower et al., 2004). The cooling effects of the LNG plume on submerged eulachon are unknown but are expected to be localized at the surface. Similarly, effects of a fire on prey species would likely be very limited to the ocean – LNG pool interface. Neither the LNG pool nor an ensuing fire would be expected to adversely affect eulachon.

**Cumulative Effects**

Cumulative effects include the effects of future state, tribal, local or private actions that are reasonably certain to occur in the action area considered in this BA. Future federal actions that are unrelated to the proposed action are not considered here because they require separate consultation pursuant to section 7 of the ESA.

As discussed above for blue whales, available information indicates that ship calls to the Port of Coos Bay have been declining since 2002. The observed declining linear trend in total annual vessel traffic over time is significant and, when used to forecast numbers of total vessel calls to Coos Bay in the future, no vessels are predicted to enter Coos Bay in 2018 with between 0 and 17.6 vessels as reasonably foreseeable when the LNG terminal is expected to begin operation in 2017 (see figure 4.2-4). And as discussed above for blue whales, it appears that the background rate of spills off the Oregon coast by fishing vessels, recreation vessels, and other vessel types is generally low, a frequency that would be expected to continue.

The foreseeable cumulative effect of 90 LNG carriers per year with anticipated total vessel traffic in 2018 would be less than effects based on past or present levels of vessel traffic calls to the Port of Coos Bay. Consequently, cumulative effects to fin whales would likely be less than the estimate of direct effects discussed in the previous section. Those effects were judged to be insignificant and discountable.

The volume of annual vessel transits within the EEZ of California, Oregon, and Washington is related to numbers of vessel calls to ports in those states. Total annual calls for all vessels at ports in California, Oregon, and Washington (MARAD, 2013) were plotted above in figure 4.2-2 for 2002 through 2011. Unlike the trend analyzed for calls to Coos Bay (see figure 4.2-4) the observed linear trend in annual vessel traffic (port calls) along the U.S. West Coast was significantly increasing at a rate of 2.1 percent per year between 2002 and 2007. The increasing trend was interrupted by the global economic crisis in 2008 but data through 2011 indicate a return to the established increasing trend prior to 2008. The pre-2008 trend predicts 21,530 vessel calls to West Coast ports in 2018 (with 95% prediction intervals ranging from 17,360 to 25,710 vessel calls), the year the JCEP and PCGP projects are expect to be in service. Even with the uncertainty generated by available data, there is a reasonably foreseeable increasing trend, albeit imprecise, for vessel traffic volume in the future (by 2018) although unforeseen global events such as future economic crises could influence the predictions. Cumulative effects of 90 LNG carriers per year to eulachon may be more or may be less than the estimate of direct effects discussed above.

Releases of diesel fuel and/or gasoline from non-project related vessels are possible in the foreseeable future. According to annual reports published by the Pacific States/British Columbia Oil Spill Task Force, Oregon DEQ reported 34 spills from fishing vessels or other harbor craft in 2002, 38 spills in 2003, and 7 spills from fishing vessels plus spills from 27 other vessel types in 2004. Those relatively consistent incidences apparently increased in 2005 with 18 spills from fishing vessels, 20 from recreational vessels, and 27 spills by other vessel types. By contrast in 2006, there were 3 spills from fishing vessels, 6 spills from recreational vessels, and only 6 spills from other vessel types. Though not known, it appears that the background rate of spills off the Oregon coast (incidence of spills in proportion to total vessel operation) by fishing vessels, recreation vessels, and other vessel types is generally low and expected to continue at low frequencies in the foreseeable future.

**Critical Habitat**

Critical habitat has been designated for this species but no critical habitat would be affected by the Proposed Action.

### 4.5.2.4 Conservation Measures

Measures developed for application within the Estuarine analysis area to conserve green sturgeon would also benefit the eulachon southern DPS if they are present within the estuarine analysis area during construction and operation of the Project.

### 4.5.2.5 Determination of Effects

**Species Effects**

The Project **may affect** Pacific eulachon (Southern DPS) because:

- Eulachon may be present within the estuarine analysis area during construction and operation of the Project;

- Eulachon may occur within the EEZ analysis area during operation of the proposed action;
- The proposed action may affect potential food resources and water quality during the short-term construction period and maintenance dredging within the estuarine and nearshore marine habitats in the EEZ analysis area;
- The discharge at Site F may directly entrap adults during dredge and discharge at this marine location;
- The proposed action may affect water quality during the long-term operation period within the EEZ analysis area.

Project components are **not likely to adversely affect** Pacific eulachon (Southern DPS), because:

- Bottom disturbance from project construction and biennial maintenance dredging may reduce benthic food supply within Coos Bay and at Site F although there is no documentation to suggest that eulachon would be present at either location;
- The possibility that discharge of dredge spoils at Site F every three years would entrap adults is very remote and discountable.

**Critical Habitat Effects**

The Project will have **no effect** on critical habitat for the Pacific eulachon (Southern DPS) because m designated critical habitat is present within the estuarine analysis area.

### 4.5.3 Coho Salmon (Southern Oregon Northern California Coast ESU)

#### 4.5.3.1 Species Account and Critical Habitat

**Status**

The Southern Oregon Northern California Coast (SONCC) ESU coho salmon was listed as a threatened species in 1997 (NMFS, 1997c). The SONCC coho ESU includes all coastal tributaries to the Pacific Ocean between Punta Gorda, California and Cape Blanco, Oregon. It includes all naturally spawning populations as well as three artificial propagation programs, of which one, the Cole Rivers Hatchery (ODFW stock #52) located on the Rogue River, is within the PCGP Project area. At the time of listing, less than 10,000 naturally reproducing SONCC coho were estimated (NMFS, 1997c).

**Threats**

At the time the SONCC coho salmon ESU was proposed for listing, various factors were included as threats to West Coast salmon populations in general but were not specific to the SONCC ESU. Logging, agricultural practices, urbanization, stream channelization, dams, wetland loss, water withdrawals with unscreened diversions for irrigation, and mining were at the start of the list of threats (NMFS, 1995a). Pathways initiated by those actions and leading to impact included soil erosion and stream sedimentation (logging and road networks), degradation of riparian zones and increased water temperatures, decreased recruitment of large woody debris (LWD) in streams and decreased habitat complexity, damage to riparian vegetation by livestock grazing, and pollution by agriculture and urbanization. Overharvest by commercial and recreational fisheries as well as disease, drought, warming ocean temperatures, and artificial propagation with associated impact of hatchery populations on wild stock have been contributory threats to all West Coast salmon (NMFS, 1995a).

NMFS published a status review in 1995 that included the SONCC coho salmon ESU (Weitkamp et al., 1995). In that document, all coho salmon populations in the ESU were depressed. In the Rogue River, wild coho salmon were heavily affected by hatchery production with little natural production in the mainstem. The declining trend of coho salmon was indicative that natural populations in the Rogue River and others within the ESU were not self-sustaining (Weitkamp et al., 1995).

NMFS published a more recent status review in 2005 (Good et al., 2005). Though coho salmon populations continue to be depressed within the ESU as a whole, the Rogue River stock has demonstrated a recent average increase in numbers of spawners. While the Rogue River run includes hatchery fish, and hatchery releases from the Cole Rivers hatchery have been relatively consistent between 1987 and 2002 (see Table 76 in Spence et al., 2005), those fish are Rogue River coho salmon (with no out-of basin fish) for which propagation began in 1973 to mitigate for impact due to construction of Lost Creek Dam (Spence et al., 2005). Consequently there is reduced genetic risk to wild stock in the Rogue River. Ocean harvest of the Rogue-Klamath stock by commercial and recreational fishers has been controlled since 1999 (not to exceed 13 percent) and river harvest within the ESU has not been allowed since 1994 (with tribal harvests excepted).

Most recently, NMFS (2012d) released a draft recovery plan for SONCC coho salmon that identified ten stress, or limiting, factors and 13 threats to various life-stages for coho in the Upper Rogue River population. Limiting factors or stresses that were determined to be very high to all life stages included 1) altered hydrologic function primarily due to reservoirs constructed to support irrigated cropland and ground water depletions for a variety of uses, 2) degraded riparian forest conditions caused by removal of large conifers, channelization, wetland drainage, and other alterations, 3) impaired water quality, principally due to increased water temperature (from lower water flows, removal of riparian trees) with lower dissolved oxygen, 4) lack of floodplain and channel structure (channelization and reduction of slow, cool edgewater habitats where coho fry and juveniles thrive), and 5) altered sediment supply from roads, timber harvest, and bank erosion following removal of riparian vegetation causing elevated fine sediment input (NMFS, 2012d). In addition, barriers to upstream migrations by small temporary agricultural dams, large diversion dams, and seasonal loss of stream flow in tributaries such as Trail Creek are a key limiting factor for the population.

Threats to all life stages having very high or high severity rankings contribute to the limiting factors discussed, above. Severe threats to the Upper Rogue River population include 1) roads and high road densities that cause chronic fine sediment and increase probabilities of landslides, 2) urban-residential-industrial developments have lead to channelization, increased non-point source storm water pollution, and resulted in loss of aquatic system function, 3) channelization-diking have impaired floodplain functions, constricted channels, and reduced surface-groundwater connections that adversely affect water temperatures and salmon carrying capacities, 4) timber harvest causing early seral stage forests and high road densities in riparian zones, 5) agricultural dams and diversions that impede upstream adult salmon passage or strand downstream-migrating juveniles, if fish screens are not in place, 6) gravel extraction has altered river channels, formed new ones, and degrading formerly productive coho salmon rearing habitats, and 7) climate change which will likely cause increased regional average temperatures over the next 50 years and is leading to ocean acidification which will affect numerous marine habitat conditions, including prey availability (NMFS, 2012d).

Historically, the SONCC coho salmon ESU inhabited the Upper Klamath Basin. However, construction of the Copco 1 Dam on the mainstem Klamath River in 1918, followed by construction of the Copco 2 Dam in 1925 and the Iron Gate Dam in 1962 were impassible to anadromous fish. Prior to construction of the dams, anadromous fish including SONCC coho salmon potentially could utilize over 600 miles of spawing, incubation, and rearing riverine habitats upstream from Iron Gate Dam (Hamilton et al., 2005). The historical extent of coho salmon upstream from Iron Gate Dam is believed to be Spencer Creek (Hamilton et al., 2005), which would have coincided with the Pacific Connector pipeline if not for the downstream barriers. Currently, the Upper Klamath River coho salmon population of coho salmon is not viable and at high risk of extinction according to the population viability criteria. Summer and winter rearing habitat is in poor condition in many areas and is limited in its extent and connectivity. Mainstem conditions during the summer are prohibitive for migration and rearing and hatchery influences on the population are very high. Overall, the removal of the four mainstem Klamath River dams up to Keno Dam is the most significant action that can be taken 15 to restore the viability of the Upper Klamath population unit. (NMFS, 2012d).

In 2008 the Oregon Fish and Wildlife Commission approved a plan to initiate effort to re-establish anadromous fish into the Oregon portion of the Klamath River Basin. Although there is no definite timetable, this could result in the ESA-listed SONCC coho salmon being present in the Klamath River system at some point in the future. Actual introduction would be unlikely to occur prior to pipeline construction.

**Species Recovery**

A draft recovery plan was released in 2012 for public review and input (NMFS, 2012d). The draft plan addressed limiting factors and threats to each coho population within the SONCC ESU including those within the Upper Rogue River population (see discussion under Threats, above). The draft plan calls for immediate habitat restoration and threat reduction in areas currently occupied by coho salmon in Evans, Trail, Elk, Big Butte, and Little Butte creeks. The greatest factor limiting recovery of coho salmon in the Upper Rogue River is the lack of suitable rearing habitat for juveniles (NMFS, 2012d). Consequently, recovery actions create and maintain juvenile rearing habitat must be restored by restoring flow, increasing habitat complexity within the channel, restoring off-channel rearing areas, and reducing threats to instream habitat.

The following actions have been proposed: 1) reconnecting channels with floodplains, 2) increasing channel complexity, 3) improving flow timing and volumes, 4) improving fish access, 5) improving large wood recruitment, bank stability, shading, and food subsidies, 6) reducing predation and competition from non-native fish species, 7) improving estuarine habitat, 8) manage fisheries consistend with recovery of SONCC coho salmon, 9) manage scientific collection consistent with recovery of SONCC coho salmon, 10) track population abundance, spatial structure, productivity, or diversity, 11) track habitat condition, 12) reduce delivery of sediment to streams, and 13) reduce pollutants.

**Life History, Habitat Requirements, and Distribution**

Five life phases are generally recognized for the coho salmon: juvenile rearing, juvenile migration, growth and development, adult migration, and spawning. Juvenile summer and winter rearing areas and spawning areas are often located in small headwater streams. Juvenile migration corridors, adult migration corridors, and spawning areas are found in tributaries as well as mainstream reaches and estuarine zones. Growth and development to adulthood happens primarily in near- and offshore marine waters. Final maturation takes place in freshwater tributaries when the adults return to spawn (NMFS, 1999b). Typically coho salmon begin their spawning migration as 3 year olds in late summer and fall and spawn by mid-winter. Eggs incubate for 1.5 to 4 months and then hatch. Juveniles rear for about 15 months in freshwater before migrating in spring to the ocean. They generally spend two growing seasons within the ocean before migrating back to their natal stream to spawn (NMFS, 1997d).

Adult coho salmon rarely migrate farther up freshwater streams greater than 150 miles and generally return to spawn at sites where they hatched. Returning to parental spawning grounds ensures repeated use of suitable redd sites (Sandercock, 1991). Straying (movements in non-natal stream systems), has been documented. In streams with deteriorated habitat such as low water flow, straying rates up to 50 percent have been documented (Sandercock, 1991).

Preferred water temperatures during adult coho salmon upstream migration range between 7.2$^{o}$C and 15.6$^{o}$C (45$^{o}$F to 60$^{o}$F) with an upper lethal limit for adult coho salmon of 25.8$^{o}$C or 78 $^{o}$F (Table 3 in Laufle et al., 1986). Preferred coho salmon spawning temperatures range from 4.4$^{o}$C to 9.4$^{o}$C (40$^{o}$F to 49$^{o}$F) while temperatures between 4.4$^{o}$C to 13.3$^{o}$C (40$^{o}$F to 56$^{o}$F) during egg incubation are preferred; the warmer the temperature, the less time before eggs hatch. The preferred range for juvenile survival systems is between 11.8$^{o}$C to 14.6$^{o}$C (53$^{o}$F to 58$^{o}$F) (Laufle et al. 1986). Elevated temperatures in streams may lead to early smoltification and ultimately premature migration towards sea during unfavorable conditions for young coho salmon (McMahon, 1983).

Productive coho salmon streams are those that have a riffle to pool ratio of close to 1:1. Smaller streams are preferred over larger rivers due to the higher proportion of slack water to midstream area (Sandercock, 1991). Substrate composition and riffles are other factors, along with terrestrial vegetation, that are important for producing aquatic and terrestrial insects which are food for coho salmon. Benthic invertebrate production is best in rubble, followed by bedrock, gravel, and sand. Coho salmon parr abundance is greatest in larger deeper pools where they can find cover near the streambank from logs, roots, debris, undercut banks, and overhanging vegetation (McMahon, 1983).

Adult coho salmon require minimum water depths of 0.18 meters or 7 inches (Laufle et al., 1986) during upstream migration. Redd sites are found in waters at least 15 cm (5.9 inch) deep, though once hatched, coho salmon fry and parr prefer water at least 0.30 meters (1 foot) deep (McMahon, 1983). During adult migrations upstream to spawn, water velocities less than 2.44 meters per second (m/sec; 8 feet/sec) are most desirable. At spawning grounds, coho salmon select redd sites where flows range between 5.0 and 6.8 cubic meters per minute ($m^3$/minute; 177 to 240 cubic feet per minute [$ft^3$/minute] or from 3 to 4 cubic feet per second [cfs]), and where stream width does not exceed 1 meter or 3.2 feet (Sandercock, 1991). For adult migration upstream, dissolved oxygen (DO) concentrations exceeding 6.3 mg/l are preferred (McMahon 1983). Incubation of eggs is best near DO saturation concentrations and weight gains by fry are maximized in water with DO concentrations between 4 and 9 mg/l (Laufle et al., 1986).

Spawning substrate is gravel size between 1.3 and 10.2 cm (0.5 to 4 inches) (Laufle et al., 1986). Gravels less than 16 cm (6.3 inches) account for 85 percent of redd sites (Sandercock, 1991). Average coho salmon redd size is 2.8 $m^2$ (30 $ft^2$); the recommended area per spawning pair is

11.7 $m^2$ or 126 $ft^2$ (Laufle et al., 1986). Egg survival to fry emergence has a positive correlation with gravel sizes between 3.35 mm and 26.9 mm (0.13 to 1.06 inches). For successful fry emergence, not more than 15 percent of the substrate should be fine sediment (McMahon 1983) because higher concentrations of fines may lead to earlier fry emergence, smaller fry, and fry with more yolk (Sandercock, 1991). Silt loads less than 25 mg/l are preferable for survival of eggs and juvenile coho salmon (Laufle et al., 1986).

Coho salmon diets in freshwater differ between locations and seasons, though young coho salmon feed mainly on aquatic and terrestrial insects, becoming more piscivorous as they grow (McMahon 1983). After emergence, fry feed mostly on various life stages of aquatic insects including dipterans (true flies), ephemeropterans (mayflies), plecopterans (stoneflies), and others as well as crustaceans and fish (Laufle et al., 1986). In the West Fork Smith River in Douglas County (Oregon), diets of juvenile coho salmon (from December through May) were mostly benthic invertebrates (larval dipterans, ephemeropterans, limnephilid caddisflies, and plecopterans), but also included salmon eggs, aquatic snails, salamanders, and terrestrial invertebrates (Olegario, 2006).

Major rivers, estuaries, and bays known to support coho salmon within the range of the SONCC ESU include the Rogue River, Smith River, Klamath River, Mad River, Humboldt Bay, Eel River, and Mattole River (NMFS, 1999b), of which the Rogue and Klamath Rivers are within the Pacific Connector pipeline area. Historically, SONCC coho inhabited the Upper Klamath Basin. However, construction of the Copco 1 Dam on the mainstem Klamath River in 1918, followed by construction of the Copco 2 Dam in 1925 and the Iron Gate Dam in 1962 were impassible to anadromous fish. Prior to construction of the dams, anadromous fish including SONCC coho salmon potentially could utilize over 600 miles of spawning, incubation, and rearing riverine habitats upstream from Iron Gate Dam (Hamilton et al., 2005). The historical extent of coho salmon upstream from Iron Gate Dam is believed to be Spencer Creek (Hamilton et al., 2005), which would have coincided with the Pacific Connector pipeline if not for the downstream barriers.

Specific timings of life history phases for SONCC coho salmon within the pipeline area are shown in figure 4.5-2. Included are the Rogue River mainstem and Upper Rogue River tributaries from Marial Creek to Lost Creek. Evident in figure 4.5-2 is the general synchrony in life phases within the mainstem and tributaries. Peak occurrence of juvenile out-migration lasts longer in tributaries than in the mainstem. In general, adult coho migrate upstream beginning in September and October and spawn during November through January. Fry emergence occurs about one month after spawning and juvenile rearing continues throughout the year with juvenile out-migration extending from February through early June.

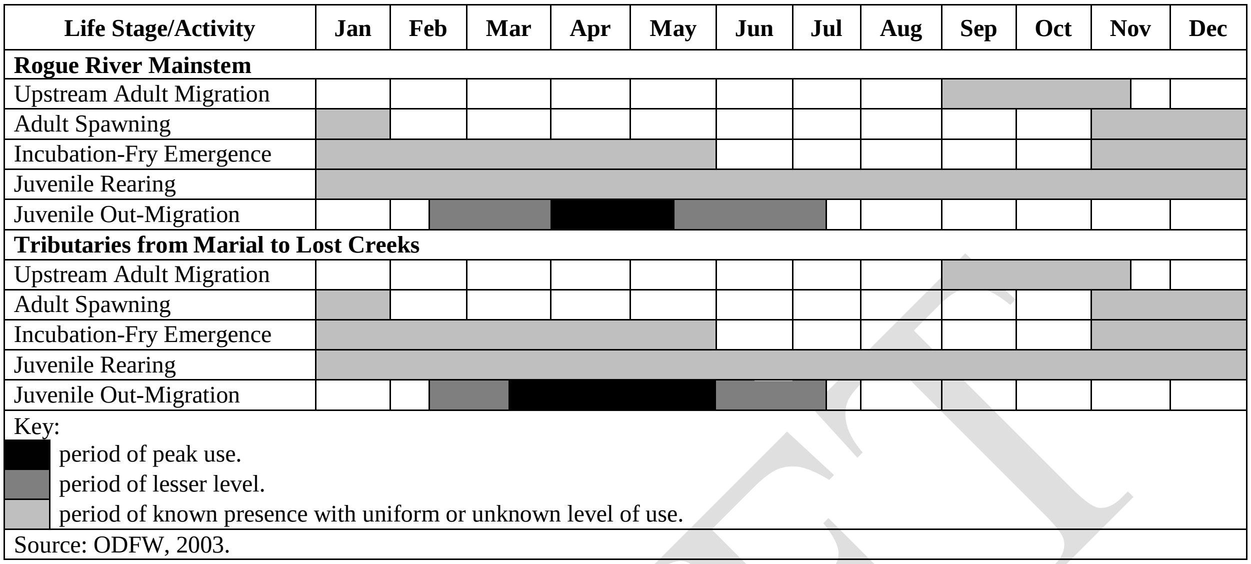

**Figure 4.5-2**
**Approximate Timing of SONCC ESU Coho Salmon Use of the Rogue River Mainstem and Tributaries from Marial to Lost Creek**

Coho in the SONCC ESU inhabit waterbodies in the following four fifth field watersheds in the Upper Rogue Sub-basin that will be crossed by the PCGP: Trail Creek (HUC 1710030706), Shady Cove-Rogue River (HUC 1710030707), Big Butte Creek (HUC 710030704), and Little Butte Creek (HUC 1710030708). Table 4.5.3-1 summarizes the number of waterbodies crossed within the PCGP Project area that are known or assumed to support SONCC coho.

**Table 4.5.3-1**
**Number of Waterbodies Crossed by the PCGP Project within the Upper Rogue Sub-basin and 5th Field Watersheds with SONCC Coho Designated Critical Habitat and Coho Presence (Known or Assumed)**

| Sub-basin and 5th Field Watersheds | Hydrologic Unit Code | Number of Waterbodies | | |
|---|---|---|---|---|
| | | Critical Habitat [1] | Coho Known [2] | Coho Assumed [3] |
| **Upper Rogue Subbasin** | **17100307** | | | |
| Trail Creek | 1710030706 | 3 | 3 | 0 |
| Shady Cove-Rogue River | 1710030707 | 1 | 1 | 1 |
| Big Butte Creek | 1710030704 | 2 | 2 | 3 |
| Little Butte Creek | 1710030708 | 2 | 2 | 5 |
| | **Total** | 8 | 8 | 9 |

[2] ODFW, 2012a.
[3] Assumed presence based on connectivity to occupied stream reaches.

**Population Status**

At the time NMFS proposed this ESU for listing, population estimates for naturally reproducing coho salmon in the SONCC ESU included escapement records from Gold Ray Dam on the upper Rogue River as well as some catch estimates from all Oregon rivers and estimates of run size in the Rogue River. During the 1940s, 2,000 adult coho salmon were counted at the Gold Ray Dam per year, but that number declined to fewer than 200 adults in the early 1970s (NMFS, 1995). The Gold Ray Dam on the Rogue River was removed in August 2010. ODFW (2012b) counted adult coho and other anadromous salmonids passing the former Gold Ray Dam as they utilized a fish ladder between late September and January. Abundance of coho returning to the Upper Rogue River above Gold Ray Dam increased from 1996 to 2002 but significantly declined from 2002 through 2009, the last year counted before the dam was removed (see figure 4.5-3).

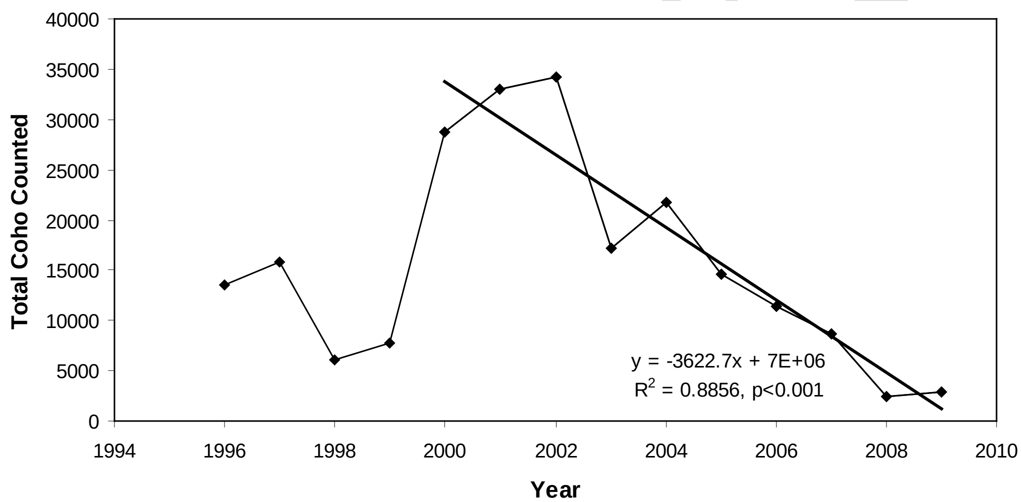

**Figure 4.5-3**

**Total Number of SONCC Adult Coho Counted at the Gold Ray Dam Fish Ladder on the Middle Rogue River, from 1996 to 2009. The decreasing trend from 2001 through 2009 is significant (data from ODFW, 2012d)**

Similar declines were demonstrated with counts made at Huntley Park, at RM 8 on the lower Rogue River, using daily totals of seine counts from 1997 to 2011 (ODFW, 2012c). Oregon has been monitoring spawner abundance on a regular basis on the Rogue River by seine estimates conducted in the vicinity of Huntley Park. Numbers of coho counted at Huntley Park represent salmon in the Illinois, Middle, and Upper Rogue populations aggregated together. From 1980 to 2004, the trend for adult spawner abundance on the Rogue River consistently increased (Spence et al., 2005), mostly due to decreased harvest. However, the trend since 2000 has been decreasing at a significant rate through 2011 such that the coho population is predicted to be zero before 2012 although the upper 95% prediction interval of 15,654 fish in 2012 indicates a high level of uncertainty in the prediction (see figure 4.5-4).

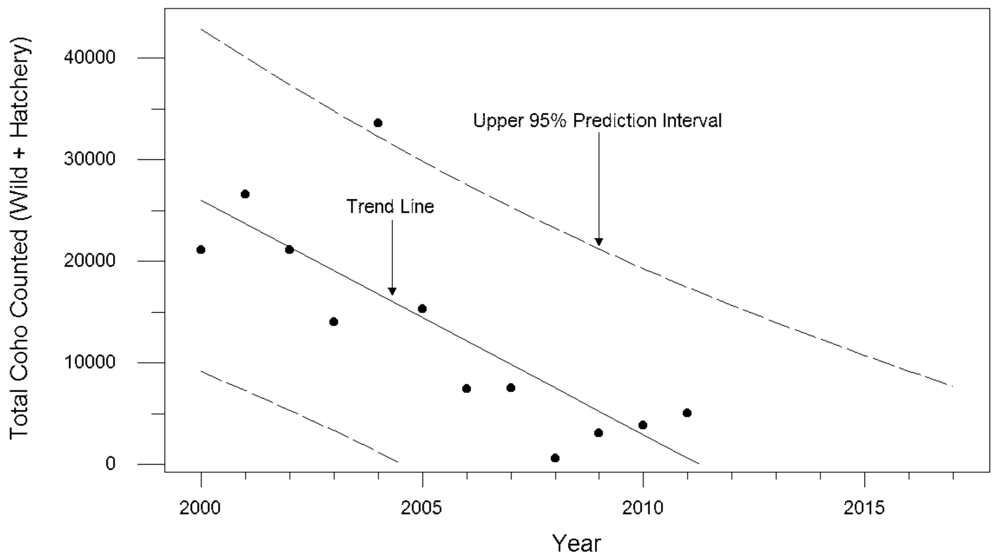

**Figure 4.5-4**
**Total Number of SONCC Coho (Wild plus Hatchery-raised) Counted at Huntley Park (RM 8) on the Rogue River, from 2000 to 2011. The decreasing trend from 2000 through 2011 (solid line) is significant ($r2 = 0.633$, $P<0.005$) with 95% Prediction Intervals (dashed lines) Through 2017 (ODFW, 2012c)**

### Critical Habitat

Critical habitat for coho salmon in the SONCC ESU has been designated (NMFS, 1999c) based on species' requirements such as space for growth and behavior, nutritional and physiological requirements, cover and/or shelter, reproduction sites, and habitats that are protected from disturbance or are representative of historically known population sites (NMFS, 1999b). Other known essential physical and biological features, referred to as primary constituent elements (PCEs), are crucial to species conservation and critical habitat. These features include, but are not limited to, spawning sites, food resources, water quality and quantity, and riparian vegetation (NFMS, 1999c).

Generally, riparian areas form the basis of healthy watersheds and impacts on them in turn affect these PCEs (NFMS, 1999c). However, the PCEs that create healthy salmonid habitat vary throughout the coho salmon's range and the extant of the adjacent riparian zone may change accordingly. A site-potential tree height is a suitable benchmark in some cases, but in order to better assess the features of a specific locale, site-specific analyses provide the best means to characterize the riparian zone (NFMS, 1999b).

Critical habitat for coho salmon in the SONCC ESU includes the accessible reaches of all rivers (including water, substrate, and adjacent riparian zone of estuarine and riverine reaches) between the Mattole River in California and the Elk River in Oregon. Within the counties traversed by the proposed pipeline, critical habitat has been designated in USGS hydrologic unit (HU) Middle Rogue (17100308 – Jackson County) up to the Emigrant Lake Dam/Emigrant Lake, HU Upper Rogue (17100307 – Jackson, Klamath, and Douglas Counties) up to the Agate Lake Dam/Agate Lake, Fish Lake Dam/Fish Lake, Willow Lake Dam/Willow Lake, and Lost Creek Dam/Lost Creek Reservoir, HU Applegate (17100309 – Jackson County) up to Applegate Dam, and HU Upper Klamath (18010206 – Jackson County) up to Irongate Dam (NMFS, 1999b). The Pacific

Connector pipeline would cross designated critical habitat within waterbodies of the Upper Rogue HU (17100307) below the Lost Creek, Willow Creek, and Fish Lake Dams (NMFS, 1999c). Eight waterbodies within the four 5$^{th}$ field watersheds crossed by the PCGP Project are known to support designated critical habitat for SONCC coho, nine others are assumed to support coho and may provide critical habitat (see table 4.5.3-1).

#### 4.5.3.2 Environmental Baseline

**Analysis Area**

Two analysis areas are applicable to coho salmon in the SONCC ESU. First is the freshwater, in-stream or riverine analysis area, which includes two components: 1) the water column and substrate of all waterbodies crossed by the Pacific Connector pipeline from the point of crossing to the extent downstream where water quality is not adversely affected by suspended sediments generated during construction and sediment generated by runoff from the construction right-of-way, and 2) waterbodies' associated riparian zones affected in the short-term during construction and in the long term by operation. Riparian zones widths are defined as the distance from each bank extending to one site-potential tree height. Only the riverine analysis area associated with fresh waterbodies within the Upper Rogue Sub-basin (HU 17100307) is applicable to coho salmon in the SONCC ESU.

In addition, the proposed action could affect the SONCC ESU within the EEZ analysis area, which extends 200 nmi offshore. Within the analysis area, effects to coho salmon within coastal marine waters would be associated with LNG carriers that are assumed to transect the EEZ perpendicularly - east and west - as they approach and depart from Coos Bay (see the discussion above under Section 4.2.1 Blue Whale).

Total suspended solid (TSS) concentrations generated during wet open-cut pipeline construction have been estimated from models developed by Reid et al. (2004). Amounts of TSS produced during dry open-cut construction (fluming, dam-and-pump) adjustments are fractions of the concentrations produced during wet-open cuts (Reid et al., 2004). Estimates of TSS produced during dry open-cut construction across waterbodies in fifth field watersheds are presented below in Section 4.5.3.3. Average sediment percentages (grain sizes including gravel, sand, silt, and organics) for streams within each fifth field watershed (below, see table 4.5.3-4 and table 4.5.3-6) were assumed as fractions of the TSS generated during construction and concentrations of each grain class at various distances downstream were estimated using Ritter's (1984) model for minor perennial waterbodies. Distances at which concentrations near zero (settle out of suspension) differ considerably for the different grain sizes and are dependent on water depths and stream discharge rates at the time of construction (see below, table 4.5.3-7). Downstream settling distances will be much greater for deeper waterbodies with high flow velocities than for shallow, slow flowing streams.

For streams within range of SONCC coho that would be crossed by the PCGP project, the average downstream distance expected to near a concentration of 0 mg/L of silt (0.0016 cm diameter, 0.023 cm/sec settling velocity) during fluming is about 208 m (682 feet); the average downstream distance expected to near a concentration of 0 mg/L of clay (0.0004 cm diameter, 0.0014 cm/sec settling velocity) is about 3,095 m (10,154 feet). These estimates are for average peak flows likely to occur during pipeline construction within the ODFW (2008) instream timing recommendations. Downstream distances to reach concentrations of 0 mg/L for silt and clay mobilized by flumed construction during average low flows would be less.

The riverine analysis area used in this biological assessment has been limited to downstream distances up to 10,154 feet (1.9 miles) within the affected fifth field watersheds in the range of SONCC coho (see figure 4.5-5).

### Species Presence

Coho salmon in the SONCC ESU are known to occur or are expected within the Upper Rogue River Hydrologic Unit (HU 17100307) and all perennial tributaries. The Pacific Connector pipeline would cross four fifth-field watersheds including Trail Creek (HUC 1710030706), Rogue River-Shady Cove (HUC 1710030707), Big Butte Creek (HUC 1710030704), and Little Butte Creek (HUC 1710030708). All affected waterbodies within the Upper Rogue Sub-basin and within the range of SONCC coho salmon ESU proximate to the Pacific Connector pipeline are included in table 4.5.3-2. There are 76 waterbodies included in the table, of which 13 are perennial, 60 are intermittent, and 3 are ponds. Coho salmon are known to occur in 8 of the waterbodies and are assumed to be present in 9 others based on connectivity to perennial streams known to support coho salmon, the presence of resident salmonids, and/or information provided by fisheries biologists.

[1] Dry open cut crossing methods include flume or dam-and-pump procedures. Dam-and-pump methods would be utilized where streambed blasting is anticipated to eliminate blasting around the flume. The dam-and-pump crossing method is the preferred crossing procedure in steep incised drainage valleys where worker safety may be compromised when placing ("threading") the pipe string under the flume pipe and where there is a risk of upsetting the flume during this operation. The dam-and-pump crossing method is also the preferred crossing method on small streams under low flow conditions during the recommended ODFW-recommended in-water work period. Pacific Connector proposes temporary/short-term fish passage restriction when completing dam-and-pump crossings within the ODFW-recommended in-water work period. Appendix M provides details of stream crossings.

[3] Assumes fisheries construction windows only apply to those waterbodies flowing at the time of construction and windows do not apply to HDD crossings.

[4] Steambed bedrock based on Pacific Connector's Wetland and Waterbody delineation surveys. Streambed bedrock may require special construction techniques to ensure pipeline design depth. Special construction techniques may include rock hammering, drilling and hammering, or blasting. The need for blasting would be determined by the construction contractor and would only be initiated after ODFW blasting permits are obtained.

**Habitat**

Existing conditions of aquatic habitats within the $5^{th}$ field watersheds in the Upper Rogue Sub-basin that would be crossed by the PCGP Project were evaluated with data collected by ODFW in their Aquatic Inventories Project (ODFW, 1997) in cooperation with other agencies, has conducted stream surveys throughout the state including streams within watersheds crossed by the PCGP Project. Four types of habitat information provide quantitative evaluations of the fish habitat condition within various fifth field watersheds to be crossed by the PCGP Project: 1) pool habitat condition, 2) riffle habitat condition, 3) woody debris habitat condition, and 4) riparian habitat condition. ODFW (Foster et al., 2001) has developed benchmark criteria for each of these habitat conditions that would represent undesirable and desirable habitat conditions. The benchmarks are provided in table 4.5.3-3 along with the various aquatic habitat conditions to which they apply. The conditions of specific streams crossed by the PCGP Project are assumed to be comparable to the average conditions for the sampled reaches in each of the four $5^{th}$ field watersheds. Compilations of ODFW stream-reach data (see appendix X) are summarized in table 4.5.3-4 for the four watersheds in the project area occupied by SONCC coho. The percent of sampled stream reaches that are at or above desirable benchmark conditions and percent that are at or below undesirable conditions indicate the aquatic habitat conditions.

Benchmark conditions are not absolute but they provide a method for comparing values of key aquatic habitat components (Foster et al., 2001). Pools provide refuges for fish during high and low stream flows. Pools provide slow water habitats for adults and juveniles, provide over-wintering habitat for some fish species, provide habitat during periods of low summer flows, and pools associated with large wood provide habitat complexity. Riffles provide spawning habitats for various salmonid species that construct nests or redds in gravels of various sizes, specific to salmonid species. Sand, silt, and organic debris can reduce suitability of spawning habitats by filling pores between gravel particles that are necessary for intergravel stream flows, availability of oxygen, and for development of embryos; high percentages of sand, silt, and organic material in riffles indicate poor conditions as spawning habitat.

Riparian trees provide shade over stream channels which reduce deleterious effects of high summer water temperatures. Roots of riparian vegetation stabilize stream banks, contribute to development of bank undercutting (thermal and hiding cover), limit erosion and sedimentation from stream banks, and provide large woody debris (LWD) as an important component of the aquatic habitat. LWD, especially contributed by riparian conifers, provides cover for fish, physical habitat complexity that influences stream flows and channel diversity, and biological complexity as substrate for macroinvertebrate communities that provide food for salmonids during different life stages (Foster et al., 2001).

| Source: Foster et al., 2001 | | |

BLM and Oregon Forest Industry Council (OFIC) surveyed 127 stream reaches in the four 5th field watersheds within the Upper Rogue Sub-basin that will be crossed by the PCGP Project: 21 in the Trail Creek HUC 1710030706, five in the Shady Cove-Rogue River HUC 1710030707, 42 in the Big Butte Creek HUC 1710030704, and 59 in the Little Butte Creek HUC 1710030708. Surveys were conducted during summers in different watersheds between 1994 and 1999. Conditions for benchmark aquatic habitat criteria in the four watersheds are included in table 4.5.3-4.

For most of the stream reaches sampled in the four watersheds, habitat conditions related to pools (area, frequency, residual depths) were between moderate levels and desirable benchmarks.

The majority of reaches were deficient in complex pools associated with LWD. Numbers of LWD pieces, LWD volume, and numbers of key pieces were below benchmark conditions in most stream reaches, which helps explain the poor state of pool complexity associated LWD. Related to low levels of LWD are the low numbers of large conifers (>20 inches diameter-at-breast-height - DBH) within sampled riparian zones. However, shade conditions are generally at moderate or desirable benchmark levels, primarily due to the narrow widths of most streams and presence of broadleaf riparian red alders and cottonwoods that provide shade during summer months (Upper Rogue Watershed Association, 2006).

In general, riffle habitat conditions are better than pool habitat conditions, but they are not at desirable conditions overall. Ratios of stream widths to depths in most stream reaches in the four watersheds were generally low, more narrow and deep than wide and shallow. However, areas of gravel substrates were not at or above desirable benchmarks in most sample reaches and areas of fine sediments in riffles generally exceeded the desirable benchmarks. However, some of this analysis is based on data from before the flood event of the winter of 1996-1997, and conditions could have changed significantly from what the data shows (Little Butte Creek Watershed Council, 2003).

Monthly average stream discharges over the annual cycle are provided in figure 4.5-6 for two waterbodies within the Upper Rogue Sub-basin, Big Butte Creek – a tributary to Rogue River with a 245 square mile watershed, and Elk Creek with a watershed area of 379 square miles.

Although highly variable, monthly flows in the Upper Rogue River below Lost Creek Lake are heavily influenced by irrigation water withdrawals. Water is also diverted for use in hydroelectric power generation (Upper Rogue Watershed Association, 2006). Monthly flows in Big Butte Creek and Elk Creek at the confluence with the Rogue River near Trail were selected as representative because neither segment is influenced by dam releases for irrigation or hydropower. Precipitation falling as snow during winter months does not affect discharges until later in the year (April through May). Minimum flows tend to occur during June, July, August, and September. The ODFW (2008a) instream construction window for Upper Rogue River and tributaries is June 15 to September 15, coinciding with low flows.

**Critical Habitat**

Critical habitat for coho salmon in the SONCC ESU (NMFS, 1999c) includes "all waterways, substrate, and adjacent riparian zones below longstanding, naturally impassable barriers (i.e., natural waterfalls in existence for at least several hundred years)." The Pacific Connector pipeline crosses designated critical habitat associated with waterbodies in the Upper Rogue Sub-basin (HU 17100307), below the Lost Creek, Willow Creek, and Fish Lake Dams. Essential features of coho salmon critical habitat in those waterbodies include adequate 1) substrate, 2) water quality, 3) water quantity, 4) water temperature, 5) water velocity, 6) cover and shelter, 7) food, 8) riparian vegetation, 9) space, and 10) safe passage conditions (NMFS, 1999c).

Critical habitat for SONCC coho salmon is designated based on species requirements such as space for growth and behavior, nutritional and physiological requirements, cover and/or shelter, reproduction sites, and habitats that are protected from disturbance or are representative of historically known population sites (NMFS, 1999c). Additionally, NMFS uses other known essential physical and biological features that are crucial to species conservation and critical habitat. These PCEs include, but are not limited to, spawning sites, food resources, water quality and quantity, and riparian vegetation (NMFS, 1999c). Activities that may affect critical habitat and PCEs include, but are not limited to, timber sales, road building, mining, dredge and fill, and bank stabilization activities (NMFS, 1999c).

Generally, riparian areas form the basis of healthy watersheds and impacts on them in turn affect these PCEs (NMFS, 1999b). However, the PCEs that create healthy salmonid habitat vary throughout the coho salmon's range and the extant of the adjacent riparian zone may change accordingly. A site-potential tree height is a suitable benchmark in some cases, but in order to better assess the features of a specific locale, site-specific analyses provide the best means to characterize the riparian zone (NMFS, 1999c).

Riparian areas provide the following functions: shade, sediment, nutrient or chemical regulation, streambank stability, and input of LWD or organic matter. In addition, critical habitat includes inaccessible headwater or intermittent streams which provide key habitat elements (e.g., LWD, gravel, water quality) crucial for coho salmon in downstream reaches (NMFS, 1999c). Widths of adjacent riparian zones may vary by site-specific and/or landscape characteristics but a distance of one site-potential tree height serves to define riparian zone widths in some cases (NMFS, 1999c). With these considerations, all perennial and intermittent streams in table 4.5.3-2 are included in critical habitat within the riverine analysis area.

### 4.5.3.3 Effects by the Proposed Action

The PCGP Project would cross 17 waterbodies which are known or presumed to be inhabited by coho salmon in the SONCC ESU (see table 4.5.3-1). Effects by the project could occur to freshwater in-water construction activities, terrestrial/riparian habitat modification, accidental spills or leaks of hazardous materials, and periodic maintenance of the pipeline. Construction of the PCGP Project could directly and/or indirectly affect SONCC coho salmon and critical habitat through one or more of the following pathways:

- Interference with key life history functions for native species.
- Acoustic shock from blasting pipe trench through bedrock streambeds or use of a track hoe or impact hammer if fish are proximate to the construction site.
- Turbidity generated during pipeline construction across waterbodies can adversely affect coho and aquatic habitats.

- Introduction and/or re-distribution of aquatic nuisance species
- Removal of riparian vegetation that can reduce shade (which could increase water temperatures), limit streambank stability, and affect recruitment of LWD.
- Accidental release of fuels and entry of other petroleum products into surface waters can adversely affect coho and other aquatic organisms.
- Application of herbicides to control noxious weeds near waterbodies may adversely affect coho.

**Direct Effects**

Timing

Waterbodies within the Upper Rogue Sub-basin would be crossed between June 15 and September 15 (ODFW, 2008) which partially coincides with adult upstream migrations of coho (see figure 4.5-3). Pacific Connector will cross fish-bearing waterbodies within the SONCC coho ESU to prevent construction during periods of sensitive fish use. In general, construction of the pipeline would be timed to miss periods of major juvenile or adult migrations. The instream construction window coincides with coho juvenile rearing. Construction across waterbodies within the Upper Rogue Sub-basin could occur during adult upstream migration, beginning in September, but would be completed before spawning in early November (see figure 4.5-3).

Acoustic Shock

There are 17 waterbodies within the SONCC coho ESU where shallow bedrock may occur where potential blasting and/or mounted impact hammers may be required to construct a trench through bedrock substrates (see table 4.5.3-2). Explosives detonated near water produce shock waves that can be lethal to fish, eggs, and larvae by rupturing swim bladders and addling egg sacs (British Columbia Ministry of Transportation, 2000). Explosives detonated underground produce two modes of seismic wave (Alaska Department of Fish and Game, ADFG, 1991), 1) body waves that are propagated as compressional primary (P) waves and shear secondary (S) waves, and 2) surface waves produced when a body wave travels to the earth surface and is reflected back. Shock waves propagated from ground to water are less lethal to fish than those from in-water explosions because some energy is reflected or lost at ground-water interface (ADFG, 1991). Peak overpressures as low as 7.2 pounds per square inch (psi) produced by blasting on a gravel/boulder beach caused 40 percent mortality in coho salmon smolts and other studies revealed 50 percent mortality in smolts with peak overpressures ranging from 19.3 to 21.0 psi (ADFG, 1991).

The best approach to protect fish species is to limit the instantaneous hydrostatic pressure change (resulting from nearby blasting) to levels below those known to be harmful to fish. ADFG (1991) reported that a pressure change of 2.7 psi is the level for which no fish mortality occurs and is from 1.7 to 4.5 psi below any level where mortality would be expected, as reported in other studies cited in the document. Based on those studies, and until additional research reveals otherwise, ADFG (1991) concluded that fish would be sufficiently protected from blasting on land by limiting overpressures to 2.7 psi. That limit has apparently been continuously applied by Alaska Department of Natural Resources (see below, in reference to ADFG ,1991).

ADFG (1991) analyzed the straight line distances through rock and other materials for a single shot explosive charge, of given weight, would dissipate to an overpressure standard of 2.7 psi (non-lethal pressure for anadromous fish). Pacific Connector may opt to blast across stream locations where consolidated rock makes traditional trenching methods unfeasible. Typical trench blasting scenarios use multiple 1- to 2-pound charges separated by an 8-milisecond delay to excavate the trench. With use of 1- to 2-pound charges in rock, the set back distance (at which 2.7 psi would occur) from the blast trench to the fish habitat is between 34 and 49 feet (see Table 3, in ADFG, 1991). Blasting would be conducted within dry streambanks isolated from the water column, most likely using dam-and-pump construction to bypass water around the dry workspace.

Several approaches have been suggested to reduce risk of injury or mortality to fish in closest proximity to blasting locations (Wright and Hopky, 1998):

- deployment of bubble curtains/air curtains to disrupt the shock wave;
- deployment of noise generating devices, such as an air compressor discharge line, to scare fish away from the site; or
- removal or exclusion of fish from the work area before the blast occurs.

A Fish Salvage Plan is provided in appendix T. The plan includes measures to exclude fish and prevent them from re-entering isolated portions within waterbodies crossed for distances sufficient to avoid or minimize adverse effects by blasting bedrock in streambeds.

Underwater Noise

Impulsive type sounds, sound generated by pile driving for example, create stress waves in the piling material that radiate sound through the surrounding media of substrate, air, and water and may propagate outward from the source through bottom sediment (Popper and Hastings, 2009). Various studies have reported fish mortality, physical injury, auditory tissue damage, decreased viability of eggs, and decreased larval growth due to noise, mostly explosive blasts, seismic survey blasts, and air gun blasts (Hastings and Popper, 2005). State agencies in Washington, Oregon, and California, along with federal agencies have developed interim noise exposure threshold criteria for pile driving effects on fish (Washington State Department of Transportation, 2011a; Popper et al., 2006).[2] The threshold noise levels are assumed to be applicable to noise from a mounted impact hammer operating on bedrock substrates for 17 waterbodies potentially affected by the PCGP Project in the Upper Rogue River sub-basin (see table 4.5.3-2, above).

Average maximum noise produced by mounted impact hammers due to impact on substrates (eg, rock) has been reported at 90 dBA from 50 feet away in the air (see Table 7-4 in Washington State Department of Transportation, 2011a).[3] Using a simplified conversion of dB between air

[2] Interim noise exposure threshold criteria for pile driving effects on fish (Washington State Department of Transportation, 2011a) include 1) a cumulative sound exposure level ($SEL_{cum}$) of 187 dB re 1 µ$Pa^2$ ● s for fishes more than 2 grams, 2) a $SEL_{cum}$ of 183 dB re 1 µ$Pa^2$ ● s for fishes less than 2 grams, and 3) a single-strike peak level ($SPL_{peak}$) of 206 dB re 1 µPa for all sizes of fishes (Washington State Department of Transportation, 2011a).

$SEL_{cum}$ is the cumulative sound pressure squared, integrated over time, and normalized to one second. $SEL_{cum}$ is calculated as SEL(single strike at 10 meters from the pile) + 10 Log(number of strikes).

[3] For consistency, the maximum noise level ($L_{max}$ of the impact hammer at 1 meter (3.28 feet) is computed as:

$$L_{max} = \text{Construction } L_{max} \text{ at 50 feet} - 25 \text{ Log}(D/D_o) = 119.58 \text{ dBA at 1 meter (3.28 feet).}$$

Where Construction $L_{max}$ = 90 dBA, D = distance from the noise source (3.28 feet) and $D_o$ = the reference measurement distance (here, 50 feet). Noise measured on the A-weighted decibel scale is based on the reference pressure of 20 micro-Pascal (µPa), where one Pascal is the pressure (force of 1 newton) exerted over an area of 1 square meter and applies to sound in the air. Sound in water is referenced (abbreviated as “re:” in reference expressions) to 1 µPa instead of 20 µPa referenced in air.

and water (see footnote, below and Pacific Marine Environmental Laboratory-NOAA, 2012), the noise produced by the impact hammer in air would be equivalent to about 182 dB re: 1 µPa @ 1 meter in water. However, there is no information available to determine whether that noise level would be equivalent to peak sound levels or root mean square (RMS) levels, which are the basis for evaluating potential harm to fish, particularly related to cumulative sound exposure levels caused by multiple impact hammer strikes.

Further, the estimate of noise produced by in-water use of an impact hammer in any waterbody would be influenced by water currents, water depth, and bottom material and topography, as well as configuration and materials of the river banks. The effects of these factors are unknown (Washington State Department of Transportation, 2011a). However, noise propagation in any waterbody, upstream and downstream from the construction site will be limited by the stream channels' sinuosity since the propagation is limited to straight-line distance from the source (Washington State Department of Transportation, 2011a). Noise produced by impact hammers will be much reduced if construction does not occur within the water column, similar to reduction set back distances from the blast trench to the fish habitat to reduce blast overpressures to below 2.7 psi, discussed above.

Sounds produced by a mounted impact hammer operating in dry conditions might be conducted through bedrock substrate to approach the hearing threshold of fish, as for example the Atlantic salmon, which is around 90 dB re: 1 µPa (see Figure 3 in Hastings and Popper, 2005). It is assumed that salmonids in the PCGP Project area at the time of construction will have hearing thresholds similar to Atlantic salmon. With that assumption, listed and non-listed salmonids present at the time of construction might detect the noise produced by animpact-hammer striking bedrock, but the noise is not expected to be of sufficient intensity to cause them injury as would SELs produced by pile driving.

Dry open-cut construction, more than likely dam-and-pump methodology, would be used at sites where blasting and/or mounted impact hammers would be required to construct a trench through bedrock substrates. When using the dam-and-pump stream crossing methodology, the typical right-of-way distribution of an isolated streambed (dry open-cut) would be no less than 25-feet on one side of the pipe trench and 50+ feet on the opposite side of the pipe trench depending on whether it's a 75 or 95 foot width crossing. Therefore an area within the waterbody crossing equivalent to length of the blasting trench and approximately 25-feet wide (in the worst-case scenario) would be exposed to instantaneous hydrostatic pressure changes above 2.7 psi. In reality the distance in water affected outside of the 25 feet on land would be less than an additional 25 feet because water does not transmit energy pressure waves as well as rock (only about 70 percent of the distance away from the charge relative to rock, the most conductive substrate of pressure waves; see calculations in ADFG, 1991), which the maximum distance is based upon.

---

The characteristic impedance of sound in water (related to the density of water and speed of sound) is approximately 3600 times the impedance in air so conversion for the intensity of sounds of equal pressures in air compared to water is 10 Log(3600) = 36 dB (Pacific Marine Environmental Laboratory-NOAA, 2012). Taking into account the different reference pressures for sound in air and in water (20 µPa and 1 µPa) the intensity measurements for sound of equal pressures differ by 26 dB + 36 dB = 62 dB (Pacific Marine Environmental Laboratory-NOAA, 2012). Using this simplified conversion of dB between air and water, the noise produced by the impact hammer in air (120 dB re: 20 µPa @ 1 m) would be equivalent to about 120 dB + 62 dB = 182 dB re: 1 µPa @ 1 m in water.

Suspended Sediment

Salmonids exposed to moderate to high levels of suspended sediment for extended periods could be adversely affected. At high levels, turbidity directly affects survival and growth of salmonids and other species, interferes with gill function, and adversely affects substrate for egg development (reviewed and compiled by Bash et al., 2001). Turbidity can also reduce macrophyte cover (over the long-term) by limiting photosynthesis (Goldsborough and Kemp, 1988), as well as adversely affecting fish vision, which is a requisite for social interactions (Berg and Northcote, 1985), feeding (Vogel and Beauchamp, 1999; Gregory and Northcote, 1993), and predator avoidance (Meager et al., 2006; Miner and Stein, 1996).

Salmonids may avoid areas of increased turbidity levels at 20 mg/L suspended sediment, and possibly lower concentrations depending on length of exposure (Newcombe and Jensen, 1996). The elevated suspended sediment conditions would be short-term during pipeline installation and would not be continuous at any one location. This would reduce the chances of continuous elevated exposure for fish that may move little. Concentrations as low as 17 mg/L have been noted to potentially have some adverse effects (e.g. gill irritation, respiration) for juvenile coho salmon (Wheeler, 2008, based on Berg and Northcote, 1985). Some other studies have found varied effects including lesser effects at these concentrations, with overall effects related to both duration as well as concentration (Newcomb and Jensen, 1996).

Newcombe and Jensen (1996) compiled research from many sources that demonstrate effects to anadromous and resident salmonids by various levels of turbidity and exposure over time. The compiled information was used to develop several models of risks to salmonids and non-salmonids. Input for each of two models (Model 1, juvenile and adult salmonids; Model 3, juvenile salmonids) includes TSS concentration (mg/L) and duration (hours) of exposure to the concentration. Output from each model is a severity-of-ill-effects (SEV) score ranging from 0 to 14 where SEV of 0 indicates no effects, SEV between 1 and 3 indicates behavioral effects, SEV from 4 to 8 indicates sublethal effects, and SEV from 9 through 14 indicate lethal and paralethal effects (see Table 1 in Newcombe and Jensen, 1996).

Before the procedures can be used to evaluate effects of suspended sediment concentrations and variable durations of exposure on fish, there must be some estimate of TSS concentrations generated during construction by the PCGP Project. The following sections develop the information that will lead to estimates of TSS entrained during pipeline construction. The following sections apply to waterbodies crossed by the project, not to the 14 waterbodies (see table 4.5.3-2) that are adjacent to the pipeline, within construction rights-of-way, and would not be crossed.

Background Turbidity and Suspended Sediment. Turbidity, generally reported in Nephelometric Turbidity Units (NTUs), is a measure of the lack of transparency (cloudiness) of water caused by suspended or dissolved substances which cause light to be scattered and adsorbed. Turbidity is often measured on-site using a turbidity meter that measures the scattering of light in a water sample relative to a known range turbidity standards. Turbidity is directly related to the concentration of sediments suspended in water but the relationship between turbidity and suspended sediment is complicated by sediment particle size, particle composition, and water color (ODEQ, 2010).

GeoEngineers (2011a and 2013b) evaluated the potential risk of turbidity increasing during construction of the PCGP across waterbodies. The qualitative evaluation was based on each affected waterbody's hydroperiod, presence of erodible clay and loam soils in streambanks, presence of clay in streambed (suspended clay contributes to turbidity), long-term stability of stream channels, and level/duration of construction effort and stabilization measures likely added at the time of construction. The turbidity risk was scored from 1 (low) to 5 (high). Of 402 canals, ditches, and waterbodies evaluated, 130 were scored with a low risk (score of 1 or 2) of turbidity increase over a 24 hour period, and 272 were scored with a moderate risk (score of 3 or 4), generally due to soil erosion potential, presence of clay or mud, and/or the presence of steep slope or an incised channel that would require construction of a deep trench (GeoEngineers, 2013a). The evaluation concluded that turbidity generated during construction may exceed Oregon water quality standards for short distances and short durations downstream from each stream crossing, either coinciding with construction across perennial waterbodies or in intermittent streams coincidental with autumn precipitation.

Ambient turbidity was not addressed by GeoEngineers (2011a and 2013b). Turbidity (NTU) has been evaluated by ODEQ (2013) and retrieved from Laboratory Analytical Storage and Retrieval (LASAR) Web Application for some of the waterbodies crossed by the PCGP Project. Turbidity within individual streams may be highly variable with highest measurements reported during winter months, usually January through March (see table 4.5.3-5a). During the period coinciding with ODFW (2008a) instream construction windows, reported turbidity has been minimal in streams for which data exists (see table 4.5.3-5b).

The majority of ODEQ LASAR data are turbidity (NTU) measurements taken in the field. TSS have occasionally been reported but mostly without measuring corresponding turbidity. Relationships between turbidity and suspended solid concentrations are determined on a stream-by-stream basis (Downing, 2008). Relationships have been reported for streams in Alaska (Lloyd, 1987; Lloyd et al., 1987) and streams in the Puget Lowlands (Packman et al., 1999); the models are non-linear. They produce differing estimates of TSS conversions from turbidity and conversions between models are most deviant at higher turbidity levels (see table 4.5.3-5a). At low turbidity levels (see table 4.5.3-5b), conversions of NTUs to TSS are relatively consistent. Based on these conversions, an overall background level of 2 mg/L is assumed for TSS concentrations for all streams crossed by the PCGP Project during the ODFW instream construction window. In support of that assumption, ODEQ (2010) reported that during dry seasons, background turbidity levels are relatively low and consistent in small streams throughout Oregon. A six-year ODEQ ambient monitoring study completed during dry seasons inventoried small wadeable stream sites in Oregon's eight ecoregions and found that overall median turbidity levels were approximately 1 NTU, regardless of lithology (resistant or erodible), or the degree of human disturbance. From the data provided in table 4.5.3-5b, background levels of 1 NTU would average about 2 mg/L or slightly less. A background TSS concentration of 2 mg/L during summer is also consistent with measurements reported by USGS in Myrtle Creek, Big Butte Creek, and the Rogue River mainstem during summers 1977, 1978, and 1979 (historical data provided by USDA-Forest Service).

Sediment in Streambed Substrate. ODFW (1997) conducted stream surveys throughout the state including streams within fifth-field watersheds crossed by the PCGP Project (see Habitat in Section 4.5.3.2). Sampled stream reaches were evaluated for 1) average percent sand, silt, and organics in the surface substrate, 2) average percent gravel in the surface substrate, 3) average percent of bedrock in the surface substrate (only reported in reaches sampled after 1999), and 4) the number of boulders ≥0.5 meter in diameter within the sampled reach. We standardized that measurement by converting numbers of boulders to boulders per meter of primary and secondary stream channel lengths. Reported values for fractions of surface area substrates were averaged for all sampled stream reaches within fifth-field watersheds crossed by the PCGP Project; averages are included in table 4.5.3-4, above and in appendix X. We assumed that there are equal parts of sand, silt and organics (clay) within the reported average percent sand, silt, and organics fraction; the assumed percent of silt and clay (fine sediments) is included in table 4.5.3-6.

As noted, the average percent of bedrock in the surface substrate has only been reported in reaches sampled after 1999 and so summaries of the average bedrock substrate component in watersheds are incomplete or not reported. The average substrate fractions in table 4.5.3-6 were incorporated into analyses of sediment effects on salmonids without modification, even though percentages do not total 100.

We assumed that the average surface substrate fractions reported in ODFW (1997) streams surveys and averaged for all sampled streams within a fifth-field watershed are applicable to other streams in the watershed that would be crossed by the PCGP Project. Sediment generated during dry open-cut construction would most likely be surface sediments disturbed during installation and removal of isolation structures (temporary dams placed upstream and downstream from the workspace) and bypass structures (flume pipe, pump intake and exit conduits). It is not necessary to assume that surface substrate fractions are similar to excavated from the pipeline trench by a track-hoe. The use of dry open-cut construction restricts excavated sediment from entering the water column unless there is some failure of the isolation structures or seals between the stream bed and structures.

Known streambed bedrock has been determined for 17 streams proposed for crossing within the Upper Rogue Sub-basin (see table 4.5.3-2) and based on Pacific Connector’s Wetland and Waterbody delineation survey. If bedrock is present at the construction site, special construction techniques to ensure pipeline design depth may be required (rock hammering, drilling and hammering, and/or blasting) but only after the workspace has been isolated with temporary dams placed upstream and downstream. Dam-and-pump construction, rather than fluming, would be used at the crossing. Since presence of bedrock mostly or entirely precludes the presence of other surface substrates, other surfaces sediment fractions for streams in fifth-field watersheds in table 4.5.3-6 would not apply to streams with bedrock present.

**Table 4.5.3-6**
**Average Fractions of Surface Substrates by Area Reported for Sampled Stream Reaches in Fifth-Field Watersheds of the Upper Rogue Sub-Basin Crossed by the PCGP Project [1]**

| Sub-Basin | Fifth Field Watershed | Average % Sand, Silt, Organics in Surface Substrate | Assumed % Silt and Organics in Surface Substrate [2] | Average % Gravel in Surface Substrate | Average % Bedrock in Surface Substrate [3] | Number of Boulders ≥0.5m Diameter per meter of Channel [4] |
|---|---|---|---|---|---|---|
| Upper Rogue | Trail Creek | 20.3 | 13.5 | 19.7 | 7.0 (inc) | 0.3 |
| | Shady Cove-Rogue River | 10.4 | 6.9 | 26.2 | 12.0 (inc) | 0.2 |
| | Big Butte Creek | 24.4 | 16.3 | 19.5 | 11.6 (inc) | 0.2 |
| | Little Butte Creek | 29.9 | 19.9 | 27.3 | not reported | 0.6 |

[2] Assuming equal fractions of sand, silt, and organics
[3] Average percent of bedrock in the surface substrate has only been reported in reaches sampled after 1999
[4] Numbers of boulders counted within the reach divided by the total length (m) of primary and secondary channels within the sampled reach.

Suspended Sediment Transport. In part, sediment transport in streams depends on stream channel characteristics. GeoEngineers (2011b and 2013c) developed a database on stream channel characteristics for 96 streams to be crossed by the PCGP Project (values for modeled streams in appendix Y). The streams were representative of each ecoregion and represent the range of widths/gradients and aspects of the stream crossings in each ecoregion traversed by the PCGP project. The database included (but was not limited to) the channel gradient (percent), bankfull width (feet), and streambed material (bedrock, boulder, cobble, gravel, sand, silt, mud, and clay). GeoEngineers (2012 and 2013d) developed additional stream-specific data to evaluate thermal impact on stream water temperatures due to removal of shading vegetation and increased solar loading within riparian zones during and after pipeline construction. The additional database included (but was not limited to) the wetted width (feet), bankfull width (feet), and predominant depth (feet).

GeoEngineers data were used to estimate the stream channel cross-section shape and cross-section area. If the predominant depth was greater than ½ the bankfull width, the cross-section channel shape was assumed to be a V. If the predominant depth was less than ½ the bankfull width, the cross-section channel shape was assumed to be a trapezoid with each bank as a 1:1 slope, dependent on predominant depth. Manning's Formula (Limerinos, 1970; Arcement and Schneider, 1989) was used to estimate **Q**, the stream discharge rate (cubic feet per second):

$$\mathbf{Q = A\ (\mathit{k}/n)\ (R^{2/3})\ (S^{1/2})}$$

with estimates of **A**, the cross-sectional area of a stream (square feet or square meters), **R**, the hydraulic radius (feet or meters, where **R = A/P**, and **P** is the wetted perimeter in feet or meters), **S**, the slope of channel (vertical feet per horizontal feet), the constant ***k*** equals 1.486 if English units are used but ***k*** equals 1 with metric units, and n is Manning's roughness coefficient. Values reported by GeoEngineers, 2011b and 2012 were used to estimate **A** and **R** and **S** (where a 100 percent gradient = 1). Manning's **n** was estimated from various sources (Chow, 1959; Limerinos, 1970; Arcement and Schneider, 1989), primarily based on streambed materials and streambank conditions reported by GeoEngineers (2011b) and included in appendix Y for each stream modeled. Stream flow rate or discharge rate, **Q**, is related to cross-sectional area (**A**) and average streamflow velocity ($\mathbf{V_A}$):

$$\mathbf{Q = A\ V_A}$$

Estimates of **Q** derived with Manning's Formula are assumed to be measures of the carrying capacity (bankfull flow) of a particular channel section (Arcement and Schneider, 1989). Carrying capacities of a channel section are assumed to occur during periods of high flow, generally during winter months in the project area. Where possible, estimates of **Q** were compared to estimates of maximum instantaneous flows that could occur once every 2 years through once every 500 years, using the USGS web-based GIS hydrologic regression tool, StreamStats (see http://water.usgs.gov/osw/ streamstats/index.html). Though not every waterbody crossed by the PCGP Project has been modeled in StreamStats, those that have provided peak flow estimates (cubic feet per second, or cfs) within the same orders of magnitude (generally within the range of maximum peak flows every 2 years through peak flows every 500 years) as estimates of **Q** derived from application of Manning's Formula to the stream data compiled by GeoEngineers (2011b and 2012).

Sediment particles will be transported distances downstream (**L**, in feet or meters) based on 1) the particle size and settling velocity ($\mathbf{V_S}$, - inches per second, micrometers per second – in water at 20$^o$C, see for example the Wentworth Grain Size Chart, USGS, 2003), 2) the average streamflow velocity, and 3) the average depth of flow (**D**, feet or meters) downstream, using the following equation (Trow Equation, see Harper and Trettel, 2002);'

$$\mathbf{L = (D\ V_A) / V_S}$$

Estimates of transport distances (**L** in feet) for various sediment particles ranging in sizes from clay to coarse gravel are provided, as examples, in table 4.5.3-7 for three of the waterbodies that would be crossed by the PCGP Project outside of the Upper Rogue River sub-basin. Particle sizes deleterious to salmonids (250 µm or less in the models of Newcombe and Jensen, 1996, above) could settle out of suspension less than 1 meter (0.2 feet) downstream (e.g., medium sand in low flows for Tributary to Catching Creek in examples, below). Alternatively, particles could remain suspended for 200 km (100 miles) or more (very fine silt during high flows in Willis Creek).

**Table 4.5.3-7**
**Estimated Downstream Transport Distances for Particles (ranging from Very Fine Silt to Coarse Gravel) in Three Streams (as examples) with Simulated High and Low Flows that Will Be Crossed by the PCGP Project**

| | | | Estimated Particle Transport Distance (L) Downstream [1] | | | | | |
|---|---|---|---|---|---|---|---|---|
| | | | Tributary to Catching Creek | | Steele Creek | | Willis Creek | |
| Particle Description | Particle Diameter | Settling Velocity ($V_S$) | High Flow [2] | Low Flow [2] | High Flow | Low Flow | High Flow | Low Flow |
| Coarse Gravel | 1.60 cm (0.63 in) | 90 cm/s (35.43 in/s) | 0 m (1 ft) | 0 m (0 ft) | 1 m (3.6 ft) | 0 m (0 ft) | 3 m (10 ft) | 0 m (0.2 ft) |
| Very Coarse Sand | 0.1 cm (0.039 in) | 15 cm/s (5.91 in/s) | 2 m (6 ft) | 0 m (0 ft) | 7 m (21 ft) | 0 m (0.3 ft) | 19 m (62 ft) | 0 m (1.4 ft) |
| Coarse Sand | 0.05 cm (0.02 in) | 8 cm/s (3.15 in/s) | 3 m (11 ft) | 0 m (0.1 ft) | 12 m (40 ft) | 0 m (0.6 ft) | 35 m (116 ft) | 1 m (2.7 ft) |
| Medium Sand | 0.025 cm (0.01 in) | 3 cm/s (1.18 in/s) | 9 m (29 ft) | 0 m (0.2 ft) | 33 m (107 ft) | 0 m (1.5 ft) | 94 m (308 ft) | 2 m (7.3 ft) |
| Fine Sand | 0.0125 cm (0.005 in) | 1.25 cm/s (0.49 in/s) | 21 m (69 ft) | 0 m (0.6 ft) | 78 m (257 ft) | 1 m (3.6 ft) | 225 m (742 ft) | 5 m (18 ft) |

| Particle Description | Particle Diameter | Settling Velocity ($V_S$) | Estimated Particle Transport Distance (L) Downstream [1] | | | | | |
|---|---|---|---|---|---|---|---|---|
| | | | Tributary to Catching Creek | | Steele Creek | | Willis Creek | |
| | | | High Flow [2] | Low Flow [2] | High Flow | Low Flow | High Flow | Low Flow |
| Very Fine Sand | 0.0062 cm (0.002 in) | 0.329 cm/s (0.13 in/s) | 80 m (260 ft) | 1 m (2.1 ft) | 297 m (970 ft) | 4 m (14 ft) | 856 m (2,798 ft) | 20 m (66 ft) |
| Coarse Silt | 0.0031 cm (0.001 in) | 0.085 cm/s (0.03 in/s) | 308 m (1,025 ft) | 3 m (8.3 ft) | 1,148 m (3,820 ft) | 16 m (53 ft) | 3,313 m (11,024 ft) | 78 m (259 ft) |
| Medium Silt | 0.0016 cm (0.0006 in) | 0.023 cm/s (0.009 in/s) | 1,139 m (3,760 ft) | 9 m (31 ft) | 4,243 m (14,008 ft) | 59 m (196 ft) | 12,244 m (40,421 ft) | 289 m (951 ft) |
| Very Fine Silt-Clay | 0.0004 cm (0.0002 in) | 0.0014 cm/s (0.0006 in/s) | 18,712 m (56,400 ft) | 153 m (459 ft) | 69,710 m (210,120 ft) | 977 m (2,932 ft) | 201,155 m (606,320 ft) | 4,742 m (14,269 ft) |

[1] Parameter values used to estimate L:

**Trib. Catching Creek:** High Flow: $V_A$ = 1.72 m/s (5.64 ft/s), D = 0.15 m (0.5 ft); Low Flow: $V_A$ =0.27 m/s (0.88 f/s), D = 0.01 m (0.03 ft).
**Steele Creek**: High Flow: $V_A$ = 1.88 m/s (6.18 f/s) D = 0.5 m (1.7 ft); Low Flow: $V_A$ = 0.53 m/s (1.73 ft/s); D = 0.03 m (0.09 ft).
**Willis Creek**: High Flow: $V_A$ = 2.10 m/s (6.89 ft/s), D = 1.2 m (4.4 ft); Low Flow: $V_A$ = 0.66 m/s (2.16 ft/s), D = 0.1 m (0.3 ft).

[2] High flows are based on highest average flows during winter months (assumed to be within bankfull stream widths) during the period of record; low flows are estimated flows during ODFW construction windows.

Seasonal Discharge. Pipeline construction across waterbodies will occur during ODFW (2008a) instream construction windows (see discussion, above). Hydrographs of monthly discharges within the Upper Rogue Sub-basin crossed by the PCGP Project (see figure 4.5-6) show peak seasonal flows during winter months, December through February. Lowest flows occur during summer months, coinciding with the ODFW construction windows. Assuming that high winter stream flows correspond to the carrying capacities of channel sections (Arcement and Schneider, 1989), instream flows during ODFW construction windows would be some fraction of the winter flows. The fractions, included in table 4.5.3-8a and table 4.5.3-8b as a percent of winter high flow during the construction window, have been estimated for waterbodies in each of the four sub-basins based on the most recent 10-year record within USGS hyodrograph data sets. Stream flows during construction windows were estimated for waterbodies in each sub-basin by reducing stream depths and affected parameters in Manning's Formula to achieve an average stream discharge rate, Q, that is the same as the percent (by mid-point) of high flows in table 4.5.3-8a and table 4.5.3-8b for the sub-basin.

**Table 4.5.3-8a**
**Recorded High Flows During Winter and Average Flows During the ODFW Instream Construction Window in Hydrographic Data in the Upper Rogue Sub-Basin by the PCGP Project.**

| Sub-basin | Hydrograph | High Flow (cfs) (Month) | Instream Construction Window | Average Flows (cfs) During Window | Percent of High Flow During Window | Percent Mid-Point |
|---|---|---|---|---|---|---|
| Upper Rogue | Big Butte Creek | 372 (Jan) | Jun 15- Sep 15 | 62.1 | 16.7 | 9.1 |
| | Elk Creek | 537 (Jan) | Jun 15- Sep 15 | 13.7 | 2.6 | |

**Table 4.5.3-8b**
**Recorded High Flows During Winter and Average Peak Flows During the ODFW Instream Construction Window in Hydrographic Data in Four Sub-basins Crossed by the PCGP Project.**

| Sub-basin | Hydrograph | High Flow (cfs) (Month) | Instream Construction Window | Average Peak Flows (cfs) During Window | Percent of High Flow During Window | Percent Mid-Point |
|---|---|---|---|---|---|---|
| Upper Rogue | Big Butte Creek | 372 (Jan) | Jun 15- Sep 15 | 111.8 | 30.1 | 19.8 |
| | Elk Creek | 537 (Jan) | Jun 15- Sep 15 | 50.8 | 9.5 | |

For example, 10-year average stream flows in the Upper Rogue Sub-basin during the ODFW instream construction window are 9.1 percent of high winter flows, based on discharge data for Big Butte Creek and Elk Creek during December (see figure 4.5-6). Stream depths for all waterbodies within the Upper Rogue Sub-basin were reduced by the same proportion. Reduced stream depths generated reduced values of **A**, **P**, and **R** in Manning's Formula. Estimates of **Q** (and $\mathbf{V_A}$) were likewise reduced for all streams in the sub-basin and were compared to **Q** generated during high winter flows. Reduction of stream depths by iteration was continued until the percent of high winter flows by average flows during the construction window was 9.1 percent for waterbodies crossed by the PCGP Project.

The same procedure was used to evaluate stream discharge rates during average peak flows that were documented in the sub-basins during instream construction windows. Peak flows were obtained from maximum daily flow data during the instream construction window and averaged for the most recent 10-year period (see table 4.5.3-8b).

Sediment Generated During Pipeline Construction. Modeled concentrations of TSS produced in waterbodies during wet open-cut pipeline construction were developed from empirical data collected during construction across 15 to 19 streams in North America (Reid et al., 2004). Models were developed to predict mean and peak TSS concentrations immediately downstream of pipeline construction sites. Models included TSS generated by all construction activities and by trenching, pipe lowering, and backfilling. The models predicting mean TSS generated by all activities (including trenching, pipe lowering, and backfilling) and mean TSS generated by trenching had the highest correlation coefficients (Reid et al., 2004). The model predicting mean TSS ($\boldsymbol{C}_{\mathbf{av}}$) by all construction activities is:

$$\boldsymbol{C_{av}} = \mathbf{1.5 \times 10^6}\ \boldsymbol{U}^{\mathbf{1.09}}\ \boldsymbol{d}_{\mathbf{50}}^{\mathbf{0.95}}\ \boldsymbol{P}_{\mathbf{f}}^{\mathbf{0.35}}\ \boldsymbol{q}^{\mathbf{-1}}$$

where $\boldsymbol{U}$ = mean flow velocity (m per second) at the crossing location during the construction period and is assumed to be equivalent to $\mathbf{V_A}$ derived using Manning's Formula; $\boldsymbol{d}_{\mathbf{50}}$ = the median sediment size (m) of the excavated material by weight; $\boldsymbol{P}_{\mathbf{f}}$ = percentage of fines (silt and clay) in the excavated material (%) and is assumed to equal the percent of silt and organics in surface substrates for all streams within a given fifth-field watershed in the Upper Rogue sub-basin tabulated in table 4.5.3-6; $\boldsymbol{q}$ = the width adjusted stream flow rate where $\boldsymbol{q = Q/B}$, ($m^2$ per second) with $\boldsymbol{B}$ = the watercourse width (m) adjusted for a particular flow rate and $\boldsymbol{Q}$ = stream flow rate ($m^3$ per second) derived using Manning's Formula. In these simulations, **Q** is related to **B** through Manning's Formula and as **B** increases numerically, **Q** also increases but at a faster numerical rate. If all other model parameters are held constant in the Reid et al. (2004) model, increased width adjusted stream flow rate, $\boldsymbol{q}$ (due high flow, **Q**, and proportionally smaller watercourse widths, $\boldsymbol{B}$) will decrease the TSS concentration ($\boldsymbol{C}_{\mathbf{av}}$) because $\boldsymbol{q}$ is factored as $\boldsymbol{q}^{\mathbf{-1}}$ or $\mathbf{1/}\boldsymbol{q}$ in the equation. Conversely, lower $\boldsymbol{q}$ values will generate higher $\boldsymbol{C}_{\mathbf{av}}$ with all other parameters in the equation held constant.

Available data do not appear suitable to estimate values for $\boldsymbol{d}_{\mathbf{50}}$. In these analyses it is assumed that $\boldsymbol{d}_{\mathbf{50}}$ = 0.00025 m (250 µm) since particles that size or less adversely affect salmonids and other fish in the evaluation procedures by Newcombe and Jensen (1996), introduced above and applied below.

In addition to developing predictive models of TSS concentrations generated by wet-open cut pipeline construction, Reid et al. (2004) measured TSS downstream from 12 flumed pipeline crossings and 23 dam-and-pump crossings (dry-open cut or isolated pipeline construction crossings) with comparisons to 11 wet open-cut construction crossings. By accounting for flow, background TSS concentrations, sampling distance downstream, and duration of construction, Reid et al. determined that mean TSS concentrations generated during dry open-cut construction for fluming were 3.7 percent of the wet open-cut concentrations and 0.85 percent of the wet open-cut concentrations for dam-and-pump construction.

Reid et al. (2004) also predicted peak TSS generated by all construction activities. The model predicting peak TSS ($\boldsymbol{C}_\mathbf{p}$) by all activities is:

$$C_p = 5.7 \times 10^5 \; U^{1.86} \, d_{50}^{0.57} \, P_f^{1.2} \, q^{-1}$$

The model has the same component descriptions and assumptions stated above for predicting the average TSS concentration ($\boldsymbol{C}_\mathbf{av}$). However, the model showed overall low explanatory value (low coefficient of multiple correlation. low multiple $r^2$) and a relatively poor predictor of peak TSS (Reid et al., 2004) and is not used in these analyses.

Short-term peak sediment releases occurred during installation and removal of isolation structures (sand bags, jersey barriers, other dam structures) and bypass components (flume, pumps). Dam-and-pump construction is a particularly effective technique to cross smaller waterbodies. The larger TSS concentrations produced during fluming were mostly related to backfilling the trench, poor containment of ditch water, poor dam seals, and longer construction times associated with fluming larger waterbodies (Reid et al., 2004).

If there was a failure of isolation structures during either type of dry open-cut construction, it is assumed that the TSS generated during the failure would be similar to TSS generated during wet open-cut construction, which is included in table 4.5.3-9. Estimates of TSS concentrations produced during pipeline construction under average and peak low flow conditions are expected to be very low, primarily due to low silt and organic fractions in surface substrates which range from 6.9 percent in Shady Cove-Rogue River to 19.9 percent in Little Butte Creek fifth field watersheds (see table 4.5.3-6). Estimated average TSS concentrations produced during fluming and dam-and pump construction are equal to or slightly above background TSS estimates (2 mg/L) between 50 and 100 meters downstream from construction sites (see table 4.5.3-9).

Estimated Downstream Distance of Suspended Sediment. Ritter (1984) provided two models (minor stream crossings and major stream crossings) for estimating concentrations of suspended sediments ($C_X$, as mg/L) some distance (x) downstream from a pipeline trench being constructed across a waterbody. The model for minor crossings was based on average stream depth of 15.2 cm (6 inches) and the model for major crossings was based on average depth of 91 cm (36 inches). The mid-point between the two depths, 53.1 cm (21 inches), is assumed to differentiate minor from major streams.

Ritter's model for downstream sediment transport distance during construction across minor streams, with complete mixing of sediment particles, estimates the concentration downstream $C_X$ by:

$$C_X = C_O \, e^{-(vs / d)(x / u)}$$

Where $\mathbf{C_O}$ (mg/L) is the initial concentration of suspended solids in the water column at the trenching site, **vs** = the settling velocity (m/second) of sediment particles, **d** = stream depth (m), **u** = stream current velocity (m/second), and **x** = distance (m) downstream.

Ritter's model for downstream sediment transport distance during construction across a major stream assumes complete mixing of sediment particles within one-half the stream width (assuming a horizontal spread of the sediment plume as 0.5 cm/sec). The concentration downstream $\mathbf{C_X}$ is estimated by:

$$\mathbf{C_X = \frac{C_O}{0.5(x)(d)} e^{-(vs / (0.5d)) (u / x)}}$$

Flows expected during pipeline construction within the ODFW instream window limit the application of the major stream crossing model. The Rogue River would be classified as the only major stream but would not be crossed using dry open cut construction and is not included in the sediment entrainment and transport analysis provided in table 4.5.3-9.

Summary. TSS concentrations are essential to evaluating project-related effects on salmoninds (see section below, Suspended Sediment Effects on Fish). Estimates of TSS concentrations generated by wet open-cut and dry open-cut (flume and dam-and-pump) were modeled for 17 waterbodies within the Upper Rogue Sub-basin that would be crossed by the PCGP Project. Concentrations of TSS generated by wet open-cut construction were estimated for each of the waterbody crossing sites (see table 4.5.3-9) and adjusted, depending on use of flumed dry open-cut or dam-and-pump dry open-cut construction. Concentrations of TSS at 10, 50, and 100 meters downstream were based on Ritter's (1984) equations. Fractions of gravel, sand, silt and organics (see table 4.5.3-6) were assumed to be characteristic for each stream within the sub-basin. Average low flows were assumed (see table 4.5.3-8a and example in text) to occur during pipeline construction and used in the Reid et al. (2004) model predicting mean TSS ($\boldsymbol{C_{av}}$) generated by all pipeline instream construction activities. The $\boldsymbol{C_{av}}$ from the Reid et al. model is equivalent to $\mathbf{C_O}$ in the Ritter model (the initial concentration of suspended solids in the water column at the trenching site). Average low flows were also used for estimating concentrations, $\mathbf{C_x}$, at three distances downstream using Ritter's (1984) model for minor streams. Average peak flows during the instream construction window (see table 4.5.3-8b) were also used to estimate concentrations ($\mathbf{C_x}$) at the three distances downstream with the same $\mathbf{C_O}$ as for average low flows. The background TSS concentration was assumed to be 2 mg/L for all streams crossed by the PCGP Project during the ODFW instream construction window (see table 4.5.3-5b).

Estimated TSS concentrations downstream from flumed dry open-cut construction ranged from less than 5 mg/L to 2 mg/L (see table 4.5.3-9). Estimated TSS concentrations downstream from dam-and-pump dry open-cut construction range from about 3 mg/L to 2 mg/L (see table 4.5.3-9). Those ranges of TSS concentrations were used in Newcombe and Jensen's (1996) models estimating risks to salmonids and non-salmonids that would be associated with variable TSS concentrations and variable durations of exposure. The durations of exposure to TSS generated during dry open-cut construction at each of the 17 waterbodies simulated in table 4.5.3-9 are assumed to be similar to those described by Reid et al. (2004) occurring during installation and removal of isolation structures (temporary dams placed upstream and downstream from the workspace) and bypass structures (flume pipe, pump intake and exit conduits). Construction-related problems may occur and my cause elevated TSS concentrations downstream and for longer periods of time, including (Reid et al., 2004): 1) pump failure or insufficient capacity, 2) dam or flume failure, 3) poor dam seal, 4) poor containment of pumped ditch water, 5) inadequate maintenance of sediment control measures. Also, construction across larger waterbodies requires longer periods of instream work, large volumes of stream flow and trench dewatering, and risks of increased sediment release.

Assumptions:

[1] All simulated waterbodies are assumed to have depths ≤ 53 cm during ODFW (2008a) instream construction windows and have been assumed to be Minor Waterbodies (see Ritter, 1984). No waterbodies with bedrock substrates are included. No waterbodies that are adjacent to but not crossed by the pipeline are included.

[2] Based on the Mean TSS model generated by <u>All Activities</u> associated with wet open-cut construction, using variable $P_f$ , the percentage of silt and clay fines materials in the watershed and $d_{50}$ = 0.25 mm or 250 µm (assumed median sediment size of the excavated material by weight) (Reid et al., 2004).

[3] TSS generated by Flumed Dry Open-Cut construction were assumed to be 3.7 percent of concentrations generated by Wet Open-Cut construction (data from Reid et al., 2004).

[4] TSS generated by Dam-and-Pump Dry Open-Cut construction were assumed to be 0.85 percent of concentrations generated by Wet Open-Cut construction (data from Reid et al., 2004)

[5] Concentrations of TSS at 10, 50 and 100 downstream were estimated for fractions of gravel, sand, silt, and organics characteristic in substrates of streams in fifth-field watersheds and settling velocities: gravel (1.6 cm diameter), vs = 90 cm/s; sand (0.025 cm diameter), vs = 3 cm/s; silt (0.0016 cm diameter), vs = 0.023 cm/s; clay (0.0004 cm diameter), vs = 0.0014 cm/s. Concentrations were added to the assumed background level of 2 mg/L.

[6] Instream average low flows and average peak flows at the time of construction (within the ODFW, 2008b recommended in-water construction periods) are assumed to be some percent of the carrying capacity flows for all of the evaluated channel sections within a specific Sub-basin; percent reduction during average flows; percent reduction during average peak flows. Sediment concentrations (Cx) at downstream distances in minor waterbody crossings (Ritter, 1984) were computed from the initial concentrations (Co) estimated by the Mean TSS model generated by <u>All Activities</u> by Reid et al., 2004. .

[7] Initial concentrations (Co) of TSS generated by Flumed Dry Open-Cut construction were assumed to be 3.7 percent of concentrations generated by Wet Open-Cut construction (Reid et al., 2004)

[8] Initial concentrations (Co) of TSS generated by Dam-and-Pump Dry Open-Cut construction were assumed to be 0.85 percent of concentrations generated by Wet Open-Cut construction (Reid et al., 2004)

Estimated average TSS concentrations produced during fluming and dam-and-pump construction are equal to or near background TSS estimates (2 mg/L) at 10, 50, and 100 meters downstream from construction sites (see table 4.5.3-9 and appendix Y). However, TSS concentrations assumed to occur during failure of isolation structures could be higher.

Suspended Sediment Effects on Coho Salmon. Newcombe and Jensen (1996) provide four additional models that have not been applied to analysis of impact of sediment to fish in the PCGP Project area because fish species for which the models were developed are not expected in the habitats for which the two models would be applicable (see species-model associations in Table 2, Newcombe and Jensen, 1996). Model 2 (adult salmonids) does not apply to coho salmon (Newcombe and Jensen, 1996) and Model 4 (eggs and larvae of salmonids and non-salmonids) does not apply to effects by this project because instream construction will not coincide with coho spawning or periods of egg incubation-fry emergence (see figure 4.5-2, above). Model 5 applies to adult estuarine non-salmonids that are particularly sensitive to effects of suspended sediments and Model 6 applies primarily to adult warmwater centrarchid species, eg. sunfish).

Input for each of the four models includes TSS concentration (mg/L) and duration (hours) of exposure to the suspended sediments. Each model has the form:

$$\mathbf{z = a + b(log_e x) + c(log_e y)}$$

where **z** = severity-of-ill-effects (SEV) score, **x** = duration of exposure in hours, **y** = concentration of suspended sediment in mg/L. Constants **a**, **b** and **c** were empirically derived for each model (see Table 3, Newcombe and Jensen, 1996):

Output from each model is severity-of-ill-effects (SEV) score ranging from 0 to 14 where SEV of 0 indicates no effects, SEV between 1 and 3 indicates behavioral effects, SEV from 4 to 8 indicates sublethal effects, and SEV from 9 through 14 indicate lethal and paralethal effects (see Table 1 in Newcombe and Jensen, 1996).

1) Behavioral Effects SEV scores: 1 = Alarm reaction; 2 = Abandonment of cover; 3 = Avoidance response
2) Sublethal Effects SEV scores: 4 = Short-term reduction in feeding rates and/or feeding success; 5 = Minor physiological stress (increase coughing rate and/or increased respiration rate); 6 = Moderate physiological stress; 7 = Moderate habitat degradation and/or impaired homing; 8 = Indications of major physiological stress (long-term reduction in feeding rate and/or feeding success, poor condition)
3) Lethal and Paralethal Effects SEV scores: 9 = Reduced growth rate and/or delayed hatching and/or reduced fish density; 10 = 0 to 20% mortality and/or increased predation and/or moderate to severe habitat degradation. 11= >20 – 40% mortality (SEV scores exceeding 11 predict increased mortality rates).

Input for each of the two models, Model 1, juvenile and adult salmonids and Model 3, juvenile salmonids, includes TSS concentration (mg/L) and duration (hours) of exposure to the concentration. Output from each model is a severity-of-ill-effects (SEV) score ranging from 0 to 14, as (see Table 1 in Newcombe and Jensen, 1996).

Reid et al., (2004) reported two flumed crossings required 23 and 51 hours of instream work while durations of four dam-and-pump crossings ranged from 9 to 41 hours. Reid et al., (2004) reported that flumed crossings averaged 64 hours of instream work (with standard error of 14.1

hours) and dam-and-pump crossing averaged 37.8 hours of instream work (with standard error of 8.4 hours). Based on these data, the assumed range of time required for flumed crossings and dam-and-pump crossings is the mean ± 2 standard errors reported for each technique by Reid et al. (2004). Consequently, estimated durations for fluming range from 36 to 96 hours (see table 4.5.3-10) and for dam-and-pump the range is from 20 to 56 hours (see table 4.5.3-11). If there is a failure of the isolation dams/structures, the durations of maximum TSS concentrations that would be similar to a wet open-cut crossing are assumed to last from 1 hour to 24 hours; the shorter durations would indicate repair of the failed structures while the longer durations would indicate completing the construction by wet open-cut.

Effects to salmonid life stages due to flumed dry open-cut construction across waterbodies that do not have bedrock substrates are included in table 4.5.3-10. The mean TSS concentration generated during flumed pipeline construction across all waterbodies within the four fifth field watersheds in Upper Rogue Sub-basin is 3 mg/L (with standard error = 0.30) 10 meters downstream from the construction site. Assuming a worst case scenario for all streams crossed during average low flow conditions (mean plus 2 standard errors) within the Upper Rogue Sub-basin and within range of SONCC coho, the TSS concentration could be as high as 4 mg/L at 10 meters downstream, declining with greater distances. During average peak flows, mean TSS concentration generated during flumed pipeline construction is 3 mg/L (with standard error = 0.37) 10 meters downstream from the construction site. During peak flows, the TSS concentration could also be as high as 5 mg/L (mean plus 2 standard errors) at 10 meters downstream. All flumed construction is assumed to be completed between 36 and 96 hours (see above).

Similarly, effects to salmonid life stages due to dam-and-pump dry open-cut construction across waterbodies that do not have bedrock substrates are included in table 4.5.3-11. The mean TSS concentration generated during dam-and-pump pipeline construction across all waterbodies within the four fifth field watersheds in Upper Rogue Sub-basin is 2 mg/L (with standard error = 0.07) 10 meters downstream from the construction site. Assuming a worst case scenario for all streams crossed (mean plus 2 standard errors) within the Upper Rogue Sub-basin and within range of SONCC coho, the TSS concentration could be 2 mg/L at 10 meters downstream. During average peak flows, mean TSS concentration generated during flumed pipeline construction is also 2 mg/L (with standard error = 0.08) 10 meters downstream from the construction site. During peak flows, the TSS concentration could be 3 mg/L (mean plus 2 standard errors) at 10 meters downstream. All dam-and-pump construction is assumed to be completed between 20 and 56 hours (see above).

Effects to SONCC Coast coho juveniles and adults due to either of the flumed dry open-cut construction and dam-and-pump dry open-cut construction procedures for waterbodies that do not have bedrock substrates are included in table 4.5.3-10 and table 4.5.3-11, respectively, for expected low flow and potential peak flow conditions during the ODFW (2008a) instream construction windows. Results from applying Model 1 for juvenile and adult coho indicate SEV scores for durations of exposure to the TSS concentrations of 4 mg/L or less would range from SEV = 4 (short-term reduction in feeding rates and/or feeding success) to SEV = 5 (minor physiological stress-increase coughing rate and/or increased respiration rate), and to SEV = 6 (moderate physiological stress) which includes the upper 95% confidence intervals (Newcombe and Jensen, 1996). Peak flows produced TSS levels nearly the same as average low flows and would generate similar SEV scores in table 4.5.3-10 and table 4.5.3-11. All expected responses by adult and juvenile salmonids to TSS produced during fluming or dam-and-pump 10 meters or more downstream would be classified as sublethal, whether during low flows or peak flows.

**Table 4.5.3-10**

[1] SEV scale of effects to fish (see Table 1 in Newcombe and Jensen, 1996) within range of model outputs:
Behavioral Effects: 2 = Abandonment of cover; 3 = Avoidance response
Sublethal Effects: 4 = Short-term reduction in feeding rates and/or feeding success; 5 = Minor physiological stress (increase coughing rate and/or increased respiration rate); 6 = Moderate physiological stress; 7 = Moderate habitat degradation and/or impaired homing; 8 = Indications of major physiological stress (long-term reduction in feeding rate and/or feeding success, poor condition)
Lethal and Paralethal Effects: 9 = Reduced growth rate and/or delayed hatching and/or reduced fish density; 10 = 0 to 20% mortality and/or increased predation and/or moderate to severe habitat degradation. 11= >20 – 40% mortality.
[2] Upper 95% confidence intervals on SEV scores (rounded to nearest integer) were approximated from values in Figures 1, 2, 3, and 4 in Newcombe and Jensen, 1996.

[1] See footnotes to table 4.5.3-10.

Failures of isolation structures to exclude streamflow during fluming or dam-and-pump would result in suspended sediment entrained downstream, assumed to be similar to TSS levels generated during wet open-cut construction (mean plus 2 standard errors from table 4.5.3-9) and included in table 4.5.3-12 along with several potential durations of exposure. Scenarios of exposures of 1 hour and 6 hours could occur while work crews repair the failed isolation structures. Longer exposures of 12 and 24 hours are assumed to occur if dry open-cut construction (flume or dam-and-pump) is abandoned and the waterbody crossing is completed using wet open-cut construction. Suspended sediments concentrations of 29 mg/L during low flows and 31 mg/L during peak flows for durations of 12 to 24 hours would not produce lethal conditions for juvenile and/or adult SONCC coho but could result in moderate physiological stress (SEV = 6) but not moderate habitat degradation and/or impaired homing (if SEV = 7).

[1] See footnotes to table 4.5.3-10.

FWS (Muck, 2010) incorporated the scaled SEV scores into section 7 consultations on bull trout such that SEV scores of 6 or higher would be expected to cause harassment using Model 1 (Juvenile and Adult Salmonids) and would justify a determination of “likely to adversely affect”. figure 4.5-7a provides combinations of TSS concentrations and exposures that would distinguish between determinations of “likely to adversely affect” and “not likely to adversely affect”.

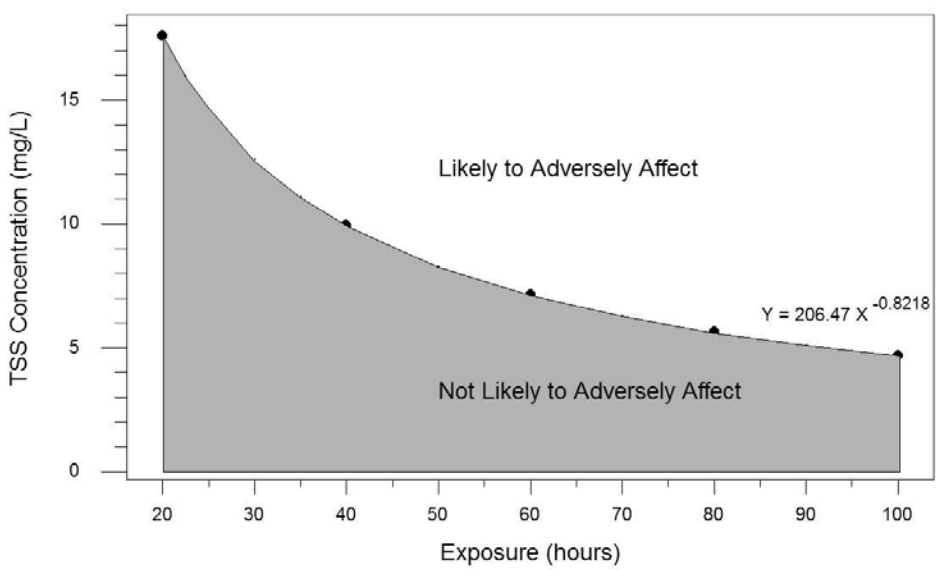

**Figure 4.5-7a**
**Combinations of TSS concentrations and Exposure that would Limit SEV Scores of 5 or Lower (Gray Area) in Model 1 (Newcombe and Jensen, 1996) with a Determination of “Not Likely to Adversely Affect” Adult and Juvenile Salmonids (Muck, 2010)**

Similarly, FWS (Muck, 2010) determined that SEV scores of 5 or higher would cause harassment with application of Model 3 (Juvenile Salmonids) and would justify a determination of “likely to adversely affect.” figure 4.5-7b provides combinations of TSS concentrations and exposures that would distinguish between determinations of “likely to adversely affect” and “not likely to adversely affect.” The same determinations of effect are assumed for coho salmon in this biological assessment.

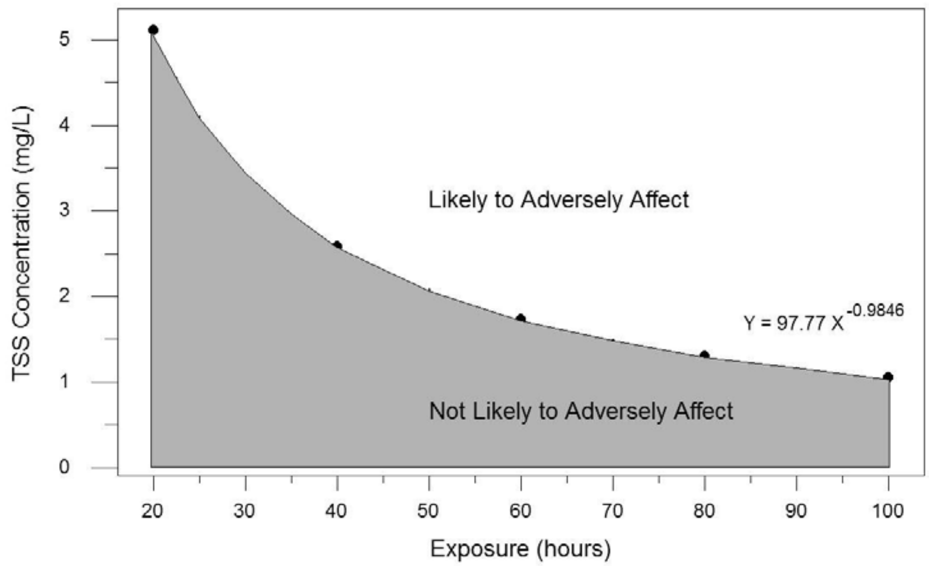

**Figure 4.5-7b**

**Combinations of TSS concentrations and Exposure that would Limit SEV Scores of 4 or Lower (Gray Area) in Model 3 (Newcombe and Jensen, 1996) with a Determination of “Not Likely to Adversely Affect” Juvenile Salmonids (Muck, 2010)**

SEV scores were computed for streams within each fifth field watershed crossed within the Upper Rogue Subbasin using TSS concentrations estimated at 5, 10, 25, 50, and 100 meters downstream from pipeline construction sites and exposure durations from 20 to 100 hours which covers the expected durations required for dam-and-pump and flumed construction. Upper 95% confidence intervals, added to SEV scores, were used to evaluate potential scenarios within each fifth field watershed depending on whether Model 1 (juvenile and adult coho) or Model 3 (juvenile coho) was considered for estimated average low flows and for estimated average peak flows occurred during the period of instream construction.

Results are shown below for TSS effects within Trail Creek (figure 4.5-8), Shady Cove-Rogue River (figure 4.5-9), Big Butte Creek (figure 4.5-10), and Little Butte Creek (figure 4.5-11) watersheds. The model outputs (SEV scores plus 95% confidence intervals) show that instream construction lasting for 20 to 40 hours would not exceed scores of 5 with Model 1 for either average low flows or average peak flows in all four watershed. Based on that model and exposures, the project would be “not likely to adversely affect” coho based on figure 4.5-7b. However, construction lasting for 20 hours or more would exceed a score of 4 with Model 3, regardless of flow rates, in all four watersheds. Based on that model and exposures, the project would be “likely to adversely affect” coho based on figure 4.5-8.

Entrainment and Entrapment

Waterbody crossings using the "dry" crossing methods, flume or dam-and-pump, may result in some fish being entrapped in streams. Flumes and dams will be completely installed and functioning before any instream disturbance. Construction across a waterbody would take up to seven days using dry open cut methods, but less for small and intermediate streams. Once streamflow is diverted through the flume pipe, but before pipeline trenching begins, fish trapped in any water remaining in the work area between the dams would be removed and released using the Fish Salvage Plan (see appendix T). Pacific Connector will contract with either ODFW or a qualified consultant to capture the fish. Personnel that would handle and/or remove fish on federal lands would be approved by the Forest Service or the BLM or be done directly by agency personnel if approved by ODFW.

Frac-Out

Although the HDD method avoids instream impacts because it eliminates the need for instream excavation, it does not completely eliminate the possibility of impacts on aquatic resources. Pacific Connector proposes to use this method to cross the Rogue Rivers. Because HDD requires a lubricant during the process, this fluid is under pressure and there is a possibility of an inadvertent release of drilling mud or fluid (also referred to as a frac-out). Drilling mud primarily consists of water mixed with bentonite, which is a naturally occurring clay material. The only other possible additives would be nontoxic solid materials (e.g., sawdust, nut shells, bentonite pellets, or other commercially available nontoxic products) that could be needed to plug an inadvertent release.

Bentonite by itself is essentially a non-toxic drilling mud (Breteler et al., 1985; Hartman and Martin, 1984; Sprague and Logan, 1979). However, bentonite, as with any fine particulate material, can interfere with oxygen exchange by the gills of aquatic organisms (EPA, 1986). The degree of interference generally increases with water temperature (Horkel and Pearson 1976). Impacts would be localized and would normally be limited to individual fish in the immediate vicinity of the frac-out. The majority of highly mobile aquatic organisms, such as fish, would be able to avoid or move away from turbidity spots and plumes (Reid and Anderson 1999). Other less mobile or immobile organisms, such as mussels and other macroinvertebrates, would incur direct mortality. Bentonite can smother macroinvertebrates and adversely affect filter-feeders (Falk and Lawrence 1973 in Hair et al. 2002 and Land 1974 in Cameron et al. 2002). Bentonite can also exacerbate or enhance the effects of toxic compounds to fish and aquatic invertebrates if those compounds are present in aquatic habitats (Hartman and Martin 1984). Similar to other fine-grained particulates, bentonite in flowing water is more likely to remain in suspension longer than in standing water. Consequently, effects to coho salmon by a release of bentonite into a waterbody would ultimately depend on volume of the release, volume of water present, and current. Coho salmon inhabiting larger waterbodies with swift currents would be less affected by a given volume of bentonite than those inhabiting small waterbodies with no current.

The effects of an instream frac-out on spawning habitat, eggs, and juvenile survival depend on the timing of the release. If spawning habitat is nearby, redds could be affected in the vicinity of frac-out (Reid and Anderson, 1999), if not concurrently, possibly within the immediate future unless high flows flush residual bentonite. During establishment of the spawning bed, a minor addition of sediment would likely be cleaned out by the female as part of the normal preparation behavior. However, a heavy sediment load dispersing downstream could settle into spawning beds and clog interstitial spaces, reducing the amount of available spawning habitat, which could be a limiting factor in areas of already reduced habitat. When redds are active, eggs could be buried, disrupting the normal exchange of gases and metabolic wastes between the egg and water (Anderson, 1996). The impacts of sediment intrusion into the redd on larval survival are more severe during the earlier embryonic stages than following development of the circulatory system of larvae, possible because of a higher efficiency in oxygen uptake by the older fish (Bash et al., 2001). Clogging of interstitial spaces also reduces cover and food availability for juvenile salmonids (Cordone and Kelley, 1961). Benthic organisms could also be affected by burial. However, bentonite is more likely to stay in suspension and less likely to immediately settle than common bottom sediment so, in flowing water areas, effects to benthic organisms from burial from frac-out are likely to be low. The locations where any frac-out may occur are all large waterbodies, which would be affected less because of the dilution factor of large volume of water from any spill.

Potential frac-outs are more common near the HDD drill entry and exit locations; however, impacts to waterbodies are minimized by locating the drill entry and exit points away from the waterbody. The probability of a frac-out may increase when the drill bit is working nearest the surface, but is dependent on numerous factors including substrate characteristics, head pressure of the drilling mud, topography, elevation, and subsurface hydrology. Pacific Connector has designed the Klamath River HDD such that areas of greatest risk from frac-out are on uplands and not adjacent to the waterbodies where much greater depth would be achieved and frac-out potential is reduced.

According to GeoEngineers' Feasibility Analysis for pipeline construction using HDD across the Rogue River (see appendix E) the design length of the Rogue River HDD crossing is approximately 3,050 feet. The proposed entry point is located in a relatively flat, lightly wooded area east of Rogue River and west of Old Ferry Road. The exit point is located near the base of a west facing slope that forms a small butte east of the exit point. The preliminary design provides approximately 58 feet of cover at the eastern and western banks of the Rogue River. GeoEngineers' preliminary evaluation determined that the construction of the Rogue River HDD crossing is likely feasible. Additional evaluation of the hydraulic fracture and inadvertent return potential will be completed for the final design.

Hydraulic fracture typically occurs when the drill path passes through relatively weak cohesive soils with low shear strength or very loose granular soils. Loose and silty sands and soft to medium stiff silts and clays typically have a higher hydraulic fracture potential. Medium dense to dense sands and gravels and very stiff to hard silts and clays have a low to moderate hydraulic fracture potential. Unfractured rock, because of its high shear strength, typically has a low potential for hydraulic fracture. HDD installations with greater depth or in formations with higher shear strength may reduce the potential for hydraulic fracturing (see appendix E).

In the event an inadvertent return occurs into the river, drilling fluid will enter the waterway causing short term, temporary water quality impacts downstream of the project area including sedimentation and turbidity. In the event drilling fluid is inadvertently released into the river, the behavioral avoidance response of SONCC coho is presumed to be triggered within the immediate vicinity of the release and the fish are expected to return and utilize the affected area shortly after the inadvertent release has been halted. If significant concentrations are found during monitoring as a result of a release, the following possible corrective measures would be taken:

1. Increase the drilling fluid viscosity in an attempt at sealing the point at which fluid is leaving the drilled hole. The drilling operation may be suspended for a short period (i.e. overnight) to allow the fractured zone to become sealed with the higher viscosity drilling fluid.
2. If increasing the drilling fluid viscosity is ineffective, lost circulation materials (LCM) may be introduced into the hole by incorporating them in the drilling fluid and pumping the material down-hole. The drilling operation may again be suspended for a short period (i.e. overnight) to allow the fractured zone to become sealed with the lost circulation materials.
3. Depending on the location of the fractured zone, a steel casing may be installed that is of sufficient size to receive the largest expected down-hole tools for the crossing. This casing installation provides a temporary conduit for drilling fluids to flow while opening the remaining section of the hole to a diameter acceptable for receiving the proposed pipe sections. To alleviate future concerns with the steel casing after the HDD installation is completed, the casing is generally extracted from the hole prior to or just after completing the HDD installation. However, there have been instances when attempts at extracting the steel casing were unsuccessful.
4. In the event drilling fluid flow is not regained through the annulus of the drilled hole and a steel casing installation is not utilized, the HDD contractor may elect to install a grout mixture into the drilled hole in an attempt to seal the fractured zone. The down-hole drilling assembly is generally extracted and existing hole is re-drilled to the point at which it had previously been drilled prior to having encountered the loss of drilling fluid.
5. In addition, a grouting program may be implemented from the surface in the event that the installation of grout into the drilled hole is unsuccessful. This approach is only practical in areas where drilling rigs with vertical drilling capabilities can access the HDD alignment. If a surface grouting program is utilized, the HDD drilling assembly is extracted from down-hole. Multiple holes are then drilled vertically on either side and along the HDD alignment to allow for grout slurry to be pumped into the fracture zone where the drilling fluid had previously been lost from the drilled hole. This process can take several days to complete in order to insert the grout in a grid pattern that covers the full fractured zone, during which time the HDD operation is suspended. Upon completion of the surface grouting program, the HDD operation will resume and the pilot hole will be reestablished through the grouted formation.

In some instances, it may be determined that the existing hole encountered a zone of unsatisfactory soil material and the hole may have to be abandoned. If the hole is abandoned, it will be filled with cuttings and drilling fluid.

<u>Movement Blockage</u>

Dry open-cut construction is expected to block upstream movement by adult salmonids, as well as withinstream movements of juvenile coho. As discussed above, fish are expected to abandon cover and/or avoid turbidity plumes generated by instream construction. Instream construction would be completed prior to most upstream migrations by SONCC coho. The fluming process is expected to require from 36 to 96 hours of instream work (see table 4.5.3-10) during which migrating adult SONCC coho could be exposed to TSS concentrations that would produce SEV scores ranging from 5 (minor physiological stress with increase coughing rate and/or increased respiration rate) to 6 (moderate physiological stress).

Flumes would maintain streamflow and fish might move upstream or downstream through the flume. With the dam and pump method, fish would not be able to move upstream or downstream through the work area until the dams have been removed. Flumes and dams would be removed as soon as possible following backfilling of the trench.

With the dam and pump method, coho would not be able to move upstream or downstream through the work area until the dams have been removed. However, dam-and-pump construction is expected to require between 20 and 56 hours of instream work (see table 4.5.3-11). Dam-and-pump construction would generate lower TSS concentrations than fluming; effects to coho would be expected to range from short-term reduction in feeding rates and/or feeding success (SEV score 4) to moderate physiological stress (SEV score 6).

**Indirect Effects**

Aquatic Habit

The same approach utilizing TSS concentration and exposure to evaluate levels of risk to fish (Newcombe and Jensen, 1996) was applied to quantifying effects of sediment on fish habitat, termed the harmful alteration, disturbance or destruction (HADD) of habitat (Anderson et al., 1996). HADD risk includes concentration and exposure to sediment along with sensitivity of the habitat affected. Most likely, suspended sediment would increase embeddedness of spawning gravels with increasing habitat effects closer to the construction location.

Sediment falling out of suspension downstream from the construction location can affect freshwater rearing sites with water quantity and floodplain connectivity to form and maintain physical habitat conditions and support juvenile growth and mobility; water quality and forage supporting juvenile development; and natural cover such as shade, submerged and overhanging large wood, logjams and beaver dams, aquatic vegetation, large rocks and boulders, side channels, and undercut banks. Based on the models for suspended sediment concentration and duration of exposure discussed above (see tables 4.5.3-10 through 4.5.3-12 and figures 4.5-8 through 4.5-11), Anderson et al. (1996) described five severity of ill effect ranks to habitat:

- SEV 3: Measured change in habitat preference.
- SEV 7: Moderate habitat degradation measured by a change in the invertebrate community.
- SEV 10: Moderately severe habitat degradation as defined by measureable reductions in the productivity of habitat for extended periods (months) or over a large area (kilometers).
- SEV 12: Severe habitat degradation as measured by long-term (years) alterations in the ability of existing habitats to support fish or invertebrates.
- SEV 14: Catastrophic or total destruction of habitat in the receiving environment.

FWS (Muck, 2010) determined that SEV scores of 5 or higher applying Model 3 would likely warrant a “likely to adversely affect” juvenile bull trout habitat although noting that abandonment of cover (SEV 2) or avoidance of habitat / change in habitat preference (SEV 3) could lead to increased predation risk and mortality if hiding cover is limited in an affected stream reach (Muck, 2010). For adult and subadult bull trout, FWS judged that abandonment of cover and avoidance may not lead to similar predation risks. Averse effects would likely occur when TSS concentrations lead to notable reduction in abundance of aquatic invertebrates and alteration in their community structure. Consequently, SEV scores (or HADD scores in Anderson et al., 1996) of 7 or higher would warrant a determination of “likely to adversely affect" adult and subadult bull trout due to indirect effects because of habitat degradation (Muck, 2010). In this biological assessment, similar levels of effect due to TSS concentrations and durations of exposure are assumed to apply to coho salmon.

The project is expected to impact salmonid habitat more than the SEV 3 level for Models 1 and 3 included in table 4.5.3-10 and table 4.5.3-11 but would not degrade habitat to the SEV 7 level, even if the upper 95% confidence levels are considered in Model 1 or Model 3 during a failure of dry open-cut construction if TSS concentrations of 29 to 31 mg/L lasted for 12 to 24 hours (see table 4.5.3-12). In cases of uninterrupted dry open-cut construction, adverse affects to coho habitats downstream are not expected.

Freshwater Stream Invertebrates

Substrates downstream from instream construction sites could be impacted by sediments. Mayflies, caddisflies, and stoneflies prefer large substrate particles in riffles and are adversely affected by fine sediment deposited in interparticulate spaces (Cordone and Kelley, 1961; Waters, 1995; Harrison et al., 2007). Fish and benthic macroinvertebrate abundances downstream of pipeline construction sites have been reported as short-term reductions (Reid and Anderson, 1999). Macroinvertebrate abundance and community composition are highly related to the degree to which substrate particles are embedded by fine material (Birtwell, 1999).

Fish emigrate from construction sites and benthic taxa drift downstream to sites where sediment deposition has not affected habitat suitability (Reid and Anderson, 1999). In Ontario, stream crossing construction using fluming produced less turbidity and sediment concentrations downstream than construction by wet open cutting streams; wet open cutting resulted in a significant decrease in aquatic invertebrates downstream three days post-construction (Baddaloo, 1978 cited in Gartman, 1984). One year after construction there were no significant differences in benthos numbers. In general, the percentage of type of stream benthos and invertebrate taxa affected by construction of the proposed pipeline would be in proportion to their abundance during the season of construction.

Rapid colonization by benthic organisms of disturbed substrate following pipeline construction has been demonstrated elsewhere. In Pennsylvania, samples taken before and 30 days after pipeline construction revealed rapid recolonization of the disturbed and newly-exposed stream substrate by benthic macroinvertebrates (Gartman, 1984). Similarly, the number and diversity of aquatic invertebrate taxa in coldwater streams in New York State were unchanged two to four years following pipeline construction from those measured prior to construction (Blais and Simpson, 1997).

Aquatic Nuisance Species

Non-indigenous aquatic species (NAS) are aquatic species that degrade aquatic ecosystem function and benefits, in some cases completely altering aquatic systems by displacing native species, degrading water quality, altering trophic dynamics, and restricting beneficial uses (Hanson and Sytsma, 2001). Currently there are 180 reported NAS in Oregon, of which 134 are documented within the USGS hydrologic basins crossed by the proposed Pacific Connector Pipeline Project (USGS, 2005). Within the Coos Bay estuary, over 67 NAS have been identified (Aquatic Nuisance Species Taskforce, 2006). All of the invertebrate NAS in the Coos Bay estuary have been introduced by ship fouling or discharge from ballast water of ocean-going vessels.

Largemouth bass and smallmouth bass, introduced as recreational species, prey on juvenile sockeye, coho, and chinook salmon (Tabor et al., 2007). Management priorities in Oregon concentrate on the species whose current or potential impacts on native species and habitats and economic and recreational activity in Oregon are known to be significant, known as aquatic nuisance species (ANS) (Hanson and Sytsma, 2001). Pacific Connector has developed BMPs to avoid the potential spread of the aquatic invasive species and pathogens of concern (see Hydrostatic Testing Plan – appendix U). If determined to be feasible for hydrostatic testing requirements, all water used in hydrostatic testing would be returned to its withdrawal source location after use; however, cascading water from one test section to another to minimize water withdrawal requirements may make it impractical to release water within the same watershed where the water was withdrawn. If it is not possible to return the water to the same water basin from where it was withdrawn, various water treatment methods would be used to disinfect water that would be transferred across water basin boundaries including screening/filtering, chlorine treatment, and discharge to upland sites. After hydrostatic test water withdrawal, all equipment used in the withdrawal process would be cleaned and sanitized to prevent the potential spread of aquatic invasives and pathogens from the use of this equipment in other waterbody sources (see appendix U).

Riparian Vegetation Removal and Modification

Aquatic resources could be affected as a result of removal of vegetation and habitat at the waterbody crossing sites as required for pipeline construction. Short-term, physical habitat disruption would occur during trenching activities. Long-term degradation of habitats could occur if the stream contours are modified in the area of the crossing; the flow patterns are changed; and if erosion of the bed, banks, or adjacent upland areas introduces sediment into the waterbody. Loss of riparian vegetation along the banks would reduce shade, potentially increasing water temperatures, remove an important source of terrestrial food for aquatic organisms, and decrease LWD and the associated reduction in habitats, and potentially increase mass failures adjacent to waterbodies.

Much of the impact to coldwater anadromous and resident fisheries by past land uses have been alterations of riparian habitats by logging, road building, agriculture, or other developments such as residences and utility corridors. A total of 105.02 acres of riparian zone habitat associated with waterbodies within range of SONCC coho ESU would be directly affected by all construction related activities. Over half of the affected vegetation (52.56 acres) would be within non-forested types but 25.26 acres of late successional-old growth forest and 24.13 acres of mid-seral forest would be removed within riparian zones (see table 4.5.3-13a). As discussed in Section 4.5.3.2- Habitat, and data presented in table 4.5.3-4, the LWD components of most aquatic habitats in watersheds occupied by SONCC coho and crossed by the PCGP Project are deficient, below benchmark conditions established by ODFW.

In forested habitats, conifer trees will be replanted within the construction right-of-way and other cleared areas outside of the 30-foot wide maintenance corridor and allowed to return to its pre-construction state. The 30-foot wide maintenance corridor centered over the pipeline will be maintained in an herbaceous/shrub state by operations during the life of the project, assumed to be 50 years (see table 4.5.3-13b). Over the long-term, 5.46 acres through riparian late successional-old growth forest and 4.25 acres through mid-seral forest would be maintained in an herbaceous/shrub state within riparian zones associated with SONCC coho (see table 4.5.3-13b).

**Table 4.5.3-13a**

[1] Project components considered in calculation of habitat "Removed": PCGP construction right-of-way, temporary extra work areas, aboveground facilities, and permanent and temporary access roads (PAR, TAR).

[2] Habitat Types within Riparian Zones generally categorized as: Late Successional (Mature) or Old Growth Forest (coniferous, deciduous, mixed ≥80 years old); Mid-Seral Forests (coniferous, deciduous, mixed ≥40 but ≤80 years old); Regenerating Forest (coniferous, deciduous, mixed ≥5 but ≤40 years old); Clearcut Forests; Wetland Forested, Unaltered Nonforested Habitat (grasslands, sagebrush, shrublands), and Altered Habitats (urban, industrial, residential, roads, utility corridors, quarries).

Pacific Connector has attempted to minimize impacts on riparian vegetation by minimizing the width of the standard construction right-of-way at waterbody crossings, and by maintaining a setback between waterbody banks and TEWAs in forested areas. Following construction, Pacific Connector will implement measures to replant or encourage regrowth in riparian areas, and will minimize vegetation maintenance by allowing the development of a riparian strip at least 25 feet wide to be permanently revegetated on private lands and 100 feet wide on federally-managed lands as measured from the edge of the waterbody. As required by FERC's Upland Plan, Pacific Connector consulted with the NRCS, BLM, and Forest Service regarding specific seeding dates and recommended seed mixtures for the project area (see Resource Report 7, Pacific Connector Gas Pipeline). The recommendations have been incorporated into the project-specific Erosion Control and Revegetation Plan (ECRP – see appendix F). The ECRP describes the procedures that will be implemented to minimize erosion and enhance revegetation success for the entire project.

Clearing the right-of-way would remove shading vegetation from uplands and riparian areas, exposing the land and water to increased sunlight, potentially resulting in both direct increases in water temperatures and indirect increases as water flows over the warmer land surface and eventually reaches the waterbody (Beschta and Taylor, 1988). For the waterbodies that would be crossed by HDD, the potential disturbance in riparian areas would be incidental trimming of vegetation using hand tools directly over the pipeline along a footpath. This minor clearing is required to facilitate the temporary deployment of HDD guidance (telemetry) cables along the ground during construction and to perform a leakage survey after installation and commissioning. This is a relatively small area along the riparian zone of any stream and would have minimal adverse effect on aquatic resources.

<u>Water Temperature</u>

The effects of water temperature on salmonid life stages have been extensively reviewed by McCullough (1999), Richter and Kolmes (2005), and others. Maximum water temperatures ranging from 22°C to 24°C (71.6°F to 75.2°F) limit distribution of many salmonid species. No salmonids can survive water temperatures exceeding 25°C (77°F) for extended periods (Ice, 2008). High water temperatures can cause migratory species (including anadromous salmonids) to delay upstream migration (Bjornn and Reiser, 1991), can decrease survival of spawners by increasing metabolic rates (Ice, 2008), can positively influence rates of embryo development and emergence but can negatively influence dissolved oxygen concentrations that limit rates of embryo development (Bjornn and Reiser, 1991). High temperatures inversely influence solubility of oxygen in water (Ice, 2008). Introduction of organic matter with decomposition by microorganisms reduces dissolved oxygen and, along with increased fines (suspended silt and clay) and decreased relative rate of oxygen input to water (reaeration) through reduction in stream flows (Ice, 2008), can adversely affect various salmonid life stages. Coho upstream migration water temperature requirements are for water from 7.2°C to 15.6°C, spawning requirements are for water from 4.4°C to 9.4°C, and for incubation from water from 4.4°C to 13.3°C; preferred temperature is 12.1°C and upper lethal temperatures range from 26.0°C to 28.8°C, depending on previous acclimation temperatures (Bjornn and Reiser, 1991).

Vegetative cover that provides shade, especially during summer, is one factor that regulates water temperature. Construction across waterbodies would necessitate removal of trees and riparian shrubs at the crossing locations. Available information on the effects of pipeline construction in other regions on water temperature has found no or immeasurable change. The total width of riparian area affected by shade tree removal would be small (less than 100 feet) relative to the length of any stream crossed. In one study, construction across two coldwater, fish-bearing streams in Alberta required removing forested riparian vegetation; water temperatures at construction sites and downstream did not increase above temperatures at control sites upstream from construction (Brown et al., 2002). Similarly, water temperatures measured at four coldwater streams in New York before and during pipeline construction and for 3 years following construction showed no short-term or long-term effects on water quality parameters, including water temperature, even though such effects were expected because streambank vegetation had to be cleared, which reduced shading (Blais and Simpson, 1997). In the Alberta study, the highest water temperature recorded was 66°F (19°C in August). In the New York study, the highest temperature was 79 F (26°C) sometime between August and October.

Following requests by the Forest Service, Pacific Connector modeled water temperatures on 6 different stream segments on NFS lands in the Umpqua River basin on tributaries to East Fork Cow Creek (5 crossings) and on the upper Rogue River basin on Little Butte Creek (North State Resources, 2009 ). Temperature models were run on 6 different stream segments on NFS lands in the Umpqua River basin on tributaries to East Fork Cow Creek (5 crossings) and on the upper Rogue River basin on Little Butte Creek (North State Resources, 2009). Of the three smallest streams modeled average temperature increase ranged from 1.0°C to 8.6°C right after construction. Because these streams were so small they likely also would have temperatures reduced rapidly downstream of the clearing from ground water inflow and likely would have no measurable effects on streams they flow into downstream.

As a rule, the effect of water temperature of a non-fish-bearing tributary on water temperature of a fish-bearing receiving stream is determined as the weighted mean of the two water temperatures, weight by respective volumes or instream flows. If $\mathbf{T_1}$ = temperature of tributary with $\mathbf{F_1}$ = flow rate, and $\mathbf{T_2}$ = temperature of receiving stream with $\mathbf{F_2}$ = flow rate, then the resulting water temperature $\mathbf{T_R}$ at the confluence of the two waterbodies would be,

$$\mathbf{T_R = (T_1\, F_1 + T_2\, F_2) / (F_1 + F_2).}$$

For example, Hydrofeature N is an unnamed tributary to East Fork Cow Creek crossed at MP 111.01. Pipeline construction would increase the water temperature by 8.6°C from its base temperature of 11°C (see North State Resources, 2009). The water temperature would be 19.6°C but its reported summer base flow is 0.002 cfs. ODEQ measured water temperature within East Fork Cow Creek during September 1998, reported at 13.5°C. No instream flow data are available for East Fork Cow Creek but USGS (Gage 14309500) has measured flows in West Fork Cow Creek, reporting an average flow of 11.4 cfs during September. Using those data as to illustrate how water temperatures would be combined by the weighted average, the resulting water temperature of Hydrofeature N and the receiving stream would be $\mathbf{T_R}$ = (19.6°C x 0.002 cfs + 13.5°C x 11.4 cfs) / (0.002 cfs + 11.4 cfs) = 13.501°C. The increase of water temperature in the receiving stream by the tributary water temperature would be immeasurable (in this illustration the increase would be 0.001°C).

In North State Resources (2009 ) study, two 5 and 6 foot wide streams would have estimated maximum increases ranging from 0.4 to 0.5°C with maximum temperature remaining at or below 15.6°C in the two streams just downstream of the pipeline crossing sites. Those temperatures would remain within suitable range for salmonids. For the largest stream (22 feet wide) in the study, the estimated increase was estimated to be 0.02 to 0.1°C depending on the temperature model applied. The modeled results, based on assumptions used about the rates of vegetation regrowth, determined that most temperature increase effects remained within the first 5 years, but were approaching pre-project temperatures within 10 years. Conditions at other streams along the pipeline route may vary from these due to site specific differences, but these results may be fairly representative of changes that may occur at forested streams along the route. Overall results suggest that other than the very smallest streams where fish resources would be limited, changes in temperature from vegetation removal are likely to remain small and immeasurable having unsubstantial effects on fish resources.

Similarly, GeoEngineers (2013c) modeled thermal impacts within 4th Field Watersheds where streams would be crossed by the pipeline where riparian shading vegetation would be removed within the 75-foot wide construction corridor and would be affected within the 30-foot maintenance corridor of the long term (e.g., table 4.5.3-13b). Model results show a maximum predicted increase of 0.16°C over one 75 foot clearing. The analysis showed that elevated water temperatures would return to ambient levels within a maximum distance of 25 feet downstream of the pipeline corridor, based on removal of existing riparian vegetation over a cleared corridor width of 75 feet (GeoEngineers, 2013d). The results are similar to the more geographically-limited results obtained by North State Resources (2009) which suggested more thermal impact. The conclusion drawn by GeoEngineers (2013d) was that the magnitude of thermal impact caused by pipeline construction would not be expected to cause a thermal barrier to fish migration.

Pacific Connector has proposed supplemental riparian plantings as outlined in Section 10.12 of the ECRP (see appendix F) to help ensure that the core cold-water habitat temperature criteria are not exceeded at the maximum point of impact. These measures are designed to speed up the rate of riparian area recovery and provide more effective shade immediately following construction. Plantings and vegetation regrowth in riparian areas would help moderate potential temperature increases in the short term (a few years). Pacific Connector would install supplemental transplanted trees on the Umpqua National Forest within the riparian areas of East Fork Cow Creek (i.e., 15-20 feet tall with full crowns) to increase riparian area canopy closure and placing large woody debris and boulders to create micro-topography within the wetted stream channel (see Section10.12 in the ECRP). Shading from transplanted vegetation and micro-topographic features incorporated into the final grading plan are likely to reduce the heat load enough to reduce the likelihood of measurable water temperature increases. Pacific Connector modeled the potential benefit of post project effective shade created by these mitigation measures on the Umpqua National Forest. The results of the 10-year post project modeling time step was used to predict the benefits of the mitigation measures because the trees that would be transplanted provide at least the same shade values as predicted for this time step. The predicted water temperature changes are small, with less than a 0.3°C (0.5°F) change at the point of maximum impact, with no increase at the stream network scale (North State Resources, 2009). Inclusion of the measures improves the certainty that riparian area clearance and stream channel disturbance activities within the construction right-of-way would not cause measurable water temperature increases at the maximum point of impact or at the stream network scale.

Large Woody Debris

Existing conditions associated with riparian vegetation within 5th Field Watersheds in the Upper Rogue Sub-basin crossed by the PCGP Project (see discussion related to table 4.5.3-4) are generally undesirable. There are too few large conifers along most stream reaches and LWD numbers, volume, and presence of key pieces tend to be below benchmark levels. The PCGP Project will remove 25.26 acres of late successional-old growth forest and 24.13 acres of mid-seral forest would be removed within riparian zones in watersheds occupied by SONCC coho (see table 4.5.3-13a) which would affect recruitment of LWD at those sites. Of the total riparian forest affected, 10.43 acres would be removed in the Trail Creek watershed, 12.81 acres within the Shady Cove-Rogue River watershed, 9.42 acres in the Big Butte Creek watershed, and 16.73 acres would be removed within the Little Butte Creek watershed.

A potential effect on fisheries that would result from forest clearing at pipeline crossings of waterbodies is the reduction of LWD in streams and on adjacent uplands (Harmon et al., 1986; Sedell et al., 1988). Large logs provide instream hydraulic complexity, which contributes to habitat complexity and the formation and maintenance of pools, riffles and other habitats which are critical to salmonid spawning and juvenile rearing. As the size of individual logs or accumulations of logs increases, the size and stability of pools that are created also increase (Beschta, 1983). Riparian forests that undergo harvesting of large trees take on secondary-growth characteristics and contribute lower quantities of woody debris than unmanaged, old-growth forests (Bisson et al., 1987). However, sufficiently wide, carefully managed riparian buffers that retain a full complement of ages, sizes, and species of native trees and vegetation can ensure adequate recruitment of LWD to streams (Bisson et al., 1987; Murphy and Koski, 1989).

Pacific Connector has proposed to use on-site mitigation for impacts to waterbodies by installing LWD at agency- and land owner-approved and appropriate areas within the construction right-of-way across certain waterbodies. The use of LWD as a mitigation measure for impacts associated with instream construction has been documented as an effective means of creating instream habitat heterogeneity, reducing streambank erosion, reducing sediment mobilization (Bethel and Neal, 2003), and enhancing local fish abundance (Scarborough and Robertson, 2002). Placement of LWD on the streambanks and in the streams can provide slight shade and increase bank stability, while vegetation is maturing following construction. Additionally, placement of LWD in streams or on streambanks can provide habitat for benthic invertebrates, an important food source for salmonids, and also increase habitat for forage species with the creation of pools and enhancement of the salmonid rearing potential of an area (Cederholm et al. 1997; Slaney et al., 1997).

As shown in table 4.5.3-4, LWD conditions are undesirable in all four fifth field watersheds of the Upper Rogue Sub-basin that would be crossed. Streams in the watersheds are deficient in numbers of LWD pieces per length of stream channel, deficient in volume of LWD, and deficient in numbers of key pieces (≥60 cm in diameter by ≥12 m in length) per unit of stream length. Based on those data, any addition of LWD to the watersheds would appear beneficial.

<u>Hydrostatic Testing</u>

Water would be required on a one-time basis near the end of construction to hydrostatically test the pipeline. Potential impacts associated with hydrostatic testing include entrainment of fish, reduced downstream flows, and impaired downstream uses if test water is withdrawn from surface waters, and erosion, scouring, and a release of chemical additives as a result of test water discharge. The Forest Service has also expressed concern that hydrostatic testing where the source and discharge locations were in different water basins could potentially transfer exotic organisms between basins. Pacific Connector would obtain its hydrostatic test water from commercial or municipal sources or surface water rights owners and come from lakes, impoundments, and streams, and has identified 15 potential source locations and 75 potential discharge locations for the test water (see Resource Report 1, Pacific Connector Gas Pipeline Project); all but seven potential discharge sites would be within the construction right-of-way.

Pacific Connector would minimize the potential effects of hydrostatic testing on these systems by adhering to the measures in its Hydrostatic Testing Plan (see appendix U), including screening intake hoses to prevent the entrainment of fish and other aquatic organisms, meeting NMFS screening criteria, and regulating the rate of withdrawal to avoid adverse impact on aquatic resources or downstream flows. Where test water cannot be returned to its withdrawal source, the water would be treated with a mild chlorine treatment and discharged to an upland location through a dewatering structure at a rate to prevent scour and erosion and to promote infiltration. Pacific Connector will obtain all necessary appropriations, withdrawal, and discharge permits through the Oregon Water Resources Department (OWRD). As part of the application process, OWRD provides the application(s) to ODEQ and ODFW for review.

Fuel and Chemical Spills

Fisheries habitats could be adversely affected if petroleum products were accidentally discharged into aquatic environments. Such materials are toxic to algae, invertebrates and fish. Of the products likely to be present during pipeline construction, data compiled from a wide range of sources indicate that diesel fuels and lubricating oils are considerably more toxic to aquatic organisms than other, more volatile products (gasoline) or heavier crude oil (Markarian et al., 1994). Release of diesel fuel in freshwater habitats significantly reduced aquatic invertebrate densities and species richness at least 3 miles downstream but invertebrate densities recovered within a year (Lytle and Peckarsky, 2001). Impacts to aquatic habitats that primarily affect aquatic substrates – hence spawning, incubating and rearing habitats – can remain for much longer periods (Markarian et al., 1994).

Construction equipment used to construct the pipeline across waterbodies can potentially release hydraulic fluid that include a variety of compounds those common of which are mineral oil-based, organophosphate esters, and polyalphaolefins (U.S. Department of Health and Human Services, 1997). Release from machinery can occur through faulty seals, hoses, sumps and reservoirs, or general system failure. Components of mineral oil and polyalpaolefins do appear to bioaccumulate in animals whereas larger molecular constituents in organophosphate esters can concentrate in fish, primarily partitioning in fat tissue (U.S. Department of Health and Human Services, 1997). In general, toxicity of organophosphate esters is greater than either mineral oil or polyalphaolefin-based hydraulic fluids for inhalation, oral, and dermal for humans but toxicities have not been clearly described for aquatic invertebrates or fish and would be dependent on specific chemical components (U.S. Department of Health and Human Services, 1997).

Inadvertent spills of fluids used during construction, such as fuels and lubricants, could contaminate wetland soils and vegetation. To minimize the potential for spills and any impacts from such spills, Pacific Connector's Spill Prevention, Containment, and Countermeasures Plan (SPCC Plan – see appendix L) will be implemented. In general, hazardous materials, chemicals, fuels, lubricating oils, and concrete-coating activities will be not be stored, nor will refueling operations be conducted within 150 feet of a wetland or waterbody in accordance with FERC's Wetland and Waterbody Procedures (see appendix C) and the SPCC Plan (see appendix L).

Herbicide Application

Following construction, Pacific Connector will implement a Noxious Weed Control Plan in part through the application of herbicides. Herbicides have the potential to cause toxic effects to different salmonid life stages and to other aquatic species, causing direct impacts, if used improperly. When herbicides are properly used according to label restrictions and BMPs to control noxious weeds, there is little to no chance of causing injury or mortality to fish or other aquatic organisms; the impact may be avoided or indirect.

Pacific Connector has developed an Integrated Pest Management Plan (IPM) in consultation with the Oregon Department of Agriculture, BLM and Forest Service (see Appendix I to the POD, available upon request) to address the control of noxious weeds and invasive plants across the project. The BMPs will minimize the potential spread of invasive species and minimize the potential adverse effects of control treatments.

According to the Pacific Northwest Weed Management Handbook (see Peachey et al., 2007), herbicides used in forests to control brush and weed-trees could include one of the following: 2,4-D, glyphosate, imazapyr, picloram, and ticlopyr which are applied during spring or fall dormancy although triclopyr or 2,4-D was not approved use by the Fremont-Winema National Forest (NF). Clopyralid may be used during summer to control thistles, other composites, and legumes while not damaging conifers. Only herbicides which are approved for use within treated lands (private, state, or federal) would be used. Chronic, long-term, elevated but sublethal toxic effects can lead to skin or eye irritation, headache, nausea, and possibly birth defects, genetic disorders, paralysis, cancer, and death (Tu et al., 2001). In general, most impact to waterbodies occurs from direct overspray or drift of herbicides (aerial applications) as well as leaching through soils into groundwater or as they are carried by surface/subsurface runoff (Tu et al., 2001). The ester form of herbicides is more toxic to fish and other aquatic species than salt or acid forms because esters are readily adsorbed through skin and gills. Esters are also water insoluble so that they are not diluted in waterbodies (Tu et al., 2001).

Herbicides potentially used during the project will breakdown over various periods of time, marked by the average half-life (the time it takes for the herbicide concentration to decline by 50% due to microbial metabolism –dependent on the microbial population, environmental pH, soil moisture and temperature - mineralization, and/or photolysis). Half-lives in soil and water are provided and known toxicities to bluegill sunfish (see Tu et al., 2001) although comparative toxicities to salmonids have not been found in the literature:

- 2,4-D – averages 10 day half-life in soils, less than 10 days in water. Salt formulations with low toxicity are registered for use against aquatic weeds, LC50 for bluegill sunfish = 263 mg/l.
- Glyphosate - ranges from several weeks to years, but averages two months. In water, glyphosate is rapidly dissipated through adsorption to suspended and bottom sediments, and has a half-life of 12 days to ten weeks. Some formulations with low toxicity are registered for aquatic use, LC50 for bluegill sunfish = 120 mg/l.
- Imazapyr – ranges from 1 to 5 months in soil. In aqueous solutions with photodegradation the half-life may be 2 days. It has low toxicity to fish and algae and other submerged vegetation are not affected, LC50 for bluegill sunfish >100 mg/l.
- Picloram- range from 1 month to several years in soils, average soil half-life of 90 days. LC50 for bluegill sunfish >14.5 mg/l.

- Triclopyr – average half-life in soils is 30 days but the salt formulation is water soluble and may photodegrade in several hours. LC50 for bluegill sunfish =148 mg/l.
- Clopyralid - half-life averages one to two months (40 days) but ranges up to one year. It is degraded almost entirely by microbial metabolism in soils and aquatic sediments. LC50 for bluegill sunfish =125 mg/l.

Of these herbicides, Picloram is the most toxic to bluegill sunfish and is potentially the longest persisting in soils and water. Similar attributes are expected for effects to salmonids. The potential for adverse effects to salmonids and other aquatic species by the other herbicides appear to be extremely remote, especially since application would be at least 100 feet from wetlands and waterbodies unless allowed by the appropriate agency. Pacific Connector will not use aerial herbicide applications and will not use herbicides for general brush/tree control within the 30-foot maintained easement. Given low toxicities to fish and short half-lives in soil and water, expected effects of the other herbicides to resident fish and anadromous salmonids would be discountable and insignificant.

Where weed control is necessary along the construction right-of-way, Pacific Connector's first priority will be to employ hand and mechanical methods (pulling, mowing, biological, disking, etc.) applicable to the species to prevent the spread of potential weed infestations, where feasible. To determine if an herbicide is to be used over other control methods, Pacific Connector will base the decision on weed characteristics and integrated weed management principles (USFS, 2005). If herbicides are used to control noxious weed infestations, they would be used when they are the most appropriate treatment method. Spot treatments and the use of selective herbicides would be utilized to minimize impact to native or non-target species. Pacific Connector will employ a state or federally-licensed herbicide applicator to ensure that the appropriate herbicides are utilized for the targeted weed species during its proper phenological period and at the specified rate. The applicator will ensure that the herbicides and any adjuvants[4] are used according to the labeling restrictions, and warnings, following all applicable laws and conforming to the appropriate land managing agency decision documents. The applicator will also ensure that the herbicides that are used are registered for their intended use. Permits or approvals for the use of herbicides and adjuvants on federal lands would be obtained prior to use/treatment, as detailed in the IPM (see Appendix I to the POD, available upon request).

Streambank Erosion

The clearing and grading of vegetation during construction could increase erosion along streambanks and turbidity levels in the waterbodies. The rootwad network of trees adjacent to stream supplies bank stability. Those within 25 feet of the stream are considered most important at providing the root source aiding in bank stability (Washington Department of Natural Resouces, 1997). To aid in maintaining this bank stability, Pacific Connector would cut most trees near the bank, except those in the trench line, at ground level leaving the root systems in place helping to maintain riparian stability. Roots would be removed over the trench line or from any steam banks that would need to be cut down or graded to accomplish the pipeline crossing.

[4] Adjuvant(s) are substances added to the pesticide formulation to enhance the toxicity of the active ingredient or to make the active ingredient easier to handle.

Alteration of the natural drainage ways or compaction of soils by heavy equipment near streambanks during construction may accelerate erosion of the banks, runoff, and the transportation of sediments into waterbodies. The degree of impact on aquatic organisms due to erosion would depend on sediment loads, stream velocity, turbulence, streambank composition, and sediment particle size. To minimize these impacts, Pacific Connector would use temporary equipment bridges, mats, and pads to support equipment that must cross the waterbody (perennial, intermittent, and ephemeral if water is present) or work in saturated soils adjacent to the waterbody. Pacific Connector would also install sediment barriers, such as silt fence and straw/hay bales, across the right-of-way at the edge of waterbodies throughout construction except for short periods when the removal of these sediment barriers is necessary to dig the trench, install the pipe, and restore the right-of way. Practices to minimize streambank erosion are provided in Section 5.0 in the ECRP (see appendix F).

Operation and Maintenance Activities

Once installed, maintenance of the pipeline would include activities such as aerial inspections, gas flow monitoring, visual inspection of surrounding vegetation for signs of leaks, and integrity management, which includes smart pigging to investigate the interior surface of the pipe for any signs of stress cracking, pitting, and other anomalies (see Section 13.0 in the ECRP, appendix F). All of the proposed maintenance activities would be outlined in the Operations and Maintenance plan that would be prepared according to operating regulations in U.S. Department of Transportation (DOT) 49 CFR Subpart L, Part 192 and would be completed prior to going in-service. These general maintenance activities would require only surface activities and usage of the existing right-of-way, such as insertion of the pig at one of the pig launching facilities.

The potential estuarine or stream channel disturbance would occur if an integrity issue with the pipeline were found. If this were to occur, the pipeline would need to be unearthed within the right-of-way and repair work done in-water. Within stream sites, repair work could require isolated flow from the section of pipe that is to be exposed. Typically, repairs would be made to the pipe within the right-of-way (within the trench) or, depending on the site-specific conditions and nature of the repair needed, a reroute around the affected section may be considered. Impacts would be similar to those discussed above for initial installation except on a much smaller scale, and would include all relevant BMPs and mitigation, dependent upon site conditions and land ownership. Such pipeline integrity-based in-water projects are very infrequent.

Vegetation maintenance would be limited adjacent to waterbodies to allow a riparian strip to permanently revegetate with native plant species across the entire right-of-way. To facilitate periodic pipeline corrosion/leak surveys, a corridor centered on the pipeline and up to 30 feet wide would be maintained in an herbaceous state. In addition, trees that are located within 15 feet of the pipeline and that are greater than 15 feet in height would be cut and removed from the right-of-way.

**Cumulative Effects**

FWS and NMFS describe cumulative effects (50 CFR § 402.02) as the result of future actions by state or private entities, not involving federal actions, but reasonably certain to occur in the action area considered in this biological assessment. Future federal actions that are unrelated to the proposed action are not considered here because they require separate consultation pursuant to section 7 of the ESA. The Pacific Connector pipeline would not be operational until at least

2017. Consequently, the foreseeable future required for cumulative effects analysis would actually occur before implementation of the proposed action, not after its implementation, which is more often the case.

Cumulative effects to SONCC coho salmon would be generated by timber harvesting on non-federal lands. Areas of Late Successional-Old Growth (LSOG) forest have been monitored as a component of the Northwest Forest Plan (NWFP). In Oregon, LSOG was evaluated in 1996 (Moeur et al., 2005) and in 2006 (Moeur et al., 2011). Differences in areas of LSOG forests were described in the four physiographic provinces that coincide with the PCGP project; from 1996 to 2006 there was an overall net loss of LSOG on non-federal lands within the Coast Range, Klamath, Western Cascades and Eastern Cascades provinces. Within the PCGP project area and range of SONCC coho, comparisons of LSOG coverage on non-federal lands within the four watersheds in the Upper Rogue Sub-basin show similar decreases from 1996 to 2006 (see figure 4.5-12). During that period, areas of LSOG on non-federal lands declined by 74 percent within Trail Creek watershed, 78 percent within Shady Cover-Rogue River watershed, 56 percent within Big Butte Creek watershed, and declined by 9 percent within Little Butte Creek watershed.

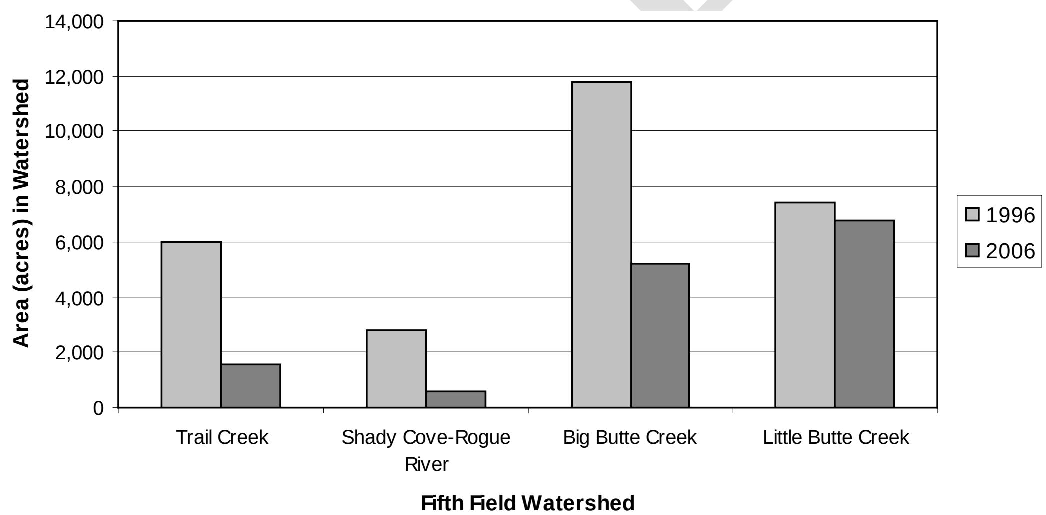

**Figure 4.5-12**
**Total Areas (acres) of Late Successional-Old Growth Forests on Non-Federal Lands in 1996 and 2006 within Four Fifth Field Watersheds within Range of SONCC coho salmon that would be Crossed by the PCGP Project. (Data from Interagency NWFP Interagency Regional Monitoring Program, 2013)**

Based on the past trend, there would be less LSOG on non-federal lands in the foreseeable future within each of the four watersheds, including less LSOG within riparian zones. Removal of additional LSOG within riparian zones on non-federal land would be a reasonably foreseeable cumulative impact. The amount of LSOG removed on non-federal land through 2016, for example, would possibly be 1) by the same percentage, or 2) at the same rate as the amounts removed between 1996 and 2006. These two scenarios are provided below in table 4.5.3-14 wherein loss at a constant annual rate predicts no LSOG left on non-federal lands by 2016 in three of the four watersheds. Alternatively, loss of LSOG by the same percent change observed between 1996 and 2006 predicts considerable declines in LSOG in 2016 but not totally eliminating it in and of the watersheds (see table 4.5.3-14).

**Table 4.5.3-14**
**Two Estimates For Areas of Late Successional-Old Growth Forest in 2016 on Non-Federal Lands In Fifth Field Watersheds Crossed by the PCGP Project**

| SONCC ESU Fifth Field Watershed | Area (acres) of LSOG on Non-Federal Land in 2006 [1] | LSOG Estimate Based on Percent Change | | LSOG Estimate Based on Rate of Change | |
|---|---|---|---|---|---|
| | | Percent Change in LSOG Since 1996 | Area (acres) of LSOG Remaining in 2016 | Rate of Change (acres per year) Since 1996 | Area (acres) of LSOG Remaining in 2016 |
| Trail Creek | 1,542 | -74.1% | 399 | -442 | 0 |
| Shady Cove-Rogue River | 604 | -78.4% | 130 | -219 | 0 |
| Big Butte Creek | 5,197 | -56.0% | 2,289 | -660 | 0 |
| Little Butte Creek | 6,759 | -9.2% | 6,135 | -69 | 6,072 |
| **Total LSOG Areas** | **14,102** | | **8,953** | | **6,072** |

[1] Data from Interagency NWFP Interagency Regional Monitoring Program, 2013

In 2016, there might be between 6,000 and 9,000 acres of LSOG within the four watersheds crossed by the PCGP project but there are no estimates for areas of LSOG within riparian zones within the watersheds. However, amounts of LSOG within the PCGP project area that would be affected by construction and amounts of LSOG that would be affected within riparian zones (eg, see table 4.5.3-13a) have been determined. We assumed that the proportions of LSOG in riparian zones to total LSOG affected by pipeline construction on non-federal lands within each watershed were representative of proportions of riparian to total LSOG on non-federal lands in each watershed. With that assumption, we computed the areas of LSOG in riparian zones on non-federal that would be removed by 2016, based on the reasonably foreseeable future estimates of remaining LSOG in table 4.5.3-14. Estimates of areas of LSOG remaining on non-federals in 2016 are provided in table 4.5.3-15, based on the percent change in LSOG since 1996 (derived in table 4.5.3-14). The estimates predict that there would have been a total of 1,711 acres of riparian LSOG on non-federal lands within all four watersheds during 2006 but, due to timber removal actions on non-federal lands (including removal of riparian LSOG) and other possible causes of removal (wildfire, disease), only 1,276 acres would remain by 2016, most of it within the Little Butte Creek watershed. Approximately 435 acres of riparian LSOG would be removed by 2016. The proposed action would contribute by removing 8.97 acres of riparian LSOG, about 2 percent, within the reasonably foreseeable future, a small portion of overall cumulative effects.

**Table 4.5.3-15**
**Potential for Cumulative Effects within Late Successional and Old Growth Riparian Forests on Non-Federal Lands within the Pacific Connector Pipeline Action Area that Coincide with the SONCC Coho Salmon ESU**

| SONCC ESU Fifth Field Watershed | Area (acres) of LSOG on Non-Federal Land in 2006 [1] | LSOG Affected by the Proposed Action on Non-Federal Land in Watershed | | | Area (acres) of Riparian LSOG on Non-Federal Land in Watershed | |
|---|---|---|---|---|---|---|
| | | Area (acres) of LSOG Affected | Area (acres) of LSOG Within Riparian Zones | Proportion of Riparian LSOG | Area (acres) of Riparian LSOG in 2006 [2] | Area (acres) of Riparian LSOG Remaining in 2016 [3] |
| Trail Creek | 1,542 | 13.73 | 2.83 | 0.21 | 318 | 82 |
| Shady Cove-Rogue River | 604 | 13.74 | 2.35 | 0.17 | 103 | 22 |
| Big Butte Creek | 5,197 | 1.55 | 0 | 0.00 | 0 | 0 |
| Little Butte Creek | 6,759 | 19.86 | 3.79 | 0.19 | 1,290 | 1,171 |
| **Total Area** | **14,102** | **48.88** | **8.97** | | **1,711** | **1,276** |

[1] Data from Interagency NWFP Interagency Regional Monitoring Program, 2013.

[3] Based on the Percent Change in LSOG Since 1996 in table 4.5.3-14.

ODF Administrative Rules (Chapter 629) include requirements for protecting riparian zones associated with streams of various size classes and uses on non-federal lands. RMA widths were assigned to "retain the physical components and maintain the functions necessary to accomplish the purposes and to meet the protection objectives and goals for water quality, fish, and wildlife". Specified riparian zones widths range from 100 feet for a large (average annual flow $\geq 10$ feet$^3$/second) Type F (fish use and domestic use) stream to 20 feet for a small (average annual flow $\leq 2$ feet$^3$/second) Type D (domestic water use, no fish) stream. While the ODF Administrative Rules provide some protection to fish-bearing streams, the narrower riparian zones described in the Rules are likely to provide less protective functions due to forest harvest practices on non-federal lands than harvest on federal lands.

### Critical Habitat

Eight waterbodies known to support coho within Table 4.5.3-2 that would be affected by construction of the PCGP pipeline are within designated critical habitat for coho salmon in the SONCC ESU. The effects to riparian zones associated with each waterbody in critical habitat that support coho are included in Table 4.5.3-13a. PCEs include, but are not limited to, spawning sites, food resources, water quality and quantity, and riparian vegetation (NMFS, 1999b). Each PCE defined for critical habitat would be adversely affected by the proposed action. Those effects have been quantified to the extent possible in the foregoing analyses.

## 4.5.3.4 Conservation Measures

Conservation measures have been proposed by Pacific Connector to minimize construction and operation impact to the estuary (estuarine analysis area), waterbodies, and riparian zones (riverine analysis area). Those measures have been compiled in table 2C in appendix N and apply to SONCC coho salmon.

Pacific Connector has also proposed measures to rectify, repair, rehabilitate, and otherwise reduce impact to waterbodies and riparian zones once construction of the Pacific Connector pipeline is complete. Those measures have been compiled in table 3C in appendix N.

## Erosion Control

Many of the conservation measures in table 3C in appendix N focus on erosion control to prevent sediment from entering surface waters. Temporary erosion controls would be installed immediately after vegetation clearing and grading and would be properly maintained throughout construction and reinstalled as necessary until replaced by permanent erosion controls or restoration is complete. At a minimum, the following temporary erosion control structures would be installed: temporary slope breakers, sediment barriers, mulch, and erosion control fabric.

Temporary Slope Breakers

Pacific Connector would install temporary slope breakers over the backfilled, recontoured construction right-of-way as specified in FERC staff's Plan. The outfall of each temporary slope breaker would be to a stable, well-vegetated area or to an energy-dissipating device at the end of the slope breaker off the construction right-of-way. Slope breakers reduce runoff velocity, thereby intercepting sediment and allowing it to drop out of suspension. They also can effectively divert runoff away from a disturbed site to a stable outlet (Goldman et al., 1986).

Sediment Barriers

Pacific Connector would primarily rely upon silt fence and staked hay or straw bales to confine sediment to the construction right-of-way. These structures would be used adjacent to wetland and waterbody crossings consistent with the requirements of FERC staff's Procedures. Straw bales and filter fabric (silt fence) can be used together to create a highly effective sediment barrier, a combination that compensates for the limitations of each used in isolation; straw bales provide extra support and the fabric provides greater filtering capability (Goldman et al., 1986).

All straw or hay bales used for sediment barriers would be certified as weed-free. Temporary sediment barriers would be maintained in-place until permanent revegetation measures are successful or until the upland areas adjacent to wetlands, waterbodies or roads are stabilized. The structures would be removed once vegetation in the area has been successfully restored.

Mulch

Under certain circumstances, the FERC staff's Plan requires the application of mulch to stabilize the soil surface. If it becomes necessary to delay final cleanup, including final grading and installation of permanent erosion control measures, beyond 10 days after the trench is backfilled in a specific area, Pacific Connector would apply mulch to the disturbed areas before seeding, consistent with the requirements of FERC staff's Plan. Mulch would also be applied if construction and restoration activity is interrupted for extended periods. In these cases mulch would be applied at a rate of three tons/acre on all slopes within 100 feet of waterbodies and wetlands.

A number of areas would be crossed with slopes in excess of eight percent. In these areas, mulch would be applied uniformly to cover at least 75 percent of the ground surface at a rate of two tons/acre of straw or hay or its equivalent. All straw or hay mulch would be certified weed-free.

Erosion Control Fabric

Pacific Connector would install erosion control fabric (such as jute or excelsior) on waterbody banks at the time of recontouring. The fabric would be anchored using staples or other appropriate devices. Although there are no measures specific to pipeline construction, data related to cut-and-fill slopes treated during construction of forest roads indicate varying effectiveness of different types of stabilization measures designed to control surface erosion (EPA, 2001). On fill slopes, combining straw mulch and netting decreased erosion by 99 percent. Excelsior mulch alone decreased erosion by 92 percent on fill slopes. On cut slopes, straw mulch by itself decreased erosion in a range from 32 to 97 percent (EPA, 2001). Applications of mulches and/or fabric are effective measures promoting slope stabilization until vegetation can successfully be reestablished. These measures also promote plant growth (EPA, 2001).

Cleanup and Permanent Erosion Control

Pacific Connector would make every effort to complete final cleanup of an area within ten days after backfilling the trench. Final cleanup would include final grading and installation of permanent erosion control structures. In no case would Pacific Connector delay final cleanup beyond the end of the next recommended seeding season. During final cleanup Pacific Connector would remove all construction debris and grade disturbed areas to preconstruction grades to the extent practicable. An adequate seedbed would be prepared at the conclusion of cleanup. Pacific Connector would install permanent slope breakers consistent with the requirements of FERC staff's Plan.

Fish Salvage Plan

All waterbodies that would be crossed by dry open cut construction would be done prior to adult coho salmon upstream migration, within ODFW in-stream construction windows. A Fish Salvage Plan has been provided in appendix T. The plan has been developed to minimize adverse effects to listed salmonids (SONCC coho salmon, Oregon Coast coho salmon), non-listed salmonids (Chinook salmon, steelhead, and cutthroat trout) and listed catostomids (Lost River sucker, shortnose sucker). The portions of the plan relevant to salvaging salmonids were adapted from the protocol developed by WSDOT (2014). The protocol specifies procedures to 1) isolate the work area; 2) remove fish and dewater the work area; 3) handle, hold and release fish; 4) document fish that have been captured, handled, held, and released; and 5) notify NMFS and FWS. Only trained professionals would conduct electroshocking and fish removal.

## Revegetation

As required by the FERC staff's Plan, Pacific Connector has identified procedures for the preparation and planting of live stakes or sprigs and for the planting bare root tree seedlings. Those procedures are included in appendix R. Within the range of SONCC coho salmon, construction of the Pacific Connector pipeline would remove 70.91 acres of riparian forested habitats of which 14.35 acres are late-successional (mature) old-growth, 55.61 acres are mid-seral forests, and 0.95 acre is forested wetlands. Within the Trail Creek watershed 10.43 acres of riparian forest would be removed; 12.88 acres would be removed within the Shady Cove-Rogue River watershed; 9.51 acres in the Big Butte Creek watershed and 16.73 acres in the Little Butte Creek watershed would be removed (see table 4.5.3-13a).

Existing forested riparian zones in which forest would be removed during construction would be re-planted with conifers to within 15 feet of each side of the pipeline centerline. Permanent effects – persisting longer than the assumed 50-year life of the pipeline – would occur by removing 14.35 acres of late-successional (mature) old-growth riparian forest. Even though the riparian zone would be replanted, the newly planted trees would not attain late-successional or old-growth status within 50 years. Permanent effects would also last along the 30-foot wide maintenance corridor centered on the pipeline. Those effects to former late-successional (mature) old-growth riparian forest, Mid-Seral riparian forest and other existing riparian vegetation are included in table 4.5.3-13b. Replanting conifers within each affected forested riparian zone would leave an estimated 9.75 acres of non-forested vegetation within former forested riparian zones over the long-term or permanently (see table 4.5.3-13b).

ORV Barriers

The FERC staff's Plan requires the Project to offer to each owner or manager of forested lands to install and maintain measures to control unauthorized vehicle access to the right-of-way and states that such measures may include signs; fences with locking gates; slash and timber barriers, pipe barriers, or a line of boulders across the right of way; and conifers or other appropriate trees or shrubs across the right-of-way. Slash, stumps and or logs, if available, would be placed on the right-of-way within the riparian zones to discourage ORV crossings of streams and provide carbon and nutrients if allowed by the landowner. If not allowed, Pacific Connector would discuss with the landowner the use of other methods, as noted above. At a minimum the area would be revegetated and re-seeded.

**Streambank Stability**

The root network of trees adjacent to streambanks is essential to maintaining streambank stability (WDNR 1997). Because root strength decreases significantly at distances beyond one-half the tree crown diameter, trees promoting streambank stability lie within half a tree crown diameter from the streambank. Trees within 25 feet of the streambank are assumed to promote streambank stability (WDNR 1997). Generally, trees that must be removed during construction would be cut at ground level with the roots left in place, except where located within the trenchline. Although roots would decay overtime, streambank stability would be retained by their presence until revegetation is successful.

**In-stream Gravel**

Waterbodies supporting fisheries would be backfilled with material removed from the trench with the upper 1 foot of the trench backfilled with clean gravel or native cobbles. Pacific Connector has requested a variance from Section V.C.1. of FERC staff's Procedures in fish-bearing streams that do not have gravel, cobble, or other rock substrates prior to construction. This variance was requested because many of the streams crossed by the pipeline are remote and are located in steep valley or ravine bottoms. Therefore hauling rock to these steams is impractical especially where these streams do not have gravel or cobble substrate characteristics prior to construction. The bottom and banks would be returned to preconstruction contours; banks would be stabilized; and temporary sediment barriers would be installed before returning flow to the waterbody channel.

**Large Woody Debris**

In several instances, mitigation would contribute to restoring an aquatic habitat indicator's functional level, such as placement of LWD within and/or adjacent to streams and placing LWD on floodplains, where appropriate, to provide microsites for riparian vegetation and/or vegetation protection during flood events. Placement of LWD in streams and/or on streambanks has been one focal point of recent stream rehabilitation procedures (Slaney and Martin, 1997; Cederholm et al. 1997; EPA, 2001) as well as a central consideration in the Compensatory Mitigation Plan (see appendix O).

As indicated in table 4.5.3-4, baseline watershed conditions crossed by the pipeline are lacking in LWD due to historical disturbance and LWD presence is typically below benchmark thresholds to be properly functioning. LWD is an important habitat feature providing in-stream structure, channel and habitat complexity among other benefits, and that promote salmonid productivity. Pacific Connector proposes to install LWD on-site during construction as an appropriate habitat enhancement feature to mitigate for potential pipeline impacts and to benefit watershed conditions, which are generally lacking.

LWD placement would be in addition to the Project conservation measures (see appendix N) that have been designed to minimize the potential Project effects, including utilizing dry open cut crossing methods, applying in-stream construction timing restrictions, and implementing erosion control measures and revegetation methods. Because of the overall lack of LWD in the affected watersheds, LWD also provides an appropriate mitigation model for the Project's potential waterbody crossing impacts that are temporary, short-term, and unavoidable (see Compensatory Mitigation Plan in appendix O). The LWD would also serve to mitigate for potential long-term Project impacts - impacts lasting for the 50-year life of the pipeline - such as the loss of forested riparian vegetation within the pipeline's 30-foot operational corridor (see table 4.5.3-13b). Even though the riparian zone would be replanted, the planted trees would not attain late-successional or old-growth status within 50 years. Placement of LWD would, in some measure, reduce though not eliminate the impact due to the removal of late-successional (mature) old-growth riparian forest.

For low-gradient streams, Cederholm et al. (1997) suggests using logs with diameters at least 18 inches (less in areas of low velocity) placed by vertical angling into the stream channel. Logs could be used to create a stepped-channel profile with the rootwads and encourage woody debris accumulations in pool margins. For streams with steeper gradients, they suggest that logs with smaller diameters might be used if larger logs are unavailable. Near headwaters, LWD is often suspended over the channel so that it can become functional during periods of maximum runoff. Smaller debris may be retained during those periods and help develop pools that would be functional during summer (see Cederholm et al., 1997).

Guidelines for LWD placement, provided by ODF and ODFW (1995), suggest using the following: 1) larger diameter wood pieces because they are more effective at creating pools and complex channels which improve fish populations (see table 4.5.3-16 for minimum diameter LWD per bankfull width); 2) LWD that are at least twice the length of the waterbody bankfull width (1.5 times the bankfull width if the rootwad is attached) to increase the likelihood that the LWD would remain in place; and 3) conifer logs, especially western red cedars if available, because they are more durable. In larger waterbodies, smaller diameter, shorter LWD could be used if bundled and anchored together to provide the same benefits of the longer, larger diameter LWD (ODF and ODFW 1995).

Trees classified as late-successional or old-growth are assumed to have attained heights equal to the site-potential tree heights that are included above in table 4.5.3-13a as Riparian Zone Widths. Site-potential tree heights range from 157 feet (for example, the Rogue River-Shady Cove Watershed) to 187 feet (as in the Big Butte Creek Watershed). If Douglas-fir trees in the Oregon Cascades grow in height at the rate of 20 inches per year and in diameter by 0.25 inches per year (Cox, 2008), a 20-inch tall seedling planted the year after construction of the Pacific Connector pipeline would be an estimated 85 feet tall and 12 to 13 inches in diameter (assumed dbh) after 50 years. Trees with those dimensions would provide suitable LWD for streams with bankfull widths from 0 to 10 feet but not larger streams (see table 4.5.3-16). Even in these streams recruitment of wood may be reduced as the young age of the forest would reduce recruitment from natural mortality as the rate would be less relative to older trees. But recruitment of wood is not solely dependent on natural tree mortally but includes important contributing factors such as bank erosions, disease, fires, slides, and windthrow (Reeves et al. 2003, Martin and Benda 2001, Gregory et al. 2003). LWD contribution would occur from these areas even though natural mortality contribution would be reduced.

**Table 4.5.3-16**
**Minimum Diameter LWD for Placement in Waterbody Based on Bankfull Width**

| Bankfull Width (feet) | Minimum Diameter LWD (inches) |
|---|---|
| 0 to 10 | 10 |
| 10 to 20 | 16 |
| 20 to 30 | 18 |
| Over 30 | 22 |
| Source: ODF and ODFW, 1995. | |

The Pacific Connector pipeline would actually cross 14 perennial streams within the range of SONCC ESU coho salmon. Nine of those perennial streams have existing riparian forest ranging from Mid-Seral stage (approximately 40 to 80 years old) to older late-successional and old-growth; 6.92 acres of existing riparian forest would be removed by construction. Five more perennial streams would also be crossed but construction would not affect riparian forest vegetation (see table 4.5.3-17). In addition, the PCGP project would cross 29 intermittent streams, 27 of which support riparian forest, so that 21.69 acres total of riparian forest would be removed. Two additional intermittent streams with no riparian forest would be crossed as well (see table 4.5.3-17).

To offset impact from removal of riparian trees (reducing LWD recruitment potential) and to provide an overall benefit by enhancing stream habitat with no potential for LWD recruitment, Pacific Connector proposes to place LWD at the waterbody flow types identified by watershed in table 4.5.3-17, based on the following applications:

- four pieces for each perennial stream crossed with riparian forest removed (two pieces in-stream and/or keyed into the streambank, two pieces within riparian zone on the bank);
- two pieces for each intermittent stream and unknown stream crossed with riparian forest removed (one or both LWD pieces placed in-stream, keyed into the bank, or placed on the bank);
- two pieces for each perennial, intermittent, and unknown stream crossed but with no riparian forest removed (one or both LWD pieces paced in-stream keyed into the bank, or placed on the bank); and
- one piece each for a perennial, intermittent, and unknown stream not crossed but adjacent to the construction right-of-way, with or without riparian forest removed (LWD placed on bank).

Because the construction right-of-way at stream crossings would be 75 feet wide, Pacific Connector anticipates only enough space for two pieces of LWD, preferably with rootwads attached, either placed in-stream or with stems keyed into streambanks. Unless site-specific conditions dictate otherwise, the preferable location for each in-stream LWD is downstream from the pipeline to prevent scour of the pipe. LWD would also be placed near or adjacent to streambanks within riparian zones to provide for and/or enhance microsites for riparian vegetation and/or vegetation protection during flood events.

In all, Pacific Connector proposes 116 pieces of LWD for placement within the four fifth-field watersheds that coincide with SONCC ESU coho salmon and designated critical habitat. Placement of LWD is subject to approval by each affected landowner. If a landowner rejects the proposed placement of LWD, the number of pieces that would have been applied onsite would be reserved and provided to appropriate watershed councils for their use and placement, preferably elsewhere within the affected fifth-field watershed.

Pacific Connector anticipates that during construction, in some cases, the waterbody size, landowner restrictions, or construction constraints would limit LWD placement according to the proposed LWD schedule provided in table 4.5.3-17. Further, the overall benefit of installation of LWD at some pipeline waterbody crossings (i.e., intermittent headwater streams) may not warrant LWD placement. In these situations, Pacific Connector's Environmental Inspector would record the uninstalled LWD as a deficit during construction. After construction is completed, unutilized LWD would be provided to local watershed conservation organizations or agencies for use in local enhancement projects within the affected watersheds. (Also see the discussion on the use of LWD for mitigation in Compensatory Mitigation Plan in appendix O.)

**Compensatory Mitigation**

Appendix O provides the draft Compensatory Mitigation Plan, which includes proposed projects within watersheds in the Upper Rogue Sub-Basin.

### 4.5.3.5 Determination of Effects

**Species Effects**

The Project **may affect** coho salmon in the SONCC ESU because:

- Several stages and activities of coho salmon (upstream adult migration, juvenile rearing, and juvenile out-migration) are expected to occur at various locations in the riverine analysis area during construction and operation of the proposed action.

While several project actions are not likely to cause adverse effects, those resulting effects from Project components that are **likely to adversely affect** coho salmon in the SONCC ESU include:

- Total Suspended Sediments (TSS) could adversely affect juvenile coho salmon. Exposure of juveniles to TSS concentrations during dry open-cut construction (fluming or dam-and-pump) for more than 20 hours could potentially exceed SEV 4 for 100 meters or more downstream. Such an effect could cause a short-term reduction in feeding rate and short-term reduction in feeding success.
- Exposure of juveniles to TSS concentrations during dry open-cut construction (fluming or dam-and-pump) for 40 hours of more could potentially exceed SEV 5 for 100 meters or more downstream. Such an effect could cause minor physiological stress in juvenile coho salmon.

**Table 4.5.3-17**

**Proposed Application of Large Woody Debris to Waterbodies and Riparian Zones Affected by Construction of the Proposed Action within the Range of Southern Oregon Northern California Coast Coho Salmon**

| Fifth Field Watershed | Watershed Parameter [1] | Waterbody Type | | | | | | Total in Watershed | Pieces of LWD Applied to Fifth Field Watershed [2] | | |
|---|---|---|---|---|---|---|---|---|---|---|---|
| | | Perennial | | Intermittent | | Unknown | | | | | |

| | No Riparian Forest | 5 | 0 | 2 | 7 | 0 | 0 | 14 | 14 | 7 | 21 |
| | | | | | | | | **Total LWD** | **104** | **12** | **116** |

[1] Riparian Forest assumed to be coniferous, deciduous, or mixed forest 40 years old and older.

[2] Proposed schedule for applying LWD to different waterbody types, subject to landowner approval:

- 4 pieces for each perennial stream crossed with riparian forest removed (2 pieces instream, 2 pieces within riparian zone on the bank);
- 2 pieces for each intermittent stream and unknown stream crossed with riparian forest removed (one or both pieces placed instream or on bank);
- 2 pieces for each perennial, intermittent, and unknown stream crossed but with no riparian forest removed (one or both pieces paced instream or on bank).
- 1 piece each for perennial, intermittent, and unknown stream not crossed but adjacent to ROW with or without riparian forest removed (placed on bank).

- If a failure occurs during peak flow periods while dry open-cut construction is underway, possible effects to juvenile coho (SEV = 6) could include moderate physiological stress.
- TSS produced by dry open-cut construction methods to cross streams are estimated to temporarily affect the water columns within 10,000 feet downstream from all in-stream construction sites (not simultaneously) if peak flows occur during construction.
- Construction requiring blasting at 17 streams could cause mortality to fish by rupturing swim bladders. Adult and juvenile coho salmon would be removed and/or prevented from being within 50 feet of blasting sites to the maximum extent possible.
- Fish salvage would occur within isolated construction sites, possibly when adult and juvenile coho salmon are present. Coho salmon are considered vulnerable to electrofishing, subject to injury and mortality. Fish salvage would primarily rely on seining but may require electrofishing as a last resort, only DC or pulsed DC current would be used. Seining, electrofishing and handling may adversely affect Oregon Coast coho salmon.
- Lack of LWD is a limiting factor in most streams within range of SONCC coho salmon. Removal of Mid-Seral riparian forest (40-80 years old) would have long-term effects to recruitment of LWD and removal of Late Successional or Old-Growth forest (≥80 years old) would have permanent effects to recruitment of LWD because planted conifers would not attain those age classes within the 50-year life of the project.

**Critical Habitat Effects**

The Project **may affect** designated critical habitat for coho salmon in the SONCC ESU because the Pacific Connector pipeline crosses designated critical habitat within waterbodies of the Upper Rogue HU (17100307) below the Lost Creek, Willow Creek, and Fish Lake Dams.

Project components are **likely to adversely affect** proposed critical habitat for coho salmon in the SONCC ESU because:

- Freshwater spawning sites would potentially be affected over the short-term by dry open cut and diverted open cut construction methods that would remove substrate at crossing sites and produce turbidity downstream that could affect previously utilized redds.
- Turbidity is expected to temporarily affect the water quality within a total of 10,154 feet downstream from dry open cut construction sites (not simultaneously) generated by mobilized clay (organics) if peak flows occur during construction.
- Food resources would potentially be affected over the short-term by dry open cut and diverted open cut construction methods that would remove substrate and benthos at crossing sites and produce turbidity downstream in all streams likely to support SONCC coho salmon.
- Freshwater migration corridors would potentially be affected over the short-term by dry open cut and diverted open cut construction methods that would produce turbidity downstream and create temporary barriers to in-stream movements while construction sites are isolated.
- Approximately 105 acres of native riparian vegetation (forest, wetlands, nonforested habitats) and of altered habitat would be removed during construction within riparian zones associated with designated critical habitat. Adverse effects to riparian zones would be long-term or permanent depending on whether mid-seral riparian forests (24.13 acres) or late-successional/old-growth riparian forests (25.26 acres) are removed.

### 4.5.4 Coho Salmon (Oregon Coast ESU)

#### 4.5.4.1 Species Account and Critical Habitat

**Status**

National Marine Fisheries Service (NMFS, 1995b) conducted a status review of coho salmon in 1995 that lead to proposed listing of several evolutionarily significant units (ESUs) as threatened, including the Oregon Coast ESU, in 1995. The final listing was delayed due to disagreements about conclusions drawn from available information and the original proposal to list as threatened was withdrawn in 1997. In 1998, the District Court for Oregon determined that NMFS' 1997 withdrawal of the proposed listing status was arbitrary and capricious and vacated the determination. Following the Court decision, NMFS issued a final rule to list the Oregon Coast ESU as threatened in August 1998. That determination was based entirely on information collected prior to the proposed rule in 1997. However, the District Court set aside the 1998 final rule determining threatened status for the Oregon Coast ESU (a result of the *Alsea* ruling) and NMFS undertook an updated status review of 27 West Coast salmon ESUs in 2003, which included the coho salmon Oregon Coast ESU. During the status review, the Biological Review Team considered the uncertainty of the ESU becoming endangered. Nevertheless, NMFS again proposed listing the coho salmon Oregon Coast ESU as threatened in June 2004 based on the review (NMFS, 2006f).

In December 2004, critical habitat was also proposed. NMFS designated critical habitats for several salmon ESUs in a final rule published in September 2005 but critical habitat for the coho salmon Oregon Coast ESU was not included because there had not been a final rule listing the ESU as threatened. In that new proposed rule, the ODFW was conducting an assessment of the population viability of Oregon Coast coho salmon. From that, ODFW concluded that Oregon Coast coho salmon are "inherently resilient at low abundance" and such response would prevent extinction. With that information and other products from the ODFW *Oregon Coastal Coho Assessment*, NMFS withdrew its proposals to list Oregon Coast coho salmon as threatened and to designate critical habitat in January 2006 (NMFS 2006f). In that decision to withdraw the proposed rules, NMFS declared that listing under ESA was not warranted at the time but the decision was challenged in Oregon District Court, which ruled that NMFS' withdrawal be invalidated and remanded to NMFS (Lohn, 2007). The present listing status for the Oregon Coast coho salmon ESU is threatened with corresponding critical habitat (NMFS, 2008d). After proposing the ESU for listing, withdrawing the proposal, and re-proposing listing the ESU as threatened under scrutiny of Oregon federal district court, NMFS issued a final rule in 2011 (NMFS, 2011i) retaining the threatened listing for the coho in the Oregon Coast ESU.

**Threats**

At the time the Oregon Coast ESU was first proposed for listing as threatened in 1995, threats to West Coast salmon populations were discussed in general but were not specific to the Oregon Coast ESU. The same factors noted above as threats to coho salmon in the SONCC ESU applied to coho salmon in the Oregon Coast ESU.

NMFS published a more recent status review in 2005 (Good et al., 2005). The U.S. District Court found NMFS' 1998 decision, listing the Oregon Coast coho salmon ESU, as unlawful because the ESU includes hatchery and naturally spawned coho salmon but NMFS only considered naturally spawned fish in their decision (Lawson, 2005). Following the delisting, multiple parties petitioned NMFS to re-list all stocks within the Oregon Coast ESU as threatened based on new information about coho salmon abundance, variability in survival and abundance, threats to genetic integrity of stocks, and stochastic events including El Niño conditions and floods (Lawson, 2005).

The short-term trend in escapement of adult spawners within the Oregon Coast ESU increased substantially in 2001 and 2002, including trends within the Umpqua, Coos, and Coquille Sub-basins due to increased marine survival and considerable restrictions on ocean harvests (Lawson, 2005 and see discussion below). Alternatively, trends in short-term recruitment were less positive within the ESU, especially in the Coos and Coquille Rivers (Lawson, 2005).

In 1994, most coho salmon harvest was prohibited and has been restricted since then, though mortalities still occur coincidentally with Chinook salmon fisheries for hatchery (marked) coho salmon (Lawson, 2005). Subsequent analyses indicated that management for a proportional maximum harvest rate of 35 percent resulted in lower risk of extinction for the ESU than management for an escapement goal or quota of 200,000 spawners ESU-wide. As expected, a harvest of zero further reduces extinction risk (Lawson, 2005).

Freshwater restoration projects to improve water quality and watershed conditions have been implemented throughout the Pacific Northwest since the late 1990s (e.g., the Coastal Salmon Restoration Initiative in 1997), though measurable results would take time (Lawson 2005). Poor marine survival for Oregon coho salmon began with climatological changes detected in the mid-1970s and worsening in the 1990s. Those conditions ameliorated in the late 1990s and extend into the early 2000s so that coho salmon marine survival improved. Such fluctuations have occurred in the past as variable cycles but future cycles would likely be within the context of global warming, which would likely prohibit predictions from past conditions (Lawson, 2005).

Compared to the Oregon Coast ESU as a whole, the proportion of escapements by coho salmon produced in hatcheries to wild spawners has been quite low in the Umpqua, Coos, and Coquille Rivers (Table 71 in Lawson, 2005), though correct identification of hatchery and wild fish has been an issue in such surveys. As noted above, decreasing the proportion of hatchery spawners benefits wild stock.

**Species Recovery**

No recovery plan has been published.

**Life History, Habitat Requirements, and Distribution**

Miller and Sadro (2003) found that approximately one-half of each brood of coastal coho salmon in Winchester Creek/South Slough (which empties into Coos Bay approximately 5 miles south of the LNG terminal/Port slip area) in 1999 and 2000 moved to the estuary as sub-yearlings (age 0). A portion of these juveniles lived in the ecotone between freshwater and saline portions of the estuary for up to 8 months and then moved back upstream to overwinter. Fish that moved to the ecotone in fall and winter had a mean residency of 48 days in 1999 and 64 days in 2000. Some of these fish resided in an off-channel beaver pond. In spring, age 1 smolts had a mean residence time in the ecotone of only 18 days and a mean residence time in the estuary of 5.8 days. Coastal coho salmon smolts would not be expected to utilize the more saline waters near the LNG terminal area for the extended periods of time as they were shown to reside in the ecotone.

Radiotelemetry studies conducted by Oregon State University researchers (Schreck et al., 2002) in the Nehalem River estuary indicate that coho salmon smolts spend about 2 weeks in the estuary before moving into the ocean. Fish monitoring in Tillamook Bay (approximately 170 miles to the north) indicated that coho salmon smolts (age 1+) were rarely found in shallow edge habitat during their residency period in the bay (Ellis 1999, 2002a, 2002b). Most of the yearling smolts appear to move quickly through the estuarine environment to the ocean. ODFW seining surveys conducted at the McCullough Bridge and Trestle sampling sites in summer 2005 and 2006 did capture juvenile coho salmon (ODFW, 2006b), but coho salmon smolts are not expected to rear within the estuarine analysis area in the estuary for significant periods of time. Coho salmon smolts resided in the stream-estuary ecotone of South Slough for a range of 12 to 40 days (Miller and Sadro, 2003).

Figure 4.5-13 provides the typical timing of use for coho salmon in the estuarine analysis area and riverine analysis areas utilized by fish in the Oregon Coast ESU. Within the estuary, some coho salmon rearing occurs but most juvenile use is during migration to the ocean (Gray, 2007). During the period between October 1 and February 15 when all in-water construction would occur, juvenile coho salmon in the estuary and lower Coos River are likely to be absent but adult coho salmon would be holding and/or migrating upstream (see figure 4.5-13).

Life stage requirements of coho salmon within freshwater habitats in the Oregon Coast ESU are expected to be similar to those described above for coho salmon in the SONCC ESU (see Section 4.5.3.1). Within the entire ESU, adults generally enter coastal streams in the fall and spawn from November through possibly March. Peak spawning is during December or January (NMFS, 2004). After hatching in spring, parr inhabit areas of slow flows and spend a second winter in freshwater before outmigration to the ocean as smolts, generally March through June (NMFS, 2004).

Specific timings of life history phases for Oregon Coast coho salmon are shown in figure 4.5-13 within the in-stream portion of the pipeline project area are available for individual rivers or tributaries in the vicinity of waterbodies crossed by the Pacific Connector pipeline. Smolt outmigration in the Umpqua River mainstem and tributaries lasts from March through June, with peak outmigration from April through mid-May. Similarly, peak outmigration in the Coquille River is from late March to early May, although the duration of outmigration is shown in figure 4.5-13 to extend from mid-February to mid-June.

Peak timing of river entry by adults to the Umpqua, Coos, and Coquille is early to mid-October although adults begin entrance to all three drainages in early September through January. Spawning in the Umpqua River begins in early October, and lasts through January, peaking in November and December (see figure 4.5-13). Though not shown in figure 4.5-13, spawning in the Coos River lasts from mid-November through late January, peaking in mid December as well as in the Coquille River though spawning there lasts from mid-November through early February (Weitkamp et al., 1995, see Appendix Table C-4). In-stream construction within tributaries to the Coos, Coquille, and South Umpqua Rivers and within range of the Oregon Coast ESU would be from July 1 through September 15. Coho salmon adult upstream migration would be occurring during the end of the in-stream construction window but spawning would not yet have started. Incubation and fry emergence from gravel, juvenile rearing and juvenile out-migration would not be occurring between July 1 and September 15 (see figure 4.5-13).

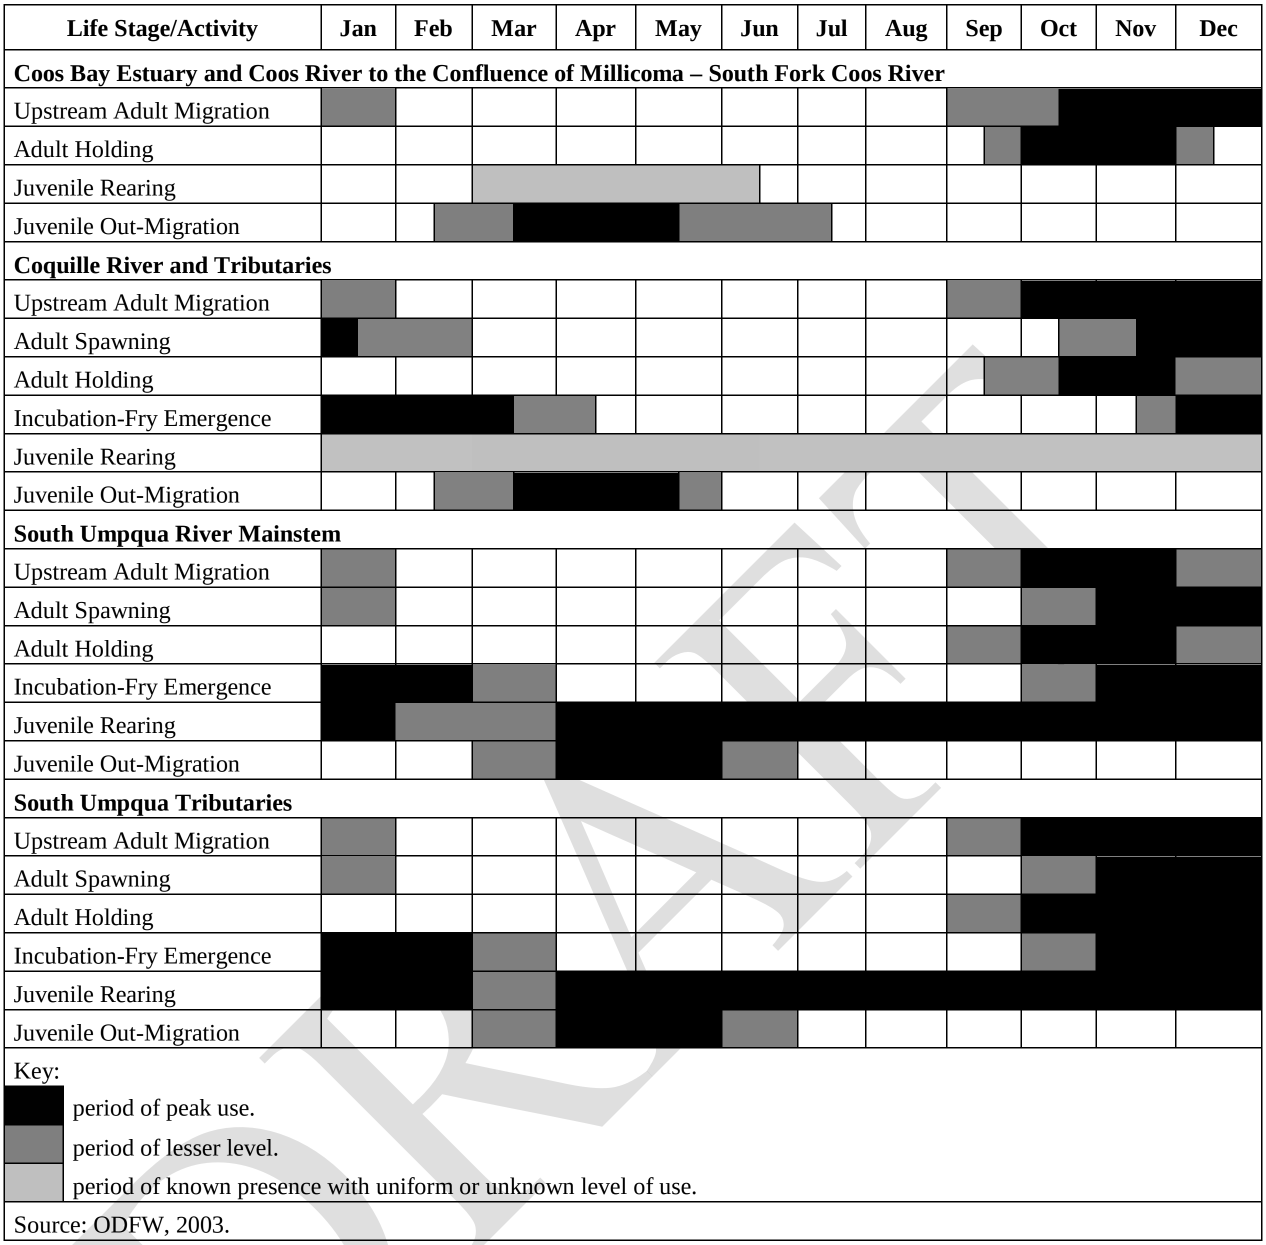

**Figure 4.5-13**
**Approximate Timing of Oregon Coast ESU Coho Salmon Use of the Coos Bay Estuary, Coos River and Tributaries, Coquille River and Tributaries, and South Umpqua River and Tributaries**

Based on genetic data and recoveries of tagged fish, the Oregon Coast coho ESU extends to Pacific Ocean tributaries from Cape Blanco north to the Columbia River. Coho in the ESU inhabit waterbodies in the following 10 fifth field watersheds that will be crossed by the PCGP: Coos Bay-Frontal Pacific Ocean (HUC 1710030403), Coquille River (HUC 1710030505), North Fork Coquille River (1710030504), East Fork Coquille River (HUC 1710030503), Middle Fork Coquille River (HUC 1710030501), Olalla Creek-Lookingglass Creek (HUC 1710030212), Clark Branch-South Umpqua River (HUC 1710030211), Myrtle Creek (HUC 1710030210), Days Creek-South Umpqua River (HUC 1710030205), and Upper Cow Creek (HUC 1710030206). Table 4.5.4-1 summarizes the number of waterbodies crossed within the PCGP Project area that are known or assumed to support Oregon Coast coho.

**Table 4.5.4-1**
**Number of Waterbodies Crossed by the PCGP Project within River Sub-basins and 5th Field Watersheds with Oregon Coast Coho ESU Designated Critical Habitat and Coho Presence (Known or Assumed).**

| Sub-basins and 5th Field Watersheds | Hydrologic Unit Code | Number of Waterbodies | | |
|---|---|---|---|---|
| | | Critical Habitat [1] | Coho Known [2] | Coho Assumed [3] |
| **Coos Sub-basin** | **17100304** | | | |
| Coos Bay-Frontal Pacific Ocean | 1710030403 | 10 | 10 | 7 |
| **Coquille Sub-basin** | **17100305** | | | |
| Coquille River | 1710030505 | 0 | 0 | 2 |
| North Fork Coquille River | 1710030504 | 3 | 3 | 0 |
| East Fork Coquille River | 1710030503 | 2 | 2 | 4 |
| Middle Fork Coquille River | 1710030501 | 1 | 1 | 0 |
| **South Umpqua Sub-basin** | **17100302** | | | |
| Olalla Creek-Lookingglass Creek | 1710030212 | 2 | 2 | 12 |
| Clark Branch-South Umpaqua River | 1710030211 | 7 | 7 | 3 |
| Myrtle Creek | 1710030210 | 3 | 3 | 2 |
| Days Creek-South Umpqua River | 1710030205 | 2 | 2 | 1 |
| Elk Creek [4] | 1710030204 | 0 | 0 | 0 |
| Upper Cow Creek | 1710030206 | 0 | 0 | 0 |
| | **Total** | 30 | 30 | 31 |

[1] NMFS, 2008e; ODFW, 2012a.
[2] Assumed presence based on connectivity to occupied stream reaches.
[3] Elk Creek Watershed would be crossed but no waterbodies would be affected within the watershed.

## Population Status

Abundance of naturally producing coho within the Coos Subbasin peaked at 33,595 spawners in 2001 but has generally diminished since then to 11,000 spawners in 2011 and to 9,400 in 2012; the declining trend in spawner abundance since 2001 is significant (see figure 4.5.4-14A).

Coho spawner abundance in the Coquille Subbasin (see figure 4.5.4-14B) and South Umpqua Subbasin (see figure 4.5.4-14C) had both been increasing at significant rates between 1997 and 2011 but declined dramatically in 2012, the fewest wild spawners since 2008 in the South Umpqua and fewest since 1999 in the Coquille Subbasin. The overall trend in total number of spawners in all three sub-basins, combined (see figure 4.5.4-14D) had likewise been increasing through 2011 but numbers of spawners in 2012 were the fewest since 2000 in the analysis area for Oregon Coast coho salmon. The same increasing trend through 2011 and decline in 2012 was apparent in all populations of the Oregon Coast ESU (ODFW, 2013).

During the 20th century, there had been a prolonged decline in numbers of recruits per spawner (Weikamp et al., 1995; Good et al., 2005) wherein recruits from the return years 1997–1999 failed to replace parental spawners. Since 2000, increased marine survival rates and higher rainfall have likely contributed to a recent upswing in recruits (NMFS, 2011f; Stout et al., 2012). But that trend was interrupted during return years 2005, 2006, and 2007 as recruits again failed to replace parental spawners. Possible explanations for recent recruitment failures include the possibility that higher spawning abundance levels in recent years had reached the current carrying capacity of the degraded freshwater environment. Further, as total spawning abundance has been at highest levels since the 1950s, the total numbers of recruits remain lower than in the 1950s–1970s (NMFS, 2011f; Stout et al., 2012). These possibilities indicate that degraded freshwater habitat conditions may limit the Oregon Coast coho ESU from rebounding from another prolonged period of poor marine survival of recruits, should that occur in the future. The possibility that either of these factors, individually or together, contributed to the extreme population declines observed in 2012 has not been reported.

**D. All Sub-basins in Analysis Area**

**Figure 4.5-14**
**Estimated Abundance of Wild Adult Coho Spawners in the Oregon Coast Coho ESU, 1997 to 2012, within Three Sub-basins Crossed by the PCGP Project. (Source: ODFW, 2013)**

**Critical Habitat**

Critical habitat for the Oregon Coast coho salmon ESU was first proposed in May 1999 (NMFS 1999c). Proposed critical habitat included all river reaches accessible to Oregon Coast coho salmon ESU which were listed as threatened at the time (see discussion above). Proposed critical habitat consisted of water, substrate, and adjacent riparian zones of estuaries and rivers including those in the Umpqua (HU 17100302), Coos (HU 17100304) and Coquille (HU 17100305) HUs (NMFS 1999c). Though not specifically identified, the Coos Bay estuary would have been included. The 1999 proposal was terminated when the District Court set aside the 1998 final rule determining threatened status for the Oregon Coast ESU (see discussion above).

Following re-proposing Oregon Coast coho salmon ESU for listing as threatened in June 2004, critical habitat for the ESU was likewise re-proposed in December 2004 (NMFS, 2004). The new proposed critical habitat designated three critical habitat units that coincide with each of the three Project components: Unit 9 – South Umpqua Subbasin (HU 17100302) affected by the Pacific Connector pipeline; Unit 11 – Coos Subbasin (HU 17100304), which includes the Coos Bay estuary) affected by the Port, the LNG terminal, and the Pacific Connector pipeline; and Unit 12 – Coquille Subbasin (HU 17100305) affected by the Pacific Connector pipeline.

Similar to critical habitat designated for coho salmon in the SONCC ESU, critical habitat included stream channels laterally to the ordinary high water mark (OHWM) (or bankfull elevation or bankfull width). NMFS also defined critical habitat in estuarine and nearshore marine zones as areas contiguous with the shoreline from the extreme highwater mark out to a depth no greater that 30 meters (98 feet) below the mean low water mark (NMFS, 2004).

Within these areas, NMFS (2004) identified primary constituent elements (PCEs) of critical habitat that include sites essential to support one or more coho life stages (spawning, rearing, migration, and foraging). Those sites each are associated with physical and biological features essential coho conservations (e.g., spawning gravels, water quality, water quantity, side channels, food base). The following are PCEs for designated critical habitat for the Oregon Coast coho (NMFS, 2008d):

1. Freshwater spawning sites with water quantity and quality conditions and substrate supporting spawning, incubation, and larval development.
2. Freshwater rearing sites with water quantity and floodplain connectivity to form and maintain physical habitat conditions and support juvenile growth and mobility; water quality and forage supporting juvenile development; and natural cover such as shade, submerged and overhanging large wood, log jams and beaver dams, aquatic vegetation, large rocks and boulders, side channels, and undercut banks.
3. Freshwater migration corridors free of obstruction with water quantity and quality conditions and natural cover such as submerged and overhanging large wood, aquatic vegetation, large rocks and boulders, side channels, and undercut banks a) supporting juvenile and adult mobility and survival, b) supporting juvenile use of various of habitats that allow them to avoid high flows, avoid predators, successfully compete, begin the behavioral and physiological changes needed for life in the ocean, and ability to reach the ocean, and c) essential for nonfeeding adults to successfully swim upstream, avoid predators, and reach spawning areas on limited energy stores.
4. Estuarine areas free of obstruction with water quality, water quantity, and salinity conditions supporting juvenile and adult physiological transitions between fresh- and

saltwater; natural cover such as submerged and overhanging large wood, aquatic vegetation, large rocks and boulders, and side channels; and juvenile and adult forage, including aquatic invertebrates and fishes, supporting growth and maturation.

5. Nearshore marine areas free of obstruction with water quality and quantity conditions and forage, including aquatic invertebrates and fishes, supporting growth and maturation; and natural cover such as submerged and overhanging large wood, aquatic vegetation, large rocks and boulders, and side channels.
6. Offshore marine areas with water quality conditions and forage, including aquatic invertebrates and fishes, supporting growth and maturation.

Designated critical habitat for the Oregon Coast coho does not include unoccupied areas. The lateral extent of critical was defined as the width of the stream channel defined as the ordinary high-water line (NMFS, 2008d). Human actions on land outside of the stream channel can modify or degrade physical and biological features of the stream and associated PCE at the site and/or in downstream reaches of designated critical habitat.

#### 4.5.4.2 Environmental Baseline

**Analysis Area**

Three action area components are applicable to coho salmon in the Oregon Coast ESU. The first is the EEZ analysis area, which extends 200 nmi offshore from the Coos Bay Head (see figure 4.2-1, under Section 4.2.1.3 blue whale) and within the EEZ from San Diego, California, to Cape Flattery, Washington. Within the analysis area, effects to coho salmon within coastal marine waters would be associated with LNG carriers that are assumed to transect the EEZ perpendicularly - east and west - as they approach and depart from Coos Bay (see the discussion above under see under section 4.3.3.3 marbled murrelet). The second is the estuarine analysis area that was described above for marbled murrelets (see figure 4.3-6 under section 4.3.3.2 marbled murrelet). The third is a riverine analysis area similar to that described above for coho salmon in the SONCC ESU. The estuarine analysis area includes 1) operational activities by LNG carriers entering and exiting Coos Bay, 2) construction-related effects to approximately 3.1 miles downstream from the proposed LNG terminal and upstream to a point 2.2 miles from that site for potential worst-case dispersion of turbidity, as provided by Moffatt and Nichol, 2006), and 3) the 2.80-mile within-estuary route of the Pacific Connector pipeline after leaving the Weyerhaeuser Cove Pipe Yard at MP 1.7, crossing Haynes Inlet to where the pipeline emerges from the estuary at MP 4.1.

The riverine analysis area is the second component and includes two components: 1) the water column and substrate of all waterbodies crossed by the Pacific Connector pipeline from the point of crossing to the extent downstream where water quality is adversely affected by turbidity generated during construction and sediment generated by runoff from the construction right-of-way, and 2) waterbodies' associated riparian zones affected in the short-term during construction and in the long-term by operation. For coho salmon in the Oregon Coast ESU, the riverine analysis area is limited to fresh waterbodies within Coos Subbasin (HU 17100304 – figure 4.5-15A), Coquille Subbasin (HU 17100305 – figure 4.5-15B) and South Umpqua Subbasin (HU 17100302 – figure 4.5-15C).

Total suspended solid (TSS) concentrations generated during wet open-cut pipeline construction have been estimated from models developed by Reid et al. (2004). Amounts of TSS produced during dry open-cut construction (fluming, dam-and-pump) adjustments are fractions of the concentrations produced during wet-open cuts (Reid et al., 2004). Estimates of TSS produced during dry open-cut construction across waterbodies in fifth field watersheds are presented below in Section 4.5.4.3. Average sediment percentages (grain sizes including gravel, sand, silt, and organics) for streams within each fifth field watershed (see table 4.5.4-7 below in this section and table 4.5.4-12 in Section 4.5.4.3) were assumed as fractions of the TSS generated during construction and concentrations of each grain class at various distances downstream were estimated using Ritter's (1984) model for minor perennial waterbodies. Distances at which concentrations near zero (settle out of suspension) differ considerably for the different grain sizes and are dependent on water depths and stream discharge rates at the time of construction (see Table 4.5.3-7 in Section 4.5.3.3, SONCC coho). Downstream settling distances will be much greater for deeper waterbodies with high flow velocities than for shallow, slow flowing streams.

For streams within range of Oregon Coast coho that would be crossed by the PCGP project, the average downstream distance expected to near a concentration of 0 mg/L of silt (0.0016 cm diameter, 0.023 cm/sec settling velocity) during fluming is about 114 m (374 feet); the average downstream distance expected to near a concentration of 0 mg/L of clay (0.0004 cm diameter, 0.0014 cm/sec settling velocity) is about 1,500 m (4,921 feet). These estimates are for average low flows likely to occur during pipeline construction within the ODFW (2008) instream timing recommendations.

Downstream distances to reach concentrations of 0 mg/L for silt and clay mobilized by flumed construction during average peak flows would be greater. The average downstream distance expected to near a concentration of 0 mg/L of silt (0.0016 cm diameter, 0.023 cm/sec settling velocity) during fluming is about 620 m (2,034 feet); the average downstream distance expected to near a concentration of 0 mg/L of clay (0.0004 cm diameter, 0.0014 cm/sec settling velocity) is about 9,800 m (32,152 feet).

The riverine analysis area used in this biological assessment for Oregon Coast coho has been limited to downstream distances up to 32,152 feet (6.1 miles) within the affected fifth field watersheds in the range of Oregon Coast coho (see figure 4.5-15).

**Species Presence**

Based on genetic data and recoveries of tagged fish, the Oregon Coast coho ESU extends to Pacific Ocean tributaries from Cape Blanco north to the Columbia River. Coho in the ESU inhabit waterbodies in 10 fifth field watersheds that will be crossed by the PCGP (see table 4.5.4-2). An eleventh, the Elk Creek Watershed (HUC1710030204), would be crossed but no waterbodies would be affected within the watershed. The project would cross the following that are inhabited by Oregon Coast coho: Coos Bay-Frontal Pacific Ocean (HUC 1710030403), Coquille River (HUC 1710030505), North Fork Coquille River (1710030504), East Fork Coquille River (HUC 1710030503), Middle Fork Coquille River (HUC 1710030501), Olalla Creek-Lookingglass Creek (HUC 1710030212), Clark Branch-South Umpqua River (HUC 1710030211), Myrtle Creek (HUC 1710030210), Days Creek-South Umpqua River (HUC 1710030205), and Upper Cow Creek (HUC 1710030206). Upstream migrations by coho in the Middle Fork Coquille River are blocked (Bradford Falls) at River Mile 27.3, about 5.3 miles southwest of Camas Valley, OR.

**Table 4.5.4-2**
**Summary of River Sub-basins and 5th Field Watersheds Coinciding With the Proposed Pipeline Route, within Range of Oregon Encountered from West to East**

| Sub-basins and 5th Field Watersheds | Hydrologic Unit Code | Number of Waterbodies [1] | | | | |
|---|---|---|---|---|---|---|
| | | Estuary | Perennial | Intermittent | Pond [2] | Total |
| **Coos Sub-basin** | **17100304** | | | | | |
| Coos Bay-Frontal Pacific Ocean | 1710030403 | 1 | 40 | 24 | 1 | **66** |
| **Coquille Sub-basin** | **17100305** | | | | | |
| Coquille River | 1710030505 | | 5 | 1 | | **6** |
| North Fork Coquille River | 1710030504 | | 3 | 10 | | **13** |
| East Fork Coquille River | 1710030503 | | 7 | 7 | | **14** |
| Middle Fork Coquille River | 1710030501 | | 5 | 8 | | **13** |
| **South Umpqua Sub-basin** | **17100302** | | | | | |
| Olalla Creek-Lookingglass Creek | 1710030212 | | 4 | 11 | | **15** |
| Clark Branch-South Umpqua River | 1710030211 | | 6 | 13 | | **19** |
| Myrtle Creek | 1710030210 | | 5 | 5 | | **10** |
| Days Creek-South Umpqua River | 1710030205 | | 5 | 4 | | **9** |
| Elk Creek [3] | 1710030204 | | | | | **0** |
| Upper Cow Creek | 1710030206 | | 5 | 2 | | **7** |
| | **TOTAL** | **1** | **85** | **85** | **1** | **172** |

[1] includes waterbodies crossed and waterbodies not crossed but immediately adjacent to the pipeline and within the right-of-way.
[2] includes stock ponds, industrial ponds.
[3] Elk Creek Watershed would be crossed but no waterbodies would be affected within the watershed.

The pipeline would actually cross 149 of the waterbodies in table 4.5.4-3, 143 of them by dry open cutting, while the South Umpqua River would be crossed twice, once by a Direct Pipe crossing at MP 71.30 and again by a diverted open cut at MP 94.73. Kentuck Slough would be crossed by a conventional bore at MP 6.28R, Catching Slough would also be bored at MP 11.11, and the Coos River would be crossed using HDD at MP 11.13R. The Coos Bay estuary would be crossed by using a wet open cut procedure. Twenty-two of the waterbodies listed in 4.5.4-3 would not be crossed by the pipeline but are adjacent to the pipeline centerline. Blasting may be necessary to construct across 30 streams that would be crossed by dry open cut methods (see Project Description) because the streambed of each is bedrock (see table 4.5.4-3).

All affected waterbodies within the three sub-basins and 10 fifth field watersheds that are within the range of Oregon Coast coho salmon ESU proximate to the Pacific Connector pipeline are included in table 4.5.4-3. There are 172 waterbodies included in the table, of which 85 are perennial, 85 are intermittent, 1 is an estuary and another is a pond. Coho salmon are known to occur in 32 of the waterbodies and are assumed to be present in 27 others based on connectivity to perennial streams known to support coho salmon, the presence of resident salmonids, and/or information provided by fisheries biologists.

**Table 4.5.4-3**
**Waterbodies Crossed or Adjacent to the Pacific Connector Pipeline within the Coos Sub-basin (HUC 17100304), Coquille Sub-basin (HUC 17100305), and South Umpqua Sub-basin (HUC 17100302) and in the Range of the Oregon Coast Coho Salmon ESU.**

[1] Dry open cut crossing methods include flume or dam-and-pump procedures. Dam-and-pump methods would be utilized where streambed blasting is anticipated to eliminate blasting around the flume. The dam-and-pump crossing method is the preferred crossing procedure in steep incised drainage valleys where worker safety may be compromised when placing ("threading") the pipe string under the flume pipe and where there is a risk of upsetting the flume during this operation. The dam-and-pump crossing method is also the preferred crossing method on small streams under low flow conditions during the recommended ODFW-recommended in-water work period. Pacific Connector proposes temporary/short-term fish passage restriction when completing dam-and-pump crossings within the ODFW-recommended in-water work period. Appendix M provides details of stream crossings.

[2] Oregon Department of Fish and Wildlife. 2012a. Fish Distribution Data, 1:24,000 Scale. Oregon Department of Fish and Wildlife Natural Resources Information Management Program. Online: https://nrimp.dfw.state.or.us/nrimp/default.aspx?pn=fishdistdata).

[3] Assumes fisheries construction windows only apply to those waterbodies flowing at the time of construction and windows do not apply to HDD crossings.

[4] Steambed bedrock based on Pacific Connector's Wetland and Waterbody delineation surveys. Streambed bedrock may require special construction techniques to ensure pipeline design depth. Special construction techniques may include rock hammering, drilling and hammering, or blasting. The need for blasting would be determined by the construction contractor and would only be initiated after ODFW blasting permits are obtained.

## Habitat

**Estuarine Habitats.** The estuarine habitat in Coos Bay along the proposed pipeline route is located in mostly shallow regions of the Haynes Inlet and in the Coos River. Tidally influenced waters extend over seven miles upstream in Catching Slough and Coos River, downstream from the location crossed by the pipeline. Tidal gates at the mouths of Kentuck Slough and Willanch Slough have changed salt water inundation and flow regimes in the lower reaches of those waterbodies. All four waterbodies will be crossed by the proposed pipeline.

Substrates within the estuary include sub-tidal (continuously submerged) and intertidal (periodically submerged by tidal action) zones. Both zones support various habitats that have been classified by type of bottom material (including rock, sand, mud, and wood/organic debris) and relative position within the estuary (aquatic bed, shore, flat, beach/bar, and tidal marsh) by Oregon Department of Land Conservation and Development (ODLCD, 1987). Sub-tidal and intertidal habitats within the Coos Bay Estuary were mapped in 1987 as a pilot project for the ODLCD Coastal Management Program Dynamic Estuary Management Information System, or DEMIS (ODLCD, 1998). The proposed pipeline route and associated work areas coincide with shallow intertidal and sub-tidal fine bottom and unconsolidated bottom habitat, with a few regions of mixed seabeds of eelgrass, attached algae, and tidal marsh.

Tidal mud flats and eelgrass beds are found on the west shore of Coos Bay; both habitats are utilized by most fish species within the bay at some time during the year (Cummings and Schwartz, 1971). Eelgrass densities in Coos Bay are greatest at relatively shallow depths, slightly above and below the mean low water level (Thom et al., 2001). Distribution of eelgrass within the estuary has apparently changed slightly since 1987 (ODLCD, 1998). Preliminary distribution of eelgrass (interpreted from infrared imagery, with some field verification) was evaluated in the vicinity of the project area during 2005 (Clinton, 2007). Eelgrass on intertidal mud flats between Glasgow Point (Kentuck Inlet) and Russell Point (Haynes Inlet) decreased since 1987 while eelgrass beds on intertidal mud and mud/sand flats extending outward from Kentuck Inlet had apparently increased.

Natural turbidity in the estuary was judged to be higher at upper bay locations, away from water influx from the ocean (Moffatt and Nichol, 2006). Turbidity (measured in Nephelometric Turbidity Units – NTUs, see turbidity discussion in Suspended Sediment, section 3.2.3.1) was evaluated at the Charleston Bridge, near the entrance to Coos Bay, and estimated as Total Suspended Solids (TSS - measured in milligrams per liter - mg/L) for modeling dredge-generated turbidity during construction of the proposed Jordan Cove Terminal (Moffatt and Nichol, 2006). At that location, turbidity varied from 3.7 to 18.1 NTU (5.7 to 45.7 mg/L) but sometimes exceeded 200 NTU.

Summaries of watershed health indicators have been reported by the Coos Watershed Association for tideland habitats accessible by Oregon Coast coho salmon (Oregon Watershed Enhancement Board, 2007). Table 4.5.4-4 provides conditions in the following three estuarine zones:

- **Tidal wetlands**: Marshes and swamps; a vegetated wetland that is periodically inundated by tidal waters. Tidal wetlands include emergent, scrub-shrub, and forested wetland types.
- **Tidal flat**: An area inundated by all high tides and exposed only at low tide. Some tidal flats have extensive growth of algae or seagrass; others are bare mud.

- **Sub-tidal zone**: Sub-tidal estuarine habitats include channel bottoms, slope bottoms, and the open water above them.

Wetland functions within the estuary have been affected by dikes, tide gates, roads and railroads, ditches, and dams that restrict tidal flows and/or have changed tidal flow patterns. Agricultural land uses have contributed to erosion of channels and, along with channel armoring, has affected vegetation diversity in wetlands, channel shading, and salmonid habitat function; tidal wetlands have also been affected excavations and disposal of dredged materials (Oregon Watershed Enhancement Board, 2007).

**Table 4.5.4-4**
**Watershed Health Indicators for Three Tidal Habitat Zones in the Coos Bay Estuary**

| Tideland Habitat Zone | Hydro-Modification | Sediment Regime | Water Quality | Vegetation Modification | Invasive Species | Habitat Loss |
|---|---|---|---|---|---|---|
| Tidal Wetlands | Limiting >40% historic wetlands modified | Limiting >40% wetlands affected by major change in sediment regime | Moderate DEQ water quality criteria met <90% of samples | Limiting 40% wetland vegetation altered by land use | Moderate Limited Invasive species impact on tidal wetland function | Limiting >40% zone with complete fill or conversion |
| Tidal Flat Zone | Limiting >40% historic tidal flats modified | Moderate 20-40% tidal flats affected by major change in sediment regime | Moderate DEQ water quality criteria met <90% of samples | N/A | Moderate Limited Invasive species impact on tidal flat function | Moderate 20-40% zone with complete fill or conversion |
| Sub-Tidal Zone | Moderate 20-40% historic zone modified | Moderate 20-40% sub-tidal zone affected by major change in sediment regime | Moderate DEQ water quality criteria met <90% of samples | N/A | Moderate Limited Invasive species impact on sub-tidal zone function | Moderate 20-40% zone with complete fill or conversion |
| Source: Oregon Watershed Enhancement Board, 2007. | | | | | | |

NMFS performed a preliminary survey of benthic invertebrates in the vicinity of the Coos Bay navigation channel in 1989 (Miller et al., 1990). The study characterized the macroinvertebrate community at 20 sites in and adjacent to the navigation channel in support of channel deepening in Coos Bay. There were 121 different invertebrate taxa identified with a mean density of 2,617 individuals/square meter ($m^2$). The highest invertebrate densities were observed in the lower bay, downstream from the LNG terminal site (CM 2 to CM 5). One of the sites (Station 11) was located in the navigation channel, immediately adjacent to the LNG terminal where 16 different taxa were identified and the mean density was 552 individuals/$m^2$. The polychaete worm, *Glycera tenuis*, dominated the taxa at this location (n=23). Nearby sampling stations also were found to support high numbers of polychaetes, including *Glycera tenuis* and *Heteropodarke heteromorpha*. *Corophium salmonis*, an amphipod important as juvenile salmonid prey, was rarely found in the study area. Total benthic invertebrate densities in Coos Bay ranged from 375 to 13,546/$m^2$ and were found to be lower than densities observed in the Umpqua River estuary (range from <200 to >50,000/$m^2$) and the Columbia River estuary (range from <1,000 to >60,000/$m^2$) (Bottom et al., 1985; Miller et al., 1989; Durkin and Emmett, 1980).

Previous studies by ODFW have shown that benthic macroinvertebrates in Coos Bay may not comprise a major portion of the diet for juvenile salmonids. Stomach contents of wild Chinook salmon and hatchery coho salmon juveniles were analyzed from July to September 1980 (Nicholas and Lorz, 1984). The survey was performed during the outmigration period for juvenile salmonids, when juveniles are expected to be abundant within the estuary. The major prey species consumed by juvenile Chinook salmon (in order of abundance) were Pacific sand lance (n=89), terrestrial insects (n=59), and decapods (e.g. crab zoea and shrimp larvae) (n=27) (Nicholas and Lorz, 1984). Only five amphipods (likely *Corophium* spp.) were identified in 143 Chinook salmon stomach samples. However, amphipods were the major prey species identified in juvenile coho salmon stomach samples (n=105). Other prey species found included terrestrial insects (n=27) and Pacific sand lance (n=25). Previous studies in Coos Bay have found that *Corophium* spp. are abundant in intertidal areas and constitute an important diet element for juvenile Chinook salmon and striped bass (USDI, 1971). Shallow water habitats near the LNG terminal/Port slip site have been mapped as habitat for *Corophium* spp (Coos County Planning Department, 1979).

Based on the presence of juvenile salmonids at nearby ODFW sampling sites, it is likely that juvenile coho and other fish species utilize the shallow water areas at the LNG terminal slip site for foraging during periods of the year. The shoreline has been mapped as potential habitat for the amphipod *Corophium* spp., which is considered an important prey species (Coos County Planning Department, 1979) and was shown to be consumed in large numbers by coho salmon (Nicholas and Lorz, 1984).

However, benthic studies conducted by NMFS within and in the vicinity of the Coos Bay navigation channel found that *Corophium salmonis* occurred in much lower densities than other Oregon estuaries (Miller et al., 1990; Bottom et al., 1985; Miller et al., 1989; Durkin and Emmett 1980). Based on site observations made in November 2006, it appears that shallower habitats at the LNG terminal site contain a higher percentage of fine substrates, and thus could support a greater abundance of benthic macroinvertebrates than had been observed within the navigation channel, which is dominated by coarser sand.

**Freshwater Habitats**. NMFS (1996) developed an approach and criteria for evaluating human-related effects to anadromous salmonid habitats which focuses on the following six pathways of potential impact: 1) water quality, 2) habitat access, 3) habitat elements, 4) channel condition and dynamics, 5) flow/hydrology, and 6) watershed condition. BLM and Forest Service developed watershed analyses, in part to meet requirements of their respective land management plans, specifically to comply with the objectives of the Aquatic Conservation Strategey (ACS) in the Northwest Forest Plan (NWFP). In addition to federal agencies, watershed assessments have been developed by local watershed councils and Oregon's natural resource agencies and are available through the Oregon Watershed Enhancement Board (OWEB). Watershed assessments provide evaluations of fish habitats and water quality and describe how natural process and human activities are affecting those resources (Governor's Watershed Enhancement Board, 1999). Available watershed analyses developed by these sources are listed in table 4.5.4-5 for the $5^{th}$ field watersheds crossed by the PCGP Project.

The various watershed documents address fish habitats but use different approaches and descriptors. Oregon Department of Fish and Wildlife (ODFW, 1997), in cooperation with other agencies, has conducted stream surveys throughout the state including streams within watersheds crossed by the PCGP Project. Four types of habitat information provide quantitative evaluations of the fish habitat condition within the various watersheds: 1) pool habitat condition, 2) riffle habitat condition, 3) woody debris habitat condition, and 4) riparian habitat condition. ODFW (Foster et al., 2001) has developed benchmark criteria for each of these habitat conditions that would represent undesirable and desirable habitat conditions. The benchmarks are provided in table 4.5.4-6 along with the various aquatic habitat conditions to which they apply.

**Table 4.5.4-5**

Benchmark conditions are not absolute but they provide a method for comparing values of key aquatic habitat components (Foster et al., 2001) that are used in this Resource Report to establish baseline conditions within watersheds to be crossed by the PCGP Project. Pools provide refuges for fish during high and low stream flows. Pools provide slow water habitats for adults and juveniles, provide over-wintering habitat for some fish species, provide habitat during periods of low summer flows, and pools associated with large wood provide habitat complexity.

Riffles provide spawning habitats for various salmonid species that construct nests or redds in gravels of various sizes, specific to salmonid species. Sand, silt, and organic debris can reduce suitability of spawning habitats by filling pores between gravel particles that are necessary for intergravel stream flows, availability of oxygen, and for development of embryos; high percentages of sand, silt, and organic material in riffles indicate poor conditions as spawning habitat.

Riparian trees provide shade over stream channels which reduce deleterious effects of high summer water temperatures. Roots of riparian vegetation stabilize stream banks, contribute to development of bank undercutting (thermal and hiding cover), limit erosion and sedimentation from stream banks, and provide large woody debris (LWD) as an important component of the aquatic habitat. LWD, especially contributed by riparian conifers, provides cover for fish, physical habitat complexity that influences stream flows and channel diversity, and biological complexity as substrate for macroinvertebrate communities that provide food for salmonids during different life stages (Foster et al., 2001).

**Table 4.5.4-6**
**Oregon Department of Fish and Wildlife Aquatic Inventory and Analysis Project Criteria for Aquatic Habitat Conditions and Benchmarks**

| Aquatic Habitat Condition | Benchmark Level for Condition | |
|---|---|---|
| | **Undesirable** | **Desirable** |
| **Pools** | | |
| • Pool Area (% total stream area) | <10 | >35 |
| • Pool Frequency (channel widths between pools) | >20 | 5-8 |
| • Residual Pool Depth (m) | | |
| Small Streams (<7m wide) | <0.2 | >0.5 |
| Medium Streams (≥7m and <15m width) | | |
| Low Gradient (slope <3%) | <0.3 | >0.6 |
| High Gradient (slope >3%) | <0.5 | >1.0 |
| Large Streams (≥15m width) | <0.8 | >1.5 |
| • Complex Pools (pools with ≥3 LWD pieces / km of reach length) | <1 | >2.5 |
| | | |
| **Riffles** | | |
| • Width/Depth Ratio (active channel based) | | |
| East Side | >30 | <10 |
| West Side | >30 | <15 |
| • Gravel (% area) | <15 | ≥35 |
| • Silt-Sand-Organics (% area) | >20 | <10 |
| Volcanic Parent Material | >15 | <8 |
| Sedimentary Parent Material | >20 | <10 |
| Channel Gradient <1.5% | >25 | <12 |
| | | |
| **Shade** (Reach Average, Percent) | | |
| Stream Width <12 meters | | |
| West Side | <60 | >70 |
| Northeast | <50 | >60 |
| Central-Southeast | <40 | >50 |
| Stream Width >12 meters | | |
| West Side | <50 | >60 |
| Northeast | <40 | >50 |
| Central-Southeast | <30 | >40 |
| | | |
| **Large Woody Debris** | | |
| • Pieces/100m Stream Length | <10 | >20 |
| • Volume ($m^3$)/100m Stream Length | <20 | >30 |
| • "Key" Pieces (>60cm and 10m long)/100m | <1 | >3 |
| **Riparian Conifers** (30m From Both Sides of Channel) | | |
| • Number >20in DBH/1000ft Stream Length | <150 | >300 |
| • Number >35in DBH/1000ft Stream Length | <75 | >200 |

Data used to evaluate aquatic habitat conditions, reported by ODFW Aquatic Inventories Project (2011), are provided in appendix X for each stream reach included in the inventories and evaluations of benchmark conditions are summarized in tables 4.5.4-7 and 4.5.4-8, below.

Coos Sub-basin - HUC 17100304. Data available from the ODFW Aquatic Inventories Project (2011) provided aquatic habitat conditions for 37 stream reaches within the Coos Bay-Frontal Pacific Ocean 5$^{th}$ Field Watershed (HUC 710030403) surveyed between 1990 and 2002. The sampled reaches were of first, second or third order (Strahler numbers 1, 2, 3) streams with active channel widths averaging 3.2 meters and active channel heights averaging 0.6 meter.

Desirable conditions for pool habitat in surveyed reaches ranged from only 8% for pool frequency to 35% for residual pool depth (see table 4.5.4-7). In general, pool habitat conditions were undesirable or less than desirable (moderate) for most streams within the watershed. Riffle habitats were relatively abundant (68% of stream reach areas) but degraded by high levels of silt, sand and organic materials and width to depth ratios of sampled reaches tended to be high, indicative of relatively shallow wide stream channels that provide less suitable habitat than deep, narrow channels (see benchmarks in table 4.5.4-6).

Riparian conditions in streams surveyed within the Coos Bay Frontal-Pacific Ocean watershed are mostly undesirable. Trees in less than half of the reaches provide adequate shade of stream channels and the numbers of large conifer trees within surveyed riparian zones were undesirable; large conifers were absent in many of the surveyed reaches. It is not surprising that the amount of LWD, including key pieces (pieces of large wood ≥0.60 meters diameter and ≥12 meters long), is undesirable, less than benchmark. Low estimates of riparian shade is indicative of lower gradient streams and floodplains that have been altered by past land uses in the watershed. As one consequence, summer stream temperatures in lower reaches exceed levels suitable as juvenile salmonid summer rearing habitats (Coos Watershed Association, 2006). The ODFW (2008a) instream construction window for coastal tributaries is July 1 to September 15 although work in the Coos Bay Estuary and Coos River mainstem is allowed from October 1 to February 15.

The pipeline will cross Kentuck Slough and Wallanch Creek upstream from tide gates, in low gradient reaches with associated low gradient floodplains. Echo Creek will be crossed upstream from the confluence with the Coos Bay estuary, a reach that is not tidally influenced. Specific aquatic habitat conditions in those streams (Coos Watershed Association, 2006) are consistent with conditions reported for stream reaches surveyed in by ODFW Aquatic Inventories Project and summarized in table 4.5.4-7.

Stream discharges over the annual cycle are provided in figure 4.5-16 for two streams within the Coos Sub-basin, Pony Creek – a small, tidally influenced stream and tributary to Coos Bay draining a watershed 3.88 square miles, and West Fork Millacoma River – a large tributary to the Coos River, draining a 46.90-square mile watershed. Seasonal discharges in West Fork Millacoma River are representative of large and small waterbodies crossed by the PCGP Project within the Coos Sub-basin. However, flows in Pony Creek have been influenced by releases from Upper Pony Creek Reservoir since construction of the new dam, completed in 2001 (Sol Coast Consulting & Design, LLC and Parsons Brinckerhoff, 2009).

**Table 4.5.4-7**
**Aquatic Habitat Conditions from Samples Taken by ODFW in Stream Reaches within 5th Field Watersheds of the Coos Bay and Coquille Sub-basins Crossed by the PCGP Project**

| Aquatic Habitat Condition | Mean Values (with Standard Errors) in Relation to Benchmark Conditions in Surveyed Reaches (by %) of Watersheds[1] | | | | | | | | | |

[1] Values unweighted by surveyed reach length.
[2] Assumes sedimentary parent material in all surveyed reaches.
[3] D= diameter, L = length

Highest monthly discharges occur between December and April in both waterbodies along with the largest range in variability (maximum and minimum discharge for a given month). Lowest discharges occur between June and October. In all months, minimum discharges in Pony Creek were zero (see figure 4.5-16A) and minimum discharges in West Fork Millicoma River were less than 10 cubic feet per second (cfs) during July, August, September and October in some years (see Figure 4.5-16B). The ODFW (2008a) instream construction window for coastal tributaries is July 1 to September 15.

<u>Coquille Sub-basin - HUC 17100305.</u> ODFW, BLM, and Oregon Forest Industry Council (OFIC) surveyed 336 stream reaches in the four 5th field watersheds within the Coquille Sub-basin that will be crossed by the PCGP Project: 18 in the Coquille HUC 1710030505, 76 in the North Fork Coquille River HUC 1710030504, 95 in the East Fork Coquille River HUC 1710030503, and 147 in the Middle Fork Coquille River HUC 1710030501. Surveys were conducted during summers in different watersheds between 1990 and 2005. Conditions for aquatic habitats in the four watersheds are included in table 4.5.4-7. Sampled reaches of first through fifth order (Strahler numbers 1 through 5) streams had active channel widths averaging <3 meters and active channel heights averaging <0.6 meter.

Conditions associated with riparian vegetation are generally undesirable in each of the watersheds: there are too few large conifers along most stream reaches and LWD numbers, volume, and presence of key pieces tend to be below benchmark levels, especially for reaches in the Coquille River watershed. Pool conditions tend to more desirable than in the Coos Bay-Frontal Pacific Ocean watershed except for pool complexity formed by LWD, not surprising given the overall undesirable condition for LWD in surveyed streams. Overall, amounts of shade for reaches in the North Fork, East Fork, and Middle Fork Coquille watersheds are at desirable levels (see table 4.5.4-7), covering more than 60 to 70 percent of stream channels.

Streams in the four watersheds are mostly deep and narrow (low width/depth ratios) but spawning gravels appear to be limiting in the Coquille River watershed, less so in reaches within the other three watersheds. However, fine sediments (silt, sand, and organic materials) are present at undesirable levels within most riffle habitat units. These conditions are consistent with summaries of watershed health indicators reported by the Coquille Watershed Association for aquatic/instream habitats accessible by Oregon Coast coho salmon (Oregon Watershed Enhancement Board, 2007) in lower Coquille River, North Fork Coquille River, East Fork Coquille River, and Middle Fork Coquille River. Conditions for aquatic habitats in the watersheds are included in table 4.5.4-7.

Juvenile salmonid habitat complexity in low gradient streams requires some form(s) of shelter as large wood, pools, connected off-channel alcoves, beaver ponds, lakes, interconnected floodplains and wetlands that provide refugia and shelter from extreme water temperatures and hiding cover from predators (Oregon Watershed Enhancement Board, 2007). Spawning gravel quantities, measured by percent of riffle areas covered with gravel and gravel quality depends on embeddedness (percent of riffle areas in silt, sand, and organic fines). Waterbodies in the four watersheds within the Coquille Sub-basin that would be crossed by the pipeline are primarily limited in these and most other aquatic habitat health indicators (see table 4.5.4-9).

**Table 4.5.4-9**
**Comparisons of Aquatic Habitat Watershed Indicators in 5th Field Watersheds within the Coquille Sub-Basin that Would Be Crossed by the PCGP Project from West to East**

| 5th Field Watershed (HUC) | Winter Rearing Habitat Complexity | Summer Rearing Habitat Complexity | Spawning Gravel Quantity | Spawning Gravel Quality | Channel Modification | Large Wood | Water Quality | Water Temperature |
|---|---|---|---|---|---|---|---|---|
| Coquille River (1710030505) | Limiting | Limiting | Limiting | Limiting | Limiting | Limiting | Limiting | Limiting |

Source: Oregon Watershed Enhancement Board, 2007.
Aquatic habitat categories:

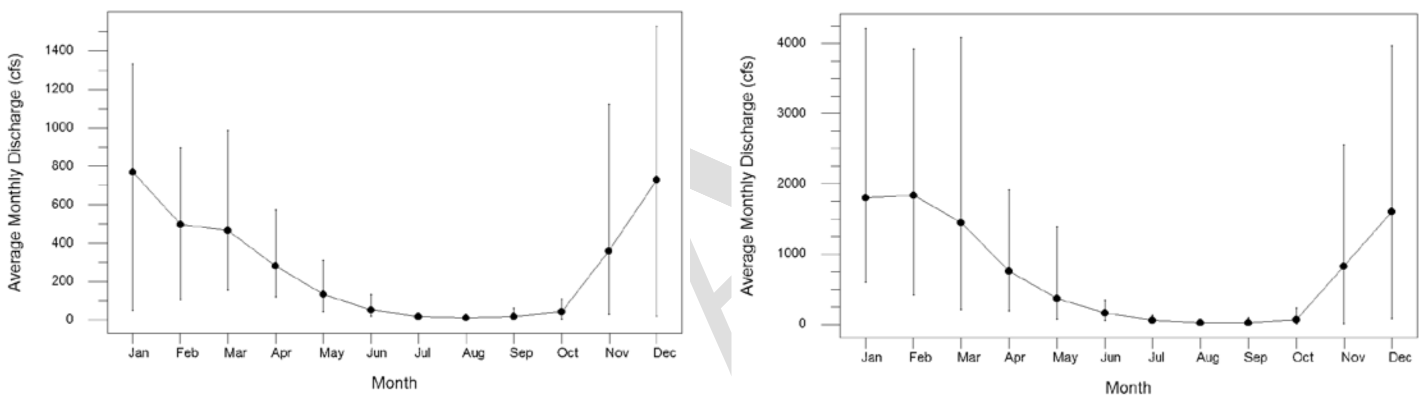
- **Limiting**: indication of degraded watershed health and a significant amount of restoration action is needed to improve watershed conditions.
- **Moderate**: indication of less than desirable watershed health and moderate to significant levels of restoration action is needed to improve watershed conditions.
- **Adequate**: indication of functional watershed health and minimal restoration activities are needed to maintain exiting watershed conditions.

Stream discharges over the annual cycle are provided in figure 4.5-17 and tributary to Coquille River draining a watershed 73.90 square miles, and Middle Fork Coquille River – a larger tributary to the Coquille River, draining a 305-square mile watershed.

Highest monthly discharges occur between November and April in both waterbodies along with the largest range in variability (maximum and minimum discharge for a given month). Lowest discharges occur between June and October. Minimum discharges in North Fork Coquille River were less than 10 cfs during August, September, and October in some years (see Figure 4.5-17A) and were less than 20 cfs during August, September, October, and November in some years in the Middle Fork (see Figure 4.5-17B). The ODFW (2008a) instream construction window for the Coquille River and tributaries is July 1 to September 15.

South Umpqua Sub-basin - HUC 17100302. The proposed pipeline route will cross five 5th field watersheds in the South Umpqua sub-basin. Between 1991 and 2010, the BLM and Umpqua Basin Fisheries Restoration Initiative surveyed 57 stream reaches in the Olalla-Lookingglass Creek watershed (HUC 1710030212), 97 reaches within the Clark Branch-South Umpqua River watershed (HUC 1710030211), 52 reaches within the Myrtle Creek watershed (HUC 1710030210), 34 reaches within the Days Creek-South Umpqua River watershed (HUC 1710030205), and 28 reaches within the Upper Cow Creek watershed (HUC 1710030206). Conditions for aquatic habitats in the five watersheds are included in table 4.5.4-8.

Stream reaches sampled in the Olalla-Lookingglass Creek watershed had significantly ($P<0.05$) more area of pool habitats than reaches in the other watersheds of the South Umpqua Sub-basin (see table 4.5.4-8). However, complex pools associated with LWD were undesirably limited (too few pieces per reach length) in most stream reaches for all six watersheds. Conditions for residual pool depths and pool frequencies were mostly intermediate (moderate), neither undesirable nor desirable for most of the sampled reaches in watersheds to be crossed by the pipeline.



**A** **B**

**Figure 4.5-17**

**Average Monthly Discharge (cfs) in (A) North Fork Coquille Fiver (USGS Gage 14326800) from 1963 to 1981, and (B) Middle Fork Coquille River (USGS Gage 14326500) from 1930 to 1946. Vertical lines show maximum and minimum discharges during the periods of record**

Ratios of stream widths to depths in most stream reaches in the six watersheds were generally low, more narrow and deep than wide and shallow. Areas of gravel in riffle habitats were mostly desirable or moderate conditions. Areas of fine sediments in riffles would be undesirable for the majority of stream reaches in the Upper Cow Creek watershed but at moderate or desirable conditions in reaches sampled in the other five watersheds (see table 4.5.4-8).

Shade conditions would be considered desirable for the majority of stream reaches in all six watersheds but numbers of large conifers in riparian zones were below desirable benchmark levels. LWD conditions in most stream reaches were also below desirable benchmark conditions (see table 4.5.4-8) for all of the watersheds to be crossed by the pipeline.

Stream discharges over the annual cycle are provided in figure 4.5-18 for two waterbodies within the South Umpqua Sub-basin, North Myrtle Creek – a small tributary to Myrtle Creek and the

South Umpqua River with a 54.2 square mile watershed, and the mainstem South Umpqua River with a watershed area of 1,670 square miles.

Highest monthly discharges occur between November and April in both waterbodies along with the largest range in variability (maximum and minimum discharge for a given month). Lowest discharges occur between June and October. Minimum discharges in North Myrtle Creek were less than 5 cfs during July, August, September, and October in some years (Figure 4.5-18A) and were less than 100 cfs during July, August, and September in some years in the South Umpqua River mainstem (see Figure 4.5-18B). The ODFW (2008a) instream construction window for tributaries to the South Umpqua River is July 1 to September 15 and from July 1 to August 31 for the South Umpqua River.

**Figure 4.5-18**
**Average Monthly Discharge (cfs) in (A) North Myrtle Creek (USGS Gage 14311000) from 1955 to 1986, and (B) South Umpqua River (USGS Gage 14312000) from 1906 to 2011. Vertical lines show maximum and minimum discharges during the periods of record**

### Critical Habitat

Using available spatial data from ODFW on specific occupied stream reaches, NMFS developed critical habit information based on fifth field watersheds to designate specific streams as critical habitat within watersheds, including the 10 watersheds that would be crossed by the PCGP Project. Included in the designation of critical habitat for the Oregon Coast coho are estuaries associated with the watersheds, beginning at the estuary mouth, including the entrance to the Coos Bay estuary at the land end of North Jetty and South Jetty. Critical habitats for Oregon Coast coho in specific waterbodies crossed by the PCGP Project are compiled in appendix M and are summarized in table 4.5.4-1. Critical habitat includes the Coos Bay Estuary and 29 freshwater streams in which coho salmon have been documented (NMFS, 2008d with shapefiles available from FWS at http://criticalhabitat.fws.gov/crithab/; ODFW, 2012c).

### 4.5.4.3 Effects by the Proposed Action

Analyses of effects are addressed separately for the EEZ analysis area, Estuarine analysis area, and Riverine analysis area. Together, those three analysis areas comprise the action area for coho salmon in the Oregon Coast ESU

## Direct Effects – EEZ Analysis Area

Project-related effects to Oregon Coast coho would be caused by the action and occur at the same time and place, including the following direct impacts within the within the EEZ analysis area could include: 1) sediment discharge at Site F, 2) acoustic effects to coho from LNG ships transiting the EEZ, and 3) spills and releases of LNG at sea.

Turbidity at Site F

Discharge of the maintenance dredging at Site F, about 1.6 miles off the mouth of Coos Bay, would generate a turbidity plume that could affect coho adults and juveniles within the EEZ analysis area. Use of and sediment discharge at Site F were addressed in Section 4.5.1.3 for green sturgeon, above.

Site F coincides with nearshore marine areas and offshore marine areas that are components of designated critical habitat for coho salmon in the Oregon Coast ESU. It is assumed that either the existing approved permit to utilize Site F would remain valid or that the COE and EPA would be coordinating with NMFS to have offshore disposal areas, similar to and including Site F. However disposal at this site may cause short term turbidity plume that local coho salmon would avoid, potentially causing some short-term displacement of these fish. Some local burial of potential benthic food resources may also occur. Effects to coho salmon of both turbidity plume displacement and burial of potential food resources at Site F would not be substantial.

Some juvenile coho salmon may be entrained and killed during discharge of the tailings at Site F. Turbidity generated from discharge at Site F would be rapidly dissipated and may cause some short-term avoidance of the area by coho during discharge. But there is the possibility that subadult coho, if they were present directly under the sediment discharge from the barge or ship would be unable to dart out of the plume of sediment and become trapped in the sediment during active discharge. Potential adverse effects would occur to smaller subadults if they were present within the area.

In assessment of similar discharge operations off the Umpqua and Rogue Rivers (NMFS, 2009d, NMFS 2009e), NMFS noted that rearing coho juveniles from the local rivers may be unable to avoid the tailings plume during discharge and be directly killed from this operation. Overall numbers of fish however are likely very small due to season when few small fish would be present, likely dispersion of the fish, ability juvenile fish to mostly avoid the plume. Similar conditions would likely occur at Site F. Overall numbers of coho salmon affected would not be substantial. Effects to coho salmon from discharge at Site F would be of little overall change from normal maintenance dredging operations.

## Acoustic Effects

Underwater noise may affect coho salmon in the Oregon Coast ESU. LNG carriers transiting the EEZ would produce underwater noise. Underwater noise levels are expected to vary by ship type and also by vessel length, gross tonnage, vessel speed, and to some extent, vessel age - older vessels tended to be louder than newer vessels (see discussion in Section 4.2.1.3 for blue whales). Based on the general trend for higher underwater noise generated by larger vessels (McKenna et al., 2012), it is possible for many of the LNG carriers that would utilize the Jordan Cove terminal to generate more noise than the the LNG tanker built in 2003 with 138,028 $m^3$ capacity reported by Hatch et al. (2008) that produced sound levels (with 1 standard error) of 182 ± 2 dB re: 1 μPa @ 1 meter.

State agencies in Washington, Oregon, and California, along with federal agencies have developed interim noise exposure threshold criteria for pile driving effects on fish (Washington State Department of Transportation, 2011a; Popper et al., 2006). Interim noise exposure threshold criteria for pile driving effects on fish (Washington State Department of Transportation, 2011a) include 1) a cumulative sound exposure level ($SEL_{cum}$) of 187 dB re 1 $\mu Pa^2$ s for fishes more than 2 grams, 2) a $SEL_{cum}$ of 183 dB re 1 $\mu Pa^2$ s for fishes less than 2 grams, and 3) a single-strike peak level ($SPL_{peak}$) of 206 dB re 1 μPa for all sizes of fishes (Washington State Department of Transportation, 2011a). $SEL_{cum}$ is the cumulative sound pressure squared, integrated over time, and normalized to one second. $SEL_{cum}$ is calculated as SEL(single strike at 10 meters from the pile) + 10 Log(number of strikes). Although ship noises reported by Hatch et al. (2008) and McKenna et al. (2013) are not directly equivalent to pile driving noise, or the interim noise exposure criteria, any LNG carrier noise generated in the EEZ would be below thresholds for adverse effects to fish, including Oregon Coast coho. Noise from LNG carriers would likely increase the background noise within the EEZ, and which is occurring globally (Slabbekoorn et al., 2010). Oregon Coast coho in the EEZ might detect noise from LNG carriers but are not expected to be adversely affected by the projected since vessel traffic due to LNG carries is expected to add to the projected vessel traffic in 2017-2018 by 1.2 percent increase in shipping in coastal Oregon and Washington over the 2017-2018 estimates (see discussion in Section 4.2.1.3 for blue whales). Neither underwater noise generated during construction (see below) nor ship noises from LNG carriers transiting the EEZ are expected to adversely affect Oregon Coast coho.

Releases and Fire at Sea

Oil or LNG spills at sea or offshore are unlikely to harm coho salmon. The low amount of petroleum product on LNG vessels and low chance of LNG spill or fish contacting a spill greatly reduce chance of impacts in the marine environment from spills. Any potential spills that could occur and that could affect coho would more likely be fuels or lubricants associated with the operation of the LNG carrier. These products are kept in relatively small quantities on ships and would not result in the types of effects associated with a spill from an oil tanker.

If an unignited LNG spill were to occur along the LNG carrier transit, some cooling of the upper water layers closest to the LNG spill would be expected, but would not likely cause the overall water column to cool to the point of affecting Oregon Coast coho in the water, given the ambient water temperatures in the transit route, the adaptability of Oregon Coast coho to varying water temperatures, and their foraging patterns on benthos rather than the epipelagic or photic zone near the surface.

Characteristics of LNG released at sea were described in Section 4.2.1.3 for blue whales and Section 4.3.3.3 for marbled murrelets. At the water-vapor LNG pool interface, the cryogenically cooled LNG would begin to vaporize but, because of its relatively high density, the plume would remain at or close to the surface interface (Hightower et al., 2004). The cooling effects of the LNG plume on submerged coho salmon are unknown but are expected to be localized at the surface. Similarly, effects of a fire on prey species would likely be very limited to the ocean – LNG pool interface. Neither the LNG pool nor an ensuing fire would be expected to adversely affect coho salmon.

**Direct Effects – Estuarine Analysis Area**

Project-related effects to coho salmon in the Oregon Coast ESU would be caused by the action and occur at the same time and place, including the following direct impacts within the estuarine analysis area: 1) turbidity effects from dredging the slip and access channel, 2) turbidity effects from LNG vessel propeller wash and ship wake, 3) turbidity effects from constructing the Pacific Connector pipeline within the estuary, 4) stranding Oregon Coast coho by LNG vessel propeller wash and ship wake, 5) introduction of exotic, invasive species from ballast water, 6) entrainment and impingement of Oregon Coast coho in LNG carriers' intake port, 7) estuary water cooling during LNG carrier cargo loading, 8) potential effects by effects by operational lighting, and 9) acoustic effects to coho during LNG terminal construction.

**Timing**

In-water construction of the JCE and PCGP Project within the Coos Bay estuary is planned from October 1 through February 15 following ODFW's recommendation. Approximately one-half of each brood of coastal coho salmon in Winchester Creek/South Slough (tributaries to Coos Bay moved to the estuary as sub-yearlings (Miller and Sadro (2003). The estuary provides feeding and migratory habitat for adult and maturation habitat for juvenile coho that inhabit the ecotones between freshwater and saline portions of the estuary for up to 8 months and then moved back upstream to overwinter. By October, adult coho would likely have migrated from critical habitat in the estuary to upstream spawning habitats but the timing and progress of upstream migration could be influenced by drought and autumn precipitation. For example in fall 2011, significant rainfall did not occur until late December and adult coho held in mainstem pools for an extended period, waiting for rainfall, followed by increased discharge (ODFW, 2012d). Adult coho could be present in designated critical habitat within the estuary, coincidental with in-water construction for the JCE and PCGP Project. Principal direct impact during in-water construction would most likely be related to turbidity generated by construction of the slip, dredging the access channel, and construction of Pacific Connector's pipeline across Haynes Inlet.

**Turbidity Effects –Slip and Access Channel**

Construction of the LNG terminal slip will require the excavation and dredging of approximately 4.3 million cubic yards (cy) of material (2.3 million cy excavated and 2.0 million cy dredged) and the construction of the access channel will require the dredging of 1.3 million cy for a total of approximately 5.6 million cy (see discussion in Section 4.5.1.3, green sturgeon). The majority of the dredging for the slip will be conducted in isolation from the waters of Coos Bay. While the future slip area is being excavated and dredged, a berm will be maintained to provide complete separation of the excavation and dredging activities from the bay, resulting in no turbidity being released to the waters of Coos Bay. Dredging of the berm separating the portion of slip from the bay and the access channel will result in temporary siltation and sedimentation impacts similar to those that currently occur during maintenance dredging activities. The dredging activity will occur only during the in-water work window established by ODFW.

On average, the USACE removes approximately 550,000 cy from the bar, 200,000 cy from Channel Mile (CM) 2-12 and 150,000 cy from CM 12-15 each year. In comparison, approximately 500,000 cy will be removed in the water during the removal of the berm and dredging of the access channel. Since the duration of the dredging in the bay will be 4-6 months and only during the in-water work window from October 1 to February 15 (ODFW, 2008a), the minimal amount of turbidity created will be relatively short term and localized. Turbidity modeling demonstrated that turbidity levels dropped to near background levels beyond 200 meters (660 feet) of the dredging activity.

Turbidity was modeled for the new construction and maintenance dredging operations based on the anticipated geotechnical and environmental conditions for this project using the United States Army Corps of Engineers (USACE) DREDGE model and two dimensional numerical model Mike21 (see discussion in Section 4.5.1.3, green sturgeon). During the project construction period, the maximum modeled suspended sediment concentrations (primarily sand) produced by the DREDGE model for an open “clamshell” dredge were less than 6,000 mg/L at the dredge location and decreased to less than 50 mg/L at 200 m (approximately 660 feet). For the hydraulic cutterhead dredge the TSS levels were significantly lower with maximum of 500 mg/L in the vicinity of the dredge. The TSS concentrations decreased to a maximum of 14 mg/L at 60 meters (200 ft) away from the dredge vicinity.

During the project maintenance dredging period, the dredged material is expected to be primarily fines (mud, clay, silt). Concentration predicted with the DREDGE model for the open “clamshell” dredge were lower than during the construction stage with the maximum of 830 mg/l in vicinity of the dredge and decreasing to 125 mg/l at 200 m (approximately 660 feet). The results from the Mike21 simulations show that distribution of the generated plume depends on location of the dredge in the channel and basin area. For dredging with an open “clamshell” dredge in the channel the generated sediment plume (concentration higher than 150 mg/l) can move up to 1.2–1.9 miles from the dredging location at highest ebb or flood currents; however, the duration of such entrainment is limited by not more than a two hour period and the time average concentrations do not exceed natural ambient concentrations (10–30 mg/l) outside the dredging area. During maintenance dredging with an open “clamshell” dredge, the maximum concentrations in the generated plume do not exceed 50 mg/L. Based on these results it is not anticipated that turbidity generation at the dredging site will be an adverse effect to Oregon Coast coho.

**Turbidity Effects –Propeller Wash and Ship Wake**

Propeller wash from LNG vessels and tug boat propellers associated with the Project, as well as ship wakes breaking on shore, could cause increased erosion along the shoreline and re-suspend the eroded material within the water column. This may affect the diversity and health of the benthic community regarding food availability and feeding conditions for foraging and migrating fish species (see discussion in Section 4.5.1.3, green sturgeon).

Hydrodynamic effects from pressure field velocities measured along the sensitive shoreline from existing deep-draft vessels exceed the pressure field velocities that may be generated by future LNG carriers. The USCG has mandated that all LNG carriers be escorted by a minimum of two tractor tugs which allows the LNG carrier to transit at a lower speed than the existing vessels which transit without tug assist. Vessel velocity, rather than size, has a much greater impact on the amplitude of the pressure wave which would be less impact on coastal process at the sensitive shoreline by LNG carriers than from the existing deep-draft vessels using the estuary.

The results of the swash transport calculations generated by vessel wake effects (see discussion in Section 4.5.1.3, green sturgeon) show a small increase in wake-generated swash sediment transport at the areas of interest due to LNG carriers. The results show that the increase in swash sediment transport from combined inbound and outbound carrier traffic would not exceed six percent at Pigeon Point, eight percent at Clam Island, and five percent at the Airport sensitive shorelines. The total sediment transport for future inbound and outbound LNG carrier traffic will be less than eight percent of the existing and future wind-wave swash sediment transport. The estimated increase in swash sediment transport due to the LNG carrier traffic is a small fraction of the swash sediment transport due to the natural wind-wave conditions. This increase most likely would not be detected in a general balance of swash sediment transport due to yearly variability of wind-wave conditions and swash sediment transport. Based on these results it is not anticipated that suspended sediment generated by propeller wash and ship wake will be adverse effects to Oregon Coast coho.

**Turbidity Effects – Pipeline Construction**

Pacific Connector will construct the proposed pipeline across Haynes Inlet between October 1 and February 15, the in-water construction period recommended by ODFW (2008). It is possible that adult and/or juvenile coho would be present in the Coos Bay estuary during pipeline construction across Haynes Inlet. Construction would increase turbidity in the immediate vicinity of the construction right-of-way across Haynes Inlet but coho, if present, would be expected to avoid local turbid conditions. Natural turbidity in the Coos Bay estuary was judged to be higher at upper bay locations, away from water influx from the ocean (Moffatt and Nichol, 2006). Modeled turbidity due to dredging in Coos Bay suggests a very narrow range of elevated suspended sediment (>100 mg/L) during low tidal velocity extending a few hundred feet from the dredge, while during typical tidal cycle values were as high as 50 mg/L from 0.2 to 0.3 mile away from the dredge. Moderately low values of 25 to 50 mg/L may extend out to about 3.5 miles depending on flow, sediment, and equipment used (Moffatt and Nichol, 2006). Sediment concentrations from pipeline trenching in Haynes Inlet would be similar to winter background levels for much of the construction period and few fish would be near the highest plume concentration due to active avoidance.

Trench excavation to install the pipeline in the bay would bury, displace, or injure benthic organisms (see discussion in Section 4.5.1.3, green sturgeon). However, benthic communities on mud substrates in Coos Bay that had been disturbed by previous dredging activities recovered to pre-dredging levels in four weeks (Newell et al., 1998). Some impacts may be long-term if important habitat elements are affected, such as the effects of turbidity on eelgrass growth (Martin and Tyrrel, 2002). Based on the survey of the route in 2008, there were about 1.0 acre of eelgrass beds that will be directly affected by the construction right-of-way (including temporary extra work areas - TEWAs). Most of the area affected would be low density eel grass, and none were categorized as high-density eel grass. Approximately 0.1 percent of the total eelgrass beds present in Coos Bay would be directly disturbed from pipeline construction across Haynes Inlet (Ellis Ecological Services, 2013).

The pipeline will cross the Coos River using a HDD (see discussion, below, under Riverine Analysis Area) and will cross Catching Slough using a conventional bore. Other waterbodies within critical habitat will be crossed by dry-open cut construction between July 1 and September 15, the recommended in-water construction dates for Boone Creek, Catching Slough, Monkey Gulch, and Stock Slough (ODFW, 2008a). Sediment released during dry open-cut construction is generally restricted to short-term peaks associated with installation and removal of isolation (temporary dams) and bypass structures (see discussion, below, sediment effects under Riverine Analysis Area). Estuarine environments often have moderately elevated suspended sediment concentrations (i.e. >15 mg/L) and they are very productive (Gregory and Northcote, 1993). The amount of sediment produced by open cutting depends on multiple characteristics at the construction site including depth and width of the waterbody (effects mixing of the sediment plume in the water column), current velocity and local turbulence at the site and downstream, concentrations of suspended sediment initially at the site and at some distance downstream, particle diameter, specific weight, and settling velocity of the excavated and backfilled materials (Ritter, 1984; Reid et al., 2004). Based on sediment transport modeling, dispersal of the exposed and disturbed sediments will be very minor in intertidal areas of Haynes Inlet due to the low water velocities and sediment composition in that area and turbidity is not expected to adversely affect coho salmon.

**Stormwater Discharge at LNG Terminal**

Stormwater discharge has the potential to contain chemicals toxic to coho salmon. However the NPDES permit that the applicant would be obtained requires discharges to not modify state water quality standards of the receiving water (see discussion in Section 4.5.1.3, green sturgeon). The proposed oil and grease treatment system is designed to limit discharges of oil and grease to no more than 15 mg/l daily maximum. This system design would ultimately need approval from the State to obtain the NPDES permit (see discussion in Section 4.5.1.3, green sturgeon).

The exact levels of other runoff chemicals can not be predicted at this time. However Washington State, in a review of all of their permitted monitored stormwater discharge facilities, found that copper and zinc, two chemicals commonly of concern to aquatic organisms, were relatively high often exceeding benchmark standards (WDOE, 2009). They noted that the sources of metals pollution include oils and lubricants from motor vehicles, tire dust, brake pad dust, raw material and products, and exposed galvanized metal surfaces on buildings, fences, and equipment (see discussion in Section 4.5.1.3, green sturgeon). Juvenile coho salmon are sensitive to both copper and zinc in fairly low concentrations; downstream migrations were affected in individuals exposed to dissolved copper (Lorz et al., 1978); dissolved copper affects behaviors involved in growth reproduction, and predator avoidance all of which contribute to survival Hecht et al., 2007). Deaths of juveniles were attributed to exposure to copper and zinc when fish were challenged with seawater (Lorz et al., 1978). However, only adult and sub-adult Oregon Coast coho would potentially be exposed to metal components in stormwater discharge and exposure effects to adults are unlikely.

**Stranding from Ship Wake and Propeller Wash**

Fish stranding can occur when fish become caught in a vessel's wake and are deposited on shore by the wave generated by the vessel wake. Stranding typically results in mortality unless another wave carries the fish back into the water. A series of interlinked factors act together to produce stranding during vessel traffic and may include water surface elevations, with low tides more likely to result in strandings than high tide; beach slope, with strandings more likely on low gradients than high; wake characteristics influenced by vessel size, hull form, depth underwater (draught), and speed; and biological factors, such as numbers of small fish present near the shoreline and whether fish are strong swimmers or not (see discussion in Section 4.5.1.3, green sturgeon). Size of juvenile coho in the estuary are expected to be comparable to sizes of juvenile chinook salmon (<9 cm) which became stranded by ship wakes in the Columbia River (Pearson et al., 2006); juvenile coho may be susceptible to stranding by ship wake.

Ship wakes produced by deep-draft vessels traveling at speeds greater than the estimates for LNG carrier speeds within the Coos Bay estuary have been observed to cause occasional stranding of juvenile salmon (Pearson et al., 2006); however, no strandings were observed as a result of vessels traveling at speeds under 9 knots (10.4 mph). The hull geometry of the LNG carriers is such that bow wakes are minimized, especially at the slower speeds of 4 to 6 knots that would occur during most of the transit route through Coos Bay. Therefore, the LNG carriers would be traveling at speeds less than that observed (Pearson et al., 2006) to cause stranding. In models and research conducted by the JCEP, wave heights produced by LNG carrier traffic would not exceed that of normal conditions in Coos Bay and overall waves would contribute to a small portion of the total waves that occur in the bay. In addition, the LNG carriers would be arriving and leaving at high tide, which is a period when gently sloping beaches are mostly covered and less likely dewatered from waves. Considering that LNG marine traffic would enter and leave at high slack tide, have low vessel speeds, and wave height would be in normal range, it appears unlikely that the Project would contribute to stranding of Oregon Coast coho within Coos Bay.

Exotic, Invasive Species

There are no current studies that evaluate the impact of introduced fishes on coho salmon (ODFW, 2005b). The introduced species, striped bass and shad, presents the highest risk of impact to coho salmon in the Coos Bay Estuary (ODFW, 2005b). However, navigational dredging within Coos Bay has altered salinity levels which have impacted striped bass egg and larval survival, reducing numbers and threat of striped bass predation on coho.

Loaded with water from the surrounding ports and coastal waters throughout the world, ships can carry a diverse assemblage of marine organisms in ballast water that may be foreign and exotic to the ship's port of destination. The transfer of water from port-to-port can result in aquatic biological invasions. Invasive species threaten to outcompete and exclude native species and the overall health of an ecosystem, causing algal blooms and hypoxic conditions and affecting all trophic levels resulting in a decline in biodiversity. Invasions of zebra mussel (*Dreissena polymorpha*), Chinese mitten crab (*Eriocheir sinensis*), and hydrilla (*Hydrilla verticillata*) can potentially affect Oregon Coast coho (Stout et al., 2012). For example, Oregon Coast coho smolts during out-migration consume a mudshrimp (*Upogebia pugettensis*), the major food sources in Yaquina Bay (Stout et al., 2012). These intertidal benthic invertebrates have been dramatically affected by the recently introduced isopod parasite (*Orthione griffenis*), likely introduced from Asia in the 1980s (Dumbauld et al., 2011).

Ballast water from ships' precedent ports would be emptied and exchanged with ocean seawater approximately 200 nmi offshore, at the outer edge of the EEZ. The ballast water exchange (BWE) process is mandatory under the National Ballast Water Management Program – originally established by Nonindigenous Aquatic Nuisance Prevention and Control Act of 1990 and further amended by National Invasive Species Act of 1996 and National Aquatic Invasive Species Act of 2003 – amended in 2005 and again in 2007. On March 23, 2012, the USCG issued its Rule regarding Standards for Living Organisms in Ships' Ballast Water Management Discharged in U.S. Waters, which amends the existing regulations and creates a standard for the allowable concentration of living organisms in ballast water discharged in U.S. waters consistent with the International Maritime Organization's International Convention for the Control and Management of Ship's Ballast Water and Sediments (BWM Conventions). This Rule will require all vessels equipped with ballast tanks bound for (or departing) U.S. ports to utilize at least one Ballast Water Management method described in the Rule (77 FR 17254). The most likely convention given the advanced technologies used by LNG carriers will involve a complete BWE in an area 200 nautical miles from any shore prior to discharging ballast water.

LNG ships will discharge ballast concurrently with the LNG cargo loading at the LNG terminal. The amount of ballast water discharged must, at a minimum, be adequate to maintain the LNG ship in a positive stability condition and with an adequate operating draft while the LNG cargo is loaded. The ballast water discharged at the terminal will be that from 200 miles out in the open sea as occurred as part of the mandated BWE process to eliminate or minimize risks of introducing exotic, invasive species.

Entrainment and Impingement

LNG carriers would re-circulate water while loading LNG at the berth and the amount of cooling water to be re-circulated is a function of the propulsion system for the vessels. Once the LNG fleet has been identified, cooling water flow rates and the amount of water required can be further addressed. It is likely that some organisms small enough to pass through the screens covering the carrier's intake port will be drawn in with the cooling water and will be lost from the population in the slip area; however, it is anticipated that the effect associated with the intake of cooling water will be minimal. Juvenile fish would need to be present in the slip area near the carrier's intake screens and be small enough to fit through the sea chests which are covered with screens composed of 4.5 mm thick bars spaced 24 mm apart and located approximately 32 feet below the water line, or 5.6 feet from the keel of the LNG carrier. The intake velocities for cooling water are low enough that it is not anticipated that any larger organisms (fish, marine mammals, or invertebrates) would be impinged on the intake screen. Generally the total water intake would occur over a 24-hour period during each loading period, about 90 times per year.

The LNG ships will also re-circulate water for engine cooling while loading LNG at the berth. The power requirements for loading LNG in the export mode are less than those for unloading LNG in the import mode because the LNG carrier does not have to use on board LNG pumps to handle LNG cargo; hence both the LNG carrier engine requirement and the required amount of cooling water flow are reduced. For reasons discussed in Section 4.5.1.3, green sturgeon, it is anticipated that the effect associated with the intake of cooling water will be minimal. The intake velocities for the cooling water are low enough that it is not anticipated that any larger organisms (fish, marine mammals and reptiles or amphibians) will be impinged on the intake screen.

Water Cooling

The LNG ships will also re-circulate water for engine cooling while loading LNG at the berth. The engines will be running to provide power for standard hotelling activities as well as running the ballast water pumps. The activities that will require LNG carrier power and the assumptions used to develop the cooling water flow requirements are as follows:

- Hotelling operations require the generation of 1.9 MW of power during the entire time that the LNG carrier remains in the slip. The vessel is anticipated to be within the slip for a total of 17.5 hours.
- A typical auxiliary power unit for an LNG carrier is the Wartsila 34DF. This is a dual fuel (liquid and natural gas) unit that is a complete primary driver/generator package capable of being sized upwards to 6.9 MW output. Fuel to power conversion is 7,700 kilojoules (kJ) per kilowatt-hour (kWh) (kJ/kWh) (7,305 British thermal units (Btu) per kWh (Btu/kWh)). This system has an overall fuel to power efficiency of 46.7 percent, thereby resulting in the rejection of 3,893 Btu of heat into the cooling water for each kWh of power generated.

- All calculations that follow are based upon the transfer of 148,000 $m^3$ of LNG from the LNG storage tanks to the LNG carrier. The 148,000 $m^3$ carrier is set as the basis because it represents the largest vessel authorized to call on the LNG Terminal.

The total gross waste heat discharged into the slip from the cooling water stream will be due primarily from the hotelling operations (including the power required to run the ballast water discharge pumps) as the shore side LNG pumps will be used to transfer the LNG from the LNG storage tanks to the LNG carrier. The hotelling operations were assumed to be as follows:

- Hotelling Operations -17.5 total hours x 1,900 kW x 3,983 Btu/kWh = 132.5 million Btu (MMBtu). The total amount of heat discharged into the slip during each vessel call is approximately 132.5 MMBtu.

Because of the extreme differential of the temperature of the cargo in the LNG carrier (-260$^{o}$F) and that of the surrounding air and water (nominally 45$^{o}$F) there is a constant uptake of heat by the LNG carrier from its surroundings. This heat uptake is manifested by the amount of LNG cargo that changes state from liquid to vapor on a daily basis. The typical LNG carrier sees 0.25 percent of its liquid cargo converted to the gaseous state each 24 hours. In this process 219 Btu of heat is absorbed for each pound of LNG converted to vapor. This results in a total of 53 MMBtu absorbed by a typical 148,0000 $m^3$ LNG carrier during the 17.5 hours it is within the slip. Given the distribution of vessel surfaces between those surfaces in contact with water as opposed to those surfaces in contact with air it is reasonable to assume that 50 percent or more of the heat take up by the vessel is extracted from the water. This assumption is further reinforced by the fact that the heat transfer coefficient between water and steel is significantly higher than the heat transfer coefficient between air and steel. Applying this allocation of heat absorption sources results in having 26.5 MMBtu being removed from the slip by the LNG vessel during its stay. Thus a portion of the 132.5 MMBtu of thermal energy discharged into the slip from the cooling water is offset by the uptake of 26 MMBtu by the LNG vessel itself, resulting in a net heat input to the slip of 106.5 MMBtu per 148,000 $m^3$ LNG carrier call.

Analysis and numerical modeling were performed to identify potential impacts of LNG carrier cooling water discharge on water quality in the slip and adjacent area of Coos Bay. The modeling was initially performed with two different numerical models: the 3-D UM3 model and the DKHW model. The models simulate hydrodynamic mixing processes of submerged discharges and predict temperature fields and dispersion of non-conserved substances in ambient water bodies. Cooling water numerical modeling requires input of steady-state flow velocity in the modeling domain. The results of tidal flowing modeling using the SELFE model showed that ambient current velocities inside the LNG Terminal area vary, depending on tidal stage. Peak current speeds in the berth only exceed approximately 0.32 ft/sec less than two percent of the time. Therefore, for cooling water modeling, two steady state ambient flow velocities were assumed and used further in the analysis: high velocity = 0.32 ft/sec and typical velocity = 0.16 ft/sec.

The following conservative assumptions were used in the analysis. The assumptions are conservative in that a steam powered ship was used. The steam powered ships tend to be older than the newer more modern dual fuel diesel electric ships that require lower quantities of cooling water.

- LNG carriers are steam-powered with a cargo capacity of 148,000 $m^3$.

- Maximum pump capacity for main condenser cooling is 10,000 $m^3$/hr (44,030 gpm) and maximum pump capacity for LNG carrier's equipment cooling is 3,000 $m^3$/hr (13,209 gpm). Total capacity being used at a given time is typically in the range of 6,300 $m^3$/hr (27,739 gpm). For the analysis, 6,300 $m^3$/hr (27,739 gpm) was used.
- Diameter of the horizontal discharge port is 1.1 meters (3.6 feet).
- Depth of discharge port below still water is 10.0 meters (32.8 feet).
- Maximum heating of cooling water at time of discharge is 3 ºC (5.4 ºF) above ambient temperature.

Results of the modeling showed that for typical ambient flow conditions at a distance of 50 feet from the discharge point (LNG carrier sea chest), temperatures will not exceed 0.3 ºC (0.54 ºF) above the ambient temperature. This difference will decrease with further distance.

<u>Effects of Operational Lighting</u>

Localized changes in light regime have been shown to affect fish species behavior in a variety of ways (Simenstad et al., 1999; Valdimarsson et al., 1997; Tabor et al., 2004, Nightingale and Simenstad 2001). Disorientation may cause delays in migration, while avoidance responses may cause diversion of migratory routes into deeper, less protected waters. In some cases, increased light may attract both predators and potential prey species (Simenstad et al. 1999; Valdimarsson et al. 1997; Tabor et al. 2004).

Lighting at the LNG Terminal and onshore facilities would likely include a mixture of low-power fluorescent lighting and higher intensity security lighting that would primarily be located on shore, in and adjacent to the slip. When an LNG carrier is not in the berth, the lighting would be reduced to that required for security. It would be focused upon the structures and not be in proximity to the water so as to serve as an attractant or deterrent to fish species. When an LNG carrier is at the berth, it would physically block the lighting on the berth from the slip waters and, due to its proximity to the slip wall, would block the fish from getting too close to the lighting on the berth. Lighting used would be similar to that already in place at other Coos Bay facilities.

Lighting on the tug dock would be low intensity lighting for safety, providing sufficient light for personnel movements on the trestle out to the tug berth and for movement on the berth itself. There is no intention to provide lighting near the water line or high intensity lighting that would be associated with activities other than the simple berthing of the tugs at this location. The reduced lighting levels near the water would reduce or eliminate any behavioral effects to fish in the Project vicinity. Increased lighting from facility operations are not expected to significantly affect coho salmon in the Oregon Coast ESU.

**Acoustic Effects**

Underwater noise may affect coho salmon. Prior to the excavation work starting for the LNG carrier slip, an open cell sheet pile bulkhead and retaining wall will be installed. The sheetpile system will serve as a retaining wall for the shoreline on the east side and support the LNG ship loading dock and associated berthing and mooring facilities. The open cell sheet pile wall system consists of face sheetpiles for retaining the soils as well as tailwalls for anchorage of the retaining wall. All sheetpiles and tailwalls will be driven from the land while the slip construction activities are isolated from Coos Bay.

Underwater noise may be generated by driving sheet piles on land (dry piles) since some noise propagates through ground and sediments (especially through harder substrates such as rock and clay), and may transfer to the water column somewhere else (known as sound flanking). Sound in the water column would be at a lower level than at the source (Washington State Department of Transportation, 2011a) since most sound energy does not travel through water but through the sediment. There would be minimal chance that driving pilings on land could physically injure fish from the impact of percussive sound pressure in the same way as driving piles in water (see Popper, et al. 2006).

**Indirect Effects – Estuarine Analysis Area**

Project-related indirect effects to Oregon Coast coho would be caused by the action (induced by the action as human presence and use increase), and are later in time or farther removed in distance, but are still reasonably foreseeable include the following: 1) localized reduction of benthic and epibenthic invertebrates, 2) removal of eelgrass, and 3) shading the water surface by overhead structures.

**Habitat Effects –Slip and Access Channel**

Benthic and epibenthic invertebrates that presently inhabit shallow intertidal and subtidal regions within the boundaries of the proposed access channel dredging area would be removed with the dredged material. Ghost shrimp and sand shrimp (adults, juveniles and larvae), amphipods, clams, Dungeness crab, and various fish species are important prey for Oregon Coast coho. Therefore, the loss of invertebrates and vertebrates at the access channel would result in a reduction in fish food available to coho salmon in those areas affected by the Project.

As noted above, benthic communities in Coos Bay inhabiting mud substrates recovered to pre-dredging conditions in four weeks (Newell et al., 1998). Although the substrate proposed for maintenance dredging in the access channel and berth would largely be sand and silt, it is anticipated that recovery would occur within a similar time frame, resulting in only short-term effects to the benthic community and potential food resources for Oregon Coast coho.

**Habitat Effects – Pacific Connector pipeline**

Construction of the pipeline across the Haynes Inlet of Coos Bay estuary would span 2.45 miles and disturb approximately 0.068 mile of eelgrass or 2.8 percent of that amount, most of which classified as low-density eelgrass beds. Eelgrass can be adversely affected by turbidity because the depth and distribution of eelgrass is strongly associated with water clarity and depth of light penetration (Dennison and Orth, 1993; Thom et al., 1998) as well as nutrient availability (Short et al., 1995), salinity, and water temperatures (Thom et al., 2003). Construction of the pipeline across the estuary is planned from October 1 through February 15 following ODFW's recommendation. During most of that period, eelgrass in Coos Bay would be dormant, coinciding with low temperatures and short photoperiods (Fonseca et al., 1998).

Ellis Ecological Services, Inc. (2013) conducted a survey of eelgrass beds within Coos Bay along the pipeline route. Based on the survey of the route in 2013, there was 5.0 acres of eelgrass beds that will be directly affected by the construction right-of-way (including temporary extra work areas - TEWAs). Eelgrass beds were placed into three categories based on density: low, medium, and high. Most of the area affected would be low density, and none were categorized as high-density eelgrass. Approximately 0.1 percent of the total eelgrass beds present in Coos Bay would be directly disturbed from pipeline construction across Haynes Inlet (Ellis Ecological Services, 2013). During in-water pipeline installation within Coos Bay, fish and other aquatic resources could be impacted. The current pipeline route in the bay will cross 2.5 miles and disturb approximately 75.6 acres (33.2 acres of subtidal and 36.25 acres of mud/sandflats) of habitats.

**Shading Effects**

Shading from over-water structures reduces the amount of light available to phytoplankton and aquatic macrophytes. However, the area where shading LNG terminal facilities would occur is intended for industrial uses and not the creation of new habitat. The general habitat in the slip's region would not be conducive for many marine resources because of depth and steep rip/raped armored banks, so relatively few resources would likely utilize this newly created area. The water areas within the slip are being created from upland areas and therefore shading of currently un-shaded habitat would occur, and no net loss in productivity due to shading would occur. Project components that potentially could shade the new open water created by the construction of the slip include:

- At the proposed slip, the access gangway to the LNG facility is narrow and well above the water surface and would have open mesh grating. Shade produced by the gangway is expected to be biologically insignificant.
- The unloading platform for the LNG facility is 60 feet wide and would be located at an elevation of +30 feet NAVD88. Because the platform is located offshore in deep water, no shading of shallow water habitat would occur.
- The tug dock is the only structure to be built over open water portion of the newly developed slip and it is 400 feet long by 12 feet wide. Shading would be minimized by open mesh grating, which is now commonly used on piers to reduce effects to marine resources from shading.
- The tug dock would be connected from shore by a narrow gangway. The dock would be 12 feet in width and located at +12 feet NAVD88. This too would have open mesh grating to reduce shading. Consequently, shading impacts would be small and probably insignificant.

Most fish, including coho salmon, have developed countershading as an adaptation to avoid predation (Moyle and Cech 2000) from above (dark dorsal surface blends with bottom substrate) and from below (light ventral surface blends with light from the surface). Fish within a shaded area would be more easily detected by a predator, especially from below because light colored ventral surfaces would stand out against a shaded water surface. Predation potential, based on some observed fish behavior, is a concern (Nightingale and Simenstad, 2001). However actual increased occurrence in predator numbers from even substantial overwater structures has rarely been documented. Additionally review of many marina and pier studies have not documented actual increased predation at these facilities (Nightingale and Simenstad, 2001). For example, marine marina studies have found no documentation of increased concentrations of juvenile salmonid predators and some predators such as birds may be of lower abundance than under natural shoreline conditions (Cardwell et al., 1980, and Heiser and Finn, 1970, as cited in NMFS, 2005c). The extent to which any of these predators affect juvenile or adult coho salmon in shaded areas created by the proposed action is unknown. But the actions taken (open mesh grating of all structures) should reduce the probability of this occurring.

**Direct Effects – Riverine Analysis Area**

The pipeline route will cross 2.40 miles of estuarine habitat in Coos Bay and would actually cross 150 of the waterbodies in table 4.5.4-3 (summarized below in table 4.5.4-10), 144 of them by dry open cutting, while the South Umpqua River would be crossed twice, once by a Direct Pipe crossing at MP 71.30 and again by a diverted open cut at MP 94.73. Kentuck Slough would be crossed by a conventional bore at MP 6.28R, Catching Slough would also be bored at MP 11.11, and the Coos River would be crossed using HDD at MP 11.13R. The Coos Bay estuary would be crossed by using a wet open cut procedure. Twenty-two of the waterbodies listed above in 4.5.4-3 and summarized in table 4.5.4-10 would not be crossed by the pipeline but are adjacent to the pipeline centerline. Blasting may be necessary to construct across 30 streams that would be crossed by dry open cut methods (see Project Description) because the streambed of each is bedrock (see table 4.5.4-3 and table 4.5.4-10).

**Table 4.5.4-10**
**Proposed Pipeline Construction Methods for Crossing Waterbodies within Sub-basins and 5th Field Watersheds Coinciding With the Proposed Pipeline Route and coho in the Oregon Coast ESU.**

| Sub-basins and 5th Field Watersheds | Number of Waterbodies with Construction Method | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| | HDD or Direct Pipe | Bore | Wet Open-Cut | Diverted Open-Cut | Dry Open-Cut | Total Crossed | Adjacent Not Crossed[1] | Bedrock [2] |
| **Coos Sub-basin** | | | | | | | | |
| Coos Bay-Frontal Pacific Ocean | 1 | 2 | 1 | | 52 | **56** | 10 | 1 |
| **Coquille Sub-basin** | | | | | | | | |
| Coquille River | | | | | 6 | **6** | | 2 |
| North Fork Coquille River | | | | | 11 | **11** | 2 | 3 |
| East Fork Coquille River | | | | | 13 | **13** | 1 | 5 |

| **TOTAL** | **2** | **2** | **1** | **1** | **144** | **150** | **22** | **30** |

1 Waterbodies within the construction right-of-way that will not be crossed
2 Bedrock streambeds will be crossed by dry open-cuts but may require special construction techniques to ensure pipeline design depth including rock hammering, drilling and hammering, or blasting. The need for blasting would be determined by the contractor and would only be initiated after ODFW blasting permits are obtained.

All affected waterbodies within the three sub-basins and 10 fifth field watersheds that are within the range of Oregon Coast coho salmon ESU proximate to the Pacific Connector pipeline are included in table 4.5.4-10. There are 172 waterbodies included in the table, of which 85 are perennial, 85 are intermittent, 1 is an estuary and another is a pond (see table 4.5.4-2, above).

The PCGP Project would cross 61 waterbodies which are known or presumed to be inhabited by coho salmon in the Oregon Coast ESU (see table 4.5.4-1, above). Effects by the project could occur to freshwater in-water construction activities, terrestrial/riparian habitat modification, accidental spills or leaks of hazardous materials, and periodic maintenance of the pipeline. Construction of the PCGP Project could directly and/or indirectly affect Oregon Coast coho salmon and critical habitat through one or more of the following pathways:

- Interference with key life history functions for native species.
- Acoustic shock from blasting pipe trench through bedrock streambeds or use of a track hoe or impact hammer if fish are proximate to the construction site.
- Turbidity generated during pipeline construction across waterbodies can adversely affect coho and aquatic habitats.
- Introduction and/or re-distribution of aquatic nuisance species

- Removal of riparian vegetation that can reduce shade (which could increase water temperatures), limit streambank stability, and affect recruitment of LWD.
- Accidental release of fuels and entry of other petroleum products into surface waters can adversely affect coho and other aquatic organisms.
- Application of herbicides to control noxious weeds near waterbodies may adversely affect coho.

**Timing**

Pacific Connector will cross fish-bearing waterbodies within the Oregon Coast coho ESU to prevent construction during periods of sensitive fish use and would typically allow construction only in periods of lower flow rates in streams. Within Haynes Inlet, Pacific Connector would limit pipeline trenching and other in-water activities to the October 1 through February 15 in-water work window recommended by ODFW. Timing of in-water work for the Coos Bay Estuary and Coos River (upstream to Millicoma-South Coos River confluence) is from October 1 to February 15 (ODFW, 2008a), which coincides with adult upstream migrations of coho (see figure 4.5-13, above). The ODFW (2008a) instream construction window for coastal tributaries, the Coquille River and tributaries, and tributaries to the South Umpqua River is July 1 to September 15. Instream work within the South Umpqua River mainstem is permitted from July 1 to August 31.

In general, construction of the pipeline would be timed to miss periods of major juvenile or adult migrations in freshwater based on allowed fishery construction windows, typically July 1 to mid-September for most streams, and some other dates for specific waterbodies. Timing of in-water work in aquatic habitats within the Coquille and South Umpqua sub-basins generally coincide with low flows and high water temperatures during summer and early autumn, discussed above in Section 4.5.4.2 (see figure 4.5-16, Coos Sub-basin; figure 4.5-17, Coquille Sub-basin; figure 4.5-18, and South Umpqua Sub-basin). The instream construction windows coincide with upstream adult migration by coho. Construction across waterbodies within the Coquille and South Umpqua sub-basins would be completed before spawning (see figure 4.5-13). However, juvenile coho would be present and migrating adults might be present within waterbodies flowing at the time of construction.

**Acoustic Shock**

There are 30 waterbodies within the Oregon Coast coho ESU where shallow bedrock may occur where potential blasting and/or mounted impact hammers may be required to construct a trench through bedrock substrates (see table 4.5.4-3, summarized above in table 4.5.4-10). Explosives detonated near water produce shock waves that can be lethal to fish, eggs, and larvae by rupturing swim bladders and addling egg sacs (British Columbia Ministry of Transportation, 2000). Explosives detonated underground produce two modes of seismic wave (Alaska Department of Fish and Game, ADFG, 1991), 1) body waves that are propagated as compressional primary (P) waves and shear secondary (S) waves, and 2) surface waves produced when a body wave travels to the earth surface and is reflected back. Shock waves propagated from ground to water are less lethal to fish than those from in-water explosions because some energy is reflected or lost at ground-water interface (ADFG, 1991). Peak overpressures as low as 7.2 pounds per square inch (psi) produced by blasting on a gravel/boulder beach caused 40 percent mortality in coho salmon smolts and other studies revealed 50 percent mortality in smolts with peak overpressures ranging from 19.3 to 21.0 psi (ADFG, 1991).

The best approach to protect fish species is to limit the instantaneous hydrostatic pressure change (resulting from nearby blasting) to levels below those known to be harmful to fish (see discussion above in Section 4.5.3.3 for coho salmon SONCC ESU). Pacific Connector may opt to blast across stream locations where consolidated rock makes traditional trenching methods unfeasible. Typical trench blasting scenarios use multiple 1- to 2-pound charges separated by an 8-milisecond delay to excavate the trench. With use of using 1- to 2-pound charges in rock, the set back distance (at which 2.7 psi would occur) from the blast trench to the fish habitat is between 34 and 49 feet (see Table 3, in ADFG, 1991). Blasting would be conducted within dry streambanks isolated from the water column, most likely using dam-and-pump construction to bypass water around the dry workspace.

Several approaches have been suggested to reduce risk of injury or mortality to fish in closest proximity to blasting locations (Wright and Hopky, 1998):

- deployment of bubble curtains/air curtains to disrupt the shock wave;
- deployment of noise generating devices, such as an air compressor discharge line, to scare fish away from the site; or
- removal or exclusion of fish from the work area before the blast occurs.

A Fish Salvage Plan is provided in appendix T. The plan includes measures to exclude fish and prevent them from re-entering isolated portions within waterbodies crossed for distances sufficient to avoid or minimize adverse effects by blasting bedrock in streambeds.

<u>Underwater Noise</u>

Impulsive type sounds, sound generated by pile driving for example, create stress waves in the piling material that radiate sound through the surrounding media of substrate, air, and water and may propagate outward from the source through bottom sediment (Popper and Hastings, 2009). Various studies have reported fish mortality, physical injury, auditory tissue damage, decreased viability of eggs, and decreased larval growth due to noise, mostly explosive blasts, seismic survey blasts, and air gun blasts (Hastings and Popper, 2005). State agencies in Washington, Oregon, and California, along with federal agencies have developed interim noise exposure threshold criteria for pile driving effects on fish (Washington State Department of Transportation, 2011a; Popper et al., 2006, and see discussion above in Section 4.5.3.3 for coho salmon SONCC ESU). The threshold noise levels are assumed to be applicable to noise from a mounted impact hammer operating on bedrock substrates for 30 waterbodies potentially affected by the PCGP Project in the Coos, Coquille, and South Umpqua sub-basins (see table 4.5.4-9, above).

Average maximum noise produced by mounted impact hammers due to impact on substrates (eg, rock) has been reported at 90 dBA from 50 feet away in the air (see Table 7-4 in Washington State Department of Transportation, 2011a). Using a simplified conversion of dB between air and water (see footnotes and discussion above in Section 4.5.3.3 for coho salmon SONCC ESU) the noise produced by the impact hammer in air would be equivalent to about 182 dB re: 1 µPa @ 1 meter in water. However, there is no information available to determine whether that noise level would be equivalent to peak sound levels or root mean square (RMS) levels, which are the basis for evaluating potential harm to fish, particularly related to cumulative sound exposure levels caused by multiple impact hammer strikes.

Further, the estimate of noise produced by in-water use of an impact hammer in any waterbody would be influenced by water currents, water depth, and bottom material and topography, as well as configuration and materials of the river banks. The effects of these factors are unknown (Washington State Department of Transportation, 2011a). However, noise propagation in any waterbody, upstream and downstream from the construction site will be limited by the stream channels' sinuosity since the propagation is limited to straight-line distance from the source (Washington State Department of Transportation, 2011a). Noise produced by impact hammers will be much reduced if construction does not occur within the water column, similar to reduction set back distances from the blast trench to the fish habitat to reduce blast overpressures to below 2.7 psi, discussed above.

Sounds produced by a mounted impact hammer operating in dry conditions might be conducted through bedrock substrate to approach the hearing threshold of fish, as for example the Atlantic salmon, which is around 90 dB re: 1 µPa (see Figure 3 in Hastings and Popper, 2005). It is assumed that salmonids in the PCGP Project area at the time of construction will have hearing thresholds similar to Atlantic salmon. With that assumption, listed and non-listed salmonids present at the time of construction might detect the noise produced by an impact-hammer striking bedrock, but the noise is not expected to be of sufficient intensity to cause them injury as would SELs produced by pile driving.

**Suspended Sediment**

Salmonids exposed to moderate to high levels of suspended sediment for extended periods could be adversely affected. At high levels, turbidity directly affects survival and growth of salmonids and other species, interferes with gill function, and adversely affects substrate for egg development (reviewed and compiled by Bash et al., 2001). Turbidity can also reduce macrophyte cover (over the long-term) by limiting photosynthesis (Goldsborough and Kemp, 1988), as well as adversely affecting fish vision, which is a requisite for social interactions (Berg and Northcote, 1985), feeding (Vogel and Beauchamp, 1999; Gregory and Northcote, 1993), and predator avoidance (Meager et al., 2006; Miner and Stein, 1996).

Salmonids may avoid areas of increased turbidity levels at 20 mg/L suspended sediment, and possibly lower concentrations depending on length of exposure (Newcombe and Jensen, 1996). The elevated suspended sediment conditions would be short-term during pipeline installation and would not be continuous at any one location. This would reduce the chances of continuous elevated exposure for fish that may move little. Concentrations as low as 17 mg/L have been noted to potentially have some adverse effects (e.g. gill irritation, respiration) for juvenile coho salmon (Wheeler, 2008, based on Berg and Northcote, 1985). Some other studies have found varied effects including lesser effects at these concentrations, with overall effects related to both duration as well as concentration (Newcomb and Jensen, 1996).

Newcombe and Jensen (1996) compiled research from many sources that demonstrate effects to anadromous and resident salmonids by various levels of turbidity and exposure over time. The compiled information was used to develop several models of risks to salmonids and non-salmonids. Input for each of two models (Model 1, juvenile and adult salmonids; Model 3, juvenile salmonids) includes TSS concentration (mg/L) and duration (hours) of exposure to the concentration. Output from each model is a severity-of-ill-effects (SEV) score ranging from 0 to 14 where SEV of 0 indicates no effects, SEV between 1 and 3 indicates behavioral effects, SEV from 4 to 8 indicates sublethal effects, and SEV from 9 through 14 indicate lethal and paralethal effects (see Table 1 in Newcombe and Jensen, 1996).

Before the procedures can be used to evaluate effects of suspended sediment concentrations and variable durations of exposure on fish, there must be some estimate of TSS concentrations generated during construction by the PCGP Project. The following sections develop the information that will lead to estimates of TSS entrained during pipeline construction. The following sections apply to waterbodies crossed by the project, not to the 14 waterbodies (table 4.5.3-2, above) that are adjacent to the pipeline, within construction rights-of-way, and would not be crossed.

Background Turbidity and Suspended Sediment**.** Turbidity, generally reported in Nephelometric Turbidity Units (NTUs), is a measure of the lack of transparency (cloudiness) of water caused by suspended or dissolved substances which cause light to be scattered and adsorbed. Turbidity is often measured on-site using a turbidity meter that measures the scattering of light in a water sample relative to a known range turbidity standards. Turbidity is directly related to the concentration of sediments suspended in water but the relationship between turbidity and suspended sediment is complicated by sediment particle size, particle composition, and water color (Oregon Department of Environmental Quality, 2010).

GeoEngineers (2011a and 2013a) evaluated the potential risk of turbidity increasing during construction of the PCGP across waterbodies. The qualitative evaluation was based on each affected waterbody's hydroperiod, presence of erodible clay and loam soils in streambanks, presence of clay in streambed (suspended clay contributes to turbidity), long-term stability of stream channels, and level/duration of construction effort and stabilization measures likely added at the time of construction. The turbidity risk was scored from 1 (low) to 5 (high). Of 402 canals, ditches, and waterbodies evaluated, 130 were scored with a low risk (score of 1 or 2) of turbidity increase over a 24 hour period, and 272 were scored with a moderate risk (score of 3 or 4), generally due to soil erosion potential, presence of clay or mud, and/or the presence of steep slope or an incised channel that would require construction of a deep trench (GeoEngineers, 2013a). The evaluation concluded that turbidity generated during construction may exceed Oregon water quality standards for short distances and short durations downstream from each stream crossing, either coinciding with construction across perennial waterbodies or in intermittent streams coincidental with autumn precipitation.

Ambient turbidity was not addressed by GeoEngineers (2011a and 2013b). Turbidity (NTU) has been evaluated by ODEQ (2013) and retrieved from Laboratory Analytical Storage and Retrieval (LASAR) Web Application for some of the waterbodies crossed by the PCGP Project. Turbidity within individual streams may be highly variable with highest measurements reported during winter months, usually January through March (see table 4.5.4-11a). During the period coinciding with ODFW (2008a) instream construction windows, reported turbidity has been minimal in streams for which data exists (see table 4.5.4-11b).

**Table 4.5.4-11a**
**Turbidity (NTU) Records Measured by ODEQ during All Times of Year in Waterbodies Crossed by the PCGP Project in the Coos, Coquille, and South Umpqua Sub-Basins and Conversion to TSS by Available Models**

| Sub-Basin | Waterbody | Number of Records | Period of Record | Mean Turbidity (NTU) (Maximum) (Minimum) | Model Conversion to TSS (mg/L) [1] Model 1 Mean TSS (Maximum) (Minimum) | Model 2 Mean TSS (Maximum) (Minimum) | Model 3 Mean TSS (Maximum) (Minimum) | Model 4 Mean TSS (Maximum) (Minimum) |

[1] See footnote to table 4.5.4-11a.

The majority of ODEQ LASAR data are turbidity (NTU) measurements taken in the field. TSS have occasionally been reported but mostly without measuring corresponding turbidity. Relationships between turbidity and suspended solid concentrations are determined on a stream-by-stream basis (Downing, 2008). However, relationships of turbidity to suspended solids have been reported for streams in Alaska (Lloyd, 1987; Lloyd et al., 1987) and streams in the Puget Lowlands (Packman et al., 1999); the models are non-linear. They produce differing estimates of TSS conversions from turbidity and conversions between models are most deviant at higher turbidity levels (see table 4.5.4-11a). At low turbidity levels (see table 4.5.4-11b), conversions of NTUs to TSS are relatively consistent. Based on these conversions, an overall background level of 2 mg/L is assumed for TSS concentrations for all streams crossed by the PCGP Project during the ODFW instream construction window. In support of that assumption, ODEQ (2010) reported that during dry seasons, background turbidity levels are relatively low and consistent in small streams throughout Oregon. A six-year ODEQ ambient monitoring study completed during dry seasons inventoried small wadeable stream sites in Oregon's eight ecoregions and found that overall median turbidity levels were approximately 1 NTU, regardless of lithology (resistant or erodible), or the degree of human disturbance. From the data provided in table 4.5.4-11b, background levels of 1 NTU would average about 2 mg/L or slightly less. A background TSS concentration of 2 mg/L during summer is also consistent with measurements reported by USGS in Myrtle Creek, Big Butte Creek, and the Rogue River mainstem during summers 1977, 1978, and 1979 (historical data provided by USDA-Forest Service).

Sediment in Streambed Substrate. ODFW (1997) conducted stream surveys throughout the state including streams within fifth-field watersheds crossed by the PCGP Project (see Habitat in Section 4.5.4.2, above). Sampled stream reaches were evaluated for 1) average percent sand, silt, and organics in the surface substrate, 2) average percent gravel in the surface substrate, 3) average percent of bedrock in the surface substrate (only reported in reaches sampled after 1999), and 4) the number of boulders ≥0.5 meter in diameter within the sampled reach. We standardized that measurement by converting numbers of boulders to boulders per meter of primary and secondary stream channel lengths. Reported values for fractions of surface area substrates were averaged for all sampled stream reaches within fifth-field watersheds crossed by the PCGP Project; averages are included in table 4.5.4-7 and table 4.5.4-8, above and in appendix X. We assumed that there are equal parts of sand, silt and organics (clay) within the reported average percent sand, silt, and organics fraction; the assumed percent of silt and clay (fine sediments) is included in table 4.5.4-12, below.

As noted, the average percent of bedrock in the surface substrate has only been reported in reaches sampled after 1999 and so summaries of the average bedrock substrate component in watersheds are incomplete or not reported. The average substrate fractions in table 4.5.4-12 were incorporated into analyses of sediment effects on salmonids without modification, even though percentages do not total 100.

We assumed that the average surface substrate fractions reported in ODFW (1997) streams surveys and averaged for all sampled streams within a fifth-field watershed are applicable to other streams in the watershed that would be crossed by the PCGP Project. Sediment generated during dry open-cut construction would most likely be surface sediments disturbed during installation and removal of isolation structures (temporary dams placed upstream and downstream from the workspace) and bypass structures (flume pipe, pump intake and exit conduits). It is not necessary to assume that surface substrate fractions are similar to excavated from the pipeline trench by a track-hoe. The use of dry open-cut construction restricts excavated sediment from entering the water column unless there is some failure of the isolation structures or seals between the stream bed and structures.

Known streambed bedrock has been determined for 30 streams proposed for crossing within the Coos, Coquille, and South Umpqua sub-basins (see table 4.5.4-3 and summarized in table 4.5.4-10) and based on Pacific Connector's Wetland and Waterbody delineation survey. If bedrock is present at the construction site, special construction techniques to ensure pipeline design depth may be required (rock hammering, drilling and hammering, and/or blasting) but only after the workspace has been isolated with temporary dams placed upstream and downstream. Dam-and-pump construction, rather than fluming, would be used at the crossing. Since presence of bedrock mostly or entirely precludes the presence of other surface substrates, other surfaces sediment fractions for streams in fifth-field watersheds in table 4.5.4-12 would not apply to streams with bedrock present.

<u>Suspended Sediment Transport</u>. In part, sediment transport in streams depends on stream channel characteristics. GeoEngineers (2011b and 2013c) developed a database on stream channel characteristics for 96 streams to be crossed by the PCGP Project (values for modeled streams in appendix Y). The streams were representative of each ecoregion and represent the range of widths/gradients and aspects of the stream crossings in each ecoregion traversed by the PCGP project. The database included (but was not limited to) the channel gradient (percent), bankfull width (feet), and streambed material (bedrock, boulder, cobble, gravel, sand, silt, mud, and clay). GeoEngineers (2012 and 2013d) developed additional stream-specific data to evaluate thermal impact on stream water temperatures due to removal of shading vegetation and increased solar loading within riparian zones during and after pipeline construction. The additional database included (but was not limited to) the wetted width (feet), bankfull width (feet), and predominant depth (feet).

**Table 4.5.4-12**
**Average Fractions of Surface Substrates by Area Reported for Sampled Stream Reaches in Fifth-Field Watersheds Crossed by the PCGP Project.** [1]

| Sub-Basin | Fifth Field Watershed | Average % Sand, Silt, Organics in Surface Substrate | Assumed % Silt and Organics in Surface Substrate [2] | Average % Gravel in Surface Substrate | Average % Bedrock in Surface Substrate [3] | Number of Boulders ≥0.5m Diameter per meter of Channel [4] |
|---|---|---|---|---|---|---|
| Coos | Coos Bay-Frontal Pacific Ocean | 60.7 | 40.5 | 11.1 | 22.7 (inc) | 0 |
| Coquille | Coquille River | 78.7 | 52.5 | 13.6 | not reported | 0 |
| | North Fork Coquille River | 33.5 | 22.3 | 25.5 | 11.2 (inc) | 0.3 |
| | East Fork Coquille River | 24.1 | 16.1 | 28.8 | 10.3 (inc) | 0.4 |
| | Middle Fork Coquille River | 22.9 | 15.3 | 24.8 | 12.6 (inc) | 0.3 |
| South Umpqua | Olalla Ck-Lookingglass Ck | 24.5 | 16.3 | 32.6 | 10.1 (inc) | 0.3 |
| | Clark Branch-S. Umpqua River | 22.8 | 15.2 | 35.3 | 10.9 (inc) | 0.2 |
| | Myrtle Creek | 39.1 | 26.1 | 24.8 | not reported | 0.1 |
| | Days Ck-S. Umpqua River | 14.4 | 9.6 | 43.8 | not reported | 0.1 |
| | Upper Cow Creek | 30.4 | 20.3 | 36.1 | not reported | 0.4 |

[1] Data from ODFW, 1997
[2] Assuming equal fractions of sand, silt, and organics
[3] Average percent of bedrock in the surface substrate has only been reported in reaches sampled after 1999
[4] Numbers of boulders counted within the reach divided by the total length (m) of primary and secondary channels within the sampled reach.

GeoEngineers data were used to estimate the stream channel cross-section shape and cross-section area. If the predominant depth was greater than ½ the bankfull width, the cross-section channel shape was assumed to be a V. If the predominant depth was less than ½ the bankfull width, the cross-section channel shape was assumed to be a trapezoid with each bank as a 1:1 slope, dependent on predominant depth. Manning's Formula (Limerinos, 1970; Arcement and Schneider, 1989) was used to estimate **Q**, the stream discharge rate (cubic feet per second):

$$\mathbf{Q = A\ (\mathit{k}/n)\ (R^{2/3})\ (S^{1/2})}$$

with estimates of **A**, the cross-sectional area of a stream (square feet or square meters), **R**, the hydraulic radius (feet or meters, where **R = A/P**, and **P** is the wetted perimeter in feet or meters), **S**, the slope of channel (vertical feet per horizontal feet), the constant ***k*** equals 1.486 if English units are used but ***k*** equals 1 with metric units, and n is Manning's roughness coefficient. Values reported by GeoEngineers, 2011b and 2012 were used to estimate **A** and **R** and **S** (where a 100 percent gradient = 1). Manning's **n** was estimated from various sources (Chow, 1959; Limerinos, 1970; Arcement and Schneider, 1989), primarily based on streambed materials and streambank conditions reported by GeoEngineers (2011b) and included in appendix Y for each stream modeled. Stream flow rate or discharge rate, **Q**, is related to cross-sectional area (**A**) and average streamflow velocity ($\mathbf{V_A}$):

$$\mathbf{Q = A\ V_A}$$

Estimates of **Q** derived with Manning's Formula are assumed to be measures of the carrying capacity (bankfull flow) of a particular channel section (Arcement and Schneider, 1989). Carrying capacities of a channel section are assumed to occur during periods of high flow, generally during winter months in the project area. Where possible, estimates of **Q** were compared to estimates of maximum instantaneous flows that could occur once every 2 years through once every 500 years, using the USGS web-based GIS hydrologic regression tool, StreamStats (see http://water.usgs.gov/osw/ streamstats/index.html). Though not every waterbody crossed by the PCGP Project has been modeled in StreamStats, those that have provided peak flow estimates (cubic feet per second, or cfs) within the same orders of magnitude (generally within the range of maximum peak flows every 2 years through peak flows every 500 years) as estimates of **Q** derived from application of Manning's Formula to the stream data compiled by GeoEngineers (2011b and 2012).

Sediment particles will be transported distances downstream (**L**, in feet or meters) based on 1) the particle size and settling velocity (**$V_S$**, - inches per second, micrometers per second – in water at 20$^{o}$C, see for example the Wentworth Grain Size Chart, USGS, 2003), 2) the average streamflow velocity, and 3) the average depth of flow (**D**, feet or meters) downstream, using the following equation (Trow Equation, see Harper and Trettel, 2002);'

$$\mathbf{L = (D\ V_A) / V_S}$$

For illustrative purposes, estimates of transport distances (**L** in feet) for various sediment particles ranging in sizes from clay to coarse gravel were provided in table 4.5.3-7, Section 4.5.3.3 under SONCC coho, for three of the waterbodies that would be crossed by the PCGP Project. Particle sizes deleterious to salmonids (250 µm or less in the models of Newcombe and Jensen, 1996, above) could settle out of suspension less than 1 meter (0.2 feet) downstream (e.g., medium sand in low flows for Tributary to Catching Creek in examples, below). Alternatively, particles could remain suspended for 200 km (100 miles) or more (very fine silt during high flows in Willis Creek).

<u>Seasonal Discharge</u>. Pipeline construction across waterbodies will occur during ODFW (2008a) instream construction windows (see discussion, above). Hydrographs of monthly discharges were provided above in Section 4.5.4.2 for the Coos Sub-basin (see figure 4.5-16); Coquille Sub-basin (see figure 4.5-17), and South Umpqua Sub-basin (see figure 4.5-18). The hydrographs show peak seasonal flows during winter months, December through February. Lowest flows occur during summer months, coinciding with the ODFW construction windows. Assuming that high winter stream flows correspond to the carrying capacities of channel sections (Arcement and Schneider, 1989), instream flows during ODFW construction windows would be some fraction of the winter flows. The fractions, included in table 4.5.4-13a and table 4.5.4-13b as a percent of winter high flow during the construction window, have been estimated for waterbodies in each of the four sub-basins based on the most recent 10-year record within USGS hydrograph data sets. Stream flows during construction windows were estimated for waterbodies in each sub-basin by reducing stream depths and affected parameters in Manning's Formula to achieve an average stream discharge rate, **Q**, that is the same as the percent (by mid-point) of high flows in table 4.5.4-13a and table 4.5.4-13b for streams in each sub-basin.

**Table 4.5.4-13a**
**Recorded High Flows During Winter and Average Flows During the ODFW Instream Construction Window in Hydrographic Data in Four Sub-basins Crossed by the PCGP Project.**

| Sub-basin | Hydrograph | High Flow (cfs) (Month) | Instream Construction Window | Average Flows (cfs) During Window | Percent of High Flow During Window | Percent Mid-Point |
|---|---|---|---|---|---|---|
| Coos | Pony Creek [1] | 17 (Feb) | Jul 1-Sep15 | 0.01 | 0.03 | 1.4 |
| | W.Fk. Millacoma River | 489 (Jan) | Jul 1-Sep15 | 13.7 | 2.8 | |
| Coquille | Mid.Fk. Coquille River | 2,220 (Feb) | Jul 1-Sep15 | 40.5 | 1.8 | 2.0 |
| | N.Fk. Coqulle River | 630 (Dec) | Jul 1-Sep15 | 14.4 | 2.3 | |
| South Umpqua | N. Myrtle Creek | 182 (Dec) | Jul 1-Sep15 | 4.8 | 2.6 | 2.8 |
| | S. Umpqua River | 6,862 (Dec) | Jul 1-Aug 31 | 196 | 2.9 | |

[1] Ten-year flows in Pony Creek were evaluated from 1992 to 2001 rather than from the most recent 10-years, 1999 to 2008, because of releases from Upper Pony Creek Reservoir since completion of the new dam in 2001.

**Table 4.5.4-13b**
**Recorded High Flows During Winter and Average Peak Flows During the ODFW Instream Construction Window in Hydrographic Data in Four Sub-basins Crossed by the PCGP Project.**

| Sub-basin | Hydrograph | High Flow (cfs) (Month) | Instream Construction Window | Average Peak Flows (cfs) During Window | Percent of High Flow During Window | Percent Mid-Point |
|---|---|---|---|---|---|---|
| Coos | Pony Creek [1] | 17 (Feb) | Jul 1-Sep15 | 0.14 | 0.8 | 9.2 |
| | W.Fk. Millacoma River | 489 (Jan) | Jul 1-Sep15 | 85.5 | 17.5 | |
| Coquille | Mid.Fk. Coquille River | 2,220 (Feb) | Jul 1-Sep15 | 132.3 | 6.0 | 8.4 |
| | N.Fk. Coqulle River | 630 (Dec) | Jul 1-Sep15 | 67.8 | 10.8 | |
| South Umpqua | N. Myrtle Creek | 182 (Dec) | Jul 1-Sep15 | 15.1 | 8.3 | 8.0 |
| | S. Umpqua River | 6,862 (Dec) | Jul 1-Aug 31 | 527.1 | 7.7 | |

[1] Ten-year flows in Pony Creek were evaluated from 1992 to 2001 rather than from the most recent 10-years, 1999 to 2008, because of releases from Upper Pony Creek Reservoir since completion of the new dam in 2001.

For example, 10-year average stream flows in the South Umpqua Sub-basin during the ODFW instream construction window are 2.8 percent of high winter flows (see table 4.5.4-13a), based on discharge data for North Myrtle Creek and South Umpqua River during December (see figure 4.5-18). Stream depths for all waterbodies within the South Umpqua Sub-basin were reduced by the same proportion. Reduced stream depths generated reduced values of **A**, **P**, and **R** in Manning's Formula. Estimates of **Q** (and $\mathbf{V_A}$) were likewise reduced for all streams in the sub-basin and were compared to **Q** generated during high winter flows. Reduction of stream depths by iteration was continued until the percent of high winter flows by average flows during the construction window was 2.8 percent for waterbodies crossed by the PCGP Project.

The same procedure was used to evaluate stream discharge rates during average peak flows that were documented in the sub-basins during instream construction windows. Peak flows were obtained from maximum daily flow data during the instream construction window and averaged for the most recent 10-year period (see table 4.5.4-13b).

<u>Sediment Generated During Pipeline Construction</u>. Modeled concentrations of TSS produced in waterbodies during wet open-cut pipeline construction were developed from empirical data collected during construction across 15 to 19 streams in North America (Reid et al., 2004). Models were developed to predict mean and peak TSS concentrations immediately downstream of pipeline construction sites. Models included TSS generated by all construction activities and by trenching, pipe lowering, and backfilling. The models predicting mean TSS generated by all activities (including trenching, pipe lowering, and backfilling) and mean TSS generated by

trenching had the highest correlation coefficients (Reid et al., 2004). The model predicting mean TSS ($C_{av}$) by all construction activities is:

$$C_{av} = 1.5 \times 10^6 \; U^{1.09} \, d_{50}^{0.95} \, P_f^{0.35} \, q^{-1}$$

where $U$ = mean flow velocity (m per second) at the crossing location during the construction period and is assumed to be equivalent to $V_A$ derived using Manning's Formula; $d_{50}$ = the median sediment size (m) of the excavated material by weight; $P_f$ = percentage of fines (silt and clay) in the excavated material (%) and is assumed to equal the percent of silt and organics in surface substrates for all streams within a given fifth-field watershed in the Coos, Coquille, and South Umpqua sub-basins tabulated in table 4.5.4-12; $q$ = the width adjusted stream flow rate where $q = Q/B$, ($m^2$ per second) with $B$ = the watercourse width (m) adjusted for a particular flow rate and $Q$ = stream flow rate ($m^3$ per second) derived using Manning's Formula. In these simulations, **Q** is related to **B** through Manning's Formula and as **B** increases numerically, **Q** also increases but at a faster numerical rate. If all other model parameters are held constant in the Reid et al. (2004) model, increased width adjusted stream flow rate, $q$ (due high flow, **Q**, and proportionally smaller watercourse widths, $B$) will decrease the TSS concentration ($C_{av}$) because $q$ is factored as $q^{-1}$ or $1/q$ in the equation. Conversely, lower $q$ values will generate higher $C_{av}$ with all other parameters in the equation held constant.

Available data do not appear suitable to estimate values for $d_{50}$. In these analyses it is assumed that $d_{50}$ = 0.00025 m (250 µm) since particles that size or less adversely affect salmonids and other fish in the evaluation procedures by Newcombe and Jensen (1996), introduced above and applied below.

In addition to developing predictive models of TSS concentrations generated by wet-open cut pipeline construction, Reid et al. (2004) measured TSS downstream from 12 flumed pipeline crossings and 23 dam-and-pump crossings (dry-open cut or isolated pipeline construction crossings) with comparisons to 11 wet open-cut construction crossings. By accounting for flow, background TSS concentrations, sampling distance downstream, and duration of construction, Reid et al. determined that mean TSS concentrations generated during dry open-cut construction for fluming were 3.7 percent of the wet open-cut concentrations and 0.85 percent of the wet open-cut concentrations for dam-and-pump construction.

Reid et al. (2004) also predicted peak TSS generated by all construction activities. The model predicting peak TSS ($C_p$) by all activities is:

$$C_p = 5.7 \times 10^5 \; U^{1.86} \, d_{50}^{0.57} \, P_f^{1.2} \, q^{-1}$$

The model has the same component descriptions and assumptions stated above for predicting the average TSS concentration ($C_{av}$). However, the model showed overall low explanatory value (low coefficient of multiple correlation. low multiple $r^2$) and a relatively poor predictor of peak TSS (Reid et al., 2004) and is not used in these analyses.

Short-term peak sediment releases occurred during installation and removal of isolation structures (sand bags, jersey barriers, other dam structures) and bypass components (flume, pumps). Dam-and-pump construction is a particularly effective technique to cross smaller waterbodies. The larger TSS concentrations produced during fluming were mostly related to backfilling the trench, poor containment of ditch water, poor dam seals, and longer construction times associated with fluming larger waterbodies (Reid et al., 2004).

If there was a failure of isolation structures during either type of dry open-cut construction, it is assumed that the TSS generated during the failure would be similar to TSS generated during wet open-cut construction, which is included in table 4.5.4-14. Estimates of TSS concentrations produced during pipeline construction under average and peak low flow conditions are expected to be highly variable primarily due to the wide range in silt and organic fractions in surface substrates which vary from 6.9 percent in Days Creek-South Umpqua River to 52.5 percent in Coquille River fifth field watersheds (see table 4.5.4-12). Estimated average TSS concentrations produced during fluming and dam-and pump construction are equal to or slightly above background TSS estimates (2 mg/L) between 50 and 100 meters downstream from construction sites (see table 4.5.3-14).

Estimated Downstream Distance of Suspended Sediment. Ritter (1984) provided two models (minor stream crossings and major stream crossings) for estimating concentrations of suspended sediments ($C_X$, as mg/L) some distance (x) downstream from a pipeline trench being constructed across a waterbody. The model for minor crossings was based on average stream depth of 15.2 cm (6 inches) and the model for major crossings was based on average depth of 91 cm (36 inches). The mid-point between the two depths, 53.1 cm (21 inches), is assumed to differentiate minor from major streams.

Ritter's model for downstream sediment transport distance during construction across minor streams, with complete mixing of sediment particles, estimates the concentration downstream $\mathbf{C_X}$ by:

$$\mathbf{C_X = C_O\, e^{-(vs/d)(x/u)}}$$

Where $\mathbf{C_O}$ (mg/L) is the initial concentration of suspended solids in the water column at the trenching site, **vs** = the settling velocity (m/second) of sediment particles, **d** = stream depth (m), **u** = stream current velocity (m/second), and **x** = distance (m) downstream.

Ritter's model for downstream sediment transport distance during construction across a major stream assumes complete mixing of sediment particles within one-half the stream width (assuming a horizontal spread of the sediment plume as 0.5 cm/sec). The concentration downstream $\mathbf{C_X}$ is estimated by:

$$\mathbf{C_X = \frac{C_O}{0.5(x)(d)}\, e^{-(vs/(0.5d))(u/x)}}$$

Flows expected during pipeline construction within the ODFW instream window limit the application of the major stream crossing model. Coos River and South Umpqua River would be classified as major streams at the time of construction but would not be crossed using dry open cut construction and are not included in the sediment entrainment and transport analysis provided in table 4.5.4-14.

Summary. TSS concentrations are essential to evaluating project-related effects on salmoninds (see section below, Suspended Sediment Effects on Fish). Estimates of TSS concentrations generated by wet open-cut and dry open-cut (flume and dam-and-pump) were modeled for 36 waterbodies within the Coos Sub-basin, 24 waterbodies within the Coquille Sub-basin, and 21 waterbodies within the South Umpqua Sub-basin that would be crossed by the PCGP Project. Concentrations of TSS generated by wet open-cut construction were estimated for each of the waterbody crossing sites (see table 4.5.4-14) and adjusted, depending on use of flumed dry open-cut or dam-and-pump dry open-cut construction. Concentrations of TSS at 10, 50, and 100 meters downstream were based on Ritter's (1984) equations. Fractions of gravel, sand, silt and organics (see table 4.5.4-12) were assumed to be characteristic for each stream within the sub-basin. Average low flows were assumed (see table 4.5.4-13a and example in text) to occur during pipeline construction and used in the Reid et al. (2004) model predicting mean TSS ($\boldsymbol{C_{av}}$) generated by all pipeline instream construction activities. The $\boldsymbol{C_{av}}$ from the Reid et al. model is equivalent to $\mathbf{C_O}$ in the Ritter model (the initial concentration of suspended solids in the water column at the trenching site). Average low flows were also used for estimating concentrations, $\mathbf{C_x}$, at three distances downstream using Ritter's (1984) model for minor streams. Average peak flows during the instream construction window (see table 4.5.4-13b) were also used to estimate concentrations ($\mathbf{C_x}$) at the three distances downstream with the same $\mathbf{C_O}$ as for average low flows. The background TSS concentration was assumed to be 2 mg/L for all streams crossed by the PCGP Project during the ODFW instream construction window (see table 4.5.4-11b and associated discussion).

Estimated TSS concentrations downstream from flumed dry open-cut construction ranged from less than 55 mg/L to 2 mg/L (see table 4.5.4-14). Estimated TSS concentrations downstream from dam-and-pump dry open-cut construction range from about 14 mg/L to 2 mg/L. Those ranges of TSS concentrations were used in Newcombe and Jensen's (1996) models estimating risks to salmonids and non-salmonids that would be associated with variable TSS concentrations and variable durations of exposure. The durations of exposure to TSS generated during dry open-cut construction at each of the 81 waterbodies simulated in table 4.5.4-14 are assumed to be similar to those described by Reid et al. (2004) occurring during installation and removal of isolation structures (temporary dams placed upstream and downstream from the workspace) and bypass structures (flume pipe, pump intake and exit conduits). Construction-related problems may occur and my cause elevated TSS concentrations downstream and for longer periods of time, including (Reid et al., 2004): 1) pump failure or insufficient capacity, 2) dam or flume failure, 3) poor dam seal, 4) poor containment of pumped ditch water, 5) inadequate maintenance of sediment control measures. Also, construction across larger waterbodies requires longer periods of instream work, large volumes of stream flow and trench dewatering, and risks of increased sediment release.

Estimated average TSS concentrations produced during fluming and dam-and-pump construction are equal to or near background TSS estimates (2 mg/L) at 10, 50, and 100 meters downstream from construction sites (see table 4.5.4-14 and appendix Y). However, TSS concentrations assumed to occur during failure of isolation structures could be higher.

Assumptions:

[1] All simulated waterbodies are assumed to have depths ≤ 53 cm during ODFW (2008a) instream construction windows and have been assumed to be Minor Waterbodies (see Ritter, 1984). No waterbodies with bedrock substrates are included. No waterbodies that are adjacent to but not crossed by the pipeline are included.

[2] Based on the Mean TSS model generated by <u>All Activities</u> associated with wet open-cut construction, using variable $P_f$ , the percentage of silt and clay fines materials in the watershed and $d_{50}$ = 0.25 mm or 250 µm (assumed median sediment size of the excavated material by weight) (Reid et al., 2004).

[3] TSS generated by Flumed Dry Open-Cut construction were assumed to be 3.7 percent of concentrations generated by Wet Open-Cut construction (data from Reid et al., 2004).

[4] TSS generated by Dam-and-Pump Dry Open-Cut construction were assumed to be 0.85 percent of concentrations generated by Wet Open-Cut construction (data from Reid et al., 2004)

[5] Concentrations of TSS at 10, 50 and 100 downstream were estimated for fractions of gravel, sand, silt, and organics characteristic in substrates of streams in fifth-field watersheds and settling velocities: gravel (1.6 cm diameter), vs = 90 cm/s; sand (0.025 cm diameter), vs = 3 cm/s; silt (0.0016 cm diameter), vs = 0.023 cm/s; clay (0.0004 cm diameter), vs = 0.0014 cm/s. Concentrations were added to the assumed background level of 2 mg/L.

[6] Instream average low flows and average peak flows at the time of construction (within the ODFW, 2008b recommended in-water construction periods) are assumed to be some percent of the carrying capacity flows for all of the evaluated channel sections within a specific Sub-basin; percent reduction during average flows; percent reduction during average peak flows. Sediment concentrations (Cx) at downstream distances in minor waterbody crossings (Ritter, 1984) were computed from the initial concentrations (Co) estimated by the Mean TSS model generated by <u>All Activities</u> by Reid et al., 2004. .

[7] Initial concentrations (Co) of TSS generated by Flumed Dry Open-Cut construction were assumed to be 3.7 percent of concentrations generated by Wet Open-Cut construction (Reid et al., 2004)

[8] Initial concentrations (Co) of TSS generated by Dam-and-Pump Dry Open-Cut construction were assumed to be 0.85 percent of concentrations generated by Wet Open-Cut construction (Reid et al., 2004)

Suspended Sediment Effects on Coho Salmon. Newcombe and Jensen (1996) provide four additional models that have not been applied to analysis of impact of sediment to fish in the PCGP Project area because fish species for which the models were developed are not expected in the habitats for which the two models would be applicable (see species-model associations in Table 2, Newcombe and Jensen, 1996). Model 2 (adult salmonids) does not apply to coho salmon (Newcombe and Jensen, 1996) and Model 4 (eggs and larvae of salmonids and non-salmonids) does not apply to effects by this project because instream construction will not coincide with coho spawning or periods of egg incubation-fry emergence (see figure 4.5-13, above). Model 5 applies to adult estuarine non-salmonids that are particularly sensitive to effects of suspended sediments and Model 6 applies primarily to adult warmwater centrarchid species, eg. sunfish).

Input for each of the four models includes TSS concentration (mg/L) and duration (hours) of exposure to the suspended sediments. Each model has the form:

$$\mathbf{z = a + b(logex) + c(logey)}$$

where **z** = severity-of-ill-effects (SEV) score, **x** = duration of exposure in hours, **y** = concentration of suspended sediment in mg/L. Constants **a**, **b** and **c** were empirically derived for each model (see Table 3, Newcombe and Jensen, 1996):

Output from each model is severity-of-ill-effects (SEV) score ranging from 0 to 14 where SEV of 0 indicates no effects, SEV between 1 and 3 indicates behavioral effects, SEV from 4 to 8 indicates sublethal effects, and SEV from 9 through 14 indicate lethal and paralethal effects (see Table 1 in Newcombe and Jensen, 1996).

4) Behavioral Effects SEV scores: 1 = Alarm reaction; 2 = Abandonment of cover; 3 = Avoidance response
5) Sublethal Effects SEV scores: 4 = Short-term reduction in feeding rates and/or feeding success; 5 = Minor physiological stress (increase coughing rate and/or increased respiration rate); 6 = Moderate physiological stress; 7 = Moderate habitat degradation and/or impaired homing; 8 = Indications of major physiological stress (long-term reduction in feeding rate and/or feeding success, poor condition)
6) Lethal and Paralethal Effects SEV scores: 9 = Reduced growth rate and/or delayed hatching and/or reduced fish density; 10 = 0 to 20% mortality and/or increased predation and/or moderate to severe habitat degradation. 11= >20 – 40% mortality (SEV scores exceeding 11 predict increased mortality rates).

Input for each of the two models, Model 1, juvenile and adult salmonids and Model 3, juvenile salmonids, includes TSS concentration (mg/L) and duration (hours) of exposure to the concentration. Output from each model is a severity-of-ill-effects (SEV) score ranging from 0 to 14, as (see Table 1 in Newcombe and Jensen, 1996).

Reid et al., (2002) reported two flumed crossings required 23 and 51 hours of instream work while durations of four dam-and-pump crossings ranged from 9 to 41 hours. Reid et al., (2004) reported that flumed crossings averaged 64 hours of instream work (with standard error of 14.1 hours) and dam-and-pump crossing averaged 37.8 hours of instream work (with standard error of 8.4 hours). Based on these data, the assumed range of time required for flumed crossings and dam-and-pump crossings is the mean ± 2 standard errors reported for each technique by Reid et al. (2004). Consequently, estimated durations for fluming range from 36 to 96 hours (see table

4.5.4-15) and for dam-and-pump the range is from 20 to 56 hours (see table 4.5.4-16). If there is a failure of the isolation dams/structures, the durations of maximum TSS concentrations that would be similar to a wet open-cut crossing are assumed to last from 1 hour to 24 hours; the shorter durations would indicate repair of the failed structures while the longer durations would indicate completing the construction by wet open-cut.

Effects to salmonid life stages due to flumed dry open-cut construction across waterbodies that do not have bedrock substrates are included in table 4.5.4-15. The mean TSS concentrations generated during flumed pipeline construction across all waterbodies within the Coos Sub-basin is estimated at 12 mg/L (with standard error = 0.89), at 6 mg/L (with standard error = 1.58) in the Coquille Sub-basin, and the mean is estimated at 3 mg/L (with standard error = 0.22) in the South Umpqua Sub-basin 10 meters downstream from construction sites. During average peak flows, mean TSS concentration generated during flumed pipeline construction within the Coos Sub-basin is estimated at 29 mg/L (with standard error = 1.41), at 12 mg/L (standard error = 4.15) in the Coquille Sub-basin, and is estimated at 4 mg/L (with standard error = 0.36) in the South Umpqua Sub-basin; all estimates are for 10 meters downstream from the construction sites. All flumed construction is assumed to be completed between 36 and 96 hours (see above).

Similarly, effects to salmonid life stages due to dam-and-pump dry open-cut construction across waterbodies that do not have bedrock substrates are included in table 4.5.4-16. The mean TSS concentrations generated during dam-and-pump pipeline construction across all waterbodies within the Coos Sub-basin is estimated at 4 mg/L (with standard error = 0.20), at 3 mg/L (with standard error = 0.36) in the Coquille Sub-basin, and the mean is estimated at 4 mg/L (with standard error = 0.05) in the South Umpqua Sub-basin 10 meters downstream from construction sites. During average peak flows, mean TSS concentration generated during dam-and-pump pipeline construction within the Coos Sub-basin is estimated at 8 mg/L (with standard error = 0.32), at 4 mg/L (standard error = 0.95) in the Coquille Sub-basin, and the estimated mean is 2 mg/L (with standard error = 0.08) in the South Umpqua Sub-basin; all estimates are for 10 meters downstream from the construction sites. All dam-and-pump construction is assumed to be completed between 20 and 56 hours (see above).

Effects to Oregon Coast coho juveniles and adults due to either of the flumed dry open-cut construction and dam-and-pump dry open-cut construction procedures for waterbodies that do not have bedrock substrates are included in table 4.5.4-15 and table 4.5.4-16, respectively, for expected low flow and potential peak flow conditions during the ODFW (2008a) instream construction windows. Results from applying Model 1 for juvenile and adult coho indicates SEV scores for durations of exposure to the TSS concentrations of 20 mg/L or less would range from SEV = 5 (minor physiological stress-increase coughing rate and/or increased respiration rate), to SEV = 6 (moderate physiological stress), and SEV = 7 (moderate habitat degradation and/or impaired homing) which includes the upper 95% confidence intervals (Newcombe and Jensen, 1996). Peak flows produced TSS levels higher than average low flows, especially in the Coos and Coquille sub-basins, and would generate similar SEV scores in table 4.5.4-15 and table 4.5.4-16. All expected responses by adult and juvenile salmonids to TSS produced during fluming or dam-and-pump 10 meters or more downstream would be classified as sublethal, whether during low flows or peak flows.

**Table 4.5.4-15**

**Application of Three Models for Estimating Severity of Effects to Oregon Coast Coho 10 Meters Downstream Due to TSS Concentrations Produced by Flumed Pipeline Construction Ranging from 36 to 96 hours During Low Flow and Peak Flow Conditions**

| Model Number (and particle size) | Exposure (hours) | Average Low Flows: TSS Concentration (mg/L) | Average Low Flows: Modeled Severity of Effects (SEV) [1] | Average Low Flows: With Upper SEV (95% CI) [2] | | Average Peak Flows: TSS Concentration (mg/L) | Average Peak Flows: Modeled Severity of Effects (SEV) [1] | Average Peak Flows: With Upper SEV (95% CI) [2] |

[1] See footnotes to table 4.5.4-16.

Failures of isolation structures to exclude streamflow during fluming or dam-and-pump would result in suspended sediment entrained downstream, assumed to be similar to TSS levels generated during wet open-cut construction (mean plus 2 standard errors from table 4.5.4-14) and included in table 4.5.4-17 along with several potential durations of exposure. Scenarios of exposures of 1 hour and 6 hours could occur while work crews repair the failed isolation structures. Longer exposures of 12 and 24 hours are assumed to occur if dry open-cut construction (flume or dam-and-pump) is abandoned and the waterbody crossing is completed using wet open-cut construction. Suspended sediments concentrations of 793 mg/L during low flows and 1,827 mg/L during peak flows for durations of 12 to 24 hours would not produce lethal conditions for juvenile and/or adult Oregon Coast coho but could result in moderate physiological stress (SEV = 6), moderate habitat degradation and/or impaired homing (if SEV = 7), and major physiological stress (if SEV = 8). Lethal doses (exposures to high TSS concentrations for long durations) with reduced growth rate and/or delayed hatching and/or reduced coho density (with SEV =9) could occur if failure of an isolation structure led to wet open-cut construction, principally within the Coquille Sub-basin with TSS concentrations =1,827 mg/L (mean of 1,428 + 2 standard errors) for 24 hours under either low flow or peak flow conditions.

**Table 4.5.4-17**
**Application of Two Models for Estimating Severity of Effects to Oregon Coast Coho 10 Meters Downstream due to TSS Concentrations Produced by Failure of Isolating Structures During Low Flow and Peak Flow Conditions under Different Exposure Durations**

[1] See footnotes to table 4.5.4-16.

The South Umpqua River at MP 94.73 would be crossed using a diverted open-cut. This is similar to a dry open cut in that all in channel construction would be done in the "dry" but would require diversion of the flow to one side of the channel at a time. None of the models for sediment entrainment would apply to diverted open-cuts but TSS generated by wet open-cut construction has been used to evaluate potential effects. Juvenile and adult coho in the South Umpqua River would likely be affected by TSS concentrations less than 72 mg/L which is the mean TSS concentration plus 2 standard errors for a wet open-cut in the Days Creek-South Umpqua River Watershed (see table 4.5.4-14). Diverted open-cut could take about 14 days (336 hours) to complete. If coho were continually exposed to 72 mg/L for 336 hours, the SEV score would be SEV = 8 (indications of major physiological stress with long-term reduction in feeding rate and/or feeding success, poor condition) but that would not occur because the TSS concentration would likely be less than 72 mg/L at the construction site and fish would be able to avoid a plume of suspended sediment because construction would only occur on one side of the river at any time.

FWS (Muck, 2010) incorporated the scaled SEV scores into section 7 consultations on bull trout such that SEV scores of 6 or higher would be expected to cause harassment using Model 1 (Juvenile and Adult Salmonids) and would justify a determination of "likely to adversely affect." Figure 4.5-19 provides combinations of TSS concentrations and exposures that would distinguish between determinations of "likely to adversely affect" and "not likely to adversely affect."

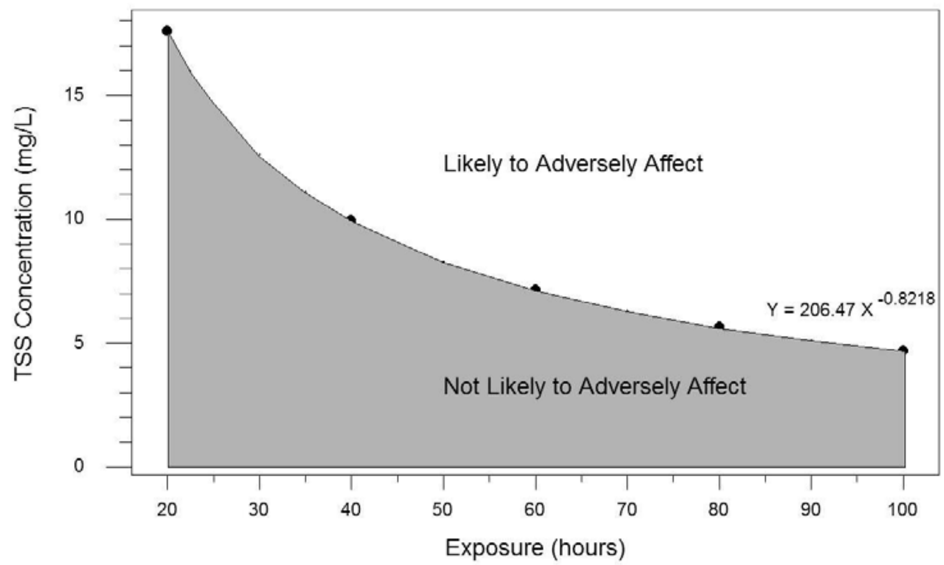

**Figure 4.5-19**
**Combinations of TSS concentrations and Exposure that would Limit SEV Scores of 5 or Lower (Gray Area) in Model 1 (Newcombe and Jensen, 1996) with a Determination of "Not Likely to Adversely Affect" Adult and Juvenile Salmonids (Muck, 2010)**

Similarly, FWS (Muck, 2010) determined that SEV scores of 5 or higher would cause harassment with application of Model 3 (Juvenile Salmonids) and would justify a determination of "likely to adversely affect." Figure 4.5-20 provides combinations of TSS concentrations and exposures that would distinguish between determinations of "likely to adversely affect" and "not likely to adversely affect." The same determinations of effect are assumed for coho salmon in this biological assessment.

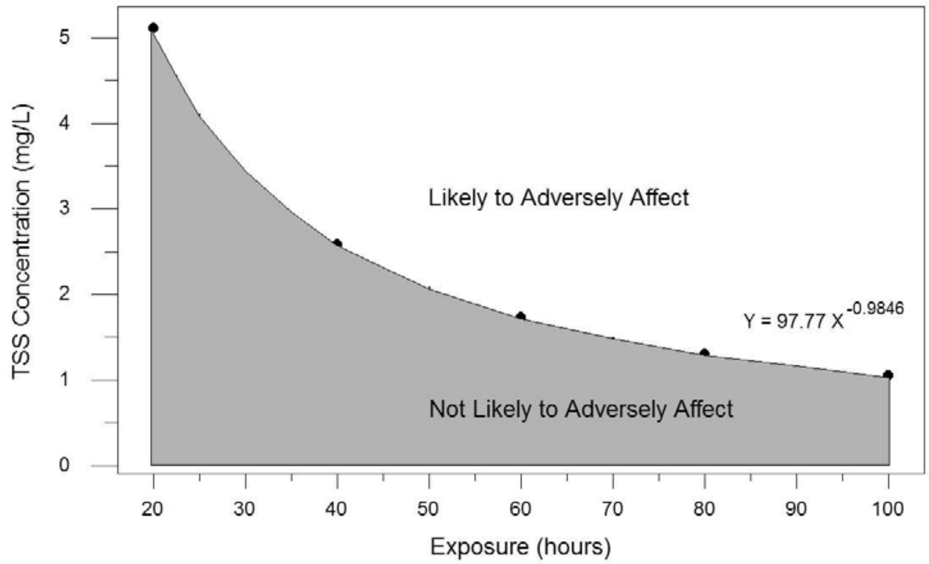

**Figure 4.5-20**
**Combinations of TSS concentrations and Exposure that would Limit SEV Scores of 4 or Lower (Gray Area) in Model 3 (Newcombe and Jensen, 1996) with a Determination of "Not Likely to Adversely Affect" Juvenile Salmonids (Muck, 2010)**

SEV scores were computed for streams within each fifth field watershed crossed within the Coos, Coquille, and South Umpqua sub-basins using TSS concentrations estimated at 5, 10, 25, 50, and 100 meters downstream from pipeline construction sites and exposure durations from 20 to 100 hours which covers the expected durations required for dam-and-pump and flumed construction. Upper 95% confidence intervals, added to SEV scores, were used to evaluate potential scenarios within each fifth field watershed depending on whether Model 1 (juvenile and adult coho) or Model 3 (juvenile coho) was considered for estimated average low flows and for estimated average peak flows occurred during the period of instream construction.

Results are shown below for TSS effects in fifth field watersheds within the Coos Sub-basin (figure 4.5-21), the Coquille Sub-basin (see figure 4.5-22 through figure 4.5-25), and the South Umpqua Sub-basin (see figure 4.5-26 through figure 4.5-30). The model outputs (SEV scores plus 95% confidence intervals) for the Coos Bay-Frontal Pacific Ocean Watershed (Figure 4.5-21), Coquille River Watershed (see figure 4.5-22), North Fork Coquille River Watershed (see figure 4.5-23), East Fork Coquille River Watershed (see figure 4.5-24), Middle Fork Coquille River Watershed (see figure 4.5-25), Olalla Creek-Lookingglass Creek Watershed (see figure 4.5-26), Myrtle Creek Watershed (figure 4.5-28), and Upper Cow Creek Watershed (see figure 4.5-30) show that instream construction lasting for 20 to 40 hours could exceed scores of 5 with Model 1 for both average low flows or average peak flows in all four watershed. Based on that model and exposures, the project would be "likely to adversely affect" coho based on figure 4.5-19. However, construction lasting for 20 hours or more would exceed a score of 4 with Model 3, regardless of flow rates, in all four watersheds. Based on that model and exposures, the project would be "likely to adversely affect" juvenile coho based on figure 4.5-20.

Entrainment and Entrapment

Waterbody crossings using the “dry” crossing methods, flume or dam-and-pump, may result in some fish being entrapped in streams. Flumes and dams will be completely installed and functioning before any instream disturbance. Construction across a waterbody would take up to seven days using dry open cut methods, but less for small and intermediate streams. Once streamflow is diverted through the flume pipe, but before pipeline trenching begins, fish trapped in any water remaining in the work area between the dams would be removed and released using the Fish Salvage Plan (see appendix T). Pacific Connector will contract with either ODFW or a qualified consultant to capture the fish. Personnel that would handle and/or remove fish on federal lands would be approved by the Forest Service or the BLM or be done directly by agency personnel if approved by ODFW.

Frac-Out

Although the HDD method avoids instream impacts because it eliminates the need for instream excavation, it does not completely eliminate the possibility of impacts on aquatic resources. Pacific Connector proposes to use this method to cross the Coos River. Because HDD requires a lubricant during the process, this fluid is under pressure and there is a possibility of an inadvertent release of drilling mud or fluid (also referred to as a frac-out). Drilling mud primarily consists of water mixed with bentonite, which is a naturally occurring clay material. The only other possible additives would be nontoxic solid materials (e.g., sawdust, nut shells, bentonite pellets, or other commercially available nontoxic products) that could be needed to plug an inadvertent release.

Direct Pipe construction would be used to cross the South Umpqua River at MP 71.30. Direct Pipes are completed using an articulated, steerable microtunnel boring machine (MTBM) mounted on the leading end of the product pipe or casing which is jacked into position using a pipe thrusting machine mounted at or near the ground surface. Soil and rock are excavated by the cutting head and removed through pressurized slurry pipes to the launching pit at a rate that is balanced with the advance rate of the machine, as the MTBM and pipe are jacked through the formation. A pipe thrusting machine located in or near the launching pit provides the necessary force to advance the product pipe and provide the face pressure required for excavation. Small sections of pipe are welded to the back of subsequent sections after each section is advanced. Friction between the pipe and surrounding soil can create significant resistance during Direct Pipe installation. To reduce the frictional resistance, over cutting is employed to create a small annular space between the pipe and external soil. The over cut is typically on the order of 1 to 2 inches. The use of bentonite slurry helps reduce the frictional resistance between the pipe and soil as well as reducing the risk of collapse of the annulus around the pipe. Bentonite lubrication is typically added from the launch seal and from a specialized lubrication ring located behind the MTBM and in front of the jacking pipe. According to GeoEngineers’ Technology Overview for Direct Pipe (see appendix E), the bentonite lubrication system used to lubricate the annulus between the product pipe and the excavation is introduced at a relatively low pressure reducing the potential for hydraulic fracture and inadvertent drilling fluid returns. Because the excavated hole is continuously supported and the risk of hydraulic fracture is low, the Direct Pipe alignment can be designed much shallower than is typical for HDD.

Bentonite by itself is essentially a non-toxic drilling mud (Breteler et al., 1985; Hartman and Martin, 1984; Sprague and Logan, 1979). However, bentonite, as with any fine particulate material, can interfere with oxygen exchange by the gills of aquatic organisms (EPA, 1986). The degree of interference generally increases with water temperature (Horkel and Pearson 1976). Impacts would be localized and would normally be limited to individual fish in the immediate vicinity of the frac-out. The majority of highly mobile aquatic organisms, such as fish, would be able to avoid or move away from turbidity spots and plumes (Reid and Anderson 1999). Other less mobile or immobile organisms, such as mussels and other macroinvertebrates, would incur direct mortality. Bentonite can smother macroinvertebrates and adversely affect filter-feeders (Falk and Lawrence 1973 in Hair et al. 2002 and Land 1974 in Cameron et al. 2002). Bentonite can also exacerbate or enhance the effects of toxic compounds to fish and aquatic invertebrates if those compounds are present in aquatic habitats (Hartman and Martin 1984). Similar to other fine-grained particulates, bentonite in flowing water is more likely to remain in suspension longer than in standing water. Consequently, effects to coho salmon by a release of bentonite into a waterbody would ultimately depend on volume of the release, volume of water present, and current. Coho salmon inhabiting larger waterbodies with swift currents would be less affected by a given volume of bentonite than those inhabiting small waterbodies with no current.

The effects of an instream frac-out on spawning habitat, eggs, and juvenile survival depend on the timing of the release. If spawning habitat is nearby, redds could be affected in the vicinity of frac-out (Reid and Anderson, 1999), if not concurrently, possibly within the immediate future unless high flows flush residual bentonite. During establishment of the spawning bed, a minor addition of sediment would likely be cleaned out by the female as part of the normal preparation behavior. However, a heavy sediment load dispersing downstream could settle into spawning beds and clog interstitial spaces, reducing the amount of available spawning habitat, which could be a limiting factor in areas of already reduced habitat. When redds are active, eggs could be buried, disrupting the normal exchange of gases and metabolic wastes between the egg and water (Anderson, 1996). The impacts of sediment intrusion into the redd on larval survival are more severe during the earlier embryonic stages than following development of the circulatory system of larvae, possible because of a higher efficiency in oxygen uptake by the older fish (Bash et al., 2001). Clogging of interstitial spaces also reduces cover and food availability for juvenile salmonids (Cordone and Kelley, 1961). Benthic organisms could also be affected by burial. However, bentonite is more likely to stay in suspension and less likely to immediately settle than common bottom sediment so, in flowing water areas, effects to benthic organisms from burial from frac-out are likely to be low. The locations where any frac-out may occur are all large waterbodies, which would be affected less because of the dilution factor of large volume of water from any spill.

Potential frac-outs are more common near the HDD drill entry and exit locations; however, impacts to waterbodies are minimized by locating the drill entry and exit points away from the waterbody. The probability of a frac-out may increase when the drill bit is working nearest the surface, but is dependent on numerous factors including substrate characteristics, head pressure of the drilling mud, topography, elevation, and subsurface hydrology. Pacific Connector has designed the Klamath River HDD such that areas of greatest risk from frac-out are on uplands and not adjacent to the waterbodies where much greater depth would be achieved and frac-out potential is reduced.

According to GeoEngineers' Feasibility Analysis for pipeline construction using HDD across the Coos River (see appendix E) the design length of the Coos River HDD crossing is approximately 1,602 feet. The proposed entry point is located approximately 500 from the north bank of the

Coos River; the exit point is approximately 650 feet from the south bank. The entry and exit points allow for adequate depth beneath the Coos River. The preliminary design provides a minimum of 43.6 feet of cover below the Coos River. GeoEngineers' preliminary evaluation determined that the construction of the Coos River HDD crossing is likely feasible. Additional evaluation of the hydraulic fracture and inadvertent return potential will be completed for the final design.

Hydraulic fracture typically occurs when the drill path passes through relatively weak cohesive soils with low shear strength or very loose granular soils. Loose and silty sands and soft to medium stiff silts and clays typically have a higher hydraulic fracture potential. Medium dense to dense sands and gravels and very stiff to hard silts and clays have a low to moderate hydraulic fracture potential. Unfractured rock, because of its high shear strength, typically has a low potential for hydraulic fracture. HDD installations with greater depth or in formations with higher shear strength may reduce the potential for hydraulic fracturing (see appendix E).

In the event an inadvertent return occurs into the river, drilling fluid will enter the waterway causing short term, temporary water quality impacts downstream of the project area including sedimentation and turbidity. In the event drilling fluid is inadvertently released into the river, the behavioral avoidance response of Oregon Coast coho is presumed to be triggered within the immediate vicinity of the release and the fish are expected to return and utilize the affected area shortly after the inadvertent release has been halted. If significant concentrations are found during monitoring as a result of a release, the following possible corrective measures would be taken:

5. Increase the drilling fluid viscosity in an attempt at sealing the point at which fluid is leaving the drilled hole. The drilling operation may be suspended for a short period (i.e. overnight) to allow the fractured zone to become sealed with the higher viscosity drilling fluid.
6. If increasing the drilling fluid viscosity is ineffective, lost circulation materials (LCM) may be introduced into the hole by incorporating them in the drilling fluid and pumping the material down-hole. The drilling operation may again be suspended for a short period (i.e. overnight) to allow the fractured zone to become sealed with the lost circulation materials.
7. Depending on the location of the fractured zone, a steel casing may be installed that is of sufficient size to receive the largest expected down-hole tools for the crossing. This casing installation provides a temporary conduit for drilling fluids to flow while opening the remaining section of the hole to a diameter acceptable for receiving the proposed pipe sections. To alleviate future concerns with the steel casing after the HDD installation is completed, the casing is generally extracted from the hole prior to or just after completing the HDD installation. However, there have been instances when attempts at extracting the steel casing were unsuccessful.
8. In the event drilling fluid flow is not regained through the annulus of the drilled hole and a steel casing installation is not utilized, the HDD contractor may elect to install a grout mixture into the drilled hole in an attempt to seal the fractured zone. The down-hole drilling assembly is generally extracted and existing hole is re-drilled to the point at which it had previously been drilled prior to having encountered the loss of drilling fluid. 5. In addition, a grouting program may be implemented from the surface in the event that the installation of grout into the drilled hole is unsuccessful. This approach is only

practical in areas where drilling rigs with vertical drilling capabilities can access the HDD alignment. If a surface grouting program is utilized, the HDD drilling assembly is extracted from down-hole. Multiple holes are then drilled vertically on either side and along the HDD alignment to allow for grout slurry to be pumped into the fracture zone where the drilling fluid had previously been lost from the drilled hole. This process can take several days to complete in order to insert the grout in a grid pattern that covers the full fractured zone, during which time the HDD operation is suspended. Upon completion of the surface grouting program, the HDD operation will resume and the pilot hole will be reestablished through the grouted formation.

In some instances, it may be determined that the existing hole encountered a zone of unsatisfactory soil material and the hole may have to be abandoned. If the hole is abandoned, it will be filled with cuttings and drilling fluid.

**Movement Blockage**

Dry open-cut construction is expected to block upstream movement by adult salmonids, as well as withinstream movements of juvenile coho. As discussed above, fish are expected to abandon cover and/or avoid turbidity plumes generated by instream construction. Instream construction would be completed prior to most upstream migrations by Oregon Coast coho. The fluming process is expected to require from 36 to 96 hours of instream work (see table 4.5.4-15) during which migrating adult Oregon Coast coho could be exposed to TSS concentrations that would produce SEV scores ranging from 5 (minor physiological stress with increase coughing rate and/or increased respiration rate) to 6 (moderate physiological stress) and possibly 7 moderate habitat degradation and/or impaired homing).

Flumes would maintain streamflow and fish might move upstream or downstream through the flume. With the dam and pump method, fish would not be able to move upstream or downstream through the work area until the dams have been removed. Flumes and dams would be removed as soon as possible following backfilling of the trench.

With the dam and pump method, coho would not be able to move upstream or downstream through the work area until the dams have been removed. However, dam-and-pump construction is expected to require between 20 and 56 hours of instream work (see table 4.5.4-16). Dam-and-pump construction would generate lower TSS concentrations than fluming; effects to coho would be expected to range from short-term reduction in feeding rates and/or feeding success (SEV score 4) to moderate physiological stress (SEV score 6). All expected responses by adult and juvenile salmonids to TSS produced during fluming or dam-and-pump 10 meters or more downstream would be classified as sublethal, whether during low flows or peak flows.

At one crossing of the South Umpqua River, a diverted open cut crossing would be used. This is similar to a dry open cut in that all in channel construction would be done in the “dry” but would require diversion of the flow to one side of the channel at a time. This method could take about 14 days to complete per site. Because one channel would be open during the entire crossing, no passage of fish would be impeded and no fish removal would be required.

**Indirect Effects**

<u>Aquatic Habit</u>

The same approach utilizing TSS concentration and exposure to evaluate levels of risk to fish (Newcombe and Jensen, 1996) was applied to quantifying effects of sediment on fish habitat, termed the harmful alteration, disturbance or destruction (HADD) of habitat (Anderson et al., 1996). HADD risk includes concentration and exposure to sediment along with sensitivity of the habitat affected. Most likely, suspended sediment would increase embeddedness of spawning gravels with increasing habitat effects closer to the construction location.

Sediment falling out of suspension downstream from the construction location can affect freshwater rearing sites with water quantity and floodplain connectivity to form and maintain physical habitat conditions and support juvenile growth and mobility; water quality and forage supporting juvenile development; and natural cover such as shade, submerged and overhanging large wood, logjams and beaver dams, aquatic vegetation, large rocks and boulders, side channels, and undercut banks. Based on the models for suspended sediment concentration and duration of exposure discussed above (see tables 4.5.4-15 through 4.5.4-17 and figures 4.5-21 through 4.5-30), Anderson et al. (1996) described five severity of ill effect ranks to habitat:

SEV 3: Measured change in habitat preference.
SEV 7: Moderate habitat degradation measured by a change in the invertebrate community.
SEV 10: Moderately severe habitat degradation as defined by measureable reductions in the productivity of habitat for extended periods (months) or over a large area (kilometers).
SEV 12: Severe habitat degradation as measured by long-term (years) alterations in the ability of existing habitats to support fish or invertebrates.
SEV 14: Catastrophic or total destruction of habitat in the receiving environment.

FWS (Muck, 2010) determined that SEV scores of 5 or higher applying Model 3 would likely warrant a "likely to adversely affect" juvenile bull trout habitat although noting that abandonment of cover (SEV 2) or avoidance of habitat / change in habitat preference (SEV 3) could lead to increased predation risk and mortality if hiding cover is limited in an affected stream reach (Muck, 2010). For adult and subadult bull trout, FWS judged that abandonment of cover and avoidance may not lead to similar predation risks. Averse effects would likely occur when TSS concentrations lead to notable reduction in abundance of aquatic invertebrates and alteration in their community structure. Consequently, SEV scores (or HADD scores in Anderson et al., 1996) of 7 or higher would warrant a determination of "likely to adversely affect" adult and subadult bull trout due to indirect effects because of habitat degradation (Muck, 2010). In this biological assessment, similar levels of effect due to TSS concentrations and durations of exposure are assumed to apply to coho salmon.

The project is expected to impact salmonid habitat more than the SEV 3 level for Models 1 and 3 included in table 4.5.4-15 and table 4.5.4-16. The project would degrade habitat to the SEV 7 level with the upper 95% confidence levels or above in Model 1 or Model 3 during a failure of dry open-cut construction if TSS concentrations of 793 to 1,827 mg/L lasted for one hour or more (see table 4.5.4-17). In cases of uninterrupted dry open-cut construction, adverse affects to coho habitats downstream are not expected.

**Freshwater Stream Invertebrates**

Substrates downstream from instream construction sites could be impacted by sediments. Mayflies, caddisflies, and stoneflies prefer large substrate particles in riffles and are adversely affected by fine sediment deposited in interparticulate spaces (Cordone and Kelley, 1961; Waters, 1995; Harrison et al., 2007). Fish and benthic macroinvertebrate abundances downstream of pipeline construction sites have been reported as short-term reductions (Reid and Anderson, 1999). Macroinvertebrate abundance and community composition are highly related to the degree to which substrate particles are embedded by fine material (Birtwell, 1999).

Fish emigrate from construction sites and benthic taxa drift downstream to sites where sediment deposition has not affected habitat suitability (Reid and Anderson, 1999). In Ontario, stream crossing construction using fluming produced less turbidity and sediment concentrations downstream than construction by wet open cutting streams; wet open cutting resulted in a significant decrease in aquatic invertebrates downstream three days post-construction (Baddaloo, 1978 cited in Gartman, 1984). One year after construction there were no significant differences in benthos numbers. In general, the percentage of type of stream benthos and invertebrate taxa affected by construction of the proposed pipeline would be in proportion to their abundance during the season of construction.

Rapid colonization by benthic organisms of disturbed substrate following pipeline construction has been demonstrated elsewhere. In Pennsylvania, samples taken before and 30 days after pipeline construction revealed rapid recolonization of the disturbed and newly-exposed stream substrate by benthic macroinvertebrates (Gartman, 1984). Similarly, the number and diversity of aquatic invertebrate taxa in coldwater streams in New York State were unchanged two to four years following pipeline construction from those measured prior to construction (Blais and Simpson, 1997).

Aquatic Nuisance Species

Non-indigenous aquatic species (NAS) are aquatic species that degrade aquatic ecosystem function and benefits, in some cases completely altering aquatic systems by displacing native species, degrading water quality, altering trophic dynamics, and restricting beneficial uses (Hanson and Sytsma, 2001). Currently there are 180 reported NAS in Oregon, of which 134 are documented within the USGS hydrologic basins crossed by the proposed Pacific Connector Pipeline Project (USGS, 2005). Within the Coos Bay estuary, over 67 NAS have been identified (Aquatic Nuisance Species Taskforce, 2006). All of the invertebrate NAS in the Coos Bay estuary have been introduced by ship fouling or discharge from ballast water of ocean-going vessels.

Largemouth bass and smallmouth bass, introduced as recreational species, prey on juvenile sockeye, coho, and chinook salmon (Tabor et al., 2007). Management priorities in Oregon concentrate on the species whose current or potential impacts on native species and habitats and economic and recreational activity in Oregon are known to be significant, known as aquatic nuisance species (ANS) (Hanson and Sytsma, 2001). Pacific Connector has developed BMPs to avoid the potential spread of the aquatic invasive species and pathogens of concern (see Hydrostatic Testing Plan – appendix U). If determined to be feasible for hydrostatic testing requirements, all water used in hydrostatic testing would be returned to its withdrawal source location after use; however, cascading water from one test section to another to minimize water withdrawal requirements may make it impractical to release water within the same watershed where the water was withdrawn. If it is not possible to return the water to the same water basin from where it was withdrawn, various water treatment methods would be used to disinfect water that would be transferred across water basin boundaries including screening/filtering, chlorine treatment, and discharge to upland sites. After hydrostatic test water withdrawal, all equipment used in the withdrawal process would be cleaned and sanitized to prevent the potential spread of aquatic invasives and pathogens from the use of this equipment in other waterbody sources (see appendix U).

Riparian Vegetation Removal and Modification

Aquatic resources could be affected as a result of removal of vegetation and habitat at the waterbody crossing sites as required for pipeline construction. Short-term, physical habitat disruption would occur during trenching activities. Long-term degradation of habitats could occur if the stream contours are modified in the area of the crossing; the flow patterns are changed; and if erosion of the bed, banks, or adjacent upland areas introduces sediment into the waterbody. Loss of riparian vegetation along the banks would reduce shade, potentially increasing water temperatures, remove an important source of terrestrial food for aquatic organisms, and decrease LWD and the associated reduction in habitats, and potentially increase mass failures adjacent to waterbodies.

Much of the impact to coldwater anadromous and resident fisheries by past land uses have been alterations of riparian habitats by logging, road building, agriculture, or other developments such as residences and utility corridors. A total of 292.65 acres of riparian zone habitat associated with waterbodies within range of Oregon Coast coho ESU would be directly affected by all construction related activities. Less than half of the affected vegetation (142.50 acres) would be within non-forested types but 14.35 acres of late successional-old growth forest and 55.61 acres of mid-seral forest would be removed within riparian zones (see table 4.5.4-18a). As discussed in Section 4.5.4.2- Habitat, and data presented in table 4.5.4-7 and table 4.5.4-8, the LWD components of most aquatic habitats in watersheds occupied by Oregon Coast coho and crossed by the PCGP Project are deficient, below benchmark conditions established by ODFW.

In forested habitats, conifer trees will be replanted within the construction right-of-way and other cleared areas outside of the 30-foot wide maintenance corridor and allowed to return to its pre-construction state. The 30-foot wide maintenance corridor centered over the pipeline will be maintained in an herbaceous/shrub state by operations during the life of the project, assumed to be 50 years (see table 4.5.4-18b). Over the long-term, 3.39 acres through riparian late successional-old growth forest and 12.45 acres through mid-seral forest would be maintained in an herbaceous/shrub state within riparian zones associated with Oregon Coast coho (see table 4.5.4-18b).

Pacific Connector has attempted to minimize impacts on riparian vegetation by minimizing the width of the standard construction right-of-way at waterbody crossings, and by maintaining a setback between waterbody banks and TEWAs in forested areas. Following construction, Pacific Connector will implement measures to replant or encourage regrowth in riparian areas, and will minimize vegetation maintenance by allowing the development of a riparian strip at least 25 feet wide to be permanently revegetated on private lands and 100 feet wide on federally-managed lands as measured from the edge of the waterbody. As required by FERC's Upland Plan, Pacific Connector consulted with the NRCS, BLM, and Forest Service regarding specific seeding dates and recommended seed mixtures for the project area (see Resource Report 7, Pacific Connector Gas Pipeline). The recommendations have been incorporated into the project-specific Erosion Control and Revegetation Plan (ECRP – see appendix F). The ECRP describes the procedures that will be implemented to minimize erosion and enhance revegetation success for the entire project.

[1] Project components considered in calculation of habitat "Removed": PCGP construction right-of-way, temporary extra work areas, aboveground facilities, and permanent and temporary access roads (PAR, TAR).

[2] Habitat Types within Riparian Zones generally categorized as: Late Successional (Mature) or Old Growth Forest (coniferous, deciduous, mixed ≥80 years old); Mid-Seral Forests (coniferous, deciduous, mixed ≥40 but ≤80 years old); Regenerating Forest (coniferous, deciduous, mixed ≥5 but ≤40 years old); Clearcut Forests; Wetland Forested, Unaltered Nonforested Habitat (grasslands, sagebrush, shrublands), and Altered Habitats (urban, industrial, residential, roads, utility corridors, quarries).

Clearing the right-of-way would remove shading vegetation from uplands and riparian areas, exposing the land and water to increased sunlight, potentially resulting in both direct increases in water temperatures and indirect increases as water flows over the warmer land surface and eventually reaches the waterbody (Beschta and Taylor, 1988). For the waterbodies that would be crossed by HDD, the potential disturbance in riparian areas would be incidental trimming of vegetation using hand tools directly over the pipeline along a footpath. This minor clearing is required to facilitate the temporary deployment of HDD guidance (telemetry) cables along the ground during construction and to perform a leakage survey after installation and commissioning. This is a relatively small area along the riparian zone of any stream and would have minimal adverse effect on aquatic resources.

**Water Temperature**

The effects of water temperature on salmonid life stages have been extensively reviewed by McCullough (1999), Richter and Kolmes (2005), and others. Maximum water temperatures ranging from 22°C to 24°C (71.6°F to 75.2°F) limit distribution of many salmonid species. No salmonids can survive water temperatures exceeding 25°C (77°F) for extended periods (Ice, 2008). High water temperatures can cause migratory species (including anadromous salmonids) to delay upstream migration (Bjornn and Reiser, 1991), can decrease survival of spawners by increasing metabolic rates (Ice, 2008), can positively influence rates of embryo development and emergence but can negatively influence dissolved oxygen concentrations that limit rates of embryo development (Bjornn and Reiser, 1991). High temperatures inversely influence solubility of oxygen in water (Ice, 2008). Introduction of organic matter with decomposition by microorganisms reduces dissolved oxygen and, along with increased fines (suspended silt and clay) and decreased relative rate of oxygen input to water (reaeration) through reduction in stream flows (Ice, 2008), can adversely affect various salmonid life stages. Coho upstream migration water temperature requirments are for water from 7.2$^{o}$C to 15.6$^{o}$C, spawning requirements are for water from 4.4$^{o}$C to 9.4$^{o}$C, and for incubation from water from 4.4$^{o}$C to 13.3$^{o}$C; preferred temperature is 12.1$^{o}$C and upper lethal temperatures range from 26.0$^{o}$C to 28.8$^{o}$C, depending on previous acclimation temperatures (Bjornn and Reiser, 1991).

Vegetative cover that provides shade, especially during summer, is one factor that regulates water temperature. Construction across waterbodies would necessitate removal of trees and riparian shrubs at the crossing locations. Available information on the effects of pipeline construction in other regions on water temperature has found no or immeasurable change. The total width of riparian area affected by shade tree removal would be small (less than 100 feet) relative to the length of any stream crossed. In one study, construction across two coldwater, fish-bearing streams in Alberta required removing forested riparian vegetation; water temperatures at construction sites and downstream did not increase above temperatures at control sites upstream from construction (Brown et al., 2002). Similarly, water temperatures measured at four coldwater streams in New York before and during pipeline construction and for 3 years following construction showed no short-term or long-term effects on water quality parameters, including water temperature, even though such effects were expected because streambank vegetation had to be cleared, which reduced shading (Blais and Simpson, 1997). In the Alberta study, the highest water temperature recorded was 66°F (19°C in August). In the New York study, the highest temperature was 79 F (26°C) sometime between August and October.

Following requests by the Forest Service, Pacific Connector modeled water temperatures on 6 different stream segments on NFS lands in the Umpqua River basin on tributaries to East Fork

Cow Creek (5 crossings) and on the upper Rogue River basin on Little Butte Creek (North State Resources, 2009). Temperature models were run on 6 different stream segments on NFS lands in the Umpqua River basin on tributaries to East Fork Cow Creek (5 crossings) and on the upper Rogue River basin on Little Butte Creek (North State Resources, 2009). Of the three smallest streams modeled average temperature increase ranged from 1.0$^{o}$C to 8.6$^{o}$C right after construction. Because these streams were so small they likely also would have temperatures reduced rapidly downstream of the clearing from ground water inflow and likely would have no measurable effects on streams they flow into downstream.

As a rule, the effect of water temperature of a non-fish-bearing tributary on water temperature of a fish-bearing receiving stream is determined as the weighted mean of the two water temperatures, weight by respective volumes or instream flows. If $\mathbf{T_1}$ = temperature of tributary with $\mathbf{F_1}$ = flow rate, and $\mathbf{T_2}$ = temperature of receiving stream with $\mathbf{F_2}$ = flow rate, then the resulting water temperature $\mathbf{T_R}$ at the confluence of the two waterbodies would be,

$$\mathbf{T_R = (T_1\ F_1 + T_2\ F_2) / (F_1 + F_2).}$$

For example, Hydrofeature N is an unnamed tributary to East Fork Cow Creek crossed at MP 111.01. Pipeline construction would increase the water temperature by 8.6$^{o}$C from its base temperature of 11$^{o}$C (see North State Resources, 2009). The water temperature would be 19.6$^{o}$C but its reported summer base flow is 0.002 cfs. ODEQ measured water temperature within East Fork Cow Creek during September 1998, reported at 13.5$^{o}$C. No instream flow data are available for East Fork Cow Creek but USGS (Gage 14309500) has measured flows in West Fork Cow Creek, reporting an average flow of 11.4 cfs during September. Using those data as to illustrate how water temperatures would be combined by the weighted average, the resulting water temperature of Hydrofeature N and the receiving stream would be $\mathbf{T_R}$ = (19.6$^{o}$C x 0.002 cfs + 13.5$^{o}$C x 11.4 cfs) / (0.002 cfs + 11.4 cfs) = 13.501$^{o}$C. The increase of water temperature in the receiving stream by the tributary water temperature would be immeasurable (in this illustration the increase would be 0.001$^{o}$C).

In the North State Resources (2009 ) study, two streams, 5- and 6- feet wide would have estimated maximum temperature increases ranging from 0.4 to 0.5$^{o}$C with maximum temperature remaining at or below 15.6$^{o}$C in the two streams just downstream of the pipeline crossing sites. Those temperatures would remain within suitable range for salmonids. For the largest stream (22 feet wide) in the study, the estimated increase was estimated to be 0.02 to 0.1$^{o}$C depending on the temperature model applied. The modeled results, based on assumptions used about the rates of vegetation regrowth, determined that most temperature increase effects remained within the first 5 years, but were approaching pre-project temperatures within 10 years. Conditions at other streams along the pipeline route may vary from these due to site specific differences, but these results may be fairly representative of changes that may occur at forested streams along the route. Overall results suggest that other than the very smallest streams where fish resources would be limited, changes in temperature from vegetation removal are likely to remain small and immeasurable having unsubstantial effects on fish resources.

Similarly, GeoEngineers (2013c) modeled thermal impacts within 4$^{th}$ Field Watersheds where streams would be crossed by the pipeline where riparian shading vegetation would be removed within the 75-foot wide construction corridor and would be affected within the 30-foot maintenance corridor of the long term (e.g., see table 4.5.4-18b, above). Model results show a maximum predicted increase of 0.16°C over one 75 foot clearing. The analysis showed that elevated water temperatures would return to ambient levels within a maximum distance of 25 feet downstream of the pipeline corridor, based on removal of existing riparian vegetation over a cleared corridor width of 75 feet (GeoEngineers, 2013c). The results are similar to the more geographically-limited results obtained by North State Resources (2009) which suggested more thermal impact. The conclusion drawn by GeoEngineers (2013c) was that the magnitude of thermal impact caused by pipeline construction would not be expected to cause a thermal barrier to fish migration.

Pacific Connector has proposed supplemental riparian plantings as outlined in Section 10.12 of the ECRP (see appendix F) to help ensure that the core cold-water habitat temperature criteria are not exceeded at the maximum point of impact. These measures are designed to speed up the rate of riparian area recovery and provide more effective shade immediately following construction. Plantings and vegetation regrowth in riparian areas would help moderate potential temperature increases in the short term (a few years). Pacific Connector would install supplemental transplanted trees on the Umpqua National Forest within the riparian areas of East Fork Cow Creek (i.e., 15-20 feet tall with full crowns) to increase riparian area canopy closure and placing large woody debris and boulders to create micro-topography within the wetted stream channel (see Section10.12 in the ECRP). Shading from transplanted vegetation and micro-topographic features incorporated into the final grading plan are likely to reduce the heat load enough to reduce the likelihood of measurable water temperature increases. Pacific Connector modeled the potential benefit of post project effective shade created by these mitigation measures on the Umpqua National Forest. The results of the 10-year post project modeling time step was used to predict the benefits of the mitigation measures because the trees that would be transplanted provide at least the same shade values as predicted for this time step. The predicted water temperature changes are small, with less than a 0.3°C (0.5°F) change at the point of maximum impact, with no increase at the stream network scale (North State Resources, 2009). Inclusion of the measures improves the certainty that riparian area clearance and stream channel disturbance activities within the construction right-of-way would not cause measurable water temperature increases at the maximum point of impact or at the stream network scale.

**Large Woody Debris**

Existing conditions associated with riparian vegetation within 5$^{th}$ Field Watersheds in the Upper Rogue Sub-basin crossed by the PCGP Project (see discussion related to table 4.5.4-7 and table 4.5.4-8) are generally undesirable. There are too few large conifers along most stream reaches and LWD numbers, volume, and presence of key pieces tend to be below benchmark levels. The PCGP Project will remove 14.35 acres of late successional-old growth forest and 55.61 acres of mid-seral forest would be removed within riparian zones in watersheds occupied by Oregon Coast coho (see table 4.5.4-18a) which would affect recruitment of LWD at those sites. Of the total riparian forest affected, 11.31 acres would be removed in the Coos Sub-basin, 26.63 acres within the Coquille Sub-basin, and 32.02 acres would be removed within the South Umpqua Sub-basin.

A potential effect on fisheries that would result from forest clearing at pipeline crossings of waterbodies is the reduction of LWD in streams and on adjacent uplands (Harmon et al., 1986; Sedell et al., 1988). Large logs provide instream hydraulic complexity, which contributes to habitat complexity and the formation and maintenance of pools, riffles and other habitats which are critical to salmonid spawning and. As the size of individual logs or accumulations of logs increases, the size and stability of pools that are created also increase (Beschta, 1983). Riparian forests that undergo harvesting of large trees take on secondary-growth characteristics and contribute lower quantities of woody debris than unmanaged, old-growth forests (Bisson et al., 1987). However, sufficiently wide, carefully managed riparian buffers that retain a full complement of ages, sizes, and species of native trees and vegetation can ensure adequate recruitment of LWD to streams (Bisson et al., 1987; Murphy and Koski, 1989).

Pacific Connector has proposed to use on-site mitigation for impacts to waterbodies by installing LWD at agency- and land owner-approved and appropriate areas within the construction right-of-way across certain waterbodies. The use of LWD as a mitigation measure for impacts associated with instream construction has been documented as an effective means of creating instream habitat heterogeneity, reducing streambank erosion, reducing sediment mobilization (Bethel and Neal, 2003), and enhancing local fish abundance (Scarborough and Robertson, 2002). Placement of LWD on the streambanks and in the streams can provide slight shade and increase bank stability, while vegetation is maturing following construction. Additionally, placement of LWD in streams or on streambanks can provide habitat for benthic invertebrates, an important food source for salmonids, and also increase habitat for forage species with the creation of pools and enhancement of the salmonid rearing potential of an area (Cederholm et al. 1997; Slaney et al., 1997).

As shown in table 4.5.4-7 and table 4.5.4-8, LWD conditions are undesirable in all four fifth field watersheds of the Upper Rogue Sub-basin that would be crossed. Streams in the watersheds are deficient in numbers of LWD pieces per length of stream channel, deficient in volume of LWD, and deficient in numbers of key pieces (≥60 cm in diameter by ≥12 m in length) per unit of stream length. Based on those data, any addition of LWD to the watersheds would appear beneficial.

**Hydrostatic Testing**

Water would be required on a one-time basis near the end of construction to hydrostatically test the pipeline. Potential impacts associated with hydrostatic testing include entrainment of fish, reduced downstream flows, and impaired downstream uses if test water is withdrawn from surface waters, and erosion, scouring, and a release of chemical additives as a result of test water discharge. The Forest Service has also expressed concern that hydrostatic testing where the source and discharge locations were in different water basins could potentially transfer exotic organisms between basins. Pacific Connector would obtain its hydrostatic test water from commercial or municipal sources or surface water rights owners and come from lakes, impoundments, and streams, and has identified 15 potential source locations and 75 potential discharge locations for the test water (see Resource Report 1, Pacific Connector Gas Pipeline Project); all but seven potential discharge sites would be within the construction right-of-way.

Pacific Connector would minimize the potential effects of hydrostatic testing on these systems by adhering to the measures in its Hydrostatic Testing Plan (see appendix U), including screening intake hoses to prevent the entrainment of fish and other aquatic organisms, meeting NMFS screening criteria, and regulating the rate of withdrawal to avoid adverse impact on aquatic resources or downstream flows. Where test water cannot be returned to its withdrawal source, the water would be treated with a mild chlorine treatment and discharged to an upland location through a dewatering structure at a rate to prevent scour and erosion and to promote infiltration. Pacific Connector will obtain all necessary appropriations, withdrawal, and discharge permits through the Oregon Water Resources Department (OWRD). As part of the application process, OWRD provides the application(s) to ODEQ and ODFW for review.

**Fuel and Chemical Spills**

Fisheries habitats could be adversely affected if petroleum products were accidentally discharged into aquatic environments. Such materials are toxic to algae, invertebrates and fish. Of the products likely to be present during pipeline construction, data compiled from a wide range of sources indicate that diesel fuels and lubricating oils are considerably more toxic to aquatic organisms than other, more volatile products (gasoline) or heavier crude oil (Markarian et al., 1994). Release of diesel fuel in freshwater habitats significantly reduced aquatic invertebrate densities and species richness at least 3 miles downstream but invertebrate densities recovered within a year (Lytle and Peckarsky, 2001). Impacts to aquatic habitats that primarily affect aquatic substrates – hence spawning, incubating and rearing habitats – can remain for much longer periods (Markarian et al., 1994).

Construction equipment used to construct the pipeline across waterbodies can potentially release hydraulic fluid that include a variety of compounds those common of which are mineral oil-based, organophosphate esters, and polyalphaolefins (U.S. Department of Health and Human Services, 1997). Release from machinery can occur through faulty seals, hoses, sumps and reservoirs, or general system failure. Components of mineral oil and polyalpaolefins do appear to bioaccumulate in animals whereas larger molecular constituents in organophosphate esters can concentrate in fish, primarily partitioning in fat tissue (U.S. Department of Health and Human Services, 1997). In general, toxicity of organophosphate esters is greater than either mineral oil or polyalphaolefin-based hydraulic fluids for inhalation, oral, and dermal for humans but toxicities have not been clearly described for aquatic invertebrates or fish and would be dependent on specific chemical components (U.S. Department of Health and Human Services, 1997).

Inadvertent spills of fluids used during construction, such as fuels and lubricants, could contaminate wetland soils and vegetation. To minimize the potential for spills and any impacts from such spills, Pacific Connector's Spill Prevention, Containment, and Countermeasures Plan (SPCC Plan – see appendix L) will be implemented. In general, hazardous materials, chemicals, fuels, lubricating oils, and concrete-coating activities will be not be stored, nor will refueling operations be conducted within 150 feet of a wetland or waterbody in accordance with FERC's Wetland and Waterbody Procedures (see appendix C) and the SPCC Plan (see appendix L).

**Herbicide Application**

Following construction, Pacific Connector will implement a Noxious Weed Control Plan in part through the application of herbicides. Herbicides have the potential to cause toxic effects to different salmonid life stages and to other aquatic species, causing direct impacts, if used improperly. When herbicides are properly used according to label restrictions and BMPs to control noxious weeds, there is little to no chance of causing injury or mortality to fish or other aquatic organisms; the impact may be avoided or indirect.

Pacific Connector has developed an Integrated Pest Management Plan (IPM) in consultation with the Oregon Department of Agriculture, BLM and Forest Service (see Appendix I to the POD, available upon request) to address the control of noxious weeds and invasive plants across the project. The BMPs will minimize the potential spread of invasive species and minimize the potential adverse effects of control treatments.

According to the Pacific Northwest Weed Management Handbook (see Peachey et al., 2007), herbicides used in forests to control brush and weed-trees could include one of the following: 2,4-D, glyphosate, imazapyr, picloram, and ticlopyr which are applied during spring or fall dormancy although triclopyr or 2,4-D was not approved use by the Fremont-Winema National Forest (NF). Clopyralid may be used during summer to control thistles, other composites, and legumes while not damaging conifers. Only herbicides which are approved for use within treated lands (private, state, or federal) would be used. Chronic, long-term, elevated but sublethal toxic effects can lead to skin or eye irritation, headache, nausea, and possibly birth defects, genetic disorders, paralysis, cancer, and death (Tu et al., 2001). In general, most impact to waterbodies occurs from direct overspray or drift of herbicides (aerial applications) as well as leaching through soils into groundwater or as they are carried by surface/subsurface runoff (Tu et al., 2001). The ester form of herbicides is more toxic to fish and other aquatic species than salt or acid forms because esters are readily adsorbed through skin and gills. Esters are also water insoluble so that they are not diluted in waterbodies (Tu et al., 2001).

Herbicides potentially used during the project will breakdown over various periods of time, marked by the average half-life (the time it takes for the herbicide concentration to decline by 50% due to microbial metabolism –dependent on the microbial population, environmental pH, soil moisture and temperature - mineralization, and/or photolysis). Half-lives in soil and water are provided and known toxicities to bluegill sunfish (see Tu et al., 2001) although comparative toxicities to salmonids have not been found in the literature:

- 2,4-D – averages 10 day half-life in soils, less than 10 days in water. Salt formulations with low toxicity are registered for use against aquatic weeds, LC50 for bluegill sunfish = 263 mg/l.
- Glyphosate - ranges from several weeks to years, but averages two months. In water, glyphosate is rapidly dissipated through adsorption to suspended and bottom sediments, and has a half-life of 12 days to ten weeks. Some formulations with low toxicity are registered for aquatic use, LC50 for bluegill sunfish = 120 mg/l.
- Imazapyr – ranges from 1 to 5 months in soil. In aqueous solutions with photodegradation the half-life may be 2 days. It has low toxicity to fish and algae and other submerged vegetation are not affected, LC50 for bluegill sunfish >100 mg/l.
- Picloram- range from 1 month to several years in soils, average soil half-life of 90 days. LC50 for bluegill sunfish >14.5 mg/l.
- Triclopyr – average half-life in soils is 30 days but the salt formulation is water soluble and may photodegrade in several hours. LC50 for bluegill sunfish =148 mg/l.
- Clopyralid - half-life averages one to two months (40 days) but ranges up to one year. It is degraded almost entirely by microbial metabolism in soils and aquatic sediments. LC50 for bluegill sunfish =125 mg/l.

Of these herbicides, Picloram is the most toxic to bluegill sunfish and is potentially the longest persisting in soils and water. Similar attributes are expected for effects to salmonids. The potential for adverse effects to salmonids and other aquatic species by the other herbicides appear to be extremely remote, especially since application would be at least 100 feet from wetlands and waterbodies unless allowed by the appropriate agency. Pacific Connector will not use aerial herbicide applications and will not use herbicides for general brush/tree control within the 30-foot maintained easement. Given low toxicities to fish and short half-lives in soil and water, expected effects of the other herbicides to resident fish and anadromous salmonids would be discountable and insignificant.

Where weed control is necessary along the construction right-of-way, Pacific Connector's first priority will be to employ hand and mechanical methods (pulling, mowing, biological, disking, etc.) applicable to the species to prevent the spread of potential weed infestations, where feasible. To determine if an herbicide is to be used over other control methods, Pacific Connector will base the decision on weed characteristics and integrated weed management principles (Forest Service, 2005). If herbicides are used to control noxious weed infestations, they would be used when they are the most appropriate treatment method. Spot treatments and the use of selective herbicides would be utilized to minimize impact to native or non-target species. Pacific Connector will employ a state or federally-licensed herbicide applicator to ensure that the appropriate herbicides are utilized for the targeted weed species during its proper phenological period and at the specified rate. The applicator will ensure that the herbicides and any adjuvants are used according to the labeling restrictions, and warnings, following all applicable laws and conforming to the appropriate land managing agency decision documents. The applicator will also ensure that the herbicides that are used are registered for their intended use. Permits or approvals for the use of herbicides and adjuvants on federal lands would be obtained prior to use/treatment, as detailed in the IPM (see Appendix I to the POD, available upon request).

**Streambank Erosion**

The clearing and grading of vegetation during construction could increase erosion along streambanks and turbidity levels in the waterbodies. The rootwad network of trees adjacent to stream supplies bank stability. Those within 25 feet of the stream are considered most important at providing the root source aiding in bank stability (Washington Department of Natural Resouces, 1997). To aid in maintaining this bank stability, Pacific Connector would cut most trees near the bank, except those in the trench line, at ground level leaving the root systems in place helping to maintain riparian stability. Roots would be removed over the trench line or from any steam banks that would need to be cut down or graded to accomplish the pipeline crossing.

Alteration of the natural drainage ways or compaction of soils by heavy equipment near streambanks during construction may accelerate erosion of the banks, runoff, and the transportation of sediments into waterbodies. The degree of impact on aquatic organisms due to erosion would depend on sediment loads, stream velocity, turbulence, streambank composition, and sediment particle size. To minimize these impacts, Pacific Connector would use temporary equipment bridges, mats, and pads to support equipment that must cross the waterbody (perennial, intermittent, and ephemeral if water is present) or work in saturated soils adjacent to the waterbody. Pacific Connector would also install sediment barriers, such as silt fence and straw/hay bales, across the right-of-way at the edge of waterbodies throughout construction except for short periods when the removal of these sediment barriers is necessary to dig the trench, install the pipe, and restore the right-of way. Practices to minimize streambank erosion are provided in Section 5.0 in the ECRP (see appendix F).

**Operation and Maintenance Activities**

Once installed, maintenance of the pipeline would include activities such as aerial inspections, gas flow monitoring, visual inspection of surrounding vegetation for signs of leaks, and integrity management, which includes smart pigging to investigate the interior surface of the pipe for any signs of stress cracking, pitting, and other anomalies (see Section 13.0 in the ECRP – appendix F). All of the proposed maintenance activities would be outlined in the Operations and Maintenance plan that would be prepared according to operating regulations in U.S. Department of Transportation (DOT) 49 CFR Subpart L, Part 192 and would be completed prior to going in-service. These general maintenance activities would require only surface activities and usage of the existing right-of-way, such as insertion of the pig at one of the pig launching facilities.

The potential estuarine or stream channel disturbance would occur if an integrity issue with the pipeline were found. If this were to occur, the pipeline would need to be unearthed within the right-of-way and repair work done in-water. Within stream sites, repair work could require isolated flow from the section of pipe that is to be exposed. Typically, repairs would be made to the pipe within the right-of-way (within the trench) or, depending on the site-specific conditions and nature of the repair needed, a reroute around the affected section may be considered. Impacts would be similar to those discussed above for initial installation except on a much smaller scale, and would include all relevant BMPs and mitigation, dependent upon site conditions and land ownership..

Vegetation maintenance would be limited adjacent to waterbodies to allow a riparian strip to permanently revegetate with native plant species across the entire right-of-way. To facilitate periodic pipeline corrosion/leak surveys, a corridor centered on the pipeline and up to 30 feet wide would be maintained in an herbaceous state. In addition, trees that are located within 15 feet of the pipeline and that are greater than 15 feet in height would be cut and removed from the right-of-way.

**Cumulative Effects**

FWS and NMFS describe cumulative effects (50 CFR § 402.02) as the result of future actions by state or private entities, not involving federal actions, but reasonably certain to occur in the action area considered in this biological assessment. Future federal actions that are unrelated to the proposed action are not considered here because they require separate consultation pursuant to section 7 of the ESA. The Pacific Connector pipeline would not be operational until at least 2017. Consequently, the foreseeable future required for cumulative effects analysis would actually occur before implementation of the proposed action, not after its implementation, which is more often the case.

Cumulative effects to Oregon Coast coho salmon would be generated by timber harvesting on non-federal lands. Areas of Late Successional-Old Growth (LSOG) forest have been monitored as a component of the Northwest Forest Plan (NWFP). In Oregon, LSOG was evaluated in 1996 (Moeur et al., 2005) and in 2006 (Moeur et al., 2011). Differences in areas of LSOG forests were described in the four physiographic provinces that coincide with the PCGP project showed an overall decline on all lands; from 1996 to 2006 there was an overall net loss of LSOG on non-federal lands within the Coast Range (-17.1 percent), Klamath Mountains (-6.7 percent), Western Cascades (-10.8 percent), and Eastern Cascades (-12.6 percent) provinces (see Table 7 in Moeur et al., 2011). Most of the losses in LSOG on federal lands were attributed to large fire events including the 2002 Biscuit Fire in the Klamath Mountains, the 2003 B&B Fire in the Western Cascades, and the 2003 B&B Fire and Davis Fire in the Eastern Cascades (Moeur et al, 2011). However, losses associated with wildfire were negligible on non-federal lands. Most of the decline in LSOG on non-federal lands was due to timber harvest, primarily concentrated in the Oregon Coast Range province (see Table 7 in Moeur et al., 2003)

Within the PCGP project area and range of Oregon Coast coho, comparisons of LSOG coverage on non-federal lands within the four of the fifth field watersheds in the Coos and Coquille sub-basins show opposite trends from 1996 to 2006; the only apparent loss of LSOG occurred within the Middle Fork Coquille River Watershed (see figure 4.5-31).

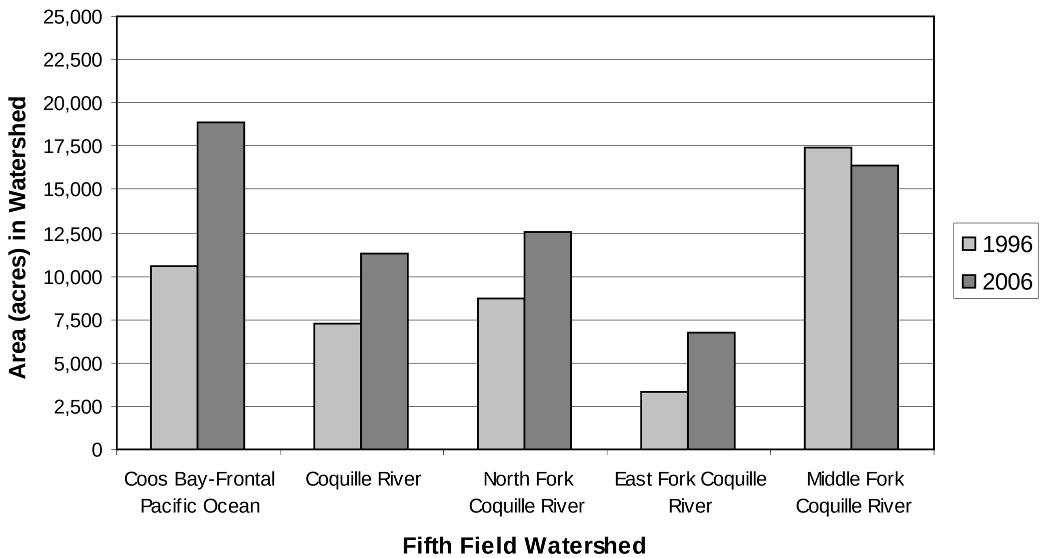

**Figure 4.5-31**
**Total Areas (acres) of Late Successional-Old Growth Forests on Non-Federal Lands in 1996 and 2006 within Five Fifth Field Watersheds (Coos and Coquille Sub-basins) within Range of Oregon Coast Coho Salmon that would be Crossed by the PCGP Project. (Data from Interagency NWFP Interagency Regional Monitoring Program, 2013)**

During the period from 1996 to 2006, areas of LSOG on non-federal lands increased by 78 percent within Coos Bay-Frontal Pacific Ocean watershed, by 57 percent within Coquille River watershed, by 46 percent within North Fork Coquille River watershed, and increased by 103 percent in the East Fork Coquille River watershed. LSOG declined by 6 percent within Middle Fork Coquille River watershed. All five fifth field watersheds are within the Oregon Coast Range Province in which there was a 17.1 percent decline of LSOG primarily due to timber harvest. The disparity between the overall decline of LSOG in the Coast Range province and increase of LSOG in the four fifth field watersheds is unexplained but may be due to measurement errors, mapping errors, and/or differences in detection or definition of LSOG between 1996 and 2006. Regardless, we use comparisons of LSOG from 1996 to 2006 to estimate cumulative effects the in the Coos and Coquille sub-basins in the reasonably foreseeable future w.

Comparisons of LSOG coverage on non-federal lands within four of the fifth field watersheds in the South Umpqua Sub-basin show declining trends from 1996 to 2006; the only apparent increase in LSOG occurred within the Olalla Creek-Lookingglass Creek Watershed (see figure 4.5-32). During the period from 1996 to 2006, areas of LSOG on non-federal lands increased by 36 percent within Olalla Creek-Lookingglass Creek watershed, but decreased by 54 percent within the Clark Branch-South Umpqua River watershed, decreased by 55 percent within the Myrtle Creek watershed, decreased by 54 percent in the Days Creek-South Umpqua River Watershed, and decreased by 91 percent in the Upper Cow Creek Watershed.

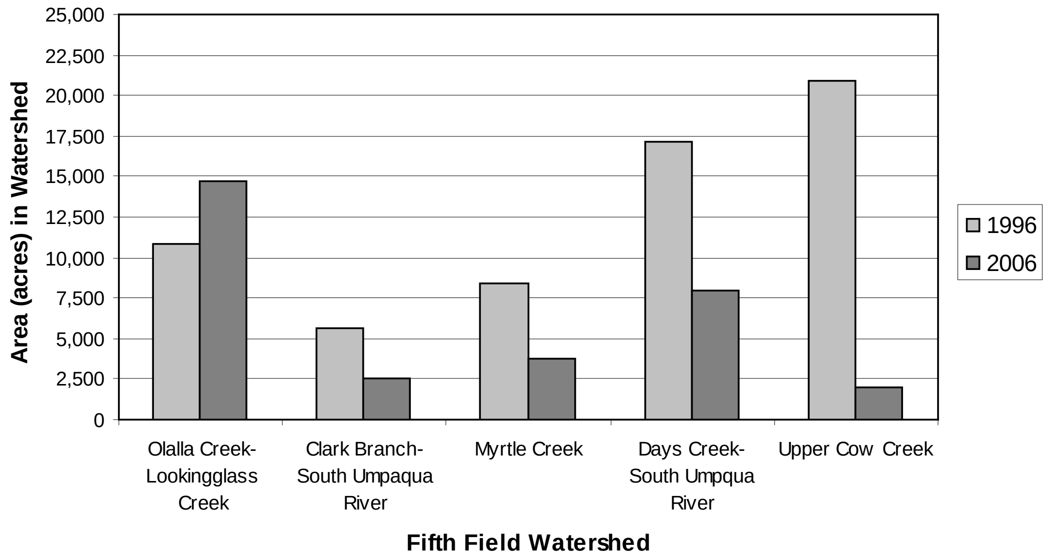

**Figure 4.5-32**
**Total Areas (acres) of Late Successional-Old Growth Forests on Non-Federal Lands in 1996 and 2006 within Five Fifth Field Watersheds (South Umpqua Sub-basin) within Range of Oregon Coast Coho Salmon that Would Be Crossed by the PCGP Project. (Data from Interagency NWFP Interagency Regional Monitoring Program, 2013)**

Based on the past trend there would be more LSOG on non-federal lands in the foreseeable future in half of the watersheds and less LSOG on the other half of watersheds affected by the PCGP project that are within range of coho salmon in the Oregon Coast ESU. Increased LSOG within riparian zones may be possible. Removal of additional LSOG within riparian zones on non-federal land would be more of a reasonably foreseeable cumulative impact. The amount of LSOG gain or loss on non-federal land through 2016, for example, would possibly be: 1) by the same percentage, or 2) at the same rate as the amounts that changed between 1996 and 2006. These two scenarios are provided below in table 4.5.4-19 wherein change (gain or loss) at a constant annual rate predicts no LSOG left on non-federal lands by 2016 in three of the watersheds. Alternatively, change of LSOG by the same percent change observed between 1996 and 2006 predicts considerable increases in LSOG in 2016 on five watersheds with decreases on five others but not totally eliminating LSOG within any of the watersheds (see table 4.5.4-19).

**Table 4.5.4-19**
**Two Estimates For Areas of Late Successional-Old Growth Forest in 2016 on Non-Federal Lands in Fifth Field Watersheds Crossed by the PCGP Project within Range of Oregon Coast Coho**

| Oregon Coast ESU Fifth Field Watershed | Area (acres) of LSOG on Non-Federal Land in 2006 [1] | LSOG Estimate Based on Percent Change | | LSOG Estimate Based on Rate of Change | |
|---|---|---|---|---|---|
| | | Percent Change in LSOG Since 1996 | Area (acres) of LSOG Remaining in 2016 | Rate of Change (acres per year) Since 1996 | Area (acres) of LSOG Remaining in 2016 |
| Coos Bay-Frontal Pacific Ocean | 18,835 | 78.4% | 33,608 | 828 | 27,114 |
| Coquille River | 11,357 | 56.6% | 17,781 | 410 | 15,461 |
| North Fork Coquille River | 12,602 | 45.5% | 18,335 | 394 | 16,543 |
| East Fork Coquille River | 6,698 | 102.8% | 13,582 | 339 | 10,093 |
| Middle Fork Coquille River | 16,392 | -5.8% | 15,435 | -102 | 15,375 |
| Olalla Creek-Lookingglass Creek | 14,690 | 35.7% | 19,942 | 387 | 18,559 |
| Clark Branch-South Umpqua River | 2,588 | -54.0% | 1,191 | -304 | 0 |
| Myrtle Creek | 3,740 | -55.4% | 1,667 | -465 | 0 |
| Days Creek-South Umpqua River | 7,924 | -53.7% | 3,670 | -919 | 0 |
| Upper Cow Creek | 1,938 | -90.7% | 130 | -1,894 | 0 |
| Total LSOG Areas | **96,764** | | **125,341** | | **103,145** |

[1] Data from Interagency NWFP Interagency Regional Monitoring Program, 2013

In 2016, there might be between 103,000 and 125,000 acres of LSOG within the ten fifth field watersheds crossed by the PCGP project within range of Oregon Coast coho but there are no estimates for areas of LSOG within riparian zones within the watersheds. However, amounts of LSOG within the PCGP project area that would be affected by construction and amounts of LSOG that would be affected within riparian zones (e.g., see table 4.5.4-18a) have been determined. We assumed that the proportions of LSOG in riparian zones to total LSOG affected by pipeline construction on non-federal lands within each watershed were representative of proportions of riparian to total LSOG on non-federal lands in each watershed. With that assumption, we computed the areas of LSOG in riparian zones on non-federal that would change (as a gain or loss) by 2016, based on the reasonably foreseeable future estimates of remaining LSOG in table 4.5.4-19. Estimates of areas of riparian LSOG present on non-federal lands in 2016 are provided in table 4.5.4-20, based on the percent change in LSOG since 1996 (derived in table 4.5.4-19). The estimates predict that there would have been a total of 20,281 acres of riparian LSOG on non-federal lands within all ten watersheds during 2006 but there would be a net gain of nearly 8,000 acres of riparian LSOG in 2016 in spite of likely timber removal actions on non-federal lands (including removal of riparian LSOG) and other possible causes of removal (wildfire, disease). However, estimates of riparian LSOG within six watersheds indicate losses between 2006 and 2016. The proposed action would remove 7.68 acres of riparian LSOG within the ten watersheds in range of the Oregon Coast coho, about 0.03 percent of the amount of riparian LSOG projected to be present in 2016, within the reasonably foreseeable future, and a small portion of overall cumulative effects.

**Table 4.5.4-20**
**Potential for Cumulative Effects within Late Successional and Old Growth Riparian Forests on Non-Federal Lands within the Pacific Connector Pipeline Action Area that Coincide with the Oregon Coast Coho Salmon ESU**

| SONCC ESU Fifth Field Watershed | Area (acres) of LSOG on Non-Federal Land in 2006 [1] | LSOG Affected by the Proposed Action on Non-Federal Land in Watershed | | | Area (acres) of Riparian LSOG on Non-Federal Land in Watershed | |
|---|---|---|---|---|---|---|
| | | Area (acres) of LSOG Affected | Area (acres) of LSOG Within Riparian Zones | Proportion of Riparian LSOG | Area (acres) of Riparian LSOG in 2006 [2] | Area (acres) of Riparian LSOG Present in 2016 [3] |
| Coos Bay-Frontal Pacific Ocean | 18,835 | 7.46 | 0.83 | 0.11 | 2,096 | 3739 |
| Coquille River | 11,357 | 0.36 | 0.36 | 1.00 | 11,357 | 17785 |
| North Fork Coquille River | 12,602 | 0.71 | 0 | 0.00 | 0 | 0 |
| East Fork Coquille River | 6,698 | 2.33 | 0.15 | 0.06 | 431 | 874 |
| Middle Fork Coquille River | 16,392 | 3.95 | 1.01 | 0.26 | 4,191 | 3948 |
| Olalla Creek-Lookingglass Creek | 14,690 | 19.80 | 1.29 | 0.07 | 957 | 1299 |
| Clark Branch-South Umpqua River | 2,588 | 7.57 | 0 | 0.00 | 0 | 0 |
| Myrtle Creek | 3,740 | 8.90 | 1.46 | 0.16 | 614 | 274 |
| Days Creek-South Umpqua River | 7,924 | 32.12 | 0.51 | 0.02 | 126 | 58 |
| Upper Cow Creek | 1,938 | 7.88 | 2.07 | 0.26 | 509 | 47 |
| Total Area | **96,764** | **91.08** | **7.68** | | **20,281** | **28,024** |

[1] Data from Interagency NWFP Interagency Regional Monitoring Program, 2013.
[2] Based on Proportion of Riparian LSOG affected by PCGP Project on Non-Federal Land
[3] Based on the Percent Change in LSOG Since 1996 in table 4.5.4-19.

ODF Administrative Rules (Chapter 629) include requirements for protecting riparian zones associated with streams of various size classes and uses on non-federal lands. RMA widths were assigned to "retain the physical components and maintain the functions necessary to accomplish the purposes and to meet the protection objectives and goals for water quality, fish, and wildlife". Specified riparian zones widths range from 100 feet for a large (average annual flow ≥ 10 $feet^3$/second) Type F (fish use and domestic use) stream to 20 feet for a small (average annual flow ≤ 2 $feet^3$/second) Type D (domestic water use, no fish) stream. While the ODF Administrative Rules provide some protection to fish-bearing streams, the narrower riparian zones described in the Rules are likely to provide less protective functions due to forest harvest practices on non-federal lands than harvest on federal lands.

### Critical Habitat

The Coos Bay Estuary and 29 freshwater streams known to support coho within table 4.5.4-1 are designated critical habitat for Oregon Coast coho. The effects to riparian zones associated with each waterbody in critical habitat that support coho are included in table 4.5.4-18a. PCEs include, but are not limited to, spawning sites, food resources, water quality and quantity, and riparian vegetation (NMFS, 2008d). Each PCE defined for critical habitat would be adversely affected by the proposed action. Those effects have been quantified to the extent possible in the foregoing analyses including effects within the EEZ analysis area, the estuarine analysis area, and the riverine analysis area.

Project effects to freshwater spawning sites would likely occur prior to coho spawning in the year of construction and there would be no effects to spawning, incubation, and larval development by suspended sediment although project-generated sediment could increase gravel embeddeness downstream. Those effects would depend on precipitation and instream flow (potential freshets) following construction that would likely flush fines downstream The project would remove small areas of riparian forest that would provide recruitment of LWD. The project would temporarily decrease water quality downstream from construction sites by entrainment of sediments. In all instances, habitat suitability (HADD) would temporarily decrease. Construction of the pipeline across Haynes Inlet and dredging of the Coos Bay shipping channel would decrease water quality and affect cover (aquatic vegetation, eelgrass). Disposal of dredged spoils at Site F could cause effects to the nearshore marine environment, similar to assumed effects that are associated with current maintenance dredging. LNG carriers could affect offshore marine areas of critical habitat if spills or releases at sea occurred and possible limited effects due to vessel noise.

#### 4.5.4.4 Conservation Measures

Conservation measures have been proposed by Pacific Connector to minimize construction and operation impact to the estuary (estuarine analysis area), waterbodies, and riparian zones (riverine analysis area). Those measures have been compiled in table 2C in appendix N and apply to Oregon Coast coho salmon.

Pacific Connector has also proposed measures to rectify, repair, rehabilitate, and otherwise reduce impact to waterbodies and riparian zones once construction of the Pacific Connector pipeline is complete. Those measures have been compiled in table 3C in appendix N.

**Erosion Control**

Many of the conservation measures in table 3C in appendix N focus on erosion control to prevent sediment from entering surface waters. Temporary erosion controls would be installed immediately after vegetation clearing and grading and would be properly maintained throughout construction and reinstalled as necessary until replaced by permanent erosion controls or restoration is complete. At a minimum, the following temporary erosion control structures would be installed: temporary slope breakers, sediment barriers, mulch, and erosion control fabric.

**Temporary Slope Breakers**

Pacific Connector would install temporary slope breakers over the backfilled, recontoured construction right-of-way as specified in FERC staff's Plan. The outfall of each temporary slope breaker would be to a stable, well-vegetated area or to an energy-dissipating device at the end of the slope breaker off the construction right-of-way. Slope breakers reduce runoff velocity, thereby intercepting sediment and allowing it to drop out of suspension. They also can effectively divert runoff away from a disturbed site to a stable outlet (Goldman et al., 1986).

**Sediment Barriers**

Pacific Connector would primarily rely upon silt fence and staked hay or straw bales to confine sediment to the construction right-of-way. These structures would be used adjacent to wetland and waterbody crossings consistent with the requirements of FERC staff's Procedures. Straw bales and filter fabric (silt fence) can be used together to create a highly effective sediment barrier, a combination that compensates for the limitations of each used in isolation; straw bales provide extra support and the fabric provides greater filtering capability (Goldman et al., 1986).

All straw or hay bales used for sediment barriers would be certified as weed-free. Temporary sediment barriers would be maintained in-place until permanent revegetation measures are successful or until the upland areas adjacent to wetlands, waterbodies or roads are stabilized. The structures would be removed once vegetation in the area has been successfully restored.

**Mulch**

Under certain circumstances, the FERC staff's Plan requires the application of mulch to stabilize the soil surface. If it becomes necessary to delay final cleanup, including final grading and installation of permanent erosion control measures, beyond 10 days after the trench is backfilled in a specific area, Pacific Connector would apply mulch to the disturbed areas before seeding, consistent with the requirements of FERC staff's Plan. Mulch would also be applied if construction and restoration activity is interrupted for extended periods. In these cases mulch would be applied at a rate of three tons/acre on all slopes within 100 feet of waterbodies and wetlands.

A number of areas would be crossed with slopes in excess of eight percent. In these areas, mulch would be applied uniformly to cover at least 75 percent of the ground surface at a rate of two tons/acre of straw or hay or its equivalent. All straw or hay mulch would be certified weed-free.

**Erosion Control Fabric**

Pacific Connector would install erosion control fabric (such as jute or excelsior) on waterbody banks at the time of recontouring. The fabric would be anchored using staples or other appropriate devices. Although there are no measures specific to pipeline construction, data related to cut-and-fill slopes treated during construction of forest roads indicate varying effectiveness of different types of stabilization measures designed to control surface erosion (EPA, 2001). On fill slopes, combining straw mulch and netting decreased erosion by 99 percent. Excelsior mulch alone decreased erosion by 92 percent on fill slopes. On cut slopes, straw mulch by itself decreased erosion in a range from 32 to 97 percent (EPA, 2001). Applications of mulches and/or fabric are effective measures promoting slope stabilization until vegetation can successfully be reestablished. These measures also promote plant growth (EPA, 2001).

**Cleanup and Permanent Erosion Control**

Pacific Connector would make every effort to complete final cleanup of an area within ten days after backfilling the trench. Final cleanup would include final grading and installation of permanent erosion control structures. In no case would Pacific Connector delay final cleanup beyond the end of the next recommended seeding season. During final cleanup Pacific Connector would remove all construction debris and grade disturbed areas to preconstruction grades to the extent practicable. An adequate seedbed would be prepared at the conclusion of cleanup. Pacific Connector would install permanent slope breakers consistent with the requirements of FERC staff's Plan.

**Fish Salvage Plan**

All waterbodies that would be crossed by dry open cut construction would be done prior to adult coho salmon upstream migration, within ODFW in-stream construction windows. A Fish Salvage Plan has been provided in appendix T. The plan has been developed to minimize adverse effects to listed salmonids (SONCC coho salmon, Oregon Coast coho salmon), non-listed salmonids (chinook salmon, steelhead, and cutthroat trout) and listed catostomids (Lost River sucker, shortnose sucker). The portions of the plan relevant to salvaging salmonids were adapted from the protocol developed by WSDOT (2014). The protocol specifies procedures to 1) isolate the work area; 2) remove fish and dewater the work area; 3) handle, hold and release fish; 4) document fish that have been captured, handled, held, and released; and 5) notify NMFS and FWS. Only trained professionals would conduct electroshocking and fish removal.

**Revegetation**

As required by the FERC staff's Plan, Pacific Connector has identified procedures for the preparation and planting of live stakes or sprigs and for the planting bare root tree seedlings. Those procedures are included in appendix R. Within the range of Oregon Coast coho salmon, construction of the Pacific Connector pipeline would remove 69.96 acres of riparian forested habitats of which 14.35 acres are late-successional (mature) old-growth, 55.61 acres are mid-seral forests, and 0.95 acre is forested wetlands (see table 4.5.4-14a).

Existing forested riparian zones in which forest would be removed during construction would be re-planted with conifers to within 15 feet of each side of the pipeline centerline. Permanent effects – persisting longer than the assumed 50-year life of the pipeline – would occur by removing 14.35 acres of late-successional (mature) old-growth riparian forest. Even though the riparian zone would be replanted, the newly planted trees would not attain late-successional or old-growth status within 50 years. Permanent effects would also last along the 30-foot wide maintenance corridor centered on the pipeline. Those effects to former late-successional (mature) old-growth riparian forest, Mid-Seral riparian forest and other existing riparian vegetation are included in table 4.5.4-18b. Replanting conifers within each affected forested riparian zone would leave an estimated 16.12 acres of non-forested vegetation within former forested riparian zones over the long-term or permanently (see table 4.5.4-18b).

**ORV Barriers**

The FERC staff's Plan requires the Project to offer to each owner or manager of forested lands to install and maintain measures to control unauthorized vehicle access to the right-of-way and states that such measures may include signs; fences with locking gates; slash and timber barriers, pipe barriers, or a line of boulders across the right of way; and conifers or other appropriate trees or shrubs across the right-of-way. Slash, stumps and or logs, if available, would be placed on the right-of-way within the riparian zones to discourage ORV crossings of streams and provide carbon and nutrients if allowed by the landowner. If not allowed, Pacific Connector would discuss with the landowner the use of other methods, as noted above. At a minimum the area would be revegetated and re-seeded.

**Streambank Stability**

The root network of trees adjacent to streambanks is essential to maintaining streambank stability (WDNR 1997). Because root strength decreases significantly at distances beyond one-half the tree crown diameter, trees promoting streambank stability lie within half a tree crown diameter from the streambank. Trees within 25 feet of the streambank are assumed to promote streambank stability (WDNR 1997). Generally, trees that must be removed during construction would be cut at ground level with the roots left in place, except where located within the trenchline. Although roots would decay overtime, streambank stability would be retained by their presence until revegetation is successful.

**In-stream Gravel**

Waterbodies supporting fisheries would be backfilled with material removed from the trench with the upper 1 foot of the trench backfilled with clean gravel or native cobbles. Pacific Connector has requested a variance from Section V.C.1. of FERC staff's Procedures in fish-bearing streams that do not have gravel, cobble, or other rock substrates prior to construction. This variance was requested because many of the streams crossed by the pipeline are remote and are located in steep valley or ravine bottoms. Therefore hauling rock to these steams is impractical especially where these streams do not have gravel or cobble substrate characteristics prior to construction. The bottom and banks would be returned to preconstruction contours; banks would be stabilized; and temporary sediment barriers would be installed before returning flow to the waterbody channel.

**Large Woody Debris**

In several instances, mitigation would contribute to restoring an aquatic habitat indicator's functional level, such as placement of LWD within and/or adjacent to streams and placing LWD on floodplains, where appropriate, to provide microsites for riparian vegetation and/or vegetation protection during flood events. Placement of LWD in streams and/or on streambanks has been one focal point of recent stream rehabilitation procedures (Slaney and Martin, 1997; Cederholm et al. 1997; EPA, 2001) as well as a central consideration in the Compensatory Mitigation Plan (see appendix O).

As indicated in table 4.5.4-7 and table 4.5.4-8, baseline watershed conditions crossed by the pipeline are lacking in LWD due to historical disturbance and LWD presence is typically below benchmark thresholds to be properly functioning. LWD is an important habitat feature providing in-stream structure, channel and habitat complexity among other benefits, and that promote salmonid productivity. Pacific Connector proposes to install LWD on-site during construction as an appropriate habitat enhancement feature to mitigate for potential pipeline impacts and to benefit watershed conditions, which are generally lacking.

LWD placement would be in addition to the Project conservation measures (see appendix N) that have been designed to minimize the potential Project effects, including utilizing dry open cut crossing methods, applying in-stream construction timing restrictions, and implementing erosion control measures and revegetation methods. Because of the overall lack of LWD in the affected watersheds, LWD also provides an appropriate mitigation model for the Project's potential waterbody crossing impacts that are temporary, short-term, and unavoidable (see Compensatory Mitigation Plan in appendix O). The LWD would also serve to mitigate for potential long-term Project impacts - impacts lasting for the 50-year life of the pipeline - such as the loss of forested riparian vegetation within the pipeline's 30-foot operational corridor (see table 4.5.3-13b, above). Even though the riparian zone would be replanted, the planted trees would not attain late-successional or old-growth status within 50 years. Placement of LWD would, in some measure, reduce though not eliminate the impact due to the removal of late-successional (mature) old-growth riparian forest.

For low-gradient streams, Cederholm et al. (1997) suggests using logs with diameters at least 18 inches (less in areas of low velocity) placed by vertical angling into the stream channel. Logs could be used to create a stepped-channel profile with the rootwads and encourage woody debris accumulations in pool margins. For streams with steeper gradients, they suggest that logs with smaller diameters might be used if larger logs are unavailable. Near headwaters, LWD is often suspended over the channel so that it can become functional during periods of maximum runoff. Smaller debris may be retained during those periods and help develop pools that would be functional during summer (see Cederholm et al., 1997).

Guidelines for LWD placement, provided by ODF and ODFW (1995), suggest using the following: 1) larger diameter wood pieces because they are more effective at creating pools and complex channels which improve fish populations (see table 4.5.4-21 for minimum diameter LWD per bankfull width); 2) LWD that are at least twice the length of the waterbody bankfull width (1.5 times the bankfull width if the rootwad is attached) to increase the likelihood that the LWD would remain in place; and 3) conifer logs, especially western red cedars if available, because they are more durable. In larger waterbodies, smaller diameter, shorter LWD could be used if bundled and anchored together to provide the same benefits of the longer, larger diameter LWD (ODF and ODFW 1995).

Trees classified as late-successional or old-growth are assumed to have attained heights equal to the site-potential tree heights that are included above in table 4.5.4-18a as Riparian Zone Widths. Site-potential tree heights range from 225 feet (for example, the Coos Bay-Frontal Pacific Ocean Watershed) to 164 feet (as in the Days Creek-South Umpqua Rover Watershed). If Douglas-fir trees in the Oregon Cascades grow in height at the rate of 20 inches per year and in diameter by 0.25 inches per year (Cox, 2008), a 20-inch tall seedling planted the year after construction of the Pacific Connector pipeline would be an estimated 85 feet tall and 12 to 13 inches in diameter (assumed dbh) after 50 years. Trees with those dimensions would provide suitable LWD for streams with bankfull widths from 0 to 10 feet but not larger streams (see table 4.5.4-21). Even in these streams recruitment of wood may be reduced as the young age of the forest would reduce recruitment from natural mortality as the rate would be less relative to older trees. But recruitment of wood is not solely dependent on natural tree mortally but includes important contributing factors such as bank erosions, disease, fires, slides, and windthrow (Reeves et al. 2003, Martin and Benda 2001, Gregory et al. 2003). LWD contribution would occur from these areas even though natural mortality contribution would be reduced.

**Table 4.5.4-21**
**Minimum Diameter LWD for Placement in Waterbody Based on Bankfull Width**

| Bankfull Width (feet) | Minimum Diameter LWD (inches) |
|---|---|
| 0 to 10 | 10 |
| 10 to 20 | 16 |
| 20 to 30 | 18 |
| Over 30 | 22 |
| Source: ODF and ODFW, 1995. | |

The Pacific Connector pipeline would actually cross 79 perennial streams within the range of Oregon Coast ESU coho salmon. Forty-two of those perennial streams have existing riparian forest ranging from Mid-Seral stage (approximately 40 to 80 years old) to older late-successional and old-growth; 28.77 acres of existing riparian forest would be removed by construction. Thirty-seven more perennial streams would also be crossed but construction would not affect riparian forest vegetation (see table 4.5.4-22). In addition, the PCGP project would cross 73 intermittent streams, 47 of which support riparian forest, so that 61.08 acres total of riparian forest would be removed. Twenty-six additional intermittent streams with no riparian forest would be crossed as well (see table 4.5.4-22).

To offset impact from removal of riparian trees (reducing LWD recruitment potential) and to provide an overall benefit by enhancing stream habitat with no potential for LWD recruitment, Pacific Connector proposes to place LWD at the waterbody flow types identified by watershed in table 4.5.4-22, based on the following applications:

- four pieces for each perennial stream crossed with riparian forest removed (two pieces in-stream and/or keyed into the streambank, two pieces within riparian zone on the bank);
- two pieces for each intermittent stream and unknown stream crossed with riparian forest removed (one or both LWD pieces placed in-stream, keyed into the bank, or placed on the bank);
- two pieces for each perennial, intermittent, and unknown stream crossed but with no riparian forest removed (one or both LWD pieces paced in-stream keyed into the bank, or placed on the bank); and
- one piece each for a perennial, intermittent, and unknown stream not crossed but adjacent to the construction right-of-way, with or without riparian forest removed (LWD placed on bank).

Because the construction right-of-way at stream crossings would be 75 feet wide, Pacific Connector anticipates only enough space for two pieces of LWD, preferably with rootwads attached, either placed in-stream or with stems keyed into streambanks. Unless site-specific conditions dictate otherwise, the preferable location for each in-stream LWD is downstream from the pipeline to prevent scour of the pipe. LWD would also be placed near or adjacent to streambanks within riparian zones to provide for and/or enhance microsites for riparian vegetation and/or vegetation protection during flood events.

In all, Pacific Connector proposes 405 pieces of LWD for placement within the ten fifth-field watersheds that coincide with Oregon Coast ESU coho salmon and designated critical habitat. Placement of LWD is subject to approval by each affected landowner. If a landowner rejects the proposed placement of LWD, the number of pieces that would have been applied onsite would be reserved and provided to appropriate watershed councils for their use and placement, preferably elsewhere within the affected fifth-field watershed.

Pacific Connector anticipates that during construction, in some cases, the waterbody size, landowner restrictions, or construction constraints would limit LWD placement according to the proposed LWD schedule provided in table 4.5.4-22. Further, the overall benefit of installation of LWD at some pipeline waterbody crossings (i.e., intermittent headwater streams) may not warrant LWD placement. In these situations, Pacific Connector's Environmental Inspector would record the uninstalled LWD as a deficit during construction. After construction is completed, unutilized LWD would be provided to local watershed conservation organizations or agencies for use in local enhancement projects within the affected watersheds. (Also see the discussion on the use of LWD for mitigation in Compensatory Mitigation Plan in appendix O.)

**Compensatory Mitigation**

Appendix O provides the draft Compensatory Mitigation Plan which includes proposed mitigation projects within watersheds in the Coos, Coquille, and South Umpqua Sub-Basins.

[1] Proposed schedule for applying LWD to different waterbody types, subject to landowner approval:

- 4 pieces for each perennial stream crossed with riparian forest removed (2 pieces instream, 2 pieces within riparian zone on the bank);
- 2 pieces for each intermittent stream and unknown stream crossed with riparian forest removed (one or both pieces placed instream or on bank);
- 2 pieces for each perennial, intermittent, and unknown stream crossed but with no riparian forest removed (one or both pieces paced instream or on bank).
- 1 piece each for perennial, intermittent, and unknown stream not crossed but adjacent to ROW with or without riparian forest removed (piece placed on bank).

### 4.5.4.5 Determination of Effects

**Species Effects**

The Project **may affect** coho salmon in the Oregon Coast ESU because:

- Several stages and activities of coho salmon (upstream adult migration, juvenile rearing, and juvenile out-migration) are expected to occur at various locations in the riverine analysis area during construction and operation of the proposed action.
- Several stages and activities of coho salmon (juveniles, adults) are expected to occur within the estuarine analysis area during construction and operation of the proposed action.
- Adult coho salmon area expected to occur within the EEZ analysis area during operation of the proposed action.

While several project actions are not likely to cause adverse effects, those resulting effects from Project components that are **likely to adversely affect** coho salmon in the Oregon Coast ESU include:

- Discharge of maintenance dredge spoils off shore at Site F would generate a turbidity plume that could affect coho adults and juveniles within the EEZ analysis area.
- Juvenile coho may be susceptible to stranding by LNG carrier wakes within the estuarine analysis area.
- Short-term effects to the benthic community and potential food resources for Oregon Coast coho would be affected by dredging the proposed access channel in Coos Bay.
- Construction of the proposed pipeline would affect aquatic vegetation (eelgrass), the benthic community, and potential food resources for Oregon Coast coho during construction across Haynes Inlet.
- Total Suspended Sediments (TSS) could adversely affect juvenile coho salmon. Exposure of juveniles to TSS concentrations during dry open-cut construction (fluming or dam-and-pump) for more than 20 hours could potentially exceed SEV 4 for 10 to 100 meters or more downstream. Such an effect could cause a short-term reduction in feeding rate and short-term reduction in feeding success.
- Exposure of juveniles to TSS concentrations during dry open-cut construction (fluming or dam-and-pump) for 40 hours of more could potentially exceed SEV 5 for 10 to 100 meters or more downstream. Such an effect could cause minor physiological stress in juvenile coho salmon.
- If a failure occurs during peak flow periods while dry open-cut construction is underway, possible effects to juvenile coho (SEV = 6) could include moderate physiological stress.
- TSS produced by dry open-cut construction methods to cross streams are estimated to temporarily affect the water columns within 32,152 feet downstream from some in-stream construction sites (not simultaneously) if peak flows occur during construction.
- TSS concentrations generated during dry open-cut construction and if failure of isolation structures occur, would adversely affect freshwater habitats by changing coho habitat preferences (SEV = 3) or causing moderate habitat degradations (SEV = 7).
- Construction requiring blasting at 30 streams could cause mortality to fish by rupturing swim bladders. Adult and juvenile coho salmon would be removed and/or prevented from being within 50 feet of blasting sites to the maximum extent possible.

- Fish salvage would occur within isolated construction sites, possibly when adult and juvenile coho salmon are present. Coho salmon are considered vulnerable to electrofishing, subject to injury and mortality. Fish salvage would primarily rely on seining but may require electrofishing as a last resort, only DC or pulsed DC current would be used. Seining, electrofishing and handling may adversely affect Oregon Coast coho salmon.
- Lack of LWD is a limiting factor in most streams within range of Oregon Coast coho salmon. Removal of Mid-Seral riparian forest (40-80 years old) would have long-term effects to recruitment of LWD and removal of Late Successional or Old-Growth forest (≥80 years old) would have permanent effects to recruitment of LWD because planted conifers would not attain those age classes within the 50-year life of the project.

**Critical Habitat Effects**

The Project **may affect** designated critical habitat for coho salmon in the EEZ analysis area, within the estuarine analysis area, and within the riverine analysis area for the Oregon Coast ESU because construction and operation of the LNG terminal and LNG carriers will occur and the Pacific Connector pipeline crosses designated critical habitat within waterbodies of the Coos, Coquile, and South Umpqua sub-basins.

Project components are **likely to adversely affect** proposed critical habitat for coho salmon in the Oregon Coast ESU because:

- Discharge of maintenance dredge spoils off shore at Site F would generate a turbidity plume that could affect coho adults and juveniles within the EEZ analysis area.
- Juvenile coho may be susceptible to stranding by LNG carrier wakes within the estuarine analysis area.
- Short-term effects to the benthic community and potential food resources for Oregon Coast coho would be affected by dredging the proposed access channel in Coos Bay.
- Construction of the proposed pipeline would affect aquatic vegetation (eelgrass), the benthic community, and potential food resources for Oregon Coast coho during construction across Haynes Inlet.
- Freshwater spawning sites would potentially be affected over the short-term by dry open cut and diverted open cut construction methods that would remove substrate at crossing sites and produce turbidity downstream that could affect previously utilized redds.
- Turbidity is expected to temporarily affect the water quality within a total of 32,152 feet downstream from some dry open cut construction sites (not simultaneously) generated by mobilized clay (organics) if peak flows occur during construction.
- TSS concentrations generated during dry open-cut construction and if failure of isolation structures occur, would adversely affect freshwater habitats by changing coho habitat preferences (SEV = 3) or causing moderate habitat degradations (SEV = 7).
- Food resources would potentially be affected over the short-term by dry open cut and diverted open cut construction methods that would remove substrate and benthos at crossing sites and produce turbidity downstream in all streams likely to support Oregon Coast coho salmon.
- Freshwater migration corridors would potentially be affected over the short-term by dry open cut and diverted open cut construction methods that would produce turbidity

downstream and create temporary barriers to in-stream movements while construction sites are isolated.

A total of 292.65 acres of riparian zone habitat associated with waterbodies within range of Oregon Coast coho ESU would be directly affected by all construction related activities. Adverse effects to riparian zones would be long-term or permanent depending on whether mid-seral riparian forests (55.61 acres) or late-successional/old-growth riparian forests (14.35 acres) are removed.

### 4.5.5 Lost River Sucker

#### 4.5.5.1 Species Account and Critical Habitat

**Status**

The Lost River sucker was listed as a federally endangered species on July 18, 1988 (FWS 1988). The Lost River sucker was listed as endangered because of the loss of habitat and access to historical range, resulting in a declining population. A 5-year review was released in July 2007 that recommended down listing the Lost River sucker from endangered to threatened status (FWS 2007g). However, no formal proposal to down list the species to threatened status has been made.

**Threats**

Lost River suckers and shortnose suckers were considered together in the final rule listing both as endangered species. Numerous factors in both species' decline were cited by FWS (1988) including historical over-fishing, dams limiting upstream movements and access to spawning habitats, introduction of non-native species that compete (fathead minnows) and prey on suckers (yellow perch, bullheads, largemouth bass, and various lepomid sunfish), and degradation of water quality due to livestock grazing, agriculture, and timber harvest. Pollution in Upper Klamath Lake has lead to algal blooms with increased mortality of suckers when oxygen depletions occur due to eutrophication. Status assessments conducted in 2001 and 2002 (FWS, 2002c) concluded that the Lost River sucker was threatened by the following: 1) drastically reduced adult populations and reduction in range; 2) extensive habitat loss, degradation, and fragmentation; 3) small or isolated adult populations as a result of dams; 4) poor water quality; 5) lack of sufficient recruitment; 6) entrainment into irrigation and hydropower diversions; 7) hybridization with the other native Klamath sucker species; 8) potential competition with introduced exotic fishes; and 9) lack of regulatory protection.

FWS (2007g) published a more recent status review of Lost River suckers in 2007. Recent habitat loss (wetlands in the upper Klamath Basin) has been minor and numerous habitat restoration projects have resulted in some positive population response by Lost River suckers. Nevertheless, poor water quality in Upper Klamath Lake and the Lost River continues, particularly during summers when high temperatures combined with nutrient loading from pumping diked wetlands and runoff from farms, roads, and other sources as well as from lake sediments create hypereutrophic conditions which lead to depletions of dissolved oxygen and fish die-offs (FWS, 2007g). Populations declined prior to listing due to habitat loss of approximately 75 percent of historic range, restricted access to spawning habitat, overharvest, and increased rates of mortality resulting from entrainment in water management structures and severely impaired water quality. Populations in Upper Klamath Lake have chronically low recruitment, reduced survivorship of adult fish, and reduced age-class diversity. Length-frequency analysis suggests that the last substantial recruitment to the spawning population occurred during the late 1990s (FWS, 2012g).

**Species Recovery**

Actions described in the recovery plan that would aid in the delisting of the Lost River sucker include improving habitat conditions through rehabilitating riparian areas and improving land management practices in the Klamath Basin watershed, developing and achieving water quality and quantity goals, and improving fish passage, spawning habitat, and other habitat conditions.

A recovery plan for Lost River sucker and short-nose sucker was finalized on March 17, 1993 (FWS 1993b). Since then there has been substantial amounts of additional information, prompting recent revision of the recovery plan (FWS, 2012g). The recovery program goal is to stop the population decline and enhance Lost River sucker and shortnose sucker populations so that ESA protection is no longer necessary.

At the time of listing, population declines were related to loss or degradation of spawning, rearing, and adult habitats. Only about 25 percent of the original habitat remains. Reductions in habitat quality compound the effects of reduced habitat quantity and availability on Lost River sucker and shortnose sucker abundance. In addition to habitat, factors currently limiting species recovery include high mortality of larvae and juveniles due to reduced rearing habitat, entrainment in water management structures, poor water quality, and adverse effects (predation, competition) from non-native, introduced fish species. Adult populations are limited by extremely limited recruitment to the population as well as high levels of stress and mortality associated with severely impaired water quality. As a whole the species are potentially limited by the lack of habitat connectivity (FWS, 2012g).

Demographic-based objectives include increasing larval production, individual survival and recruitment to spawning populations, and ultimately increasing abundance in spawning populations. The objectives of restoring spawning and nursery habitat, expanding reproduction, reducing the negative impacts from water quality on all life stages, clarifying the effects of other species on all life stages, reducing entrainment, and establishing auxiliary populations comprise the threats-based objectives. The recovery strategy is intended to produce and document healthy, self-sustaining populations by reduction of mortality, restoration of habitat, including spawning, larval and juvenile habitats, and increasing connectivity between spawning and rearing habitats. It also involves ameliorating adverse effects of degraded water quality, disease, and non-native fish. The plan provides areas of emphasis and guidelines to direct recovery actions (FWS, 2012g). There are two recovery units for Lost River suckers, the Upper Klamath Lake Unit and Lost River Basin Unit (FWS, 2012g). Upper Klamath Lake Unit includes all Lost River suckers within lake, tributaries to Upper Klamath Lake, and reservoirs within the Klamath River including Keno Reservoir and populations below Keno Reservoir. The Lost River Basin Recovery Unit includes Clear Lake Reservoir and tributaries including Willow Creek and Boles Creek, (FWS, 2012g). The Lost River is not included in designated critical habitat.

**Life History, Habitat Requirements, and Distribution**

Lost River suckers are native to the Lost River and Upper Klamath River Basin but have adapted to lake habitats and are now a lake-dwelling fish that migrates into streams to spawn (Moyle, 2002). It is a long-lived species, reaching ages over 30 years. Historically, Lost River suckers were found in the Lost River watershed, Tule Lake, Lower Klamath Lake, and Sheepy Lake. The present distribution of the Lost River sucker includes Upper Klamath Lake and its tributaries, Clear Lake Reservoir and its tributaries, Tule Lake and the Lost River up to Anderson-Rose Dam, the Klamath River downstream to Copco Reservoir, and probably Iron Gate Reservoir. In the Upper Klamath Lake watershed, the Lost River sucker spawning runs are primarily limited to Sucker Springs in Upper Klamath Lake, and the Sprague and Williamson Rivers. Spawning runs also occur in the Wood River and in Crooked Creek in this watershed. An additional run may occur in Sheepy Lake in the Lower Klamath Lake watershed and spawning has been documented in the Clear Lake watershed (FWS, 1988 and 1993b).

Although sucker spawning habitat in the Lost River is very limited, U.S. Bureau of Reclamation (Reclamation, 2007) has documented sucker spawning below Anderson-Rose Dam, in Big Springs near Bonanza and at the terminal end of the West Canal as it spills into the Lost River. Suitable spawning habitats with riffle areas and rocky substrates include the spillway area below Malone Dam, immediately upstream of Keller Bridge, immediately below Big Springs in the Lost River, below Harpold Dam, and adjacent to Station 48 (Reclamation, 2007). Suckers are primarily bottom dwellers, remaining within 1 foot of bottom substrates. Water depths and turbidity provide cover in lakes while pools and overhanging banks provide cover features in streams. In Tule Lake, most depths are less than 1 meter and adult suckers are confined to the few locations where depths exceed 1 meter (Reclamation, 2007). During periods of deteriorating water quality, especially in Upper Klamath Lake, adult suckers may utilize shallow waters with suitable water quality even though they may be more vulnerable to predators (Reclamation, 2007).

Most spawning by Lost River suckers lasts from late February to early June in the larger tributaries of inhabited lakes (FWS, 2007g). River spawning habitat in riffles or runs with gravel or cobble substrate, with moderate flows, and in water 8 to 50 inches deep. Some Lost River suckers have been noted to spawn in lakes, particularly at springs occurring along the shorelines (FWS, 2007g). Each Lost River sucker female may produce between 44,000 and 236,000 eggs in a single spawning season; larger, older females produce more eggs and contribute more to recruitment than younger females (Reclamation, 2007).

Larval Lost River suckers are present in Upper Klamath Lake from the beginning of May through mid-July. During that period, larvae utilize protective emergent vegetation along lake shorelines which provides cover from predators, currents and turbulence, and are areas of concentrated prey including zooplankton, macroinvertebrates, and periphyton (Reclamation, 2007). Similar relationships within the Lost River watershed, including Tule Lake and Lost River, have not be studied but are assumed to be similar to those in Upper Klamath Lake (Reclamation, 2007).

By mid-summer larval suckers have become juveniles, which, in Upper Klamath Lake, tend to occupy shoreline habitats less than 4 feet deep with and without emergent vegetation and/or shoreline vegetation. Abundance of juvenile suckers in the lake declines dramatically during late summer and early autumn. Some of the decline is due to emigration of juveniles into the Link River and parallel canals at the outlet of Upper Klamath Lake (Reclamation, 2007). Adult suckers (and presumably subadults) in Upper Klamath Lake tend to inhabit deeper (>1 meter) waters in the northern half of the lake (Reclamation, 2007). But, when water quality deteriorates in the north end of the lake during mid-summer with lower concentrations of dissolved oxygen, adult Lost River and shortnose suckers migrate to relatively shallow waters in Pelican Bay along the west shore (Reclamation, 2007). Similar seasonal movements have not been described for suckers inhabiting Tule Lake and the Lost River although reproduction has been documented in Tule Lake and is suspected to occur in the Lost River.

In the Upper Klamath Sub-basin (HUC 18010206) they are found in the Klamath River as far downstream as Copco Reservoir (RM 199) and possibly Iron Gate Reservoir (RM 191). The PCGP pipeline would cross the Klamath River at RM 249. In the Lost Sub-basin, they are found in the Lost River mainstem and Clear Lake Reservoir (Moyle, 2002). In the project vicinity, Lost River suckers spawn in the Lost River and are present in John C. Boyle Reservoir, downstream from the pipeline crossing at RM 225 (National Research Council, 2004). In addition to collections of Lost River suckers in J.C. Boyle Reservoir, ORBIC (2012) cites records of collections in Lake Ewauna and in the Lost River Diversion Channel connecting the Klamath River (at RM 249.8) to the Lost River at the Lost River Diversion Dam, approximately 10 river miles downstream from the PCGP crossing of the Lost River at RM 9.5.

Historically, Lost River suckers migrated upstream from Tule Lake (in California) to spawn near Bonanza. Currently, Lost River suckers migrate a short distance from Tule Lake to spawn in the Lost River below Anderson-Rose Diversion Dam (RM 17.4) south of Merrill and approximately 7.6 river miles from the pipeline crossing of the Lost River (ORBIC, 2012). Suckers also spawn below Malone Dam, downstream from Clear Lake, also in California.

**Population Status**

The Lost River sucker population in Upper Klamath Lake was estimated between 11,000 and 23,000 at the time of the Final Rule listing the species as endangered (FWS, 1988). That estimate was probably inaccurate although adults in Upper Klamath Lake and Clear Lake (in California) probably number in the tens of thousands (FWS, 2007g). There had been several die-offs during the 1990s which affected the spawning population of older adults in Upper Klamath Lake. Current information indicates possible increased recruitment of males and females with only slight population growth in the portion of the population normally spawning along the lakeshore of Upper Klamath Lake and low recruitment continues as major concern (FWS, 2007g). Limited information indicates declines of large adult suckers in Clear Lake (FWS, 2007g). Lost River suckers are known to be present in J.C. Boyle Reservoir, Copco Reservoir, and Iron Gate Reservoir but reproduction in any of the reservoirs is unknown and they are not abundant in any of the three reservoirs (Reclamation, 2007).

In the past, the Lost River was probably important spawning habitat for Lost River suckers migrating upstream from Tule Lake. Now, Lost River is highly modified, used primarily for distributing irrigation water and impaired by surface runoff and agricultural drainage (Reclamation, 2007). For several years there was no indication that Lost River or shortnosed suckers continued to inhabit Tule Lake but in 1991 both species were observed spawning below Anderson-Rose Dam, and sampling at Tule Lake in the early 1990s determined that small populations of both species were present (Reclamation, 2007). Lost River sucker spring-spawning abundance in 2007 is estimated to be 56 percent and 75 percent of 2002 abundances for males and females respectively, although the exact abundances are unknown and the spawner abundance relative to an earlier are estimates of population change rather than population size (FWS, 2012g). Tagging studies conducted on Lost River and shortnose suckers in Gerber Reservoir and Clear Lake (both impoundments are connected to the Lost River below Gerber Dam and Clear Lake Dam, respectively) indicate that numbers of large adult suckers of both species have declined since 2000. Declines in large adult Lost River suckers have been particularly pronounced in Clear Lake, possibly due to poor recruitment from younger age classes prior to 2000 (Barry et al., 2007).

### Critical Habitat

Critical habitat for the Lost River sucker and shortnose sucker was proposed by FWS in 1994 which included the majority of known populations of Lost River suckers (FWS, 1994a): Critical habitat for Lost River and shortnose suckers was re-proposed in 2011 and designated in 2012 (FWS, 2012h). In the PCGP Project area, designated critical habitat for Lost River and shortnose sucker (Unit 1 in Klamath County) includes the Link River, Lake Ewauna, and the Klamath River downstream to Keno. Unit 2 in Klamath and Lake Counties, Oregon and Modoc County California includes Clear Lake Reservoir and tributaries and Gerber Reservoir and tribuaries but does not include the Tule Lake and its tributary, the Lost River. For reasons described above (blockage by Anderson Rose Diversion Dam), neither provides spawning habitats or supports viable self-sustaining populations of Lost River or shortnose suckers (FWS, 2012h).

Primary constituent elements of critical habitat include (FWS, 2012h):

1. Water. Areas with sufficient water quantity and depth within lakes, reservoirs, streams, marshes, springs, groundwater sources, and refugia habitats with minimal physical, biological, or chemical impediments to connectivity. Water must have varied depths to accommodate each life stage: Shallow water (up to 3.28 ft (1.0 m)) for larval life stage, and deeper water (up to 14.8 ft (4.5 m)) for older life stages. The water quality characteristics should include water temperatures of less than 82.4 °F (28.0 °C); pH less than 9.75; dissolved oxygen levels greater than 4.0 mg/L; low levels of microcystin; and un-ionized ammonia (less than 0.5 mg/L). Elements also include natural flow regimes that provide flows during the appropriate time of year or, if flows are controlled, minimal flow departure from a natural hydrograph.
2. Spawning and rearing habitat. Streams and shoreline springs with gravel and cobble substrate at depths typically less than 4.3 ft (1.3 m) with adequate stream velocity to allow spawning to occur. Areas containing emergent vegetation adjacent to open water, provides habitat for rearing and facilitates growth and survival of suckers, as well as protection from predation and protection from currents and turbulence.
3. Food. Areas that contain an abundant forage base, including a broad array of chironomidae, crustacea, and other aquatic macroinvertebrates.

## 4.5.5.2 Environmental Baseline

### Analysis Area

The riverine analysis area includes two components: 1) the water column and substrate of all waterbodies crossed by the Pacific Connector pipeline from the point of crossing to the extent downstream where water quality is adversely affected by turbidity generated during construction and sediment generated by runoff from the construction right-of-way, and 2) waterbodies' associated riparian zones affected in the short-term during construction and in the long-term by operation. For Lost River suckers, the riverine analysis area is limited to fresh waterbodies within the Upper Klamath Sub-basin (HUC 18010206 – figure 4.5-33A) and Lost Sub-basin (HUC 18010204 figure 4.5-33B).

**Species Presence**

Within the Project area, the Lost River sucker has been documented within the Klamath River from Klamath Falls to Keno Reservoir, located 4.3 and 15.1 miles upstream of the Pacific Connector pipeline Project area and riverine analysis area, consecutively. The PCGP pipeline would cross the Klamath River at RM 249. The sucker is also known from Tule Lake Sump and Clear Lake in northern California, which are connected by the Lost River. Tule Lake sumps are at the lower terminus of the Lost River and the population in Tule Lake is isolated from upstream spawning areas by multiple dams including blockage by the Anderson-Rose Dam.

Historically, Tule Lake supported large populations of Lost River suckers but much of the historical lakebed area has been drained and transformed to agriculture and portions were engineered to receive high runoff flows from the Klamath River via the Lost River Diversion Channel and Lost River (Hodge and Buettner, 2009). Dams constructed on the Lost River, including the Lost River Diversion Dam, Anderson Rose Diversion Dam, Malone Dam, and Harpold Dam have blocked suckers from accessing spawning areas upstream in the Lost River. Currently, sucker spawning migrations are limited to the Lost River below the Anderson Rose Diversion Dam. Lost River suckers migrate a short distance from Tule Lake to spawn in the Lost River below Anderson-Rose Diversion Dam (RM 17.4) south of Merrill and approximately 7.6 river miles from the pipeline crossing of the Lost River (ORBIC, 2012).

Very little water flows in the Lost River below the diversion dam except during the winter and early spring. During the irrigation season, all flows are diverted at Anderson Rose Diversion Dam into the J-Canal for irrigation deliveries to the Tule Lake Irrigation District (Hodge and Buettner, 2009). From 2006 to 2008, FWS and Reclamation placed gravels below the diversion dam and released flows from mid-April to early June to entice suckers to migrate from Tule Lake and spawn in the lower Lost River. Lost River suckers and shortnose suckers sporadically spawned in the graveled riffle area below the Anderson Rose Diversion Dam and sucker larvae were documented in the Lost River during 2006 although they may have derived from Upper Klamath Lake, the Upper Lost River, and/or Clear Lake. Reclamation salvages suckers from J-Canal, which drains into Tule Lake suggesting that some entrained fish move into Tule Lake (Hodge and Buettner, 2009).

Tagged Lost River suckers spawning in the lower Lost River peaked from April 23 to May 17 and from May 27 to June 5 (Hodge and Buettner, 2009). Most of the suckers that migrated into the Lost River from Tule Lake moved to below the Anderson Rose Diversion Dam and spawn there. Larval suckers were present from May 30 to July 22, 2008. The population of Lost River suckers in Tule Lake Sump is probably in the low thousands of individuals which is higher than documented in the early 1990s (Hodge and Buettner, 2009). Currently, Tule Lake functions only as a sink for Lost River sucker populations (FWS, 2012h).

Regular spawning occurs in the Upper Klamath Lake and in Clear Lake Reservoir. Recruitment is low for the spawning population in Upper Klamath Lake. Clear Lake Reservoir, in California, supports a sustaining population of Lost River suckers which is critical to the species' recovery (FWS, 2012g; Barry et al, 2009). Growth rates for adult Lost River suckers are greater in Clear Lake than in Upper Klamath Lake, possibly due to younger individuals present in Clear Lake (Barry et al., 2009). Suckers spawn in Willow Creek, a tributary to Clear Lake Reservoir, during February and March when water temperatures range from $4^{o}$C to $12^{o}$C and larva emigrate down Willow Creek into Clear Lake from late March to mid-April (Perkins and Scoppettone, 1996).

There is limited evidence of a resident population of Lost River suckers in the Lost River above Malone Dam in the Langell Valley, Oregon (FWS, 2012h). However, Lost River suckers are prevented from accessing historically occupied habitats in Lost River mainstem and lower Lost River from Clear Lake Reservoir by Malone Dam.

**Habitat**

Dams continue to limit passage and sucker migration, impose isolation of subpopulations, and decrease available spawning habitats which have has raised the possibility of facilitating hybridization between several sucker species (Reclamation, 2007). Dams may also cause stream channel changes, alter water quality, and provide habitat for exotic fish that prey on suckers or compete with them for food and habitat (Reclamation, 2007). Although there are seven major dams in the Klamath Basin that may affect the migration patterns of listed suckers, only the Link River Dam has been recently equipped with a fish ladder that was designed specifically for sucker passage (Reclamation, 2007). Fish ladders are present at J.C. Boyle and Keno dams and, although suckers have been observed to use the ladders, they were not designed for sucker passage and generally are inadequate for sucker passage (ReclamationReclamation, 2007).

Lost River suckers continue to inhabit the Klamath River above Keno. Fish may enter the Klamath River from Upper Klamath Lake by passing through the gates at Link River Dam. Lost River suckers that survive passing through the hydroelectric facilities either die due to poor summer water quality conditions or pass downstream into the Klamath Reservoirs. At that point, fish are unlikely to return and believed to be lost from the breeding population (FWS, 2007g). The Pacific Connector pipeline would cross the Klamath River using HDD.

Adverse water quality is the most critical threat to the Lost River Sucker (FWS 2007g). Klamath River and Klamath Lake have been designated as water quality impaired, including for nutrient loads which are enhanced by drainage of irrigation water from agricultural lands adjacent to Klamath Lake. Construction of dikes and drainage systems converted wetlands to agricultural use. Soils high in organic content were subject to mineralization processes which released nutrients into the aquatic system, especially phosphorous and nitrogen (Rykbost and Charlton, 2001).

High levels of phosphorous in Klamath Lake have lead to extreme eutrophication events that promote algal blooms dominated by the blue-green algae, *Aphanizomenon flos-aquae* that reach or nearly reach theoretical biological maxima (National Research Council, 2004). As a consequence, portions of Upper Klamath Lake develop conditions of oxygen depletion or are anoxic, and accumulate high concentrations of ammonia which has resulted in mass mortality of fish, including adult suckers (National Research Councils, 2004). Lost River suckers are likely to experience high mortality if exposed to one or more of the following: pH $\geq$ 9.8, ammonia (unionized) concentration $\geq$ 0.34 mg/L, water temperatures $\geq 29.4^{o}$C ($\geq 85^{o}$F), and dissolved oxygen concentration $\leq$ 2.3 mg/L (Bellerud and Saiki, 1995).

No assessments have been conducted for either of the two $5^{th}$ field watersheds that will be crossed by the PCGP Project in the Lost Sub-basin: Lake Ewauna-Klamath River (HUC 1801020412) and Mills Creek-Lost River (HUC 1801020409). Likewise, no stream reaches have been sampled under ODFW's Aquatic Inventories Project in the watersheds. Nevertheless, modifications and degradation of aquatic habitats have been documented by FWS (1993b and 2012g), U.S. Geological Survey - USGS (Dileanis et al., 1996), U.S. Bureau of Reclamation (Reclamation, 2007), and the National Research Council (2004), among others.

Dams limit passage and fish migration, impose isolation of subpopulations, and decrease available spawning habitats (Reclamation, 2007). Klamath River and Klamath Lake have been designated as water quality impaired, including for nutrient loads which are enhanced by drainage of irrigation water from agricultural lands adjacent to Klamath Lake. Construction of dikes and drainage systems converted wetlands to agricultural use. Soils high in organic content were subject to mineralization processes which released nutrients into the aquatic system, especially phosphorous and nitrogen (Rykbost and Charlton, 2001). Sediment accumulation rates in Upper Klamath Lake indicate substantial annual increases since the late 1880s due to deforestation, drainage of wetlands, agriculture, livestock production and irrigation (Reclamation, 2007).

High levels of phosphorous in Klamath Lake have lead to extreme eutrophication events that promote algal blooms dominated by the blue-green algae, *Aphanizomenon flos-aquae* that reach or nearly reach theoretical biological maxima (National Research Council, 2004). As a consequence, portions of Upper Klamath Lake develop conditions of oxygen depletion or are anoxic and accumulate high concentrations of ammonia which has resulted in mass mortality of fish (National Research Council, 2004).

There are no recent long-term water discharge data for waterbodies in the Lost River watershed. The A Canal connects the Link River to the Lost River via the B Canal. According to USGS Gage 11507200, there is no flow in the A Canal between November and March (see figure 4.5-34), consistent with periods of water diversions from the Klamath River, discussed above.

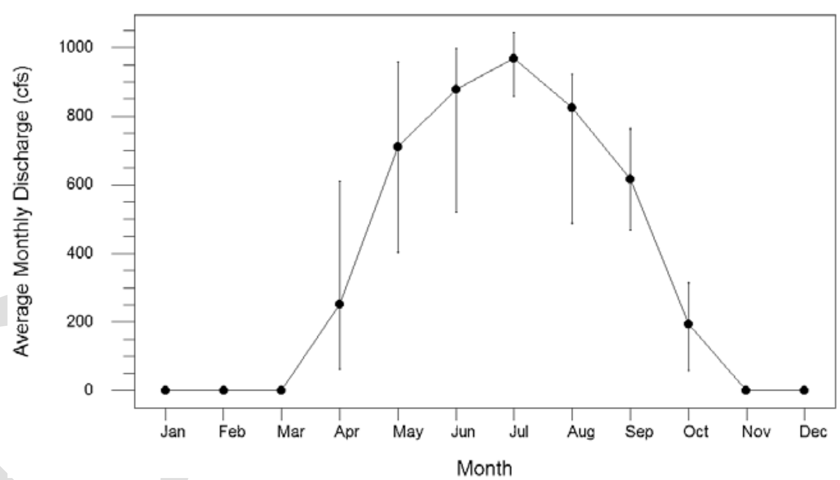

**Figure 4.5-34**
**Average Monthly Discharge in the A Canal (USGS Gage 11507200) from 1960 to 1981. Vertical lines show maximum and minimum discharges for months during the periods of record.**

### Critical Habitat

Designated critical habitat for the Lost River sucker is present within the Project area. The PCGP pipeline would cross the Klamath River at RM 249 which is within critical habitat Unit 1, Klamath County (FWS, 2012h). Unit 1 includes Upper Klamath Lake and Agency Lake, together with some wetland habitat; portions of the Williamson and Sprague Rivers; Link River; Lake Ewauna; and the Klamath River from the outlet of Lake Ewauna downstream to Keno Dam. Primary constituent elements include (FWS, 2012h, abbreviated from above):

1. Water. Areas with sufficient water quantity and depth within lakes, reservoirs, streams, marshes, springs, groundwater sources, and refugia habitats with minimal physical, biological, or chemical impediments to connectivity.
2. Spawning and rearing habitat. Streams and shoreline springs with gravel and cobble substrate at depths typically less than 1.3 m (4.3 feet) with adequate stream velocity to allow spawning to occur. Areas identified in PCE1 containing emergent vegetation adjacent to open water, provides habitat for rearing and for growth and survival of suckers.
3. Food. Areas that contain an abundant forage base, including a broad array of chironomidae, crustacea, and other aquatic macroinvertebrates.

Critical habitat Unit 2 includes Clear Lake Reservoir and its principal tributary, Willow Creek. Unit 2 does not coincide with the Project area.

#### 4.5.5.3 Effects by the Proposed Action

### Direct Effects

Timing

Pacific Connector anticipates beginning construction in the Klamath Basin area (MPs 188 to 228) in fourth quarter 2015 or early 2016. The Klamath River (MP 199.38) and the Lost River (MP 212.05) are the only perennial waterbodies crossed by the PCGP Project on Construction Spread 5. The ODFW (2008a) allows instream construction in the Klamath River (above Keno) from July 1 to January 31 and in the Lost River (below Bonanza) from July 1 to March 31. Pacific Connector would cross the Klamath River using HDD crossing methods between July and October. Upland rig-up and preparation are the only HDD activities that would occur outside the recommended ODFW instream construction window. The Lost River would be crossed by dry-open crossing methods during the ODFW-recommended crossing window (July 1 to March 31). One other intermittent drainage that would be crossed at MP 188.9 also has an ODFW-recommended crossing window between July 1 and January 31, but this minor headwater waterbody is expected to be dry at the time of construction.

There are 13 waterbodies between MPs 216.10 and 225.07 that have an ODFW-recommended construction window from July 1 to March 31. These 13 waterbodies are intermittent drainages which would be crossed using dry open-cut crossing methods if flowing at the time of construction. Although seven of the intermittent drainage are presumed to provide habitat for Lost River sucker or shortnose sucker, the PCGP Project's crossing locations are not expected to provide suitable habitat conditions for these species and all of the minor intermittent waterbodies are expected to be dry at the time of construction (see figure 3.2-3).

Fish Salvage

Suckers as a group (family Catostomidae) appears to be susceptible to many of the same deleterious effects from electroshocking that were described above for salmonids (Snyder, 2004). Although records of the effects by electroshock to Lost River suckers have not been compiled, responses by river carpsucker, longnose sucker, white suckers and razorback sucker among others indicate that they are particularly susceptible to spinal injuries and hemorrhages by electrofishing (Snyder, 2004).

Reclamation recently completed construction of fish screen at the entrance to the A-Canal in the forebay of Upper Klamath Lake to reduce high rates of sucker entrainment at this diversion site. Reclamation routinely lowers water levels in the forebay to reduce DO stress. As that takes place, Reclamation salvages all fish in the forebay of the fish screen facility using backpack electrofishers and beach seines and then returns all collected fish to Upper Klamath Lake. This annual salvage procedure alleviates potential mass mortality of all fish at the fish screen as water is removed (Reclamation, 2007).
