There is little likelihood of an LNG carrier losing steerage, running into the islands or reefs of the wildlife refuges, and either physically damaging the wildlife refuge areas or spilling LNG cargo. The LNG carriers are double hulled and in previous and similar incidents no LNG cargo has been spilled. In addition, LNG carriers will always be under tug escort when in proximity to the islands and reefs of the refuge and the tugs will keep the carriers under control in the event of a steering or other control failure.

The effect of the additional LNG carriers on refuges due to wakes disturbing mammals in haulout areas is not considered to be an issue due to the distance of the LNG carrier transit route from the refuges and the fact that the LNG carriers will be traveling at reduced speeds while in the bay. As previously described, the additional number of carriers will logically increase the chances of contact between carriers and marine mammals frequenting the refuges. However, the distance between the LNG carrier transit route and the refuges will help reduce these potential contacts to a minimum.

### 3.3.5.2 Aquatic Habitat

**Loss of Benthic and Shoreline Habitat (including EFH)**

The impact of the construction of the slip and access channel on wetlands will be the permanent loss of approximately 8.1 acres of intertidal, 3.3 acres of shallow subtidal, 15.24 acres of deep subtidal, and 2.5 acres of eelgrass. The construction dock will affect 1.6 acres of intertidal and 0.1 acre of shallow subtidal habitat and the gas processing area will affect an additional 0.7 acre of intertidal habitat.

Macroinvertebrates move, rest, find shelter, and feed on the substrate and organic material, as well as live within the substrate in these areas. The Project would physically disturb and reduce shoreline aquatic habitat, including eliminating or displacing established benthic communities and reducing prey availability in the vicinity.

Based on air photo interpretation, the distribution and spatial extent of SAV within the area to be dredged for the slip is patchy and sparse. Due to the low density and narrow extent of distribution of SAV in this area, habitat value is expected to be lower relative to the more extensive and contiguous SAV beds located elsewhere in Coos Bay. While the construction of the slip would adversely impact EFH through loss of this narrow band of SAV, the potential adverse impacts to EFH will not be substantial and dredging of the slip will create approximately 36.7 acres of new marine habitat by converting upland to subtidal habitat.

### 3.3.5.3 Water Quality

**Turbidity Levels**

Elevated turbidity levels will result from actions taken to construct the slip and the Kentuck mitigation site for estuarine habitat mitigation and south of the airport for eelgrass mitigation. Dry season construction will equate to less opportunity for precipitation-generated turbidity and will reduce the chances of juvenile fish entering the work area. Elevated turbidity from construction is expected to be localized, but would develop cumulatively for the aquatic environment affected. Turbidity plume direction movement and disbursement will be dependent on current flow. Construction during outgoing tidal flows, combined with outgoing river flows, will carry turbidity downstream. During the incoming tide, turbidity is not expected to be detectable beyond the immediate area, as tidal fluctuations and wind will drive the currents and disperse the suspended sediments into the navigation channel. Elevated turbidity levels will occur over a short time, lasting a few hours immediately after the work area is inundated by the incoming tide. The elevated turbidity levels will occur over the construction in-water work period, twice each day in relation to the high tide cycle. Turbidity is also discussed in Section 3.3.5. for slip construction and Section 3.3.5.5 for the effects of dredging on fisheries.

**Chemical Contamination**

As with all construction activities, accidental release of fuel, oil, and other contaminants may occur as the presence of construction equipment near sensitive habitats creates the potential for introduction of toxic materials from accidental spills, improper storage of petrochemicals, or mechanical failure. Operation of back-hoes, excavators, and other equipment requires the use of fuel, lubricants, etc., which, if spilled into the bay or adjacent intertidal zone, can injure or kill aquatic organisms.

Potential affects from a fuel spill, equipment malfunction, or accident is likely to be a short-term effect, but could be detrimental to aquatic habitat within the action area. Petroleum-based contaminants such as fuel, oil, and some hydraulic fluids contain poly-cyclic aromatic hydrocarbons (PAHs) which can be acutely toxic to the aquatic environment for fishes and can also cause lethal and chronic sublethal effects to aquatic organisms (Neff 1985).

Accidental spills may allow chemicals to reach Coos Bay, resulting in impacted water quality and reduced feeding opportunities for aquatic species within the action area. The large volume of water in the bay, the strong water currents and wind action, and the conservation measures proposed to minimize the amount and distance of a toxicant material spread will result in the dilution of any spill to undetectable levels in a few hours. Potential water contamination from construction activities will be controlled by the implementation of spill containment measures as specified through the permitting and approval process for the Project. However, depending on the timing, weather conditions, and response and clean-up efficiency, adverse impacts may still occur due to the proximity to aquatic habitat.

#### 3.3.5.4 Slip Construction

The construction of the slip will require the excavation of 2.3 million cubic yards (cy) of material and the dredging of 2.0 million cy of material from the slip area and dredging of 1.3 million cy from the access channel for a total of approximately 5.6 million cy. During the dredging of the slip, the water used to hydraulically convey the material dredged to the placement site will be recycled back to the dredge area as it will not be connected to the bay. Throughout this phase of the construction activity, there will be no discharges (water or turbidity) to Coos Bay. During the dredging of the access channel and removal of the berm separating the slip from the bay, the water used to hydraulically convey the material dredged to the placement site will be returned to the north side of the slip where it will mix with the water in the slip allowing any remaining turbidity to settle before mixing with water in the bay.

Much attention has been given to turbidity effects from dredging in estuaries, embayments, and enclosed waters. Turbidity from dredging can elicit a variety of benthic responses primarily because attributes of the physical environment are affected (Wiber and Clarke 2001). Large quantities of bottom material placed in suspension decrease light penetration and change the proportion of wavelengths of light reaching the bottom, leading to decreases in photosynthesis and primary productivity of benthic algae and submerged grasses. Suspended materials can prevent growth of benthic organisms, plants that provide habitat complexity, and biological structures used by some faunal species for shelter and egg attachment.

Coast and Harbor Engineering (C&H) prepared an analysis of the turbidity generated by the dredging operation at the slip and concluded that the proposed dredging activities for the slip are unlikely to have extensive adverse effects on Coos Bay. The model was developed on the basis of a sediment analysis conducted at the site of the dredging and took into consideration wind, tidal currents, seasonal flows, etc. The model approach was conservative in that it predicted turbidity levels based on dredging the entire slip while still connected to the bay, rather than the approach that is proposed by JCEP in which the majority of the slip construction will be kept isolated from the bay by a berm. Only the dredging of the berm and the access channel would occur while connected to the bay. Dredging activity would be restricted to the in-water work window of October 1 through February 15 when salmonid species are not likely present. The ambient turbidity levels in the water (generated by flows, waves, wind, and vessel traffic) create a background level of turbidity, ranging by season from 3.7 to 18.1 nephelometric turbidity units, thereby reducing the relative impact of dredging-related turbidity.

The proposed area for dredging is adjacent to the existing shipping channel, which is subject to periodic maintenance dredging. It is reported (Newell et al. 1998) that benthic communities on mud substrates in Coos Bay when disturbed by dredging recovered to pre-dredging conditions in four weeks. Thus, it is anticipated that the benthic communities in the areas to be dredged in connection with the Project will recover in the same time period, resulting in short-term effects to benthic populations on mud substrate. The dredged areas will also be subject to periodic maintenance dredging and the same cycle of disturbance and re-colonization (to an unknown extent) will likely occur. Direct mortality or injury to fish from construction equipment is not expected to occur due to mobility of the fish. Turbidity as a result of sediment re-suspension is likely to be localized and short term and is not expected to be transported up or downstream to an extent that it will kill or injure shellfish populations. Dredge operations are expected to result in effects similar to annual winter storm events, with possible higher concentrations of suspended sediments concentrated in the area of the dredging. Sessile benthic organisms (those permanently attached to a base and unable to move), shellfish, clams, and crustaceans could be injured or killed during dredging operations. Implementation of a spill plan will minimize the potential for a fuel spill and adverse effects to aquatic life and habitat during dredging.

Sedimentation and maintenance dredging requirements would likely be reduced at the access channel area over time due to natural stabilization and adjustment processes. Predicted volumes for maintenance dredging in the access channel are 26,100 cy per year after 10 years, 21,900 cy per year after 25 years, and 14,800 cy per year after 50 years.

Approximately 37,700 cy is the total maintenance dredging volume expected at year 1 and 34,600 cy is the total maintenance dredging volume expected at year 10. In the first 10 years, an approximate total of 360,000 cy would be removed and in the next 10 years approximately 330,000 cy would be removed for an approximate total of 690,000 cy in comparison to the prediction of 1.75 million cy for the previously proposed import terminal project. This is a substantial reduction in volume which in turn will reduce the demand for disposal space and the amount of turbidity associated with the dredging and disposal.

The operation of the LNG Terminal does not require or produce large quantities of hazardous materials. Solvents and paints are used during normal maintenance activities and are kept in specialized containers with secondary containment to prevent spills on the ground. Stormwater collected in areas that have no potential for contamination will be allowed to flow or be pumped directly to a system of stormwater bio-swales and ditches, which will ultimately drain to the slip. Stormwater collected in areas that are potentially contaminated with oil or grease will be pumped or will flow to oily water collection sumps. Collected stormwater from these sumps will flow though engineered oily water separator packages before discharging to the industrial wastewater pipeline. Industrial wastewater will be conveyed to the Port of Coos Bay’s existing ocean outfall pursuant to the NPDES permit. No untreated stormwater will be allowed to enter waters of the state.

During the operation of the Project, LNG carriers calling on the LNG Terminal could have accidental releases of fuels or other contaminants found on all ships. In the unlikely event that there is an accidental spill of LNG, no effects on marine life are anticipated. LNG is not toxic and if spilled on water would vaporize as it is warmed by the heat in the water. LNG is not absorbed into the water, resulting in no effects on marine life.

#### 3.3.5.5 Effects of Dredging on Fisheries

Effects of dredging on fisheries will be limited to those species found along the edge of Coos Bay where the new slip will be formed. Fish will relocate from the area of the dredging activity, with the duration of the relocation dependent on the length of time for re-colonization of food sources and habitat. Turbidity would be increased in the short-term in localized work areas and up or downstream depending on tidal action and currents. Dredging would likely create localized areas of increased (above background levels) turbidity and plumes of turbid water flowing away from the work areas in the direction of tides and currents. It is expected that sediments will settle out near work areas.

If salmonids are exposed to moderate to high levels of turbidity for prolonged periods, a number of adverse effects could occur including behavioral changes, sub-lethal effects and increased mortality from predators. Dredging is expected to create spikes of high to moderate turbidity in a localized area. Effects are not expected to be significant or measurable due to the limited area affected, timing (season) of dredging activity, and due to the short duration of proposed dredging operations. Though not anticipated to be present during the in-water work period, rearing and migrating salmonids would likely avoid active work areas.

Increased suspended sediment would affect filter-feeding organisms, including shellfish, through clogging and damaging feeding and breathing organs (Brehmer 1965, Parr et al. 1998). However, sediment re-suspension is likely to be localized and short term and is not expected to be transported up or downstream to an extent that it would kill or injure shellfish populations. There are no commercial oyster beds in the immediate vicinity of the proposed dredging areas. Sessile benthic organisms within areas to be dredged will be removed and killed. Other benthic organisms living immediately adjacent to dredge areas will be subjected to periods of high turbidity, and settling of suspended sediments, which could bury, injure or kill these organisms.

Aquatic organisms in Coos Bay are adapted to and exposed to periods of high to moderate turbidity during winter months. Dredge operations are expected to result in similar effects, possibly with higher concentrations of suspended sediments concentrated in the immediate area of the dredging.

Increases in turbidity can also reduce the depth that light penetrates in the water column, which may affect submerged plants, such as eelgrass, and temporarily reduce productivity and growth rates (Parr et al.,1998). In many bays and estuaries, and seasonally, background turbidity levels are high and organisms are able to tolerate continuous exposure to high suspended sediment concentrations for much longer than would occur during dredging operations (Peddicord and McFarland, 1978). Species living in areas where waters are normally clear, such as along a rocky coast, may be especially vulnerable to the effects of increased suspended sediments. The turbidity levels predicted to occur by conservative modeling in the area of the SAV will be well below the levels reported in the literature as resulting in adverse effects on SAV and due to the relatively short duration of the dredging (approximately 4-6 months), there are no anticipated adverse effects on SAV due to turbidity from dredging. Since the predicted turbidity levels were based on the dredging of the entire slip and not just the area inside the berm that will be left to isolate the majority of the slip construction from the waters of Coos Bay, the actual turbidity levels will be lower than what was originally predicted.

The release of organic rich sediments during dredging or disposal can result in localized removal of oxygen from the water column, which can adversely affect aquatic organisms. This effect would be temporary and tidal exchange would be expected to replenish oxygen. In most cases, where dredging and disposal occurs in open coastal waters, estuaries and bays, localized removal of oxygen has little, if any, effect on aquatic organisms (Bray et al. 1997).

The re-suspension of sediments during dredging and disposal may result in an increase in the levels of organic matter and nutrients available to aquatic organisms. The potential for algal blooms in estuarine waters is limited by turbidity and tidal flushing. Increased organic materials could increase productivity in a localized area as food for zooplankton and higher organisms is increased. This effect is expected to be insignificant based on the limited area to be affected.

Salmonids, green sturgeon, juvenile eulachon (if present), mollusks, crustaceans and other aquatic species have the potential to be adversely affected by the dredging. Neither the eulachon, green sturgeon nor the salmonids spawn near the slip site, but the eelgrass beds may provide important feeding grounds for these species, and mollusks and crustaceans utilize the intertidal zone throughout Coos Bay. However, as the amount of SAV and intertidal habitat is minimal at the slip site, impacts to fish resulting from dredging operations are expected to be short term and minimal.

#### 3.3.5.6 Ballast Water Discharge

Ballast water is discussed in depth in Resource Report 2 – Water Use and Quality. The role of ballast water as a vector for transportation and introduction of various nuisance marine species to U.S. waters has become a critical issue for many international ports in recent years. The Oregon International Port of Coos Bay is no exception to this national concern and all ships utilizing this port will be subject to the 2012 U.S. Coast Guard (USCG) Final Rule on Ballast Water Discharges. (See Final Rule on Ballast Water Discharge Standard - Standards for Living Organisms in Ships Ballast Water Discharged in U.S. Waters).

Pursuant to this Final Rule, all LNG carriers will have been required to flush their ballast tanks at least once while in the open ocean or utilize one of several USCG approved Ballast Water Management (BWM) methods in order to discharge their ballast water into the slip area while concurrently loading their LNG cargo. Because taking on ballast water would only occur at sea and the discharge of ballast water will comply with the 2012 Ballast Water Discharge Standards, the potential impact for ballast water to introduce invasive species of interest in Coos Bay will be negligible. The JCEP will continue to require that the ballast water of all LNG carriers be discharged in accordance with federal oversight and existing regulations.

#### 3.3.5.6 Emissions

Some concern has been raised as to the potential impacts to wildlife of carbon dioxide ($CO_2$), nitrogen dioxide ($NO_2$), and sulfur dioxide ($SO_2$) emissions from the LNG Terminal. Since the refrigerant compressors will be driven by electric motors, the $NO_2$ emissions will be minimal. Based on data from another LNG plant, emission levels more than a very short distance from their sources will be negligible. The typically windy nature of the site will disperse these emissions quickly and it is not expected that these emissions will be a threat to wildlife.

### 3.3.6 Mitigation, Enhancement, and Protection Measures

#### 3.3.6.1 Submerged Aquatic Vegetation and Intertidal Habitat

The impact of the construction of the slip and access channel and construction dock on wetlands will be the permanent loss of approximately 9.69 acres of intertidal, 3.38 acres of shallow subtidal, 15.24 acres of deep subtidal, and 2.49 acres of eelgrass.

The proposed mitigation strategy for offsetting impacts to 3.38 acres of intertidal unvegetated sand and 9.69 acres of algal/mud/sand flats is to restore mud flats at the Kentuck wetland mitigation site. In addition, to mitigate for impacts on approximately 2.49 acres of eelgrass, JCEP will create new eelgrass habitat in an area due south of the west end of the Southern Oregon Regional Airport runway.

The airport eelgrass mitigation site appears to contain areas that are protected from wind, waves and excessive current velocities. Water clarity is fairly good compared to upper reaches of the bay. Dense patches of eelgrass scattered about the general area of the airport site were noted during the September 14, 2006, field reconnaissance (DEA). Opportunities exist to either lower high spots or build up low spots that are currently either too shallow or deep to support eelgrass. The resulting habitat increase from the mitigation site will provide benefits to the population overall by increasing the natural cover and forage production in Coos Bay. It is likely the increased quantity of habitat will offset the losses from the LNG Terminal site.

#### 3.3.6.2 EFH/ESH

To minimize impacts to EFH and ESH, the bulk of the slip construction will take place in isolation from Coos Bay by maintaining a portion of the existing shore line as a berm. Construction activity to remove the remaining portion of the existing shoreline and connect the slip with Coos Bay will be planned during the ODFW preferred work windows (October 1 through February 15) to minimize effects on vulnerable life stages of important fish species. Monitoring will be conducted before, during, and after slip construction to ensure compliance with the design and BMPs to control the release of sediments and/or inadvertent spills will be implemented. Mitigation for habitats removed or disturbed will be conducted as previously described.

#### 3.3.6.3 Shellfish Nurseries

If an unignited LNG spill were to occur along the LNG carrier transit route in the areas where the shellfish species are located, the LNG will remain on the surface of the water until it vaporizes and will not have an adverse effect on the shellfish. Some cooling of the upper water layers closest to the LNG spill would be expected, but would not likely cause the overall water column to cool to the point of affecting the shellfish, given the ambient water temperatures in the transit route. If the vapor from an LNG spill were to come in contact with an ignition source the resulting fire would burn back to the spill source and would affect things on the water or in the area that came in direct contact with the fire. Shellfish nursery areas and shellfish in the water would not be affected as the fire would be above the water in the area of the spill where the vaporized LNG is at flammable levels. In either case of lower or higher water temperatures based on the spill scenario, mobile species will move out of the area until the water temperatures return to normal. LNG spills directly on shellfish nursery areas when exposed at low tide are unlikely as the LNG carriers will routinely exit the Port at slack high tide.

There is little likelihood of an LNG carrier losing steerage, running aground, and physically damaging shellfish areas as the channel geometry will serve to keep the LNG carrier within the confines of the channel. In addition the LNG carrier will always be under tug escort when in the channel. The tugs will keep the LNG carrier under control and not allow it to run aground in the event of a steering or other control failure.

#### 3.3.6.4 Import of Exotic Marine Species

Ballast water is held in the ballast tanks and cargo holds of LNG carriers to provide stability and maneuverability during a voyage when carriers are not carrying cargo, are not carrying enough cargo, or require more stability due to rough seas. LNG carriers will need to discharge their ballast water at the LNG Terminal in conjunction with the cargo loading process. Any ship originating from a foreign port of call (LNG or otherwise) has the potential to import an exotic species that could impact the habitat associated with the slip. In recent years the impacts of these effects have become critically manifested in almost all U.S. ports of call. A study by Carlton and Geller has identified 638 taxa of exotic species that have already been introduced into the Coos Bay environment. For years now, all vessels entering U.S. ports have been required to comply with ballast water management protocols, U.S. law (e.g., Nonindigenous Aquatic Nuisance Prevention and Control Act of 1990; 1996 National Invasive Species Act), and agency programs (Department of Defense/U.S. Environmental Protection Agency regulations at 40 CFR Part 1700, which implement Section 312(n) of the Clean Water Act), and establish discharge standards for vessel ballast water.

On March 23, 2012, the USCG issued its Rule regarding Standards for Living Organisms in Ships' Ballast Water Management Discharged in U.S. Waters, which amends the existing BWM regulations and creates a standard for the allowable concentration of living organisms in ballast water discharged in U.S. waters consistent with the International Maritime Organization's International Convention for the Control and Management of Ship's Ballast Water and Sediments (BWM Conventions). This Rule will require all vessels equipped with ballast tanks bound for (or departing) U.S. ports to utilize at least one BWM method described in the Rule (77 FR 17254). The most likely convention given the advanced technologies used by LNG carriers will involve a complete ballast water exchange (BWE) in an area 200 nautical miles from any shore prior to discharging ballast water.

JCEP has assumed that the provisions of this Act and the new Rule will apply to both the import and export of nuisance species, and by compliance with this Act and Rule, the LNG carriers will neither cause nuisance species to be introduced from the discharge of ballast water into the Project site within Coos Bay or the ports of delivery for the LNG cargo.

#### 3.3.6.5 Marine Mammals

All marine mammals are protected under the Marine Mammal Protection Act of 1972. The estuarine and open ocean habitats (out to the EEZ) of the Project area could support a variety of protected marine mammals. Only the harbor seal, Steller sea lion, gray whale, and killer whale exhibit any potential to enter the bay and only the harbor seal was observed at the slip site during field surveys. Gray whales and killer whales enter Coos Bay only on an occasional basis. The Steller sea lion is expected to occur more frequently at the bay mouth, near the Charleston harbor where it is attracted to fishing-related activities, or offshore. All four species could be affected by increased shipping traffic. However, Coos Bay has historically experienced higher levels of deep draft vessel traffic (on the order of 200 ships per year versus the current rate of 50 ships plus the additional 90 LNG carriers). Accordingly, while the increase in the number of ships may result in an increased probability of ship strikes, ship strikes should still be less than what occurred a number of years ago.

In October of 2008, NMFS established its Final Rule to Implement Speed Restrictions to Reduce the Threat of Ship Collisions with North Atlantic Right Whales on the premise that slower speeds result in reduced potential for whale/ship strike interactions. This Rule does not apply to shipping traffic (LNG carriers) within the Pacific Ocean. Likewise, the Port of Coos Bay does not have regulatory authority over ships in the open sea. However, once an LNG carrier enters U.S. waters and approaches the harbor coastline, a mandatory reduction in speed is required. Each carrier will also be assisted into the bay by pilot and tug vessels; therefore, transit to and from the slip will already be at slow speeds due to in-place operating protocols. Slower speeds will result in reduced potential for LNG carrier strikes and yield minimal wakes inside the bay, such that marine mammals will not be affected by the wakes of passing LNG carriers.

Recent research into whale/ship strike interactions has identified a “sound shadow” that is created by the vessel’s hull by blocking the engine noise generated at the stern from being projected forward toward the bow. This sound shadow essentially veils the engine noise thus catching whales unaware of the vessel’s presence until it is often too late to avoid the vessel or its propellers. Technology has been developed in the form of a submerged directional array that can be deployed at the vessel’s bow to fill the acoustical shadow with sounds detectible by marine mammals and thus avoid a ship strike. The use of sound projection within the bow shadow is currently not required.

JCEP will provide measures proposed by NMFS for avoidance of marine mammals to carriers transporting LNG cargo from the Project to further reduce the likelihood of adverse effects on these species. Some of the suggested measures could include the following:

- Provide training to LNG carrier crews that would include the use of a reference guide such as the “Marine Mammals of the Pacific Northwest, including Oregon, Washington, British Columbia and South Alaska” by Pieter Folkens. This is a pamphlet that could be carried on the LNG carriers.
- Require LNG carrier crews to maintain a watch for marine mammals and slow the carrier to avoid striking protected species.
- When whales are sighted, maintain a distance of 90 meters or greater from the whale.
- Attempt to maintain a parallel course to the animal and avoid excessive speed or abrupt changes in direction until the animal has left the area.
- Reduce vessel speed when pods or large assemblages of cetaceans are observed near a vessel underway.
- When whales are sighted in a vessel’s path or in close proximity to a moving vessel, reduce speed or shift the engine to neutral until the whales are clear of the area or path.
- LNG crews will be asked to report sightings of any injured or dead protected species immediately, regardless of whether the injury or death is caused by the vessel. If the injury or death is caused by a collision with the vessel, appropriate regulatory agencies (FERC or NMFS) will be notified within 24 hours of the incident. Information to be provided will include the date and location (latitude/longitude) of the strike, the vessel name, and the species or a description of the animal, if possible.

If an unignited LNG spill were to occur along the LNG carrier transit route in the areas used as migratory routes by marine mammals, the LNG will float on the water until it vaporizes and will not have an adverse effect on the mammals unless they come in direct contact with the LNG.

#### 3.3.6.6 Project Construction

Land disturbing activities required for the construction of the Project will be confined to the existing property. During construction of the LNG storage tanks and other facilities, disturbed soils will be exposed to potential erosion. To minimize the impacts of erosion and sedimentation on surface waters, land disturbing and construction activities will be conducted in compliance with the National Pollution Discharge Elimination System (NPDES) Permit

Number 1200-C for stormwater discharges during construction activities. Stormwater runoff from the disturbed portions of the Project site will be managed in accordance with a site-specific Erosion and Sedimentation Control Plan (ESCP) included in the NPDES permit, which incorporates stormwater pollution prevention. JCEP will install all necessary erosion and sedimentation control structures in compliance with its ESCP, as well as the provisions of FERC's Plan and FERC's Procedures, both as modified. Following appropriate treatment, all construction stormwater from the Project site will be directed towards the slip.

Spills, leaks, or other releases of hazardous materials during construction of the Project could adversely impact water quality. Hazardous materials entering Coos Bay resulting from material spills being flushed into waterbodies with stormwater runoff or entering Coos Bay directly from leaks or spills at the LNG loading berth could have an adverse impact on water quality and aquatic organisms. A site-specific preliminary spill plan for the construction phase of the Project will be included as part of the NPDES permit to minimize the potential for accidental releases of hazardous materials and to establish proper protocols concerning minimization of, containment of, remediation of, and reporting of any releases which occur.

A Spill Prevention, Containment and Countermeasure Plan (SPCCP) will be prepared for the operational phase of the Project under the NPDES permit to minimize the potential for accidental releases of hazardous materials and to establish proper protocol concerning minimization, containment, remediation, and reporting of any releases which occur. This Plan will meet the requirements of 40 CFR Part 112.

## 3.4 FEDERAL AND STATE LISTED THREATENED AND ENDANGERED SPECIES

Federal agencies are required by Section 7 of the Endangered Species Act (ESA) of 1973, as amended, to ensure that any actions authorized, funded, or carried out by a federal agency do not jeopardize the continued existence of a federally-listed threatened, endangered, or proposed species, or result in the destruction or adverse modification of designated Critical Habitat of a federally-listed species. In addition, Oregon has its own ESA that requires state agencies to protect and promote the recovery of state-listed threatened and endangered species.

For the Project, FERC is required to consult with the USFWS and NMFS for federally-listed threatened and endangered species (or proposed for listing) and Critical Habitat found in the vicinity of the Project and to determine the Project's potential effects on those species or Critical Habitat. Federal candidate species and species of concern do not require federal ESA consultation. JCEP has initiated this consultation (Table 1.8-1, Resource Report 1 – General Project Description). For this report, a list was obtained from the ORBIC on October 19, 2012, for federally-listed species and Critical Habitat occurring within two miles of the Project's action area. At that time, the action area included the LNG export terminal facility, including the South Dunes Power Plant site. The ORBIC database is continually updated and the data received must be updated every six months for compliance with the ESA.

At the state level, consultation is conducted with the ODA for state-listed plant species and the ODFW for fish and wildlife species. However, state regulations pertaining to the protection of botanical resources are limited to ORS 564 and OAR Chapter 603, Division 73. State threatened and endangered plant species that could be present within the Project's boundaries have no legal protective status in Oregon because they would occur on private land and Oregon regulations only apply on all non-federal public lands (state, county, city, etc.). For fish and wildlife species, JCEP is required to coordinate and consult with the ODFW under the Oregon ESA (ORS 496, 506, and 509) and the Oregon Fish and Wildlife Habitat Mitigation Policy (OAR

345-022-0060) regarding state-listed species to ensure conservation of fish and wildlife resources and to develop a fish and wildlife habitat mitigation plan, as appropriate.

A lack of federally-listed species or Critical Habitat for a given area does not necessarily indicate there are no significant elements present, only that there is no information recorded for the site. To ensure there are no significant elements present that may be affected by the Project, the Project site and vicinity, as applicable, have been surveyed during the appropriate season for individual listed species for the county. In addition, JCEP (and its subcontractors) conducted informal consultations with Oregon agencies to determine the presence of state-listed threatened and endangered species that may be affected by the Project, per 18 CFR § 380.12(e)(4) for FERC.

From informal consultation conducted, it appears the Project may affect listed species. In compliance with Section 7 of the ESA, FERC staff is currently preparing a Biological Assessment (BA) for the Project which will be submitted to the USFWS and NMFS with a request to initiate formal consultation. The BA reviews the status of and potential effects by the Project on listed species and Critical Habitat, and includes proposed measures to avoid, minimize, or mitigate impacts on listed species. The BA also identifies and describes EFH that may be adversely affected by the Project, which requires consultation with NMFS under the Magnuson-Stevens Act.

Formal consultation concludes after the USFWS and NMFS each prepare a BiOp that includes analysis of the impact of the Project on listed species or Critical Habitat and determines whether the Project is likely to jeopardize the continued existence of listed species. Jeopardy occurs when an action is reasonably expected, directly or indirectly, to diminish a species' numbers, reproduction, or distribution so that the likelihood of survival and recovery in the wild is appreciably reduced. For jeopardy determinations, FERC would be provided with reasonable and prudent measures that would be outlined in an incidental take statement (ITS). The ITS sets forth nondiscretionary terms and conditions, including reporting requirements, that FERC and JCEP must comply with to carry out the reasonable and prudent measures. Incidental take from actions that meet these terms and conditions would be exempt from the take of ESA-listed species. The BiOp from NMFS would also include conservation recommendations to avoid, minimize or otherwise offset potential adverse effects on EFH, and these recommendations would become a subset of the terms and conditions found in the ITS.

The environmental analysis under this section includes species that are listed by the federal or state government as threatened, endangered, or proposed for listing. Species listed under the Marine Mammal Protection Act and those included as Essential Fish Habitat are described under Section 3.3 for fisheries and marine species.

Twenty-nine federal or state-listed threatened or endangered species, including one proposed species (streaked horned lark), potentially occur in the proposed Project area (Table 3.4-1). The following sections summarize their distributions, habitat requirements, and potential occurrence. Environmental consequences of construction and operation of the Project, including in the LNG carrier transit route, are also discussed, along with proposed mitigation, enhancement, and protection measures.

### 3.4.1 Botanical Species

Five federal and state-listed plant species were identified as having the potential to occur in the Project vicinity. The western lily is the only federally-listed species. State-listed species include the pink sand verbena, Point Reyes bird's-beak, silvery phacelia, western lily, and Wolf's evening primrose. Only one state-listed species (Point Reyes bird's-beak) has been detected within the Project area. The five species are described below.

### 3.4.1.1 Pink Sand Verbena (Federal Species of Concern, State Endangered)

The pink sand verbena (*Abronia umbellata ssp. breviflora*) is the only pinkish-purple-flowered coastal *Abronia* species in Oregon. The historic range of pink sand verbena occurs from California to British Columbia, Canada (USFWS 2006). Its present range is predominantly from Cape Blanco (Curry County) in southern Oregon to Point Reyes National Seashore in Marin County, California; however, they sporadically occur along Oregon's northern and central coast. In the northern portion of its range, most populations occur on broad beaches and/or near the mouths of creeks and rivers. The species usually occurs on beaches in fine sand between the high-tide line and the driftwood zone, and in areas of active sand movement below the foredune. Associate species include sea rocket (*Cakile maritina*), silver burweed, European beachgrass, beach silvertop, and yellow sand verbena (*Abronia latifolia)*.

Suitable habitat for the species was found along the eastern portion of the LNG Terminal site in areas of actively moving dunes and European beachgrass. Surveys conducted on the Project site in 2006 for the majority of the Project site area and in 2012 and 2013 in previously unsurveyed areas for the Project, including the construction worker camp site, did not result in the detection of any individuals (SHN 2006b; SHN 2012). The Project is not expected to affect this species.

### 3.4.1.2 Point Reyes Bird's-Beak (Federal Species of Concern, State Endangered)

Point Reyes bird's-beak (*Chloropyron maritimum ssp. Palustre*, formerly *Cordylanthus maritimus ssp. palustris*) is an annual gray-green and purple-tinged herb that grows 4 to 16 inches tall and has few branched stems. Also referred to as salt marsh bird's beak, it occurs in coastal salt marshes, typically within the zone that is periodically or frequently inundated by high tides (ORBIC 2012b; Brian 2005). Point Reye's bird's-beak inhabits the upper end of maritime salt marshes and its habitat requirements are specific: approximately 7.5 to 8.5 feet above mean lower low water (MLLW), sandy soils with soil salinity of 34 to 55 parts per thousand (ppt), and less than 30 percent bare soil in summer (ODA 2013). It flowers from June to October. Associate species include those that are tolerant of high salinity levels such as salt grass, pickleweed, fleshy jaumea (*Jaumea carnosa*), sea lavender (*Limonium californicum*), and dodder (*Cuscuta salina*). Point Reyes bird's-beak occurs along the Pacific Coast from Tillamook County, Oregon, south to Santa Clara County, California. In Oregon, the species is restricted to Netarts Bay, Yaquina Bay, and Coos Bay, with the majority of known occurrences located in Coos Bay.

Several occurrences of Point Reyes bird's-beak are located in the vicinity of the Project area (ORBIC 2012). Multiple occurrences within Jordan Cove have been observed (ORNHIC 2005; SHN 2012), as shown in Figure 3.4-1. The closest known occurrence to the Project site is located within Jordan Cove along the shoreline east and west of the South Dunes Power Plant site. Potential habitat for this species has also been observed along the shoreline south of the South Dunes Power Plant site. This habitat contains an abundance of the associated species, including pickleweed. Prior to construction, an additional survey for Point Reyes bird's-beak will be conducted during the appropriate blooming period in the area defined as potential habitat for the species.

### 3.4.1.3 Silvery Phacelia (Federal Species of Concern, State Threatened)

Silvery phacelia (*Phacelia argentea*) is a hairy, fleshy perennial herb with thick leaves that are coated in long, straight, silvery hairs. They occupy open sand above the high tide line, open and partly stabilized sand dunes further inland, and coastal bluffs. They flower from late May to early August. Silvery phacelia occurs in Coos and Curry counties along the Oregon coast and Del Norte County in California, from the vicinity of Bandon, Oregon, south to Crescent City, California. There is one historic collection of the species from Clatsop County, Oregon, to the north in 1933, but there have been no reports of it from that area since. The majority of occurrences are in Oregon (ODA 2013).

Suitable habitat for silvery phacelia exists at the Project site in areas with active or semi-stabilized dunes and upper beach habitat where European beachgrass and red fescue-salt rush herbaceous vegetation associations occur. Surveys conducted on the Project site for the majority of the Project area did not result in the detection of silvery phacelia (SHN 2006b; SHN 2012). The Project is not expected to affect this species.

### 3.4.1.4 Western Lily (Federal Endangered, State Endangered)

The western lily (*Lilium occidentale*) is a member of the perennial lily family (Liliaceae) and grows up to 5 feet tall with nodding red (sometimes deep orange) flowers. The species was federally-listed as endangered on August 17, 1994, and a final recovery plan was released four years later (USFWS 1998c). It inhabits 31 small, widely separated populations in freshwater marshes and swamps, coastal scrub and prairie, and openings in coastal coniferous forest (Sitka spruce dominated) along the coast of southern Oregon and northern California. It occurs within four miles of the coast, generally on marine terraces below 300 feet above mean sea level (MSL; CNDDB 2005). The western lily is considered a bog plant and grows in areas with perched water tables which are associated with one or two soil types. Occurrences within the Coos Bay area are reported to occur in Blacklock soils (ORNHIC 2005), which are deep, poorly drained soils high in organic content (Hagen 1989); however, it also grows in soils that are well drained that have a significant layer of organic soil.

The wetlands where Western lilies occur are not what are often associated with wetlands. They are in areas where the marsh is flooded in the winter but is typically very dry in the summer. The species emerges in Oregon in late March or early April and flowers in late June or July (USFWS 1998). Species typically associated with western lily include Sitka spruce, Pacific reed grass, willows, false lily-of-the-valley, and evergreen huckleberry (Imper 2003).

The closest known western lily occurrence to the Project site is approximately 5.5 miles northeast at Hauser Bog (ORNHIC 2005). There are not any records of the western lily north of Hauser and the USFWS typically considers Hauser the northern extent along the Oregon Coast for the species (Vander Heyden pers comm. 2013). Surveys were conducted at the Project site in 2006 for the majority of the Project area and again in 2012. The surveys did not result in the detection of western lily (SHN 2006b, SHN 2012). While suitable habitat is located along the terrestrial portion of the LNG carrier transit route in Coos Bay, LNG carrier traffic is not expected to affect the western lily.

### 3.4.1.5 Wolf's Evening Primrose (Federal Species of Concern, State Threatened)

Wolf's evening primrose (*Oenothera wolfii*) is a rare species of flowering plant in the evening primrose family. It occurs in well-drained sandy soil in coastal strands, roadsides, and coastal bluffs (ODA 2013). This species is associated with a high disturbance regime and several occurrences in California are located along roadsides with sandy soil (CNDDB 2005). Wolf's evening primrose is typically associated with low elevation coastal habitats, but there have been reported occurrences in lower montane coniferous forest in California, at elevations greater than 2,500 feet above MSL (Tibor 2001).

The current range of Wolf's evening primrose is from Curry County in southern Oregon to the northern California coast. The closest known occurrence to the Project site is in Port Orford, Oregon, approximately 60 miles to the south of the Project. The species is included in this analysis as suitable habitat exists within the Project site. Surveys conducted on the Project site did not result in the detection of wolf's evening primrose (SHN 2006b, SHN 2012). The Project is not expected to affect this species.

### 3.4.2 Terrestrial Wildlife Species

#### 3.4.2.1 Reptiles and Amphibian Species

There are no terrestrial federal or state threatened or endangered (or proposed) amphibian or reptile species that occur within the Project site.

#### 3.4.2.2 Birds

Seven bird species that are federal or state-listed as threatened, endangered, or proposed have the potential to occur in the vicinity of the Project, as described below. The locations of federal species detected in the Project site vicinity are shown in Figure 3.3-7.

**Bald Eagle (Federal Delisted, State Threatened)**

The bald eagle (*Haliaeetus leucocephalus*) is a widespread breeder in Oregon, with confirmed nesting in all but four counties. When the bald eagle was delisted on July 9, 2007 (72 FR 37346-37372), legal protections provided to the bald eagle switched to the Bald and Golden Eagle Protection Act and new guidelines were developed (USFWS 2007d). The most substantive change in the guidelines was a reduction in the distance between activities and in occupied nests from 0.5 mile to 660 feet when the activity is visible from the nest (line-of-sight).

Bald eagles are usually associated with large water bodies, including lakes, rivers, and coastal nearshore habitat. Home ranges are usually about 2-3 square miles (Anthony et al. 1990, Garrett et al. 1993). Bald eagle numbers peak in late winter and early spring when breeders, transients, and winter residents are all present (Isaacs and Anthony 2003). They nest on large, prominent trees and snags, usually within a mile of water, and nests are almost always reused (Isaacs and Anthony 2003).

Bald eagles are an uncommon resident of forested habitats near water on the Oregon coast (Eltzroth 1987), including Coos County (Rodenkirk in prep.) and the North Spit (USDI 2005); however, nesting is confirmed in most of Coos County (Adamus et al. 2001). It is not believed that any suitable nest sites exist within the Project site area, but there is ample foraging habitat in and along the bay. During field surveys conducted in 2005, there were five sightings in all seasons. Only one was observed at the Project site, consisting of an incidental sighting of a perched bird, and no nests were found. The rest of the sightings were over or across the bay from the Project site (LBJ 2006). A nest site in the ORBIC database, active at least as recently as 2003, is on Mettman Ridge above Glasgow, roughly three miles from the Project site.

Bald Eagles may be encountered in any of the LNG carrier transit route zones from nearshore coastal waters to the Project site. No nests occur at the Project site and the Project is not expected to affect this species.

**Brown Pelican (Federal Delisted, State Endangered)**

The brown pelican (*Pelecanus occidentalis)*, sometimes referred to as the California brown pelican, is found in nearshore ocean waters, in large bays and river mouths, and on beaches and spits. These birds are rarely seen inland or more than 40 miles from shore and they feed mostly in shallow estuarine waters. Pelicans make extensive use of sand spits, offshore sand bars, and islets for nocturnal roosting and daily loafing, especially by nonbreeders and during the non-nesting season (USFWS 2005).

The brown pelican is considered a common to abundant post-breeding migrant on the North Spit (BLM 2005). It arrives from the south along the Oregon coast in April and becomes abundant by August and September (Eltzroth 1987, Nehls 2003a, Rodenkirk in prep.). Although most brown pelicans have withdrawn to the south by December, small numbers now winter most years in the Coos Bay area (Contreras 1998, Rodenkirk in prep.). Coos Bay adjacent to Jordan Cove is excellent habitat for this species and it was recorded foraging near the Project site more than 500 feet from the shore and loafing across the bay in moderate numbers daily during surveys in October 2012 (SHN 2012). The species was also observed during surveys conducted in 2005-2006 until early September (LBJ 2006). The Project site provides no nesting habitat for the brown pelican.

Brown pelicans may be encountered during any portion of the LNG carrier transit route but are most likely to be encountered in the coastal nearshore waters out to the 0.3 mile zone. They appear unaffected by industrial activity already taking place in and around the bay and no impact to this species is anticipated from the development of the Project.

**Marbled Murrelet (Federal Threatened, State Threatened)**

The marbled murrelet (*Brachyramphus marmoratus*) is a small, chubby seabird that has a very short neck. It was listed as threatened under the ESA on October 1, 1992, for the Pacific region (including Washington, Oregon, and California). Critical Habitat was designated for the marbled murrelet (MAMU) on May 24, 1996 (61 FR 26257-26320). Following a series of proposed revisions in 2006 and 2008, a final rule on revised Critical Habitat was issued on October 5, 2011 (76 FR 61599-61621). MAMUs are not recovering like they should be and they have a high predation rate along the coast.

MAMUs nest primarily in coastal, old growth forests within 50 miles of the coast that are characterized by large conifer trees, multi-storied stands, and moderate-to-high canopy coverage from Alaska to Monterey Bay, California. They are also known to nest in mature forests with old growth characteristics. Nest trees for MAMUs need to be 19.1 inches or greater in diameter breast height (dbh), greater than 107 feet in height, have a least one platform 4 inches or greater in diameter that occurs a minimum of 32.5 feet above the ground (due to the way the birds take off from the platform—dropping down and coming up), and have an access route through the tree canopy that a MAMU could use to approach and land on the platform. It also needs a tree branch or foliage that provides protective cover (Nelson and Wilson 2002). The platform cannot be on a snag with no cover.

MAMUs spend a majority of their life on the ocean (USFWS 2007). Nesting adults make daily foraging trips to shallow, protected, nearshore coastal waters, feeding mostly on small fish but sometimes on euphausiids (small shrimp-like crustaceans). When at sea, MAMUs are rarely found more than a few miles from the shore (Hunter et al. 2005).

The USFWS consults on projects within ¼ mile of Critical Habitat for effects from construction with heavy equipment and one mile for more complex projects such as blasting and large helicopter work (Bridgette Tuerler pers comm. 2013). The USFWS is primarily concerned about removing MAMU habitat or impacting the land or the ability of the land to grow trees. It is also concerned about possible predation to the species due to predators attracted to potential habitat in the vicinity by human activities.

For sites determined to be close to potential MAMU habitat (whether listed as Critical Habitat or not), it is assumed there will be noise associated with the proposed work and, therefore, the Project could potentially affect the species. The extent of that effect would depend on the timing, associated activities and equipment, duration, season, location, etc. If potential Critical Habitat occurs within ¼ mile of the Project, these details would need to be considered and analyzed in a Biological Assessment before the USFWS could provide concurrence, as required under the ESA.

The species is considered uncommon to rare year-round on the Oregon coast (Marshall et al 2003), but Coos Bay is within the zone of highest density (Strong et al 1995). The MAMU nests in the Elliott State Forest northeast of Coos Bay in the Oregon Coast Range, and it probably nests in the Coos Bay area as well (Adamus et al. 2001). It is considered an uncommon, year-round, offshore resident on the North Spit (BLM 2005). One to four MAMUs are observed most years during the annual Coos Bay Christmas bird count (NAS website 2012). Although none were observed during surveys conducted for the Project (LBJ 2006), it is considered possible that MAMUs could occur on the bay within the general Project area and perhaps over the Project site in transit between nesting and feeding sites. MAMUs could be also be encountered along the LNG carrier transit route, as they generally forage in the nearshore region within three miles of the shore (McShane et al. 2004).

**Northern Spotted Owl (Federal and State Threatened)**

The northern spotted owl (*Strix occidentalis caurina*) is dependent on old-growth components in coniferous forests. In Oregon, it is found in low- and mid-elevation coniferous forests in the Coast, Siskiyou, and Cascade ranges (Forsman 2003). There are many spotted owl habitat areas in the forests inland from Coos Bay. The nearest site to the Project site is approximately five miles away in the Kentuck Creek drainage (ORBIC 2012). However, the species is extremely rare on the immediate coast of Oregon (Eltzroth 1987), rare in Coos County (Rodenkirk in prep.), and absent from coastal Coos County (Adamus et al. 2001). The northern spotted owl is absent from the North Spit wildlife list (BLM 2005) and is unlikely to be encountered in any of the terrestrial habitat in or near the Project vicinity or along the LNG carrier transit route. The species is not discussed further in this document.

**Short-tailed Albatross (Federal Endangered, No State Listing)**

The short-tailed albatross (*Phoebastria albatrus*) is the largest pelagic seabird in the North Pacific. Its long, narrow wings are adapted to soaring low over the ocean. It is best distinguished from other albatrosses by its large bubblegum-pink bill. The short-tailed albatross was federally-listed as endangered throughout its range on July 31, 2000. Critical Habitat is not prudent for this species. A recovery plan, drafted in 2005, is not finalized.

Historically, millions of short-tailed albatrosses bred in the western North Pacific on several islands south of the main islands of Japan. Only two breeding colonies remain active today and both are in Japan. Single nests occasionally occur on Midway Island, Hawaii. Eggs hatch in late December through early January and chicks remain near the nest for about five months, fledging in June. After breeding, short-tailed albatrosses move to feeding areas, with juveniles remaining at sea up to ten years before returning to nest. The species is distributed widely throughout its historical foraging range of the temperate and subarctic North Pacific ocean and they are often found close to the U.S. coast. They have been known to forage up to 1,988 miles from their breeding ground (USFWS 2012).

The short-tailed albatross population is estimated to be 1,200. Of these, the total number of breeding age birds is thought to be approximately 600 birds (USFWS 2013). The worldwide population of short-tailed albatrosses continues to be in danger of extinction throughout its range due to natural environmental threats, small population size, and the small number of breeding colonies. Longline fishing, plastics pollution, oil contamination, and airplane strikes are not viewed as threats by the USFWS to the species' survival but are considered threats to the conservation and recovery of the species.

Short-tailed albatross have been documented to occur off the Oregon coast in the vicinity of Coos Bay. ORBIC data reported a number of different occurrences along the coastline that transits the Coos Bay area. In November 2006, a radio-tagged bird moved from Alaskan waters to the mouth of the Columbia River, then down the Oregon coast to Cape Blanco (between Bandon and Port Orford), then out to sea and back to the Aleutian Islands in Alaska (ORBIC 2012). From September 25-29, 2009, another radio-tagged bird moved from Alaskan waters to off the mouth of the Columbia River, then headed down the Oregon coast on September 27 and into California. Other occurrences recorded included a short-tailed albatross observed off the coast of Yachats, between Florence and Newport to the north, on April 8, 2010.

Short-tailed albatross spend much of their time feeding in nutrient-rich waters of ocean upwelling which often occur at continental shelf breaks (USFWS 2005a). The short-tailed albatross could potentially be encountered within the LNG carrier transit route zones within the EEZ.

**Streaked Horned Lark (Federal Proposed, State Sensitive-Critical)**

The streaked horned lark (*Eremophilia alpestris strigata*) is a rare subspecies of the horned lark. It migrates between Oregon and Washington with breeding populations found in the Puget Sound lowlands, Columbia River/coastal Washington, and the Willamette Valley in Oregon from late March to early August. A previous candidate for federal listing, it was proposed for listing as a threatened species under the ESA on October 11, 2012. In addition to the listing, Critical Habitat was proposed for 7 counties in Washington and 11 counties in Oregon, but did not include Coos County. The closest county with Critical Habitat is Lane County to the north.

Some individuals winter in California (Pyle 1997) and occur along the Oregon coast on migration, while a few winter on the coast. The species occurs in bare and sparsely vegetated habitats such as coastal dunes, beaches, gravel roads, airport runways, grazed pastures, and dry mudflats; however, they do not occur on rolling or steep areas at these sites. Where deflation plains occur, streaked horned larks are often behind the foredune (Pearson pers comm. 2013). Larks also occur where dredge spoils have been deposited or in areas where there is accretion (deposition) of sand causing beach areas to become wider, provided the sites are sparsely vegetated and are immediately adjacent to water. For sites not adjacent to water, the area of expanse has to be quite large, likely 300 acres or greater, although further studies are needed (Pearson pers comm. 2013).

During winter surveys conducted in 2004/2005, streaked horned larks were found on dune and beach habitat adjacent to open water with few or no trees and shrubs on the Washington coast. On the lower Columbia River they were primarily found on sparsely vegetated dredge spoils (Pearson et al. 2005). The streaked horned lark has been documented on the North Spit (BLM

2005) and may winter over on the southern Oregon coast (Pearson et al. 2005). They spend the winter in large groups of mixed subspecies of horned larks in the Willamette Valley, and in smaller flocks along the lower Columbia River and Washington Coast (Pearson et al 2005).

When new unvegetated land is created by dredge spoils and accretion, it is not used by larks for the first year or two after deposition. Once the site becomes sparsely vegetated it can be quickly colonized by larks, especially on island spoils where off-road vehicle (ORV) traffic does not occur. If the site becomes colonized by non-native beach grasses (*Ammophila spp.,* including European beachgrass) it is no longer used by streaked horned larks once it becomes densely vegetated (Pearson and Hopey 2004). There is a fairly narrow window of time when the habitat is sparsely vegetated and appropriate for larks. In addition, dredge spoils colonized by Scotch broom (*Cytisus scoparus*) or horsetail (*Equisetum sp.*) are not used by the species (Pearson et al. 2005). As sandy habitats on the coast continue to be colonized with a dense covering of beachgrass, the larks do not use these habitats for breeding or over-wintering.

There appear to be very few streaked horned larks remaining in the world (probably between 500 and 1000 birds) and preliminary genetics work suggests that the remaining birds have little genetic diversity. This result suggests that the streaked horned lark population may already be experiencing the deleterious effects of inbreeding or the results of a small founder population. The remaining populations are vulnerable to all of the threats small populations commonly face (e.g., vulnerability to environmental and demographic variability and to the loss of genetic variability)(Pearson et al. 2005).

A focused field evaluation of the Project site on the North Spit was conducted by SHN Consulting (SHN) staff on April 23, 2013, to assess the potential for streaked horned lark habitat to occur (Figure 3.4-2). One small area approximately 75' by 150' was noted at the South Dunes Power Plant site; however, it is surrounded by the previous mill site industrial footprint and is not adjacent to open water. Along the utility corridor and access road between the South Dunes Power Plant and LNG Terminal sites, sparsely vegetated portions of the rolling (and at times steep) dunes in the area was noted; again, the sites were not adjacent to open water. Small pockets of potential habitat were also noted in the upper half of the slip site, but they are surrounded by and being encroached by European beachgrass, gorse, and Scotch broom (hence making it unlikely habitat). An additional area at the northwest tip of the Project site, immediately south of the Trans-Pacific Parkway, also provides sparsely vegetated sand habitat but is not adjacent to open water.

The "weedy fields between the shoreline and dunes on the Roseburg Forest Products facility" noted in previous surveys as potential habitat (LBJ 2006) were scraped off approximately five years ago and planted with grass that has become dense. When the previous surveys were conducted in 2005 and 2006, the site was likely at the stage between unvegetated landscape and dense covering of grasses. That habitat no longer exists and the site would no longer be considered potential habitat for the streaked horned lark.

Laura Todd, USFWS Newport Field Office, in a telephone conversation with SHN staff on April 29, 2013, said the USFWS has not done long term studies regarding the streaked horned lark to date and they are not sure of the range in coastal Oregon. So far the range has been primarily noted along coastal Washington; however, the USFWS does not discount the possibility that streaked horned lark habitat could exist along the Oregon coast.

Dr. Scott Pearson, Senior Research Scientist for the Washington Department of Fish and Wildlife, has been studying avian ecology for over 20 years and his research has included focused studies on the streaked horned lark. In a telephone conversation with Dr. Pearson by

SHN staff (April 29, 2013), Pearson said he would not be surprised if streaked horned larks were found to breed on the Oregon coast as it seems the habitat is ideal. Portions of the North Spit are well-suited for lark habitat, particularly in areas where there are western snowy plovers and habitat restoration has occurred. It is possible that larks could share the same habitat with plovers. Pearson found a lark nest within 5 meters of a plover nest in Washington. They use very similar habitat, although plovers use more extreme open habitats, whereas the lark needs some vegetation.

Based on the habitat specifications provided by Dr. Pearson in addition to a literature review of reports documenting research on the streaked horned lark, although potential lark habitat appears to exist in pockets of the Project footprint, those areas do not meet the criteria described by Dr. Pearson as essential for lark occurrence. Occurrence of the streaked horned lark is not anticipated at the Project site. They may be encountered within the general Project vicinity or along the LNG carrier transit route; however, the species would likely keep a distance and avoid close interactions.

**Western Snowy Plover (Federal Threatened, State Threatened)**

The western snowy plover (*Charadrius alexandrinus nivosus*) is a small shorebird approximately 6 inches long with a thin dark bill. The Pacific Coast breeding population includes Oregon, with coastal populations typically consisting of resident and migratory birds. The North Spit of Coos Bay supports the most productive snowy plover population segment on the Oregon coast.

The Pacific Coast population of the western snowy plover was listed as a threatened species under the ESA on March 5, 1993. In addition to being listed as threatened under the ESA, Critical Habitat was designated for the Pacific Coast population in 1999 and a recovery plan for the species was developed by the USFWS (USFWS 2007b). Objectives in the recovery plan include: 1) achieving well-distributed increases in numbers and productivity of breeding adult birds, and 2) providing for long-term protection of breeding and wintering plovers and their habitat.

The southwestern portion of the North Spit is designated as Critical Habitat for the western snowy plover from the ocean beach at Horsfall to the Coos Bay north jetty and includes all federal lands at the south end. The Project site is greater than 2.5 miles from the northern extent of Critical Habitat and greater than 4.5 miles from the primary nesting areas. Nesting in Oregon may occur as early as mid-March, with peak nest initiation occurring from mid-April through mid-July. The closest nest is 2.57 miles from the Project (ORBIC 2010). On the coast, it is almost exclusively a bird of open sand beaches. It is unlikely that this species would nest in or around Jordan Cove due to the lack of primary habitat for the species. Its typical coastal nesting habitat is at the upper edge of the beach below the foredunes. It also nests on bare spits at small estuary mouths and, on the North Spit, is most prevalent on restored sand habitat east of the foredune.

Current management activities and use restrictions within the Coos Bay North Spit Recreation Management Area relative to the snowy plover population include predator management, symbolic fencing, habitat restoration, public outreach and education by BLM staff, monitoring of snowy plover populations, and recreational use restrictions in place from March 15 to September 15 of each year. Recreational use restrictions include seasonal re-routing of the foredune road along with prohibiting vehicles, camping, and dogs. Non-prohibited recreational use (i.e., jogging, beach combing, horseback riding) is restricted to the wet sand outside of roped off and signed breeding areas.

USFWS surveys conducted on the North Spit document an increase in adults from 27 in 2005 to 52 in 2012. Total adults surveyed in Oregon have increased from 100 in 2005 to 206 in 2012. The North Spit population accounts for approximately 25 percent of the total adults observed in Oregon. On the Pacific Coast (including Washington, Oregon, and California), California has the highest documented occurrence, with 1621 adults surveyed in 2012; however this number is down from 1680 adults surveyed in 2005.

There does not appear to be any typical habitat in the Project site. While an occasional individual may use the mudflats adjacent to Jordan Cove for foraging, breeding is unlikely. None were detected during field surveys conducted for the Project in 2005 and 2006, and again in 2012. Western snowy plovers may be encountered in the LNG carrier transit route zones from nearshore coastal waters to the Project.

#### 3.4.2.3 Mammal Species (Terrestrial)

**Gray Wolf (Federal Endangered, State Endangered)**

Gray wolves (*Canis lupus*) in Oregon remain listed statewide as endangered under the Oregon ESA. Wolves occurring west of Oregon Highways 395/78/95 continue to be federally protected as endangered under the federal ESA. The USFWS is in the process of evaluating the classification status of gray wolves currently listed in the contiguous U.S. In the federally listed portion of Oregon, the ODFW implements the Oregon Wolf Conservation and Management Plan (OWP) under the guidance of the Federal/State Coordination Strategy (March 2011).

Wolves occurring in Oregon today are part of the Northern Rocky Mountain wolf population. They are descendants of wolves originally captured in Canada and released in Yellowstone National Park and Idaho in the mid-1990s. Wolf numbers fluctuate throughout the year as wolves disperse, pups are born, and new packs are formed. The Oregon wolf population is officially documented at the end of each year. On December 31, 2012, the minimum Oregon population was 53 wolves. This means that at least 53 wolves were documented. It is likely that there are more, as lone wolves can be challenging to document.

Oregon's wolf population continued to increase in distribution and abundance in 2012 and at year-end the minimum wolf population was 46 wolves in six packs. All six packs met the criteria as breeding pairs. All known resident wolves occurred in Wallowa, Umatilla, Union, and Baker counties. This marks the first year that the initial OWP conservation population objective to have four breeding pairs in eastern Oregon was reached.

It is unlikely the gray wolf occurs on the North Spit and the Project vicinity, given current tracking and distribution data available (ODFW 2013). The Project is not anticipated to have any impact to the gray wolf and the gray wolf does not warrant further investigations at this time.

### 3.4.3 Fisheries (Including Marine Species)

There are no threatened or endangered fish species listed by the ODFW or NMFS that spend their entire life cycle within Coos Bay or the area where the Project will be constructed. Three federally-listed anadromous fish species spend a portion of their life cycle within the estuarine environment of Coos Bay, including the area of the access channel and slip site. Oregon Coast (OC) coho salmon (*Oncorhynchus kisutch)*, southern distinct population segment (DPS) green sturgeon (*Acipenser medirostris*), and southern DPS Pacific eulachon (*Thaleichthys pacificus*), were federally-listed (2008, 2006 & 2010, respectively) as threatened under the ESA. These three species have not warranted listing as threatened or endangered by the State of Oregon. Use of the Coos Bay system by eulachon and green sturgeon is sporadic at best (based on various ODFW seining surveys and personal communications) and there is very little habitat available for coho salmon in the Project area.

For analysis under the ESA for fish species, the action area includes all areas to be affected directly or indirectly by the Project and not merely the immediate areas involved in the action. Typically the action area extends 500 feet upstream from the Project site and 1,500 downstream from the downstream end of the Project site in Coos Bay due to potential impacts from stormwater discharge, turbidity, contaminant dispersion, and habitat loss. The action area also incorporates the construction worker camp and the Kentuck and eelgrass bed mitigation sites.

#### 3.4.3.1 Oregon Coast Coho Salmon (Federal Threatened, State Sensitive-Critical)

Oregon Coast (OC) coho salmon are one of several anadromous salmonid species that utilize Coos Bay for migration and rearing habitat for adult and juveniles on their way to and from the ocean between marine and freshwater environments. On February 4, 2008, NMFS listed the naturally spawning populations within the Evolutionary Significant Unit (ESU) of OC coho salmon as a federal threatened species under the ESA. Critical Habitat for this ESU has been designated within several freshwater sub-basins of the Coos Bay system; however, no critical habitat exists within the Project action area.

OC coho salmon occurring in the action area are part of the Coos River population that was identified as a functionally-independent population (Lawson et al. 2007). An independent population is defined as having minimal demographic influence from adjacent populations and is viable-in-isolation. An independent population is any collection of one or more local breeding units whose population dynamics or extinction risk over a 100-year time period is not substantially altered by exchanges of individuals with other populations (McElhany et al. 2000). The Coos River population is part of the Mid-South Coast biogeographic strata defined within the OC coho salmon ESU.

Annual spawning surveys conducted by the ODFW document the Coos River's population's annual abundance varies considerably from year to year. The 2012 ODFW monitoring report on the status of Oregon stocks of coho salmon for 2011 summarizes the results of status and trend monitoring for Oregon's naturally spawning coho salmon populations through the 2011 run year (October 2011 through February 2012). Monitoring results include:

1. Abundance of naturally spawning coho salmon;
2. Density (fish/mile) of naturally spawning coho salmon;
3. Coho salmon spawn timing and distribution; and
4. Proportion of hatchery (marked) coho salmon in naturally spawning populations.

Surveys conducted at 29 sites for OC coho ESU populations on the Coos River determined fish presence at 83 percent of the sites. Annual abundance estimates of naturally spawning wild adult coho salmon in the OC coho ESU for run years 1990 through 2011 document that the Coos River's population's annual abundance varies considerably from year to year (Table 3.4-2). The 2011 estimates show a recent negative trend in abundance at the ESU level for the average over the past 10 years. The 2011 estimates are more symbolic of estimates from the previous 10 years.

#### 3.4.3.2 Pacific Eulachon (Federal Threatened-Southern DPS, No State Listing)

Eulachon (commonly called smelt, candlefish, or hooligan) is a small, anadromous fish from the eastern Pacific Ocean. In North America they range from northern California into the southeastern Bering Sea. On March 18, 2010, NMFS listed the southern DPS of eulachon as threatened under the ESA, followed by designating Critical Habitat for the southern DPS on October 20, 2011 (76 FR 65323). The southern DPS ranges from Nass River, British Columbia, to Mad River, California, and includes Coos Bay and its upper reaches. NMFS has not designated EFH for the Coos Bay system. Prior to being listed as threatened under the ESA in 2010, the commercial catch of eulachon from the Columbia River from 1938 to 1992 averaged approximately 2 million pounds per year. Since the mid-1990s, however, eulachon populations have decreased dramatically. Between the years of 1993 to 1996 the average annual catch dropped to approximately 43,000 pounds, a nearly 98 percent decline.

Eulachon are plankton-feeders, chiefly eating crustaceans such as copepods and euphausiids (Barraclough 1964). They typically spend three to five years in saltwater before returning to freshwater to spawn. Many sources note that runs tend to be erratic, appearing in some years but not others (NMFS 2006). They do not feed in fresh water and remain there only a few weeks to spawn (Rogers et al. 1990).

There is currently little information available about eulachon presence in Coos Bay. Monaco et al. (1990) described eulachon as rare in Coos Bay. While eulachon were mentioned as occurring in other studies conducted in the bay in 1971, Wagoner et al. (1990) stated that “eulachon may have occurred in large numbers in past years [in Coos Bay], but they have apparently not been abundant enough in recent years to attract an active dipnet fishery”. More recently, Miller and Shanks (2005) surveyed the distribution of 28 identified larval and juvenile fish species in Coos Bay for more than three years between 1998 and 2001, but did not encounter eulachon.

Adults begin moving through the bay as early as December and spawning typically occurs from January to mid-May, with the peak in February to mid-March. When present, eulachon may utilize both shallow and deep water habitats within the estuary as they migrate to spawning grounds. They will only spawn in lower reaches of rivers and major tributaries (i.e., the Coos River), as they need moving water and large substrate to spawn. Eggs are fertilized in the water column, sink, and adhere to the river bottom typically in areas of gravel and coarse sand. Eulachon eggs hatch in 20 to 40 days, with incubation time dependent on water temperature. Shortly after hatching, the larvae are carried downstream and dispersed by estuarine and ocean currents. When the larvae reach juvenile size, they disperse to the ocean as soon as able. Juveniles may migrate out as early as February to as late as almost mid-summer (Chuck Wheeler pers comm.). Adult eulachon do not always die after spawning so they could return to the ocean.

Very little is known about the offshore distribution of adult or immature eulachon outside the spawning season, although abundances in particular locations show responses to oceanic conditions (Emmett and Brodeur 2000). Eulachon appear to live near the ocean bottom on the continental shelf at moderate depths that commonly range from 20 to 200 meters, but they may occur as deep as 500 meters (Hay and McCarter 2000).

#### 3.4.3.3 Green Sturgeon (Federal Threatened-Southern DPS, No State Listing)

Green sturgeon are long-lived, slow-growing fish, and are the most marine-oriented of the sturgeon species. Although they are members of the class of bony fishes, the skeleton of sturgeons is composed mostly of cartilage. Instead of scales sturgeon have five rows of characteristic bony plates on their body called scutes. The backbone of the sturgeon curves upward into the caudal fin, forming their shark-like tail. On the ventral, or underside, of their flattened snouts are sensory barbels and a siphon-shaped, toothless mouth.

Green sturgeon is a widely distributed and marine-oriented species. They are believed to spend the majority of their lives foraging in nearshore oceanic waters, bays, and estuaries, ranging from nearshore waters in Baja California to those in Canada. They utilize both freshwater and saltwater habitat and spawn in deep pools or holes in large, turbulent, freshwater river mainstems (Moyle et al. 1992).

There are two distinct population segments defined for green sturgeon—a northern DPS with spawning populations in the Klamath and Rogue rivers and a southern DPS that spawns in the Sacramento River (NMFS 2008). The southern DPS includes all spawning populations of green sturgeon south of the Eel River in California.

The southern DPS of the North American green sturgeon was federally-listed as threatened on April 7, 2006, under the ESA. The species has not warranted protective listing status by the State of Oregon. Studies have confirmed the migratory nature of green sturgeon between northern and southern DPS units. As such, NMFS took an inclusive approach when determining the geographical area occupied by the southern DPS and designated Critical Habitat from the Bering Sea, Alaska, to the U.S. California and Mexico border.

Younger green sturgeon reside in freshwater, with adults returning to freshwater to spawn when they are about 15 years of age and more than 4 feet in size. The species only spawns every 2 to 5 years (Moyle 2002). Adults typically migrate into freshwater beginning in late February and spawning occurs from March to July, with peak activity from April to June (Moyle et al. 1995). Specific spawning habitat preferences are unclear, but eggs likely are broadcast over large cobble substrates. They range from clean sand to bedrock substrates as well (Moyle et al. 1995). It is likely that cold, clean water is important for proper embryonic development.

The principal factor in the decline of the southern DPS is the reduction of their spawning area in California. Other threats to the southern DPS include insufficient freshwater flow rates in spawning areas, contaminants (e.g., pesticides), bycatch of green sturgeon in fisheries, potential poaching (e.g., for caviar), entrainment by water projects, influence of exotic species, small population size, impassable barriers, and elevated water temperatures. If a green sturgeon spawns in Oregon, it is not part of the southern DPS and not considered threatened under the ESA. Both southern and northern DPS green sturgeon may occur in Coos Bay, in addition to white sturgeon (Mike Gray pers comm.).

Green sturgeon spend more time in the ocean, as they have less tolerance for freshwater than white sturgeon, but they do come in and out of the bay.

The distribution of green sturgeon is not well known, although southern DPS green sturgeon are reported to congregate in coastal waters and estuaries and are present in Coos Bay. Southern DPS individuals were documented to occur by sampling in a 2006 study (Israel and May 2006). Because Coos Bay is not their natal stream, southern DPS green sturgeon are likely to be present from June through October. While in Coos Bay estuary, they are likely feeding in shallow areas and seeking out the deep water for resting.

#### 3.4.3.4 Marine Mammals

Three federally-listed marine mammals with a potential to occur near the Project site are discussed below.

**Steller Sea Lion (Federal Endangered, No State Listing)**

The Steller sea lion (*Eumetopias jubatus*), also called northern sea lion, ranges along the North Pacific coast from Japan to southern California (USFWS 2007a). It breeds on rocky beaches, often on islands, and at other times is frequently seen hauled out on select coastal rocks, jetties, marinas, and navigation buoys. It forages at sea for fish and invertebrates, sometimes to several hundred miles from land. The Oregon population was estimated at over 5,000 in 2002 and productivity appears to be increasing (NOAA website). There are no rookeries in Coos County. The nearest (one of Oregon's two primary rookeries) is at Orford Reef in Curry County (Brown 1988, NMFS 1992b). There is a haul-out site at Cape Arago in Coos County, roughly ten miles from the Project site area (ORBIC, NMFS website). While an occasional Steller sea lion might enter Coos Bay and the species is included on the North Spit wildlife list (USDI 2005), there are no suitable haul-out sites within the Project site and the species is not expected to occur there.

Steller sea lion Critical Habitat includes all major Steller sea lion rookeries and associated air and aquatic zones. Critical Habitat includes an air zone that extends 3,000 feet above areas historically occupied by sea lions at each major rookery in California and Oregon, which is measured vertically from sea level. Critical habitat includes an aquatic zone that extends 3,000 feet seaward in state and federally managed waters from the baseline or basepoint of each major rookery in California and Oregon. The following are designated as Critical Habitat in Oregon:

- Rogue Reed: Pyramid Rock; and
- Orford Reef: Long Brown Rock and Seal Rock.

Based on the above information, Critical Habitat for the Steller sea lions is not designated within the LNG carrier transit route zones. However, haulout areas at Cape Arago located in the vicinity of the LNG carrier transit route are part of the Oregon Islands National Wildlife Refuge. Steller sea lions are likely to occur within the LNG carrier transit route zones.

**Gray Whale (Federal Endangered, State Endangered)**

The gray whale *(Eschrichtius robustus)* is a large baleen whale that is distributed in the northern Pacific Ocean in western and eastern stocks. The eastern Pacific stock feeds in the summer in Chukchi Sea, western Beaufort, and the northern Bering Sea. They migrate from November through early February south to lagoons on the Pacific coast of central and southern Baja California. Northward migration occurs after the calving and breeding season, from early February to May. These whales have the longest known migration of any mammal. Adult females reach 15 meters in length and males reach up to 14.3 meters and weigh up to 33,850 kilograms. Gray whales feed on benthic species that are buried in sediments.

According to OPDR (2007), gray whales are the most predominant whales seen along the Oregon coast. They migrate twice a year during winter and spring as stated above. About 200 of them feed along the coast during the summer months. Gray whales have on occasion penetrated Coos Bay beyond the Project site areas and have been seen in Coos Bay at about the same frequency as killer whales. Gray whales may be encountered in the LNG carrier transit route zones during their southern migration from November through early February or from early February to May during the northern migration.

**Southern-Resident Killer Whale (Federal Endangered, No State Listing)**

The killer whale (*Orcinus orca*) is a wide-ranging predator of the open ocean that has a worldwide distribution but is most common in the subarctic, temperate, and subantarctic waters (Maser et al. 1981). The southern resident killer whale was proposed for delisting in 2012 and is currently under review (77 FR 70733). Along the North Pacific coast, resident killer whales occur from Oregon and Washington to the Bering Sea (NMFS 2006) and their distribution is correlated to food supplies (Maser et al. 1981). This federally-listed species feeds primarily on fish and marine mammals. According to Maser et al. (1981), killer whales are most abundant in the Puget Sound in November and late summer. Most southern California killer whale sightings occur in fall, winter, and early spring. Based on this information, killer whales could be encountered in Oregon during the fall, winter, and spring, with occasional sightings throughout the year. Killer whales occasionally enter bays in pursuit of salmon and pinnipeds and have on occasion penetrated Coos Bay beyond the Project site. They could also occur within the LNG carrier transit route zones.

#### 3.4.3.5 Waterway for LNG Marine Traffic

Additional federal threatened or endangered species that could occur within the zones of the LNG carrier transit route are described below. The locations of federal threatened or endangered species are shown in Figure 3.5-2.

**Blue Whale (Federal Endangered, State Endangered)**

Blue whales (*Balaenoptera musculus*) are distributed from the equator to polar icepacks in both the northern and southern hemispheres. The eastern North Pacific population winters off Mexico and Central America and feeds off the coast from California to British Columbia during the summer and fall from June through November. Blue whales are most likely seen off the Oregon coast from late May through June and from August through October. This species is a baleen whale that feeds on euphausiids, commonly referred to as krill. Adult male blue whales reach up to 32.6 meters in length and weigh up to 133 metric tons. Females reach 33.3 meters in length and may weigh in excess of 151 metric tons. According to the OPRD (2007), occasional blue whales are sighted off the Oregon coast. Blue whales may be encountered along the LNG carrier transit route between the summer months specified above.

**Fin Whale (Federal Endangered, State Endangered)**

Fin whales (*Balaenoptera physalus*) are widely distributed throughout the world's oceans. The wintering grounds in the Pacific Ocean are from central California to Cabo San Lucas at the southern tip of the Baja California peninsula in Mexico. Their summer range extends from California to the Chukchi Sea in the southern Arctic Ocean between Alaska and Siberia. This species likely occurs along the Pacific coast from California to Washington from May to September. Adult female fin whales reach a length of 27.3 meters and a weight up to 100 metric tons. Adult males reach a length of 24.4 meters and weigh up to 89 metric tons. Fin whales are reported to return to the same feeding grounds year after year. It is not known if feeding grounds are located within the LNG carrier transit route. This species primarily feeds on euphausiids and secondly on fishes and cephalopods (i.e., squid). According to the OPRD (2007), occasional fin whales are sighted off the Oregon coast. This species may be encountered in the LNG carrier transit route from May to September.

**Humpback Whale (Federal Endangered, State Endangered)**

The humpback whale (*Megaptera novaeangliae*) is probably best known for its breaching and underwater vocalizations. This species is distributed in both the northern and southern hemispheres, from tropical waters to the edge of the polar ice. In the eastern Pacific, humpback whales have been observed from the Chukchi Sea to southern Mexico. Adult male humpbacks reach 15 meters in length and females reach up to 18 meters in length. This species feeds on benthic and pelagic euphausiids and small schooling fishes. OPRD (2007) states that humpbacks are sometimes seen off the Oregon coast at the same time as gray whales, but are not observed as frequently because their herd size is smaller. Humpbacks may be encountered in any of the three zones of the LNG carrier transit route from spring through early fall.

**North Pacific (Right) Whale (Federal Endangered, No State Listing)**

The northern right whale *(Eubalaena glacialis)* is a large baleen whale that reaches up to 18 meters and 100 tons. The winter distribution includes the Oregon coast south to central Baja California, Mexico (Maser et al. 1981). Summer distribution is in cool temperate waters in the north Pacific from the Bering Sea to latitude 50 degrees north. Northern right whales feed solely on zooplankton consisting of copepods and euphausiids and occasionally on pteropods (Maser et al. 1981). OPRD (2007) does not list the northern right whale as one of the species that may occasionally be observed along the Oregon coast. However, based on the distribution information, the northern right whale may be encountered in the LNG carrier transit route during winter months.

**Sei Whale (Federal Endangered, State Endangered)**

Sei whales (*Balaenoptera borealis*) are distributed worldwide, including an eastern Pacific stock that is found from Alaska to Mexico This species is found off the central California coast in the late summer or early fall and appears to move farther south and offshore in the winter. No information was found for this species distribution along the Oregon coast. Sei whales feed on copepods, euphausiids, sauries, anchovies, herring, sardines, squid, and jack mackerel. Adult males reach a maximum length of 17.7 meters and females reach a maximum length of 18.6 meters in the northern hemisphere. The OPRD (2007) does not list the Sei whale as one of the species that can be observed off the Oregon Coast. However, based on the information from Maser et al. (1981), this species may be encountered in the LNG carrier transit route during summer months.

**Sperm Whale (Federal Endangered, State Endangered)**

The sperm whale (*Physeter macrocephalus*) is the largest of the toothed (Odontoceti) whales and is distributed worldwide except for the pack ice of polar regions. Their diet consists of fishes and cephalopods. Adult male sperm whales may reach up to 16.8 meters in length (the average is 14.6 meters) and females grow up to 11.7 meters and weigh 37 metric tons. Sperm whales migrate toward polar regions in the summer and to temperate regions in the winter. OPRD (2007) states that sperm whales are occasionally sighted off the Oregon coast from March to September. Sperm whales may be encountered in the LNG carrier transit route from spring to fall.

### 3.4.3.6 Sea Turtles

**Green Sea Turtle (Federal Threatened, State Endangered)**

Green sea turtles (*Chelonia mydas*) have been sighted from Baja California to southern Alaska, but most commonly occur from San Diego south (NMFS 2007a). Green sea turtles primarily use three types of habitat: oceanic beaches (for nesting), convergence zones in the open ocean, and benthic feeding grounds in coastal areas (NMFS 2007a). Green sea turtles could potentially be encountered within the LNG carrier transit route.

**Leatherback Sea Turtle (Federal Endangered, State Endangered)**

Leatherback sea turtle (*Dermochelys coriacea*) nesting grounds are located around the world, with the largest remaining nesting assemblages found on the coasts of northern South America and West Africa (NMFS 2007). Adult leatherback sea turtles are capable of tolerating a wide range of water temperatures and have been sighted along the entire coast of the United States and as far north as the Gulf of Maine and south to Puerto Rico, the U.S. Virgin Islands (USVI), and into the Gulf of Mexico (NMFS 2007). The Pacific subspecies has declined so drastically that a Pacific Leatherback Conservation Area, wherein gillnet fishing is restricted, has been established stretching from central California to central Oregon (LBJ 2006). Leatherback sea turtles could potentially be encountered within the LNG carrier transit route.

**Loggerhead Sea Turtle (Federal Endangered, State Threatened)**

Loggerhead sea turtles (*Caretta caretta*) occupy three different ecosystems during their lives—the terrestrial zone, the oceanic zone, and the neritic (coastal) zone. Loggerhead sea turtles are circumglobal in distribution, occurring throughout the temperate and tropical regions of the Atlantic, Pacific, and Indian oceans. Loggerhead sea turtles are the most abundant species of sea turtle found in U.S. coastal waters (NMFS 2007b). Occasional sightings are reported along the coasts of Washington and Oregon, but most records are of juveniles off the coast of California (NMFS 2007b). Loggerhead sea turtles could potentially be encountered within the LNG carrier transit route.

**Olive Ridley Sea Turtle (Federal Threatened, No State Listing)**

The olive ridley sea turtle (*Lepidochelys olivacea*) occurs within the tropical regions of the Pacific, Atlantic, and Indian oceans. Important nesting areas for the olive ridley include the west coast of Mexico and Central America (NMFS 1998). Olive ridley sea turtle populations had declined from former times but olive ridleys are still the most abundantly nesting turtle on the Pacific coast (Cornelius 1982). This species does not nest in the United States, but during feeding migrations olive ridley turtles nesting in the East Pacific may disperse into waters off the U.S. Pacific coast as far north as Oregon. Though remote, Olive ridley sea turtles could potentially be encountered within the LNG carrier transit route.

### 3.4.4 Environmental Consequences (Construction and Operation)

Environmental consequences for the construction and operation of the Project that have not been previously addressed in the individual sections for vegetation, wildlife, and fisheries are discussed below as they specifically relate to ESA-listed species. The most notable consequences of the Project will be the permanent loss of vegetation and wildlife habitat at the Project site. Overall potential LNG-related environmental consequences from the construction and operation of the proposed LNG export facility are discussed in Section 3.5. Of note, if an unignited LNG spill were to occur along the LNG carrier transit route in the areas where the endangered or threatened species are located, the LNG will float briefly on the water until it vaporizes and will not have an adverse effect on the species unless they come in direct contact with the LNG.

#### 3.4.4.1 Botanical Resources

**Western Lily (Federal Endangered, State Endangered)**

The western lily is one of the rarest plants on the west coast. No effects to the species are anticipated by the Project. During surveys conducted to detect its presence it has been absent from the Project site and the areas to be impacted by the Project are not expected to include western lily habitat.

**Point Reyes Bird's Beak (Federal Species of Concern, State Endangered)**

The primary threat to Point Reyes bird's-beak is habitat loss due to development. The species is also threatened by off-road vehicle use, water pollution, and habitat alteration due to invasion by non-native dense-flowered cordgrass (*Spartina densiflora*), which has not been observed at the Project site. Suitable habitat for the Point Reyes bird's-beak will be impacted by fill required for the gas processing facility and South Dunes laydown area. Though individual Point Reyes bird's-beak has not been identified in the areas of impact by the Project, large communities of the species exist in neighboring areas.

### 3.4.4.2 Terrestrial Wildlife

No direct impacts to threatened or endangered terrestrial wildlife species are anticipated as a result of the construction of the Project.

**Bald Eagles (Federal Delisted, State Threatened)**

Potential effects to bald eagle populations will be minimal. Foraging habitat occurs in and along the bay, but no suitable nesting habitat exists in the area where construction will occur. The Bald and Golden Eagle Protection Act requires protection of this species from disturbance within 660 feet from nest sites. While no nests were observed at the Project site and the nearest reported nest site in the ORBIC database, active at least as recently as 2003, is on Mettman Ridge above Glasgow, roughly three miles from the Project site, a pre-construction survey will be conducted to ensure that there is no inadvertent disturbance to this species.

**California Brown Pelican**

In the past, brown pelicans have been impacted by human disturbances at nesting colonies and roosting habitats. Nesting and roosting habitats within the Coos Bay estuary have not been documented and the species is not believed to breed in or near the Project site. Potential effects to brown pelican populations by the Project are anticipated be minimal. Foraging habitat for this species exists in Coos Bay adjacent to Jordan Cove and the brown pelican has been observed in the Project area near the proposed slip location. Noise and human activities associated with construction and operation of the proposed Project are likely to be the only direct effect to brown pelicans to the extent that brown pelicans occur near one or more of the Project's action areas. However, the possibility of adverse effects to the species is expected to be minimal as they would avoid these areas and the Coos Bay estuary provides ample foraging for the species outside of the impact area.

Onshore fish cleaning stations at various locations throughout the bay, often associated with boat ramps, have been mentioned as possibly attracting brown pelicans to possibly feed on offal (Marshall et al. 2006). The closest designated fish cleaning station is located inland at the Empire boat ramp more than two miles to the southwest on the other side of the bay. The Project is not anticipated to have a measurable effect on the foraging route of pelicans related to the Project.

**Marbled Murrelet**

The effects of the Project to be considered for MAMUs include disturbance and habitat impacts. While the Project does not occur within ¼ mile of designated Critical Habitat, its proximity to the coast requires evaluation of the Project vicinity to determine if there is habitat (i.e., nesting platforms) that may be affected by noise disturbance and human activities. Human activities attract corvids (i.e., crows, ravens, jays, magpies, etc.) to the area, largely from food and garbage related to construction activities. This gives the corvids an opportunity to have predation to MAMUs if there is nesting habitat in the vicinity. The single largest cause of murrelet nest failure found in Nelson and Hamer (1995b) was predation in 56 percent of failed nests, due mostly to corvids.

In surveys conducted for the Project (LBJ 2006, SHN 2012) no potential MAMU habitat was detected within the Project vicinity. Potential adverse effects to marbled murrelet populations will be minimal since this species does not nest on the Project site. MAMUs could occur along the bay or fly over the Project site while in transit between nesting and feeding sites. Conservation measures proposed in Section 3.4.5 would ensure that the Project site will be kept clear of construction debris and food wastes that could attract predators. No impact to MAMUs is anticipated from the construction or operation of the Project.

**Northern Spotted Owl**

No potential effects to northern spotted owl populations will occur because this species is absent from coastal Coos County and therefore not expected to occur in or near the Project site.

**Short-tailed Albatross**

Short-tailed albatross may occur within the EEZ coastal zone used by LNG carrier traffic. The species have infrequently collided with airplanes in flight but collisions with ships are unknown and are expected to be unlikely. Although the annual ship traffic will increase due to the proposed Project, LNG carriers approaching the Port of Coos Bay would be traveling slowly and escorted by tugboats from 50 miles offshore to the Port. Short-tailed albatross are expected to avoid LNG marine traffic.

The effects of a cargo spill from an LNG carrier would be quite different from results of spills from crude or refined petroleum ships. Spills or releases of LNG at sea would not cause the water column to cool to the point of affecting the potential food species (squid, fish, eggs of flying fish, shrimp, and other crustaceans) in the water. Ignited LNG would affect species on the water surface but not species submerged in the water.

Based on the double-hulled construction of LNG carriers and the outstanding operating and safety record of LNG carriers, the probability of any incidents that could result in the loss of LNG cargo is extremely low. Any potential spills that could affect short-tailed albatrosses offshore would more likely be fuels or lubricants associated with the operation of the LNG carrier. These products are kept in relatively small quantities on ships and would not result in the types of effects associated with a spill from an oil tanker.

No mitigation, enhancement, or protection measures are proposed to specifically conserve short-tailed albatross.

**Streaked Horned Lark**

Industrial development has reduced habitat available to breeding and wintering larks. Construction and operation activities occurring on or near habitat used by streaked horned larks migrating through Coos Bay or wintering over could negatively affect foraging, causing the birds to flee or to spend more time alert and less time foraging.

Potential adverse effects to streaked horned lark populations are anticipated to be negligible. It has been determined that suitable habitat does not exist in or near the Project site due to the lack of proximity to open water at the few locations where sparsely vegetated lark habitat potentially exists. In addition, encroachment by European beachgrass and other noxious weed species increasingly makes potential habitat unlikely to be used by the larks, especially given the vast amounts of potential habitat on the North Spit and along that coast that remain relatively undisturbed by human influence. While an occasional individual may show up on a mudflat in the vicinity to forage, streaked horned larks are not expected in the Project site.

**Western Snowy Plover**

Stockpiling of material dredged from the slip area was proposed as part of the import terminal project. Due to the snowy plover population on the North Spit, there was a concern that a stockpile area could attract snowy plover individuals from this population. To address this concern, stockpiling is no longer part of the Project. Potential adverse effects to snowy plover populations will be minimal because there does not appear to be any nesting habitat within the Project site. While an occasional individual may show up on a mudflat, snowy plovers are not expected in the Project area.

Some concern exists that the construction of the Project might increase the local predator population, but it is not expected since snowy plover predators already occur on the site and the Project does not include the addition of any elements (with the exception of increased human activity) likely to attract them. Snowy plover predators identified along the Oregon coast include the American crow, common raven, red fox, raccoon, striped skunk, black rat, and feral cat. An increase in the numbers of these predators could be detrimental to the recovery of snowy plover populations.

Threats to western snowy plover habitat include introduction of European beachgrass that encroaches on the available nesting and foraging habitat; disturbance from humans, dogs, and off-highway-vehicles in important foraging and nesting areas; and predators such as the American crow and common raven (FWS 2005f). Increased nest predation of western snowy plovers by corvids within the Project area and in affected occupied stands is possible, particularly if corvids are attracted to construction sites by trash or discarded food. However, the distance to the closest documented nest negates this probability.

Increased predator density related to increased human presence and habitat removal was identified as a potential concern related to terminal construction. Jordan Cove has identified measures to minimize impacts. During construction and operation, the Project site would be kept clear of construction debris and food wastes that could attract predators such as birds (e.g., American crows) and mammals (e.g., rats, raccoons). Covered, animal-proof receptacles would be provided in eating and break areas, parking lots, and at appropriate locations around the construction site. During construction the site would be policed on a daily basis to remove any food or other debris left by construction workers. During operations the facility and grounds would be regularly inspected to assure that no garbage is allowed to accumulate. This should minimize predation on snowy plover eggs and chicks; however, corvids and other predators could still be attracted to the area due to the increased activity.

### 3.4.4.3 Fisheries and Marine Species

For the purposes of this report, fisheries and marine species include federally-listed fish, marine mammals and sea turtles that have the potential to be affected by construction and operation of the Project or by the marine traffic generated along the LNG export facility transit route.

Impacts on the aquatic environment by the Project which could in turn affect fish and marine species include turbidity, chemical contamination, loss of benthic and shoreline habitat, acoustic effects from pile driving, and stranding of sea life from ship wakes. In addition, effects on aquatic resources if an unignited LNG spill were to occur along the LNG carrier transit route or if the vapor from an LNG spill were to come in contact with an ignition source resulting in a fire are remote possibilities. Analysis of these effects, along with the beneficial effects from restoration of estuary functions, are discussed in Section 3.3.6 and are incorporated by reference for this section. Additional environmental consequences related to these potential effects on federally-listed species from construction and operation of the Project are discussed below.

**OC Coho Salmon**

Direct and indirect effects from Project actions would likely affect OC coho salmon due to turbidity, potential chemical contamination, and interim habitat loss. The proposal to complete in-water work between July 1 and August 31 results in fewer OC coho salmon exposed to the activities and serves to minimize, but not eliminate, exposure to direct adverse conditions. OC coho salmon will have minimal habitat loss, but that loss will result in adverse effects to the species due to permanent loss of forage at the slip site. Beneficial estuarine compensatory mitigation is proposed to compensate for the loss of forage and ecological functions by re-introducing intertidal habitat subject to tidal flushing; however, a delay of several years is expected before the area reaches full ecological potential.

Essential physical and biological features (PCEs) for estuaries include whether an area is free of obstruction with water quality, water quantity, and salinity conditions supporting juvenile and adult physiological transitions between freshwater and saltwater, natural cover, and forage. The action area for the proposed eelgrass mitigation site for the Project contains one or more PCEs within the acceptable range of values required to support the biological processes for which the species use the habitat. Coho salmon adults and smolts would migrate through this area and use the area to make the physiological transition between marine and freshwater environments. There would not be any loss of estuarine wetlands (i.e., diking and filling) for the proposed mitigation and the net result would be increased habitat value in the Coos Bay estuary. The site, located south of the airport's runway extension project, is considered to provide relatively low ecological function, which mitigation could improve.

Coho salmon outmigrating in Coos Bay are typically larger than sub-yearling juvenile Chinook salmon and are much less susceptible to stranding from potential ship wakes than the smaller Chinook salmon in Coos Bay. As noted for the model of the waves in Section 3.3.6, ship wakes would be generally small and similar to naturally occurring waves. Considering the conditions, including vessels entering and leaving at high slack tide, low vessel speed, and wave height within normal range, along with infrequent occurrence of susceptible fish, it appears unlikely that LNG carrier traffic would contribute to juvenile coho salmon stranding.

Some loss of juvenile salmon could occur from entrainment and impingement in the cooling water required for the LNG carriers while loading LNG at the berth. This potential would be the same as any deep draft vessel while loading or unloading cargo. However, few coho salmon would be as small as 60 mm since most would be outmigrating at age 1+ and would likely be greater than 120 mm. Many of the juvenile coho salmon would actively be able to avoid being entrained or impinged. Also, the location of the intakes on most LNG carriers would be near the inner portion of the slip away from the main channel. This may, depending on coho salmon distribution, reduce the overall chance of coho salmon being in the vicinity of the intakes.

NMFS (2008) in their assessment of effects of loss of juvenile coastal coho salmon from local airport expansion assumed 4 percent of Coos Bay coho salmon smolts survived to return as adults. Even so, due to the extremely small portion of total water intake relative to the volume of Coos bay, the relative portion of juvenile salmonids that would suffer direct mortality would be small, unless fish were highly concentrated at the point of intake. The population appears to have a 96 percent mortality rate before returning as adults. Even if a salmon individual was adversely affected, the mortability rate relative to the natural mortality rate of the overall population is not anticipated to be significant.

Depending on their reaction to localized changes in the light regime in the Project action area, coho salmon may have migration delays, be moved into less protected deepwater habitat, or they may become more susceptible to predation as light increases predators' ability to see fish.

Actual distribution of juvenile coho salmon within the Project action area is unknown. However, juvenile salmonid studies in the lower Columbia River observed that juvenile coho salmon were in greater abundance away from the shoreline areas, often in deep water during their outmigration (Johnsen and Sims 1973, Dawley et al. 1986, Ledgerwood et al. 1991). Carson et al. (2001) found that in the lower Columbia River less than 20 percent of all fish were found along the shore and were about evenly split between the channel and channel margins. Based on studies in the Columbia River, there is no reason to suggest that the water intake area on vessels moored at the LNG Terminal would have any higher abundance of juvenile salmonids than the rest of the bay area, and in fact it may be lower as the fish would have to enter the off-channel slip that is out of the main flow region. Coho salmon migrating to the ocean would likely be more closely associated with the main channels than the nearshore area and the inset slip, reducing their chance of encountering the intakes.

**Euchalon (Southern DPS)**

The potential for eulachon to be affected by the Project would occur during seasonal migrations by adults to inland rivers to spawn and the outmigration of larvae and juveniles after hatching. Eulachon do not feed in fresh water and their presence in Coos Bay would be limited. Given the deep and shallow water habitats available along the bay transit route, there is a low likelihood that there would be a significant impact on the spawning runs of eulachon in Coos Bay. Adults could avoid the LNG carriers in the channel by using the shallow areas of the channel that the LNG carriers will not be using. In addition, the effects of LNG carrier traffic on spawning runs is not one of the threats listed by NMFS for the eulachon.

Eulachon are not anticipated to be present in shoreline wave areas where they could potentially be stranded. From the analysis of potential fish strandings from ship wakes discussed in Section 3.3.6, Pearson et al. (2006) conducted an extensive stranding study in the Columbia River and sampled shoreline areas in all seasons. Even though eulachon were present in the river system, the study did not report the capture of any eulachon, indicating they may not be present in shoreline waves to be stranded. As with coho salmon, eulachon would likely utilize the intertidal and eelgrass mitigation sites (once developed) for the transition between marine and freshwater environments.

The likelihood of effects to larval and juvenile stages of eulachon as they outmigrate through the Coos Bay estuary is anticipated to be minimal. During this downstream dispersal period, if the larvae somehow ended up in the slip waters they could potentially be entrained in the LNG carriers during the intake of cooling water. However, as the larvae are carried by currents and tides, it would seem highly likely that they would be carried past the slip and would not be drawn into slip waters. Once the larvae have grown to juvenile size, they naturally disperse to the ocean as soon as they are able. Any juveniles occurring in the Project action area would be migratory in nature. The low number of all stages of eulachon that are likely to be in Coos Bay further reduces the potential for the species to be affected by the Project.

**Green Sturgeon**

Southern DPS green sturgeon occurring in the Project area are expected to reside primarily in the deeper waters of the bay, depending on the time of day, tidal cycle, and activity. Project-induced turbidity or chemical contamination is discountable due to green sturgeon spatial distribution. Indirect effects may occur from the construction fill of approximately 10.6 acres of shallow water habitat for prey species consisting of ghost shrimp and clams. However, in addition to the compensatory estuarine habitat mitigation that will be implemented for the Project, there is extensive shallow water habitat available for foraging throughout the bay. The construction fill will have no impact on population spatial structure or diversity of green sturgeon.

**Marine Mammals**

Potential effects to the Steller sea lions and whales that may be encountered along the LNG carrier transit route include environmental contaminants, impacts to foraging areas, debris, and vessel collisions. Direct effects could include injury and/or mortality due to ship strikes and potential adverse effects from a ship spill and/or release of LNG at sea. Spills and/or released LNG could indirectly affect whales by impacting forage species.

Potential adverse effects to Steller sea lion populations will be minimal because sea lions do not normally occur as far into Coos Bay as the Project site. Sea lions tend to stay closer to the harbor entrance and are known to frequent the Charleston boat harbor and also to haul out on the northeast spit of clam island (created by dredge spoils). While an occasional individual might enter Coos Bay, there are no suitable haul-out sites within the Project site and the species is not expected to occur there.

Of the federally-listed whales, gray whales and killer whales are the only species that have been known to occasionally enter Coos Bay beyond the Project site, although this is an infrequent occurrence. Potential adverse effects to these populations in Coos Bay is anticipated to be minimal.

Eight species of federally listed whales have been identified that could potentially occur off the coast of Oregon. These species tend to feed during the summer in the northern latitudes and migrate to the tropical southern latitudes in the winter for breeding. However, whales could be encountered off the coast of Oregon throughout the year. The Project area applicable to whales is the EEZ, extending 200 nautical miles offshore from the Coos Bay Head. Within the EEZ area, effects to whales would be associated with LNG carriers inbound and outbound from the LNG Terminal. All of these whale species are federally protected under the Marine Mammal Protection Act (MMPA).

The Project may affect whales because they may occur within the EEZ analysis area during operation of the Project. The proposed action would increase shipping traffic (LNG carriers, tugs and barge units) within the EEZ analysis area. However, the Project is not likely to adversely affect whales because:

- Existing information indicates ship strikes to whales within the EEZ analysis area are infrequent.
- The increase in annual ship traffic due to the proposed action is expected to cause an immeasurable increase in ship strikes to whales over known frequencies of incidents.
- JCEP would provide a ship strike avoidance measures package to shippers calling on the LNG Terminal. The package will consist of multiple measures to avoid striking marine mammals.

- LNG carriers approaching and departing from the Port of Coos Bay would be traveling slowly and escorted by tractor tugs.
- Spills or releases of LNG at sea would not cause the water column to cool to the point of affecting the mammals in the water. Ignited LNG would affect species on the water surface but not mammals submerged in the water.

Conservation measures include the development of a plan to minimize potential ship strikes to cetaceans, and possibly other listed (Steller sea lion, sea turtles) and non-listed marine species by LNG carriers. LNG carriers would transit to and from the slip at slow speeds (between 4 to 6 knots once inside the Coos Bay navigation channel) and would result in minimal wakes, such that marine mammals would not be affected by the wakes of passing LNG carriers.

There is an ongoing threat of ship strikes to whales; however, from available accounts (Laist et al. 2001; Jensen and Silber 2003) ship-whale collisions occur fairly infrequently. Ship strikes of blue whales averaged 0.6 deaths or injury per year (1 death or injury per 1.67 year) in Pacific waters between 2002 and 2006 (Carreta et al. 2008). During six years, from 2002 to 2007, one blue whale was struck and killed by a ship off the coast of Oregon (Barre 2008). That computes to 0.17 blue whale death per year due to ship strikes in Oregon and Washington coastal waters. The likelihood of a ship-whale collision varies by species of whale. Researchers have found that fin and humpback whales are struck by ships relatively often (Laist et al. 2007), while killer whales have only rarely been documented as being injured or killed by a collision (Jensen and Silber 2003; NMFS 2008). However, it is assumed that many ship strikes with whales are unknown and unreported.

The incremental LNG carrier traffic of 90 ships per year plus the three attending tugs over the current annual Port traffic of approximately 50 ships will, logically, result in a higher probability of potential incidents of ships hitting species in the water. However, most mobile species will be able to avoid interaction with moving objects in the waterway.

If an unignited LNG spill were to occur along the LNG carrier transit route in the areas where the endangered or threatened species are located (Figures 3.5-2 and 3.5-3), the LNG will float on the water until it vaporizes and will not have an adverse effect on the species, unless they come in direct contact with the LNG. Some cooling of the upper water layers closest to the LNG spill would be expected, but would not likely cause the overall water column to cool to the point of affecting the species in the water, given the ambient water temperatures in the transit route. If the vapor from an LNG spill were to come in contact with an ignition source the resulting fire would burn back to the spill source and would affect species on the water or in the area that come in direct contact with the fire. Species in the water would not be affected as the fire would be above the water in the area of the spill where the vaporized LNG is flammable. In either case of lower or higher water temperatures based on the spill scenario, mobile species will move out of the area until the water temperatures return to normal.

**Sea Turtles**

Potential effects to sea turtles that may be encountered along the LNG carrier transit route include environmental contaminants, impacts to foraging areas, debris, and vessel collisions. Direct effects of the Project include injury and/or mortality due to ship strikes and potential adverse effects from a ship spill and/or release of LNG at sea, as discussed for marine mammals. Spills and/or released LNG could indirectly affect sea turtles by impacting forage species.

Increased LNG carrier traffic may increase potential vessel strikes to sea turtles within the EEZ analysis area. They can be injured or killed when struck by a vessel, especially by an engaged propeller. Based on their warm water requirements, sea turtles are likely to only be occasional visitors to waters as far north as Oregon. Given the low population and occurrence of sea turtles in Oregon coastal waters, the increase of LNG carrier transits through the EEZ analysis area is not expected to result in measurable additional ship strike-related mortality or injury to sea turtles. LNG carriers approaching or departing from the Port of Coos Bay would be traveling slowly and escorted by tractor tugs within 50 nautical miles offshore of the LNG Terminal. The possibility of ship strikes by LNG carriers paralleling the California coast may be higher because reports of strandings in California are more frequent. LNG carriers are expected to transit at least 50 miles off the coast and so would be expected to avoid nearshore feeding areas.

Spills or releases of LNG at sea would not cause the water column to cool to the point of affecting sea turtles in the water. Ignited LNG would affect species on the water but not sea turtles submerged in the water.

### 3.4.5 Mitigation, Enhancement, and Protection Measures

General mitigation, enhancement, and protection measures to reduce potential adverse effects to botanical and wildlife resources are included in Section 3.1.7 and 3.2.7, respectively. General measures to address potential adverse effects to fish and marine species from the construction of the slip and access channel for the LNG Terminal, land disturbing activities from the construction of the Project, dredging for the slip and access channel, maintenance dredging for the facility and LNG carrier route, ballast water discharge, the intake of cooling water for carriers while at the LNG berth are discussed in Section 3.3.7. These measures are incorporated by reference in this section. Additional conservation measures specific to individually listed species are discussed below.

A BA for all federal species that have the potential to be affected by the Project is required, as previously discussed, to comply with Section 7 of the ESA. JCEP will not begin construction and/or use of any of the proposed facilities, including related ancillary areas for staging, storage, temporary work areas, and new or to-be-improved access roads, until 1) the BiOp has been issued for federally-listed species; 2) associated state and federal authorizations and permits are in place; and 3) JCEP has received written notification from the FERC that construction and/or implementation of conservation measures may begin.

#### 3.4.5.1 Botanical Resources

**Western Lily**

Although the western lily has not been observed in the surveys conducted to date, to ensure that this species will not be affected by the Project, pre-construction surveys will be conducted. If surveys find an occurrence, the results would be reported immediately to the USFWS and ODA to initiate coordination and consultation to ensure potential effects to the western lily are mitigated with appropriate conservation measures, as required by Section 7 of the ESA.

**State-Listed Species**

To ensure that state-listed species will not be affected by the Project, pre-construction surveys of the affected areas of the Project site will be conducted for Point Reyes bird's-beak, pink sand verbena, silvery phacelia, and Wolf's evening primrose. Although the surveys are not required by any state or federal regulations, voluntary actions will help prevent further declines of species populations and avoid the potential need for future listing.

If a survey finds an occurrence of any state threatened or endangered species, the results will be reported and additional coordination and consultation will be initiated with the ODA and other appropriate resource agencies. This may include following existing relocation and monitoring guidance. The Point Reyes bird's beak, in particular, is a hemi-parasite that attaches to a host plant and any relocation efforts will propose removing the area around existing plants.

#### 3.4.5.2 Wildlife

**Birds**

Bald Eagle

Pre-construction surveys of the Project site for the bald eagles will be conducted by a qualified biologist. Surveys will include a search for active nests in appropriate habitat in areas in and adjacent to the Project that may provide nesting habitat. If a bald eagle nest is located less than 660 feet (line-of-site) from the planned Project construction activities, the planned Project construction activities will be adjusted accordingly or resumed as planned until one of the following has occurred:

1. The nesting season is over and the individuals have either successfully raised young and they have fledged and left the nest site;
2. Nest abandonment has been determined by the appropriate state or federal regulatory agency, and authorization for work has been given within the nesting season; or
3. Project activities are relocated more than 660 feet (line-of-sight) from the active nest.

Streaked Horned Lark

Bird surveys conducted to date did not identify the presence of the streaked horned lark within the Project vicinity. No mitigation measures are anticipated.

Western Snowy Plover

JCEP reviewed a list of conservation measures provided by the USFWS, BLM, and ODFW through the JCEP Interagency Task Force Working Group for the LNG import facility previously proposed. JCEP agreed to provide funding as enumerated below. The funding would be provided to the entity as defined by the agencies and it would be the responsibility of the particular entity to administer the funding. It should be noted that these measures were developed partially in response to the concern that a previous Port stockpile site proposed would provide potential habitat. The Port stockpile site is no longer part of the Project. JCEP is willing to provide the funding on the condition that no additional requirements would be placed on the Project relative to the snowy plover issue (other than those discussed in this section). JCEP is also requesting that the funding of these conservation measures be used in part to contribute to other habitat mitigation requirements imposed by the ODFW.

Funding by JCEP at present includes:

- Year 1 (when construction begins) JCEP would provide $60,000 for fencing, signage, application of shell hash, tree removal, and one year of maintenance.

- Years 2 and 3 JCEP would provide $30,000 each year for annual maintenance, a beachgrass elimination grant, and shell hash.
- Years 4 to 2018 JCEP would provide $10,000 for annual maintenance.

In addition to these conservation measures, JCEP has agreed to mitigate Project impacts to western snowy plovers through implementation of BMPs, along with education and outreach programs. Increased predator density related to increased human presence and habitat removal was identified as potential concerns related to Project construction. JCEP will address these concerns through the following BMPs discussed below.

Eliminating human sources of food in proximity to breeding locations (e.g., parking areas) adjacent to coastal breeding areas such as uncovered garbage and littered food scraps may indirectly help reduce predator numbers or help prevent their numbers from increasing. During construction and operation, the Project site will be kept clear of construction debris and food wastes that could attract predators. Covered, animal proof receptacles will be provided in eating and break areas, parking lots, and at appropriate locations around the construction site. During construction the site would be policed on a daily basis to remove any food or other debris left by construction workers. During operations the Project site would be regularly inspected to assure that no garbage is allowed to accumulate.

Structures associated with the Project will be monitored to discourage use by avian predator species. Frequent inspections would ensure that nests are not being constructed and all nests found would be removed immediately, in coordination and consultation with the USFWS. It is anticipated that there would be sufficient inspections and other activities mandated by safety and security requirements to keep the structures nest free. However, in the unlikely event that a nest becomes established and it is not discovered until young birds are present, the disposition of the nest would be handled in accordance with the provisions of the MBTA.

The placement of dredged material on land will be regularly policed to ensure that no denning is occurring in the hillocks. This should not be as significant a concern, as proposed placement areas will be part of the construction activities and the continuous activities will discourage use by individual birds. If necessary, nylon mesh or other exclusion fencing would be installed around the perimeter of the placement areas to prevent the establishment of coyote or skunk dens until the slopes are stabilized or constructed upon.

Surveys previously conducted indicate that 76 percent of beach visitors were unaware of restrictions associated with snowy plovers. This indicates that increased education could have a significant impact on public awareness of issues surrounding snowy plovers. Furthermore, the USFS at the Oregon Dunes National Recreation Area and BLM staff have reported that the majority of contacted individuals are more willing to comply with beach use restrictions after better understanding the reasons for them.

The JCEP would train all construction and operations staff on the need for snowy plover conservation, current snowy plover regulations and recreational use restrictions, and the importance of conservation measures, including: litter control, avoidance of nesting and foraging areas, keeping pets on a leash, and remaining on established roads and trails. The training program would be developed based on guidance provided in Appendix K of the 2007 Plover Recovery Plan, or would be contracted for through State/local agencies or organizations who may have pre-existing plover education and outreach programs experience. Prior to implementation, the training program would be submitted for comment to members of the Western Snowy Plover Working Team.

Environmental training would also be provided to operational personnel to ensure that all personnel are aware of and comply with the management tools in place to affect the recovery and maintenance of the snowy plover population on the North Spit. Printed educational materials would be posted at the Project site for the life of the Project. Materials would also be distributed to existing North Spit employers for their use in training their personnel. The types of educational materials may vary, but could include posters, table tents, maps, brochures, or factsheets. Numerous sources for existing educational materials are provided in Appendix K of the Plover Recovery Plan.

Intensive biological monitoring of snowy plover on the North Spit is presently being conducted by ORBIC and the population is one of the most closely monitored snowy plover populations on the West Coast. JCEP will fund one additional entry level Wildlife Services position dedicated to snowy plover predator monitoring and control during the 42-month construction period. This staff member would be employed by Oregon Wildlife Services, which is administered by the U.S. Department of Agriculture and Animal and Plant Health Inspection Services. The specific duties of this additional staff member would be determined by Wildlife Services based on North Spit management needs, but would concentrate on predator management. This additional position would allow Wildlife Services to better evaluate predator densities and more quickly and effectively respond in the unlikely event that predator pressure on the North Spit increases during Project construction.

In the event that a clearly demonstrable and sustained decrease in snowy plover productivity is detected by the ongoing ORBIC monitoring, JCEP would coordinate with the USFWS, ORBIC, Wildlife Services, BLM, OPRD, ODFW, and other interested parties to identify adaptive management strategies, as appropriate, to help reverse any such trend.

#### 3.4.5.3 Fisheries (included Marine Species)

Conservation measures developed for the Project within the Project action area to conserve other fish and marine species in Section 3.3.7 would also benefit coho salmon, eulachon, and green sturgeon if they are present during the construction and operation of the Project. Additional species-specific mitigation, enhancement, and protection measures are discussed below.

**Whales**

Routine activities of the LNG Terminal after construction include primarily traffic of LNG carriers and associated maritime activities. Listed marine species may be affected by the associated increase in ship traffic and could be harmed or killed from chance collisions with vessels, from eating floating plastic debris from slip site related activities, or through exposure to hydrocarbons from accidental oil spills. LNG carriers will transit to and from the slip at slow speeds that will result in minimal wakes, such that marine mammals will not be affected by the wakes of passing LNG carriers. JCEP will provide the LNG fleet servicing the LNG Terminal with measures proposed by NMFS for avoidance of marine mammals and sea turtles to further reduce the likelihood of adverse effects on these species. Mitigation, protection, and enhancement measures to address all of these potential effects are described in further detail below.

JCEP would request all LNG carriers calling on the LNG Terminal to reduce speeds to 10 knots or less within 30 nautical miles of the entrance to Coos Bay during the whale migratory period. During the 96-hour pre-notification process to be followed by all LNG carriers calling on the LNG Terminal, JCEP would check with the NMFS for information on the migratory patterns of whales within the route of the LNG carrier and would inform the ship's master of the patterns reported by NMFS. JCEP would request that all LNG carrier operators consult current whale sighting information prior to calling on the LNG Terminal and be aware of the reported locations of whales and plan their operations accordingly. LNG carriers would be requested to reduce their speed to 10 knots or less when mother and calf pairs, groups, or large assemblages are observed near an underway LNG carrier. LNG carriers would be requested to route around and maintain a 100-yard distance from the whales observed and to avoid crossing in front of the whales and maintain a parallel route, if possible.

JCEP would provide a ship strike avoidance measures package to shippers calling on the LNG LNG Terminal. This package would include the measures proposed by NMFS for avoidance of marine mammals to further reduce the likelihood of adverse effects on these species. Some of the suggested measures include the following:

- Provide training to LNG carrier crews, including the use of a reference guide such as the *Marine Mammals of the Pacific Northwest, including Oregon, Washington, British Columbia and South Alaska* by Pieter Folkens. This is a pamphlet that would be provided to LNG carriers calling on the LNG Terminal and would be included as part of the terminal use agreement to the shippers.
- Provide a copy of the NMFS CD-rom-based training program entitled *A Prudent Mariner's Guide to Right Whale Protection* as part of a ship strike avoidance measures package to all LNG carriers calling on the LNG Terminal. While this CD-rom-based training program is specific to right whales, NMFS has stated that the guidance and avoidance measures are also applicable to fin, humpback, and sperm whales.
- Require LNG carrier crews to maintain a watch for marine mammals and slow the ship to 10 knots or less to avoid striking protected species.
- When whales are sighted maintain a distance of 90 meters (or 100 yards) or greater from the whale.
- Attempt to maintain a parallel course to the animal and avoid excessive speed or abrupt changes in direction until the animal has left the area.
- Reduce ship speed to ten knots or less when pods or large assemblages of cetaceans are observed near an underway ship.
- When whales are sighted in a ship's path or in proximity to a moving ship, reduce speed to 10 knots or less or shift the engine to neutral until whales are clear of the area or path of the ship. LNG carrier masters would be requested to provide reports of sightings of marine mammal while in the EEZ action area and to provide the report upon docking at the LNG Terminal. This reporting request would be included in the Ship Strike Avoidance Measures Package provided to each LNG carrier calling on the LNG Terminal and compliance with the measures and the reporting would be included in all terminal service agreements with shippers.

LNG carrier crews would be asked to report sightings of any injured or dead protected species immediately, regardless of whether the injury or death is caused by the ship. If the injury or death is caused by collision with the ship, appropriate regulatory agencies (FERC or NMFS) would be notified within 24 hours of the incident. Information to be provided would include the date and location (latitude/longitude) of the strike, the ship name, the species, or a description of the animal, if possible.

JCEP has been working with the Coast Guard and ODE in the development of an LNG Management Plan. The LNG Management Plan is the primary process used in reducing risk through proper mitigation measures. The interagency group has been given a step by step process in how risk is mitigated in both safety and security issues.

As part of the LNG Management Plan, JCEP is proposing that LNG carriers would not be allowed to move past the 50-mile voluntary traffic lanes offshore unless it is acceptable for them to continue into the LNG Terminal. In addition, JCEP is also proposing that LNG carriers would not be allowed to anchor offshore the Oregon coast. The New Carrissa incident occurred when a ship inappropriately anchored in heavy seas just off the coast. LNG carriers would only be allowed to enter closer than 50 miles when all conditions are suitable to enter the Port.

Further, JCEP has committed to providing tractor tugs to escort each LNG carrier into the port and to the berth. This type of tug has not been previously available in the Port. These tugs have the capability to fully maneuver the LNG carriers even without ship power.

**Sea Turtles**

Measures to reduce ship speeds once inside the Coos Bay navigation channel to between 4 to 6 knots and within the EEZ when pods or large assemblages of whales and possibly Steller sea lions are observed near an underway ship would provide some protection to green turtles. However, it is highly unlikely that sea turtles would be seen from a LNG carrier. Nevertheless, the same Ship-Strike Reduction Plan, including marine mammal avoidance guidelines, and LNG Management Plan to minimize risk of spills and releases at sea that were described for whales apply to sea turtles.

# Status review update of Southern Resident killer whales

Michael J. Ford

Conservation Biology Division
Northwest Fisheries Science Center
National Marine Fisheries Service

July 31, 2013

*We are much more interested in conserving actual morphological, ecological and genetic diversity than in structuring conservation around a nebulous taxonomic level about which, in the past, there has been so much disagreement – Mallet 1995*

## Acknowledgements

Phil Morin, Barb Taylor, Robin Waples, Marilyn Dalhleim, Lynne Barre, Candice Emmons Robyn Angliss and Brad Hanson provided valuable comments on an earlier draft of this report. Kristy Long provided the summary of public comments.

## Introduction

On August 2, 2012, the National Marine Fisheries Service received a petition submitted by the Pacific Legal Foundation on behalf of the Center for Environmental Science Accuracy and Reliability, Empresas DelBosque, and Coburn Ranch to delist the endangered Southern Resident killer whale (SRKW) distinct population segment (DPS) under the Endangered Species Act (ESA). On November 28, 2012, NMFS published a 90-day finding (77 FR 70773) that the petition presented substantial scientific information indicating that the petitioned action may be warranted and that NMFS would initiate a status review. The petition focused specifically on issues of taxonomy and whether the SRKW constituted a DPS, and NMFS therefore determined that the status review would also focus on these issues rather than on the extinction risk status of the SRKW more broadly.

On March 21, 2013, after a public comment period on the 90-day finding, the NMFS Northwest Region requested that the Northwest Fisheries Science Center conduct a scientific review and evaluation of the petition, the key scientific papers cited in the petition, the biological information received from the public, and any other best available relevant information. Specifically, the Northwest Region requested the Center to consider if there is new best available information that would lead to different conclusions from those of the 2004 BRT (Krahn *et al.* 2004) regarding the existence of a North Pacific resident killer whale taxon (species or subspecies) or the discreteness or significance of the SRKW with reference to this taxon. This report is intended to address the Northwest Region's request.

## Summary of taxonomic issues addressed by the 2004 BRT

In evaluating the status of the southern resident killer whales (SRKW), the previous NMFS biological review teams (BRTs) had to explicitly address the issue of the uncertain taxonomy of the killer whale. These issues are discussed extensively in the BRT reports (Krahn *et al.* 2004; Krahn *et al.* 2002) and in the report of the NMFS Workshop on Cetacean Taxonomy (Reeves *et al.* 2004). Briefly, at the time of the first SRKW status review (Krahn *et al.* 2002), the most recently published taxonomy of killer whales placed them in a single polytypic species, *Orcinus orca*, as described by Linnaeus in 1758 (Heyning *et al.* 1988; Rice 1998). However, the 2002 BRT report stated that killer whale taxonomy was uncertain and that several authors had recently proposed new *Orcinus* species on the basis of morphological variation and potential reproductive isolation among ecologically distinct populations of killer whales in Antarctica (Berzin *et al.* 1983; Mikhalev *et al.* 1981) and the North Pacific (Baird 2000). Even general reviews of *O. orca* taxonomy, while ultimately concluding that *O. orca* should probably be considered a single species, also emphasized the uncertain taxonomy. For example, Heyning and Dahlheim (1988, p.

5, emphasis added) noted that "The genus *Orcinus currently* is considered monotypic by most authorities with geographic variation noted in size and color pattern, but *a worldwide systematic review is needed*" and "Until more substantial data are presented, a *conservative* view of recognizing only one highly variable species *probably* is warranted."

Faced with this taxonomic uncertainty, the 2002 BRT evaluated a wide variety of potential taxonomic scenarios and considered the DPS status of SRKW within hypothesized taxa (see Table 8 in Krahn *et al.* 2002). Ultimately, the BRT remained uncertain about both the global taxonomy of killer whales and whether or not the SRKW met the criteria to be considered a DPS, and faced with this uncertainty NMFS concluded that listing the SRKW under the ESA was not warranted. The agency noted the taxonomic uncertainty described by the BRT, and as a result indicated it would reassess its decision after a reconsideration of killer whale taxonomy (NMFS 2002).

Subsequent to the 2002 "not warranted" finding, in 2004 NMFS initiated another status review in response to a finding by a U.S. District Court that in using a possibly outdated taxonomy, NMFS failed to make use of the best data available. In addition to initiating a new status review, NMFS also held a cetacean taxonomy workshop that, in part, reviewed and summarized information relating to the uncertainties surrounding killer whale taxonomy (Reeves *et al.* 2004). Based on the findings of the workshop and new genetic data analyzed after the 2002 status review, the 2004 BRT concluded that the North Pacific resident killer whales satisfied Reeve's *et al.* (2004) criteria for being a subspecies (Krahn *et al.* 2004, p. 41). Specifically, the BRT cited studies noting differences between the resident and transient ecotypes in external morphology, reproductive isolation in sympatry, foraging behavior and diet; acoustic dialects and vocal behavior, and mtDNA and nuclear genetic characteristics (see Krahn *et al.* 2002; 2004). The 2004 BRT further concluded that the SRKW population met the USFWS & NMFS (1996) criteria for being a DPS of the North Pacific resident subspecies, citing differences between the SRKW and other resident populations in ecological setting, range, genetic variation, and behavioral and cultural traits (Krahn *et al.* 2004). The BRT emphasized, however, that there was some scientific uncertainty related to both the taxonomic and DPS conclusions.

## Summary of the substantive points made in the petition

After a brief summary of killer whale natural history, the petition notes that there are varying scientific opinions regarding the definition of species, and that the definitions of sub-species and other intraspecific terms such as Distinct Population Segments (DPS) are subject to even greater uncertainty and scientific debate. The petition notes that splitting taxa ever more finely does not necessarily result in conservation benefits and may result in a false perception of risk.

The petition then briefly summarizes the current *Orcinus* taxonomy, followed by a more extensive summary of the Workshop on Cetacean Taxonomy convened by

NMFS in 2004 (Reeves *et al.* 2004). After summarizing some of the conclusions in the workshop report, the petition concludes that the workshop participants were unable to identify additional species within the currently recognized species *O. orca*. The petition further indicates that in the petitioners' opinion NMFS contradicted the workshop's recommendations when it concluded that the North Pacific fish-eating ('resident') killer whales are a subspecies of *O. orca*, and that the southern resident population is a DPS of this subspecies.

The petition follows with considerable discussion questioning whether the ESA allows for identification of DPS within subspecies, a legal question beyond the scope of this biological review.

Finally, the petition reviews some published studies related to the question of whether the North Pacific resident killer whales meet the criteria for subspecies designation, focusing on the lack of a Latin trinomial name for the proposed subspecies, and the genetic, morphological or ecological evidence as it relates to the question of subspecies status. The review focuses considerable attention (nearly six pages) on a recent genetic study by Pilot *et al.* (2010), arguing that the study provides clear evidence that the putative North Pacific resident killer whale subspecies is not genetically isolated from other killer whale populations. The petition concludes by reviewing some of the morphological, behavioral, and ecological differences among the North Pacific killer whale ecotypes, arguing that these are likely to be largely learned behaviors and therefore not important to consider when identifying subspecies or conservation units. See the Appendix for a detailed review of the biological arguments made in the petition.

## Summary of public comments

The public comment period on the 90-day finding closed on January 28, 2013. The Northwest Region received over 2,750 comments. Despite the request for specific scientific and commercial information, the vast majority of commenters simply noted their opposition to the petition to delist SRKWs, while a handful of comments supported the petition. The Northwest Region did, however, receive several substantive comments regarding both the biological and legal aspects of the DPS determination as raised in the petition. The substantive points raised in the comments are briefly summarized in Table 1.

**Table 1 -- Summary of Substantive Public Comments Received on Pacific Legal Foundation (PLF) 2012 Petition to Delist Southern Resident Killer Whale (SRKW) Distinct Population Segment (DPS).**

| Organization/ Commenter | Summary of comments |
|---|---|
| Marine Mammal Commission (MMC) | • Disagrees that the petition may be warranted; recommends reversing 90-day finding and devoting resources to higher priorities<br>• Listing SRKW as a DPS of a subspecies is appropriate, using 2nd prong of Chevron analysis (*Chevron USA v. Natural Resources Defense Council*) as applied to the definition of a DPS<br>• Recommends that consistent with NMFS precedent and applicable case law, NMFS interpret ESA definition of "species" to include DPSs of both species and subspecies<br>• Research has identified multiple, geographically distinct populations of killer whales that have unique behavioral and ecological traits<br>• MMC believes PLF's arguments related to Pilot *et al.* 2010 are incorrect and inconsistent; references several new papers on genetics and speciation<br>• Pilot *et al.* 2010 findings are not sufficient to refute treatment of North Pacific residents as a putative subspecies or the designation of SRKWs as a DPS<br>• Pilot *et al.* 2010 does not provide conclusive evidence of recent mating between SRKWs and other resident populations or between resident killer whales and any other regional ecotype; used unusually liberal criteria to assign parentage based on genetic data<br>• Parsons *et al.* in review found that "estimates of genetic distance between two predominant North Pacific ecotypes [resident and transient] indicate negligible levels of gene flow." |
| Humane Society of the United States | • Opposes further consideration of the petition as it does not present substantial scientific information that the listing is no longer warranted; population is appropriately listed as endangered<br>• Disagrees with the petitioners that SRKWs are an unlistable entity under the ESA<br>• Basing conclusion that the population is not a subspecies on limited male-mediated gene flow between populations from Pilot *et al.* 2010 ignores more recent work by Ford *et al.* 2011 that detected no gene flow among populations |
| Center for Biological Diversity | • Petition fails to present substantial information that SRKWs are not a DPS; does not comport with ESA's plain language, ignores NMFS policy, and disregards scientific record that indicates significant speciation of the global taxon<br>• ESA allows NMFS to designate a DPS of a subspecies; if ESA were ambiguous, NMFS' DPS policy allows designation of a subspecies and deserves deference; case law cited by petitioners does not support their claim<br>• Data and information support speciation for North Pacific and SRKW populations such as genetic data; morphological data, including body size; behavioral variation including vocalization, food preference, and social organization |
| Animal Legal Defense Fund (ALDF) | • Opposes delisting petition on legal as well as scientific bases<br>• Petition mischaracterizes Pilot *et al.* 2010 and Morin *et al.* 2010 and took conclusions out of context<br>• Petitioners legal argument is inconsistent with case law and statutory interpretation |

| | |
|---|---|
| | • ALDF counters the three primary assumptions in the petition – (1) ESA does not require formal taxonomic recognition, (2) Pilot *et al.* 2010 does not contradict a subspecies designation, (3) Morin *et al.* 2010 unequivocally urges a subspecies designation<br>• ALDF also organized a comment campaign, we received hundreds of individual comments opposing the delisting |
| Rus Hoelzel | • Clarifies Pilot *et al.* 2010 conclusions<br>• Does not believe a subspecies must be defined before designating a DPS; see examples in Fallon *et al.* 2007 using genetic markers to designate DPSs where a subspecies has not been designated<br>• Notes that gene flow is allowed when determining discreteness<br>• Notes the petition does not address significance<br>• Supports current DPS listing |
| The Whale Museum | • Opposes delisting petition; supports 2004 status review and listing<br>• Pilot *et al.* 2010 do not reference cross ecotype mating involving SRKWs; Barrett-Lennard *et al.* 2000 supports reproductive isolation too<br>• SRKW DPS is both discrete and significant |
| Orca Conservancy | • Opposes delisting petition<br>• MMPA does not provide adequate protection for SRKWs; ESA allows protection from indirect threats, requires section 7 consultations and permits, allows more citizen oversight and recourse<br>• Morin *et al.* 2010 is more reliable than Pilot *et al.* 2010 because it relies on more base pairs and more microsatellites, which contradict conclusion of interbreeding in modern times |
| Northwest Environmental Defense Center | • Petition is inconsistent with science, court decisions on the prior listing, and the ESA.<br>• Economic concerns listed in the petition cannot be considered and would not be resolved even with delisting<br>• NMFS is within its statutory authority to list SRKW DPS<br>• Current science supports and requires the continued protection of SRKW DPS – pinnipeds can tell residents apart from transients based on acoustics; SRKWs are a demographically closed population; best available science has not changed much since 2005<br>• MMPA protections alone are insufficient to protect and recover – procedural issues (jeopardy and adverse mod), takings, and legal tools in ESA |
| Miami Seaquarium | • Agrees with petitioner that SRKW DPS is not a listable entity; ESA does not authorize listing a DPS of a subspecies; North Pacific subspecies itself is a "nonexistent and scientifically unjustifiable" listing unit<br>• "Taxonomic inflation" is occurring – unjustified elevation of subspecies to species and populations to subspecies or DPSs<br>• 2005 listing of SRKW DPS as endangered resulted in collateral issues including impacts on CA farmers and whether to include Lolita in the listing. Notes that PLF filed its petition to delist SRKW DPS "long before" PETA/ALDF filed their petition to add Lolita to the SRKW DPS. NMFS should carefully and promptly consider the PLF petition, which if granted would negate the need to consider these collateral issues. |
| Animal Welfare Institute, CBD, Center for Whale Research, EarthJustice, | • Petition is based on a narrow and incorrect construction of ESA and the best scientific and commercial data available; incorrect legal arguments and one-sided interpretation of science; do not, and cannot, address or demonstrate that status has improved or threats have been reduced<br>• ESA defines "species" broadly; authorizes listing a DPS of a subspecies - |

| | |
|---|---|
| Friends of the Earth, Friends of the San Juans, International Marine Mammal Project of Earth Island Institute, Marine Mammal Connection Society, NRDC, Oceana, Orca Network, Dr. David Bain, Will Anderson, Dr. Samuel Wasser | Congress did not intend DPSs to be constrained by taxonomy; designating DPSs of subspecies is consistent with longstanding agency interpretations<br>• PLF arguments lack merit; the justification included does not support those arguments<br>• Focus on genetics and interbreeding is misplaced as genetic data is not the sole evidence for determining "markedly separate" populations<br>• Significant scientific evidence supports designation of SRKW population as a DPS – physical separation from other KW populations; morphological data, including body size, supports speciation of NP and SRKW populations; and behavioral variation, including vocalization, food preference, and social organization meet DPS criteria<br>• SRKWs meet the ESA listing criteria – EarthJustice provides a five factor analysis |
| Whale and Dolphin Conservation | • Opposes petition; threats continue and delisting is not appropriate<br>• Notes the ESA definition of "species" and NMFS' interpretation unambiguously refute PLF's legal argument as has been the case with their recent attempts to challenge other ESA listings<br>• Notes that the DPS policy does not prohibit listing if occasional gene flow occurs beyond the listed population; Pilot *et al.*'s main conclusion from their data emphasized social cohesion of killer whales to produce genetic differences between populations despite capacity for dispersal outside their groups. |
| Change.org – Bruce Gorcyzcki | • J, K, and L pods don't associate or interbreed with other ecotypes in the North Pacific<br>• SRKWs have been determined as a discrete population with their own social groupings, dialect and behaviors<br>• SRKWs' absence from the ecosystem would upset the balance |
| Individual – Ruth Muzzin | • Petition should be denied as it does not present new information, such as population numbers, and does not demonstrate that the DPS has recovered or become extinct; none of the delisting criteria are met<br>• NMFS has listed a DPS of a subspecies previously – e.g., ringed seals, bearded seals, and Atlantic sturgeon |
| Individual – David Bain | • Describes characteristics of "newer" and "older" species in an evolutionary sense with respect to reproductive isolation, morphology (dorsal fin and jaw sizes), and geographic isolation<br>• Transients are older species and distinct in all ways species are expected to differ<br>• Residents and offshore have reached a plateau, but additional differentiation would be expected over evolutionary time, though reproductive isolation is occurring; overlap in color patters and range; SRKWs appear the only group of residents to use the CA current system thereby giving them a slightly different ecological niche.<br>• Morin *et al.* 2010 found the evidence of interbreeding in Pilot *et al.* 2010 was an artifact attributable to incomplete DNA sequencing<br>• SRKWs should be considered a subspecies and are eligible for ESA listing regardless of whether a DPS of a subspecies is eligible. Endangered status should be retained. |
| Individual – Sharon Grace | • Petition is without merit<br>• Commenter references many threats and effects on population abundance and social structure<br>• Notes Pilot *et al.* 2010 examples are not SRKWs; some inbreeding is okay for DPS designation |

| | |
|---|---|
| Individual – Jodi Smith | • Morin *et al.* 2010 confirms that genes are slow to change over time, making differentiation difficult even though it happens<br>• In addition to genetic isolation, SRKWs are distinct based on social organization, dietary preference, and behavior. Recent evidence from a review of Southern Hemisphere killer whale populations is likely to conclude distinction as well (de Bruyn *et al.* 2013)<br>• Delisting SRKWs will not alleviate water restrictions for CA farmers as many other threats exist for CA spawning salmon |

## Taxonomic issues, general principles

The petition states that it is motivated in part by a general concern about "taxonomic inflation", or the tendency to increasingly split taxa into smaller subunits based on minor differences between putative taxa (petition p. 11). The petition notes that this can be a problem even at the species level, but seems particularly concerned with the incorrect identification of subspecies, due in part to a lack of consistent and rigorous subspecies definitions in the scientific literature (petition, p. 11).

The petition is correct in its conclusion that taxonomic uncertainty is a practical and conceptual problem for implementing conservation policy, particularly under laws such as the Endangered Species Act that rely on designation of particular species or intraspecific groups of organisms for special protections. Even the definition of a species is subject to ongoing scientific debate, with dozens of species concepts circulating in the scientific literature and debate about whether species are 'real' entities or simply categories invented for human convenience (Hey *et al.* 2003; Mallet 1995). As the petition notes, subspecies concepts have been subject to less intensive theoretical treatment than have species, but even so there are numerous definitions of subspecies in the scientific literature (reviewed by Haig *et al.* 2006). Other definitions of intraspecific groupings, such as Evolutionarily Significant Units (e.g., Crandall *et al.* 2000; Moritz 1994; Waples 1991), Distinct Population Segments (DPS; USFWS *et al.* 1996), and stocks (Dizon *et al.* 1992; McElhany *et al.* 2000) have also been the subject of considerable scientific debate and controversy ( reviewed by Ford 2003; Fraser *et al.* 2001).

The petition focuses considerable attention on the societal costs associated with designating insufficiently discrete taxa, but does not discuss the converse conservation problem of failing to identify discrete taxa when they exist. Failure to identify species, subspecies or other intraspecific varieties when they do in fact exist has clear conservation costs, mostly notably the potential loss of such unique groups through failure to protect them. This problem has been extensively discussed in the scientific literature, and has provided the motivation for several explicit definitions of both subspecies and ESUs (Avise *et al.* 1990; Crandall *et al.* 2000). The potential for outdated or incorrect taxonomy, particularly at the subspecies level, has been a motivation for more explicit subspecies definitions and suggestions to review outdated taxonomic designations (Haig *et al.* 2006). For example, with regard to designation of cetacean species and subspecies, Reeves *et al.* (2004) noted that

> *There has been a tendency to err in the direction of avoiding designating too many taxa rather than making sure that all potentially recognized taxa have been designated. In other words, the direction of precaution toward stability in traditional taxonomy has not been appropriate for conservation.*

and

> *Cetacean taxonomy in the latter half of the 20th century was conservative in part as an over-reaction to the excessive splitting that occurred during the 19th century.* (p. 30)

In other words, at least in Reeves *et al.*'s view, the currently accepted cetacean taxonomy tends to err on the side of lumping discrete taxa together rather than splitting them apart. To facilitate accurate designation of new cetacean taxa, particularly at the subspecies level, Reeve's *et al.* recommended the following definition of subspecies:

> *In addition to the use of morphology to define subspecies, the subspecies concept should be understood to embrace groups of organisms that appear to have been on independent evolutionary trajectories (with minor continuing gene flow), as demonstrated by morphological evidence or at least one line of appropriate genetic evidence. Geographical or behavioral differences can complement morphological and genetic evidence for establishing subspecies. As such, subspecies could be geographical forms or incipient species.* (p. 7).

Based on the discussion above, the problem of how to deal with taxonomic uncertainty in applying laws such as the ESA is not a new issue. Neither are concerns about wasting resources or causing economic harm through listing of inappropriately designated taxa. For example, the issue of balancing the competing tensions of conserving genetic resources but doing so when only biologically warranted was a motivating factor in the development of both the NMFS ESU concept (Waples 1991) and the joint USFWS & NMFS DPS policy (USFWS *et al.* 1996). It is beyond the scope of this review to attempt to resolve all of the bigger picture issues surrounding the intersection of taxonomy and conservation status. In developing and applying its policy on DPS, however, NMFS did explicitly consider the need to identify conservation units under the ESA at an appropriate scale.

## New information since 2004

In this section we briefly summarize information relevant to both the taxonomic and DPS questions that has been published in the scientific literature since the 2004 status review.

### Morphology and color variation

The only published quantitative analysis of variation in pigmentation patterns in North Pacific killer whales remains that of Baird and Stacey (1988), which found significant differences between residents and transients and among resident populations in the frequencies of alternative saddle patch patterns. Several authors (Baird 2000; Dahlheim *et al.* 2008; Ford *et al.* 2000 ) have also described qualitative differences in morphology among the three Pacific ecotypes. All of these studies except for Dahlheim *et al.* (2008) were considered by the 2004 BRT in their status review report.

While not describing morphological variation *per se*, a study by Zerbini *et al.* (2007) demonstrated that the ecotypes can be unambiguously distinguished based on visual appearance of dorsal fin shape and saddle patch pigmentation. In that study, ecotype determination of unknown groups of whales was made independently by both visual examination of photographs and genetic analysis of the mtDNA control region. In all 32 cases where both photographs and genetic data were available, the ecotype designation based on the photographs matched that based on the mtDNA control region.

Since 2004, there have been multiple studies published on morphological and ecological variation among Antarctic killer whales, confirming and extending the more preliminary information that was available to the 2004 BRT. Pitman and Ensor (2003) describe field observations and descriptions of three distinct types of Antarctic killer whale (designated A, B, and C) differentiated by size, pigmentation, habitat and apparent prey preferences. The C type appeared to correspond to *O. glacialis*, a dwarf form of killer whale previous described by Berzin and Vladimirov (1983) but not generally accepted as a distinct species due to small sample size and lack of a type specimen (Heyning *et al.* 1988). Pitman *et al.* (2007) used aerial photographs to quantify the length distribution of a sample of 221 Type C whales, and confirmed this type as smaller than the Type A whales. Based on historical and contemporary photographs, Pitman *et al.* (2011) described a new “Type D” killer whale characterized by a very small eye patch and somewhat bulbous head and inhabiting the Southern Ocean between 40 and 60 degree south. More recently, Olsen *et al.* (2012) observed groups of east Antarctic killer whales that were intermediate in some morphological characters between types B and C.

### Feeding ecology and diet

Since the 2004 BRT report, several additional studies have been published on the diet and feeding ecology of North Pacific killer whales. Herman *et al.* (2005 ) and Krahn *et al.* (2007) examined variation in organic contaminants and fatty acid composition of blubber biopsy samples and carbon and nitrogen stable isotope ratios in dermal samples from 169 samples (between the two studies), obtained primarily from the Gulf of Alaska and the Aleutian Islands but including some samples from Puget Sound and the U.S. west coast. All three ecotypes were represented, although the number of offshore samples was small (4 in the 2005 study and 9 in the 2007 study). The studies found significant variation among the three ecotypes in fatty acid profiles and contaminant burdens and ratios, likely reflective of different diets and foraging locations (Figure 1). Nitrogen stable isotope ratios also differed significantly between transients and residents, with transients having more enriched $^{15}$N levels consistent with a marine mammal diet. Offshores had nitrogen ratios that were between residents and transients, and not significantly different from either. Alaskan residents sampled from different areas also varied considerably in both nitrogen and carbon stable isotope profiles, presumably reflecting differences in foraging location and/or prey types.

Ford and Ellis (2006) and Hanson *et al.* (2010) conducted field observations of resident killer whale predation combined with genetic analysis of prey remains and field collected fecal samples to evaluate resident killer whale diets in the Salish Sea. Both studies observed predation of only fish, and analysis of prey remains and fecal DNA indicated a summer diet dominated by Chinook salmon (*Oncorhynchus tshawytscha*). Dahlheim and White (2010) describe foraging behavior and prey preferences for Alaskan transient killer whales. Killer whale diet information, including considerable unpublished data, was further reviewed by an independent science panel in 2012 (Hilborn *et al.* 2012; NMFS 2013).

In the Antarctic, Pitman and Durban (2012) described a field study of foraging behavior of Type B killer whales, documenting predation of primarily Weddell seals (*Leptonychotes weddellii*) using a cooperative hunting behavior that involved washing the seals off of ice flows. Olsen *et al.* (2012) described Type A and B killer whales in a common feeding aggregation. Foote *et al.* (2009) describe variation in stable isotope ratios and tooth wear potentially indicative of two killer whale foraging types in the North Atlantic.

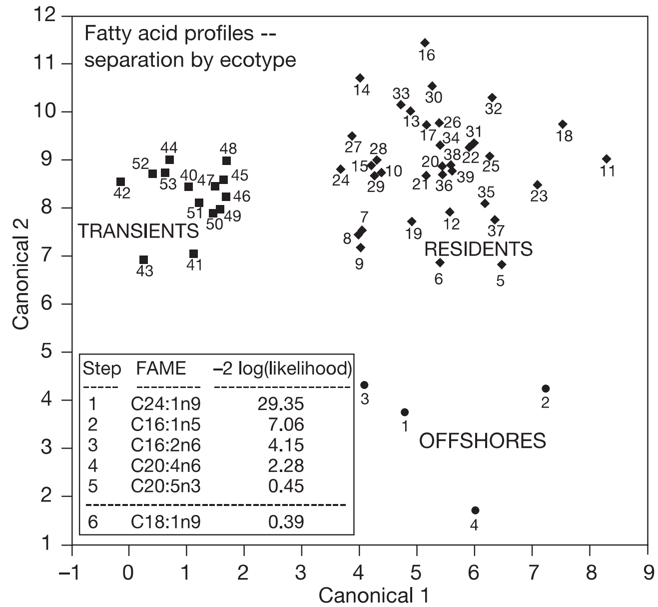

**Figure 1 -- Orcinus orca. First 2 discriminant functions showing separation of killer whale ecotypes based on fatty acid profiles of the blubber biopsies. Reproduced from Herman *et al.* (2005).**

Deecke *et al.* (2005) found significant differences in the acoustic behavior of transients and residents during foraging events, with transients calling significantly less frequently than residents. The difference appears to be related to hearing abilities of their preferred prey; marine mammals have excellent hearing in the frequency range of the killer whale calls while fish do not. These results are consistent with earlier work (Deecke *et al.* 2002) demonstrating that harbor seals displayed predator avoidance behavior during playback experiments using transient calls but not during experiments using resident calls. Deecke *et al.* (2011) and Beck *et al.* (2011) found differences in group size and acoustic behavior between seal-eating and fish-eating killer whales in the North Atlantic. Based on the phylogenetic relationships between the Atlantic and Pacific populations (Foote *et al.* 2011b; Morin *et al.* 2010), Beck *et al.* (2011) concluded that such foraging specialization and associated behaviors must have arisen independently in both oceans and be fairly plastic traits. Dahlheim *et al.* (2008) describe foraging behavior of offshore killer whales including highly worn teeth suggesting feeding on abrasive prey such as sharks. Ford *et al.* (2011a) collected prey samples from offshore killer whales and identified the prey as Pacific sleeper sharks (*Somniosus pacificus*). On a research cruise off the Oregon and Washington coasts in spring of 2013, an offshore whale was observed foraging on Chinook salmon (NWFWC unpublished data).

## Genetics

The genetic information available at the time of the 2004 status review consisted of several studies focusing on variation in the mtDNA control region and at multiple nuclear microsatellite loci (see tables 1 and 2 of Krahn *et al*. 2004). Two studies, both in the form of preliminary reports, were cited as being particularly influential due to their large sample sizes: a global study of 211 killer whales analyzed at 17 microsatellite loci (Hoelzel 2004), and a similar study of 219 whales sequenced at the mtDNA control region (LeDuc *et al.* 2004). Both studies produced a somewhat inconclusive picture of population structure, as summarized by Krahn *et al.* (2004, p. 15-16):

> *The understanding of killer whale population genetic structure has expanded considerably since the 2002 status review. In particular, the mtDNA differentiation among eastern North Pacific resident, transient, and offshore populations can now be seen in the context of variation worldwide. The most notable result from the new mtDNA data is the lack of strong mtDNA structure worldwide, suggesting that the current distribution of killer whales populations may be relatively young on an evolutionary scale (e.g., several hundred thousand years compared to the ≈5 million year old age of the Orcinus genus [Waples and Clapham 2004]) and possibly associated with a population bottleneck followed by a worldwide expansion. With respect to identifying conservation units, one of the implications of the new data is that the relative degree of mtDNA divergence among populations is not necessarily a good predictor of the length of time that the populations have evolved independently. For example, killer whales with the same haplotype as in Southern Residents have also been found in Alaska, Russia, Newfoundland, and the United Kingdom (Figure 2). Evolutionarily, these whales with the southern resident haplotype are almost certainly more closely related to other geographically proximate populations than to each other (a hypothesis supported by the microsatellite data, Table 3) and therefore, share a mtDNA haplotype purely by chance. Because of this finding, it would be inappropriate to rely heavily on simple mtDNA divergence as a criterion for identifying conservation units, especially on a global scale. On a local scale, however, mtDNA clearly remains useful for helping to identify populations, especially when combined with other types of information.*
>
> *In addition to more mtDNA data, the amount of nuclear microsatellite data has expanded greatly in the last 2 years, both in terms of whales and loci analyzed. Within the eastern North Pacific, both the mtDNA and microsatellite data remain consistent with a hypothesis of four to five resident populations, at least two to three transient populations and at least one offshore population (Figure 1). The issue of whether any contemporary gene flow occurs among eastern North Pacific populations remains unresolved, but the microsatellite data are consistent with either low levels of gene flow (at most a few mating events among populations per generation) or divergence times of at least several hundred to several thousand years (M. Ford 2004, Hoelzel 2004). Despite some uncertainty about the evolutionary history that produced the current patterns of variation, both the mtDNA and the microsatellite data indicate a high degree*

*of contemporary reproductive isolation among eastern North Pacific killer whale populations.*

As we discuss below, our understanding of global killer whale population structure has improved considerably since 2004, although some uncertainties remain.

We identified 10 studies of the genetic population structure of killer whales that have been published since the 2004 status review (Table 2). Three of these – Hoelzel *et al.* (2007), LeDuc *et al.* (2008), and Pilot *et al.* (2010) – are expanded and published versions of the preliminary reports considered by the 2004 BRT (Hoelzel 2004, LeDuc and Taylor 2004).

Hoelzel *et al.* (2007) analyzed 203 killer whales sampled from the North Pacific (including samples of the resident, transient and offshore ecotypes) and Iceland at 16 microsatellite loci and the mtDNA control region (~1000 bp). Similar to preliminary results reported to the 2004 BRT (Hoelzel 2004), they found significant differentiation among all groups of samples but estimated that rates of gene flow among most groups, including between ecotypes, was significantly greater than zero. Among North Pacific resident groups, they found that genetic differentiation at microsatellite loci was proportional to geographic distance between the groups. The most geographically distant resident groups had similar levels of genetic divergence to that between the residents and the transients. Using genetic assignment tests, they identified 5 putative migrant individuals, but none between residents and transients. In fitting a model of divergence with migration, they estimated low but non-zero (< 1 migrant/generation) rates of gene flow between residents and transients, and between the Alaskan resident and Icelandic groups. From the same type of analysis, they estimated that the divergence time between residents and transients was 4000 – 36,000 years ago, depending on mutation rate assumptions, and hypothesized that most if not all of the population structure observed evolved after the most recent glacial maximum.

Using the same data, Pilot *et al.* (2010) expanded upon Hoelzel *et al.*'s (2007) results by conducting a parentage analysis within and among populations in order to directly estimate contemporary gene flow. The study also extended the assignment test analyses of Hoelzel *et al.* (2010) using two additional methods. Out of 213 samples, they found a total of 3 putative first generation migrants (individuals sampled from a population but with a genetic profile more similar to a different population), and 8 putative second generation migrants (individuals inferred to be the offspring of a first generation migrant). Of these 11 putative migrants, 8 were within the same ecotype (exchanges between California and Alaska transients, or between Alaskan and Russian residents), 2 were between transients and the Icelandic group (both second generation), and 1 was between transients and offshores (second generation). Using a model fitting approach, rates of gene flow between residents and transients and from the offshores into residents and transients were estimated to be <1% per generation. Rates of gene flow from both residents and transients into the offshore group were estimated to 2.2 – 3.6%. Gene flow rates between resident populations were estimated to be 0.5% - 2.4%, except for the rates between Russian and Bering Sea groups and between Bering Sea and Alaskan groups which were much higher (14% - 28%).

Pilot et al's parentage analysis identified at least one parent for 95 individuals, but more than half these (57) were rejected by the authors as spurious. The remaining parentage assignments suggested low dispersal (42/43 maternal assignments were to a mother within the offspring's population) and very high male-mediated gene flow (10/22 paternal assignments were to a male not in the offspring's population). No parentage assignments were made between members of different ecotypes. The authors suggested that the discrepancy between the low rates of intra-ecotype gene flow estimated by using assignment tests and model-fitting and the high rates estimated from parentage analysis could be explained by a recent range expansion leading to increasing contact among formally isolated populations. Another possible explanation, suggested by the large number of assignments rejected as spurious, is that the parentage analysis may not have had sufficient power to exclude all false paternity assignments.

Ford *et al.* (2011b) conducted a similar parentage and assignment test analysis, but focused the parentage analysis exclusively on the southern resident population and did not attempt to identify potential parents outside of this population. The authors did test for the presence of first generation immigrants into the SRKW population, however, and found no evidence of recent gene flow into the SRKW population.

Another significant development in our understanding of global killer whale population structure has resulted from sequencing full ~16,390 bp mitochondrial genomes from a large number of individuals (Morin *et al.* 2010). Sequencing the full mitogenome has increased the number mtDNA base pairs examined by over 16 fold compared to the earlier studies that focused exclusively on the ~1000 bp control region. This increase in sequence evaluated has greatly improved the resolution of the estimated mtDNA gene trees, and significantly altered our understanding of killer whale population structure, particularly as it relates to the degree of divergence among some of the known ecotypes.

Morin *et al.* (2010) sequenced and analyzed full mitochondrial genomes from 139 killer whales sampled primarily from the North Pacific, North Atlantic, and Antarctic areas, with a smaller number of additional samples from the tropical Pacific. In contrast to earlier results based on only the control region, the phylogenetic tree constructed from the full length mitogenome sequences showed strong genetic structure associated with many of the previously identified ecotypes (Figure 2). In particular, the North Pacific residents, North Pacific transients, North Pacific offshores, and Antarctic type B and type C groups each formed distinct monophyletic clades. The North Pacific transients were particularly divergent from most other killer whale groups, including the sympatric residents and offshores. For example, there were 57 fixed sequence differences between the transients and the residents and offshores. The estimated time to the most recent common ancestor of all of the mtDNA haplotypes was ~700,000 years, and the divergence time between the haplotypes characterizing the residents and those characterizing the offshores was 177,000 years ago. Haplotypes characterizing the Antarctic B and C types were estimated to share a common ancestor 155,000 years ago. The Antarctic B and C types were also each found to have a sequence substitution inferred to be due to natural selection (Foote *et al.* 2011a). Based on the clear genetic divergence among ecotypes, combined with divergence at microsatellite loci and previously reported morphological and ecological differences, Morin *et al*. (2010) concluded that the North Pacific transients and Antarctic B and C types each met criteria for being considered full species, and the other known ecotypes (North Pacific residents, offshores, North Atlantic populations, and the Antarctic A type) each met criteria for being considered distinct subspecies, but could be elevated to species with if additional data supported evolutionary distinctiveness.

Utilizing the same dataset of mitogenome sequences, Foote *et al.* (2011b) conducted additional analyses on the relationship between North Pacific and North Atlantic populations. Based on the structure of the mitogenome tree, they suggested that over the past ~300,000 years there have been several episodes of migration of whales between the Pacific and Atlantic oceans. The timing and pattern of these inferred episodes further suggested that the Pacific resident and transient ecotypes may have initially diverged in allopatry (transients in Pacific, residents in Atlantic), and then subsequently came into contact following a migration event of residents back into the Pacific. Using the same isolation-divergence model used by Hoelzel *et al.* (2007), Foote *et al.* (2011b) also found non-zero but extremely low rates of bi-directional female gene flow between the Atlantic and Pacific (< 1 migrant / 150,000 years).

Foote *et al.* (Foote *et al.* 2009; Foote *et al.* 2011c)conducted analyses focused on understanding killer whale population structure within the North Atlantic, and found evidence for two ecological types (fish eating/mammal eating) similar to what has been observed in the Pacific and Antarctic. Genetically, the fish eating whales from Norway and Iceland formed a genetically distinct grouping based on both mtDNA control region (1000bp) sequences and microsatellite variation. Other groups of populations, particularly from Gibraltar and the Canary Islands, also clearly formed discrete populations based on the microsatellite variation, but clustered with other groups (Pacific offshores, Antarctic type A) in the mtDNA tree.

Parsons *et al.* (2013) conducted a study of population structure of a large (462) sample of resident and transient killer whales from the Gulf of Alaska, the Aleutian Islands and the Sea of Okhotsk. The focus of the study was primarily on elucidating population structure within each ecotype, but the study is also the largest study to date (in terms of whales and loci) of nuclear genetic variation between the resident and transient ecotypes. Using two different assignment methods, all samples with sufficient data (n> 20 loci) assigned unambiguously to their known ecotype. When individuals with greater levels of missing data were included, a single individual (missing data at 15/27 loci) assigned to the 'incorrect' ecotype at a low level of confidence (0.54). These results, combined with the lack of any shared mtDNA haplotypes, led the authors to conclude that there is at most negligible gene flow between the two ecotypes.

**Table 2 – Summary of published genetic analyses of killer whale population structure since the 2004 status review**

| Study[1] | Geographic focus | Number of samples | Type of data |
|---|---|---|---|
| Hoelzel *et al.* (2007), Pilot *et al.* (2010) | North Pacific plus Iceland | 203 | Microsatellites (16), mtDNA control region (~1000 bp) |
| LeDuc *et al.* (2008) | Antarctic (with comparison to published data in Pacific and Atlantic) | 80 | mtDNA control region (~1000 bp) |
| Foote *et al.* (2009) | North Atlantic | 125 | mtDNA control region (partial) |
| Morin *et al.* (2010), Foote *et al.* (2011b), Foote *et al.* (2011a) | North Pacific, North Atlantic, Antarctic, some tropical | 143 | mtDNA full genome (~16,390 bp) |
| Foote *et al.* (2011c) | North Atlantic (with comparison to published data in Pacific and Antarctic) | 85 | mtDNA control region and full genomes; microsatellites (17) |
| Ford *et al.* (2011b) | Southern Residents, North Pacific | 78 | Microsatellites (26) |
| Parsons *et al.* (2013) | North Pacific | 462 | mtDNA control region (~1000 bp); microsatellites (27) |

[1]Separate papers based on largely the same data are grouped.

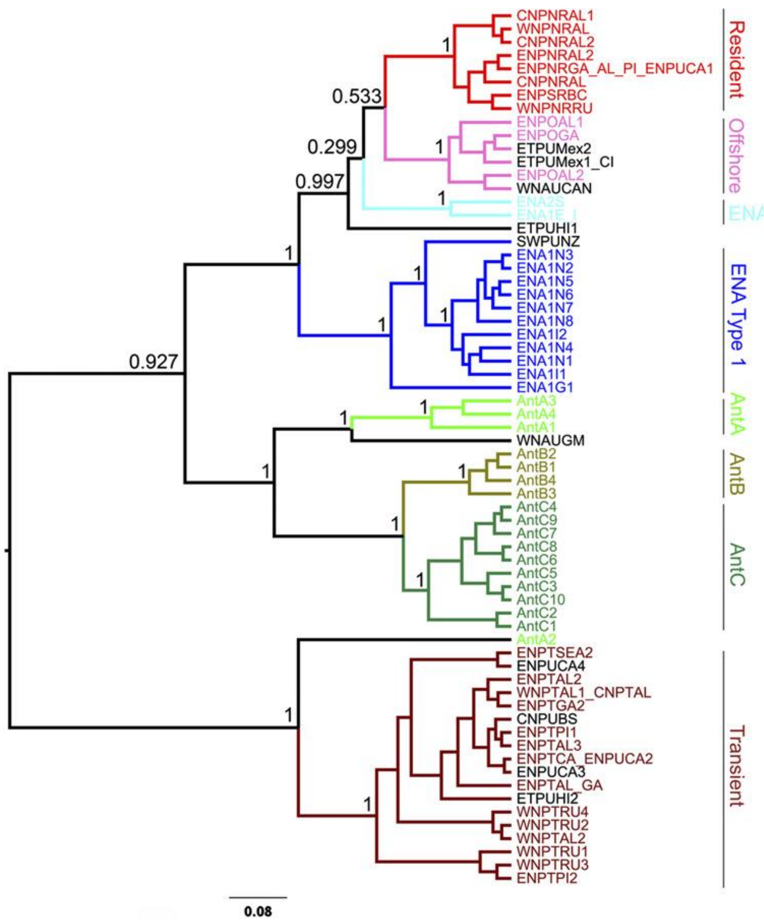

**Figure 2 -- Whole mitochondrial genome phylogeny of 66 unique killer whale haplotypes. Posterior probabilities are indicated for nodes of interest. Whales of known type are indicated in color, and those of unknown type are in black type. Reproduced from Morin *et al.* (2010).**

### *Summary, genetics*

Our understanding of killer whale population structure has improved considerably since 2004, due both to analysis of new samples, larger numbers of nuclear loci, and the collection of full mitogenome data. At least at the high latitude areas examined, the full mitogenome trees are much more geographically and ecotypically structured than was true of the control region trees available in 2004. The genetic studies published since 2004 also clearly support earlier suggestions of differentiation between some of the Antarctic ecotypes.

Despite the greater resolution provided by the mitogenome data compared to that of only the control region sequences, the total depth of the mitochondrial phylogeny within *O. orcus* remains relatively shallow compared to the levels of divergence typically observed between mammalian sister species. For example, Johns and Avise (1998), Avise *et al.* (1998) and Baker and Bradley (2006) have reviewed divergence at the mitochondrial cytochrome-b gene for a large number of mammal sister species, and levels of divergence are typically >5%, although some are much lower. The divergence between resident and transient killer whales is ~0.4% (based on sequences from Morin *et al.* (2010)), suggesting that if the ecotypes are species they are relatively young species. The relatively shallow divergence could also be consistent with incipient speciation (Riesch *et al.* 2012), or with subspecies (Reeves *et al.* 2004).

Evaluating variation at multiple nuclear genes is also important for gaining a full understanding of population structure, both to reduce the stochastic noise associated with inference at a single locus such as mtDNA and to ensure that population processes mediated by male gene flow are evaluated.

Studies of nuclear variation published since 2004 have provided results consistent with what was available to the 2004 BRT, albeit with considerable improvements in terms of numbers of samples and loci analyzed. In 2013, as in 2004, all published studies of killer whale population structure that use nuclear loci have utilized microsatellites, although the number of loci has increased from 17 (Hoelzel 2004) to 27 in the most recent study (Parsons *et al.* 2013). The studies that have most directly attempted to estimate rates of gene flow among populations using nuclear loci (Hoelzel *et al.* 2007, Pilot *et al.* 2010), estimate no contemporary gene flow between the North Pacific residents and either transients or offshores, and at most very little contemporary gene flow between transients and offshores. The most sophisticated estimates of historical gene flow (the Ima2-based estimates from Hoelzel *et al.* 2007) are all <1 migrant/generation among the Pacific ecotypes. The largest available study of microsatellite variation among North Pacific killer whales (Parsons *et al.* 2013) also found no evidence for contemporary gene flow between residents and transients. Estimates of rates of gene flow within the North Pacific resident populations vary somewhat, but most analyses indicate little gene flow, particularly into or out of the more southern populations. All of these results continue to strongly support the 2004 BRT's conclusion that there is a "… high degree of contemporary reproductive isolation among eastern North Pacific killer whale populations" (Krahn *et al.* 2004, p. 16).

Our understanding of killer whale population structure outside of the North Pacific has also progressed considerably since 2004. Studies of variation among killer whale groups in the Antarctic (Leduc *et al.* 2008; Morin *et al.* 2010) in particular have confirmed the presence of distinct groups that correspond to the ecological/morphological groups previously identified (Pitman *et al.* 2003; Pitman *et al.* 2007). Population structure in the Atlantic is also starting to be elucidated (Foote *et al.* 2009), as is the relationship between the North Atlantic and North Pacific (Foote *et al.* 2011b).

Despite this considerable progress, it is also clear that a full understanding of killer whale structure at a global scale remains incomplete. There have been no published genetic studies focusing on samples from tropical areas (although Morin *et al.* 2010 included some tropical samples), and large portions of the killer whale's range, including the coasts of South America, Africa, Australia, and eastern North America, remain essentially unanalyzed.

In addition to the lack of sampling in some areas, the issue of the evolutionary age of the Pacific ecotypes and of killer whale populations worldwide remains somewhat uncertain and subject to varying estimates. Based on the low levels of mtDNA control region divergence, Hoelzel *et al.* (2002) hypothesized that killer whales globally experienced a population bottleneck 145,000 to 210,000 years ago. By fitting population genetic models to microsatellite and mtDNA control region data, Hoelzel *et al.* (2007) estimated the divergence time between the Pacific ecotypes at 20,000-30,000 years ago. In contrast, Morin *et al.* (2010) estimated the time to the most recent common ancestor of the killer whale mitogenomes that characterize the ecotypes to be 170,000 to 700,000 years ago, implying a much deeper divergence time than had been estimated previously. However, Hoelzel *et al.* (2007) estimated divergence times between populations, whereas Morin *et al.* (2010) estimated divergence time among gene sequences and these estimates are not expected to be the same (topic reviewed by Edwards *et al.* 2000). Hoelzel *et al.*'s estimate was based on a much smaller mtDNA segment than the Morin *et al.* estimate, but Hoelzel's estimate also included information from nuclear loci. In addition, all of these estimates are sensitive to the estimated or assumed mutation rate, which differed between the studies. It is therefore not immediately obvious which of these estimates is more reflective of the true evolutionary age of the ecotypes, or even that these estimates are necessarily inconsistent with each other. Additional nuclear sequence data is likely to improve the precision of the estimated divergence times.

### Review papers

Riesch *et al.* (2012) and Foote (2012) recently reviewed evidence for ongoing ecological speciation among killer whale ecotypes. Riesch *et al.* focus particularly on the role that cultural factors might play in promoting ecological divergence and reproductive isolation. Both reviews conclude that most if not all of the behavioral, ecological and perhaps even some of the morphological (e.g., size) differences between the North Pacific ecotypes are likely to be non-heritable, culturally transmitted traits. Riesch *et al.* concluded that the reproductive and social isolation observed among ecotypes is largely culturally based, and there is no evidence for either pre or post-zygotic reproductive incompatibility. Ultimately, Riesch *et al.* concluded that there is not sufficient evidence to conclude that the ecotypes are currently separate species or subspecies, but rather that "We could be witnessing the early stages of an adaptive radiation of killer whales, whereby a variety of incipient species are beginning to exploit diverse ecological niches, or conversely, we could be looking at an old and continuing process by which new ecotypes periodically form and become extinct again." Foote (2012) evaluates much of the same information, and concludes that it is very hard to prove conclusively from field data alone that the specific process of ecological speciation (Schluter 2001; Schluter 2009) is occurring in killer whales or any "non-model" organism. Foote suggests that genome scans, by identifying specific functional genes subject to natural selection, might be a fruitful way to evaluate the causes of divergence in such systems. de Bruyn *et al.* (2013) recently reviewed information on Southern hemisphere killer whales both in Antarctica and in temperate latitudes and concluded that there is relatively little information on the social structure and ecology of killer whales in this region and that firm designation of ecotypes outside of the North Pacific may be premature.

## Summary and Conclusions

### Determination of the Taxon

Based on several lines of evidence, including differences in morphology, behavior, diet and feeding ecology, acoustical dialects and practices, and both mtDNA and nuclear DNA variation, the 2004 BRT concluded (with some uncertainty) that the North Pacific resident killer whales were a subspecies of *O. orca* distinct from the sympatric transient whales (Krahn *et al.* 2004, p. 40-41). With somewhat less confidence, the BRT also concluded that the North Pacific resident subspecies consisted of only the North Pacific residents, and did not include killer whales of the offshore ecotype or fish-eating killer whales from elsewhere in the world.

After reviewing information in the petition, the public comments, and the scientific literature published in the nine years since the 2004 status review, we found no new information that would likely lead to a different conclusion from that of the 2004 BRT. In particular, all of the new genetic data and analyses published since 2004 (Table 2), including the Pilot *et al.* (2010) paper discussed extensively by the petition, are either consistent with or strengthen the 2004 BRT's conclusion that there is a high degree of contemporary reproductive isolation among the North Pacific killer whale ecotypes. No genetic analysis published since the 2004 status review has indicated a higher level of interbreeding among the ecotypes than was indicated by the analyses considered by the 2004 BRT.

In addition to new genetic analyses, the studies on feeding ecology and diet published since 2004 are also generally consistent with or strengthen the 2004 BRT's conclusions that the ecotypes differ in diet and feeding ecology. The one new study that touches indirectly on morphological differences between the ecotypes (Zerbini *et al.* 2007) supports the 2004 BRT's conclusion (based on earlier literature) that the ecotypes can be morphologically differentiated. No new information on acoustics or behavior contradicts the conclusions of the 2004 BRT. Recent observations (NWFSC unpublished data) indicate that offshores consume at least some Chinook salmon, but stable isotope and tooth wear data also indicate substantial dietary differences. The petition discusses numerous questions regarding the morphological, behavioral and ecological data cited by the 2004 BRT, but does not raise issues not already discussed by the BRT or the 2004 Taxonomic workshop.

A broader scientific consensus regarding whether the North Pacific ecotypes are a subspecies of *O. orca* remains mixed, as was the case at the time of the 2004 BRT (Krahn *et al.* 2004; Reeves *et al.* 2004). Some experts have suggested that the ecotypes clearly meet criteria for subspecies or species designation (Morin *et al.* 2010), and at least one scientific society (the Society for Marine Mammalogy) now formally recognizes North Pacific residents and transients as subspecies (Committee on Taxonomy 2012). Other experts are less certain that either species or subspecies status is currently appropriate, based on some estimates of non-zero male mediated gene flow among ecotypes (Hoelzel public comments; de Bruyn *et al.* 2013; Riesch *et al.* 2012). Some of this lack of consensus appears to be related to differing conceptions of subspecies definitions rather than substantial disagreement about the biological differences characterizing the ecotypes.

Although the 2004 BRT concluded that the North Pacific resident killer whales meet the criteria for being a subspecies, the BRT expressed some uncertainty about whether to also include Pacific offshores, tropical Pacific killer whales, and by extension perhaps also Atlantic fish-eating killer whales in this subspecies as well (Krahn *et al.* 2004, pp. 40-41). The data available since 2004 tend to strengthen the BRT's conclusion that the North Pacific resident killer whales are taxonomically distinct from the sympatric offshores and allopatric populations of killer whales in the tropics and Atlantic. In particular, Morin *et al.* (2010) found that the North Pacific residents form a monophyletic mtDNA clade distinct from offshores, Atlantic whales and the limited number of Pacific tropical whales included in the study (Figure 1). Estimated rates of gene flow between residents and Atlantic populations differ greatly between studies, but generally suggest that such gene flow is occurring on evolutionary rather than ecological time scales. The fact that the three Pacific ecotypes retain their genetic and ecological distinctiveness when in sympatry also strongly suggests they are currently on divergent evolutionary trajectories. Nonetheless, as was the case in 2004 clearly demarcating the phylogenetic boundaries of the resident taxon remains somewhat uncertain and the rationale for taxonomically distinguishing the residents from the offshores and from fish eating whales in the Atlantic appears somewhat less compelling than taxonomically distinguishing transients from other North Pacific killer whales.

Taken together, however, the best available information clearly strengthens the lines of evidence cited by the 2004 BRT (Krahn *et al.* 2004) to support the designation of the North Pacific resident and transient killer whales as an unnamed subspecies of *O. orca.*

### Determination of the DPS

As of December 31, 2012, the SRKW population consisted of 84 individuals divided into three pods (26 in J, 19 in K, and 39 in L) (Center for Whale Research and NWFSC unpublished data). An additional captive animal originating from the SRKW population and with a genotype consistent with a southern resident origin (Hoelzel *et al.* 2007; Hoelzel pers. com.), "Lolita", has resided at the Miami Seaquarium since her capture in August of 1970 (Hoyt 1981). Lolita's original pod is not known with certainty, but her acoustic calls are typical of L pod (Ford 1987; Candice Emmons, personal communication).

The 2004 BRT concluded that there was strong evidence that the SRKW are discrete as defined by the 1996 DPS policy, citing significant genetic differentiation, separate demographic trajectories, differences in core and summer range, and behavioral differences with other resident populations (Krahn *et al.* 2004, p 44). The BRT was less certain that the SRKW met the DPS policy's criteria for significance, but concluded (by a 2-to-1 margin) that they did, citing differences in ecological setting, range, marked differences in genetic variation, and potential cultural differences.

The new information subsequent to 2004 is consistent with and generally strengthens the conclusion that the SRKW are a discrete population within the North Pacific resident taxon. In particular, recent genetic studies all indicate that SRKW are significantly differentiated from other resident populations. New information on the winter range of SRKW provides for a considerably more complete picture than was available in 2004, and continues to indicate that the SRKW (particularly L and K pods) have a winter and summer range distinct from other resident populations, although it does overlap substantially with the northern resident population. A recent analytical comparison of demographic rates found significant differences in both survival and fecundity rates between the southern resident population and the northern resident population, providing further evidence of demographic discreteness (Ward *et al.* 2013). In short, as in 2004 all the available information clearly indicates that the southern residents are a distinct population.

Compared to 2004, new information related to the significance of the SRKW to the North Pacific resident taxon provides a somewhat more nuanced picture. Each of the factors listed by the 2004 BRT in support of the significance criteria is discussed below with reference to new information.

Ecological setting and range – The 2004 BRT noted that the southern residents appeared to occupy a distinct ecological setting, being the only North Pacific resident population to spend substantial time in the California Current ecosystem and having a diet somewhat different from other resident populations, particularly those in Alaska. The BRT also cited the possibility that the southern residents historically utilized the large runs of salmon to the Sacramento and Columbia River as a major source of prey. With regard to range, the BRT noted that the southern residents were the only resident population to be observed to spend time in Puget

Sound and off the coasts of Washington, Oregon and California and that if they were to go extinct this would result in a significant gap/reduction in the resident's range.

New information since 2004 generally continues to support most of these conclusions, but also challenges some of them. In particular, new information on the coastal distribution of the southern and northern resident populations confirms that the southern residents spend substantial time in coastal areas of Washington, Oregon and California and utilize salmon returns to these areas (NWFSC unpublished data). However, there is also new information indicating that the Northern Resident population may also spend more time off the Washington coast than was previously believed (Riera *et al.* 2011; NWFSC unpublished data), and the known northern range of the southern residents is now Chatham Strait in SE Alaska based on photographs taken in 2007 (John Ford, DFO, pers. com). In addition, diet information on the Alaskan resident populations indicates that some of these populations also consume salmon, although not the Chinook salmon that dominate the southern and northern resident diets (Saulitis *et al.* 2000). Updated diet data from the southern and northern resident populations confirms that these two populations have very similar diets and consume many of the same salmon stocks (Ford *et al.* 2010; Hanson *et al.* 2010). Overall, the southern residents remain unique in occupying the most southern part of the resident's range, and are clearly occupying a somewhat different ecological setting from populations in Alaska and further west around the Pacific Rim. The southern portion of the southern resident's range is also quite distinct from that of the northern resident population, but the southern and northern residents clearly share a similar ecological setting throughout much of their range.

Genetic differentiation – Genetic data available since 2004 confirms or strengthens the conclusions that the southern resident population is genetically differentiated from other resident populations. In particular, there are no new data to change the 2004 BRT's conclusions that the southern resident population differs markedly from other North Pacific resident populations at both nuclear and mitochondrial genes.

Behavioral and cultural diversity – The 2004 BRT noted several instances of known and apparent cultural differentiation among resident killer whale populations, and hypothesized, based on studies in other long-lived mammals, that such diversity could be important for the survival of the North Pacific resident taxon as a whole. Since 2004, several studies have contributed further information to this topic. For example, Ward *et al.* (Ward *et al.* 2013; 2011) found significant differences in survival among the three southern resident pods and between the southern and northern resident populations. These differences are likely related to differences in diet and habitat use, both of which appear to be culturally determined. Riesch *et al.* (2012) and Foote (2012) reviewed cultural differences, particularly acoustic behavior and prey preferences, among killer whale populations and ecotypes, and concluded that such cultural differences may be leading to reproductive isolation and subsequent ecological speciation. On the whole, therefore, the available data appear consistent with the BRT's conclusion that such cultural differences may be important factors in the overall viability of the resident killer whale taxon.

Overall, new information on genetics and behavioral and culture diversity available since 2004 is consistent with or strengthens the 2004 BRT's conclusion that the southern resident killer whale population meets the significance criteria of the DPS policy. New information on ecological setting and range tends to weaken the 2004 BRT's conclusion somewhat, as it indicates greater overlap in range or diet with other resident and offshore populations than was previously believed. Overall, the new information available since 2004 appears consistent with the 2004 BRT's conclusion that southern resident killer whales are likely to be a DPS of the unnamed North Pacific resident subspecies.

## Appendix – Review of specific points made in the petition

### Workshop on Cetacean Taxonomy

p. 14 – "No experts in the field of cetacean taxonomy were included to inform the workshop participants." The list of participants is in Appendix 1 of workshop report (Reeves *et al.* 2004). It contains multiple experts on cetacean taxonomy, such John Heyning, Marilyn Dahlheim, William Perrin, and James Mead. In the paragraph preceding the sentence quoted above, the petition references papers by Perrin, Heyning and Dahlheim as authoritative on killer whale taxonomy.

p. 14 – 17 – In summarizing the Cetacean Taxonomy workshop, the petition fails to mention that among the workshop's conclusions was that "Overall, a majority of participants felt that Resident- and Transient-type killer whales in the ENP [Eastern North Pacific] probably merited species or sub-species status." (Reeves *et al.* 2004 pp. 5 and 72).

p. 17 – "Most importantly of all, the workshop contained the following: [C]onsideration of whether to add the 'southern resident' killer whales of the eastern North Pacific to the U.S. Endangered Species List hinged on poorly understood evolutionary relationships between this population and killer whales globally (LJ/04/KW10). In the absence of a fundamental understanding and agreement on the number of species and subspecies of killer whales, consensus could not be reached on whether this whale population was significant to the taxon to which it belongs."

The petitioners present this statement as a conclusion of the workshop. However, the text quoted appears in the first page of the workshop report and is referring to the inability of the 2002 BRT (Krahn *et al.* 2002) to reach a consensus on killer whale taxonomy. In other words, this statement is describing the motivation for the workshop, not the workshop's conclusion.

p. 17-18 – The discussion of the 2006 listing fails to cite the BRT reports (Krahn *et al.* 2002, 2004) and the discussions therein regarding killer whale taxonomy and population structure.

### Scientific basis for identification of subspecies

p. 26 – "Contradicting the scientific consensus in the cetacean's [sic] workshop, and without any support from the broader taxonomic community, the Service unilaterally created a killer whale subspecies – the North Pacific residents – based apparently on geographic distribution."

This statement is misleading. With regard to killer whale taxonomy, the taxonomy workshop report stated: "Overall, a majority of participants felt that the Resident- and Transient-type killer whales in the ENP probably merit at least species or subspecies status." (Reeves *et al.* 2004, p. 72). In addition, the BRT report discusses multiple lines of evidence both for and against sub-species, and clearly does not rely solely on geography (Krahn *et al.* 2004).

p. 26, 27 – The petition notes that NMFS has not provided a Latin trinomial for the hypothesized North Pacific Resident sub-species, and suggests that "... the Service has chosen to ignore 275 years of biological classification and taxonomic nomenclatural convention...". The issue of nomenclature was in fact explicitly discussed in the BRT report, which noted that all the biological issues surrounding the subspecies will need to be resolved before the nomenclature can be settled (Krahn *et al.* 2004, p. 18). In addition, the Cetacean Taxonomy Workshop report contains a section that specifically discusses unnamed subspecies, noting several examples and concluding that "Designation of unnamed subspecies can provide a mechanism for allowing recognition of highly differentiated forms without having to wait until its nomenclature is settled." (Reeves *et al.* 2004, p. 8). The Society for Marine Mammalogy also recognizes the residents and transients as unnamed subspecies of *O. orca* (Committee on Taxonomy 2012).

### Genetic data

The petition relies heavily on a recent paper, Pilot *et al.* (2010), that uses a variety of analyses to estimate rates of interbreeding among groups of killer whales (see section above for a summary of this paper). Much of the petition's discussion of this paper is misleading, misrepresenting both the results of the Pilot *et al.* study and how these results combine with the results of other studies to provide a more complete description of killer whale population structure.

p. 29 – "Pilot *et al.* (2010) reported that comparative assessments of kinship, parentage, and dispersal reveal high levels of kinship and male-mediated gene flow within local populations, including among ecotypes that are highly divergent within the mtDNA phylogeny."

Using the parentage and assignment methods the petition appears to prefer, Pilot *et al.* found a single putative instance of interbreeding (gene flow) between whales from different the Pacific ecotypes – an offshore whale that genetically assigned to the transient ecotype (Pilot *et al.* 2010 Appendix S3). They found no instances of putative interbreeding between the residents and transients or residents and offshores. We therefore disagree with petition's conclusion that Pilot *et al.* (2010) found "high levels" of male mediated gene flow among ecotypes. Another, larger study (in terms of whales sampled and loci genotyped) found no instances of interbreeding among ecotypes (Parsons *et al.* 2013).

p. 29 – "In contrast to the Service's insistence that its speculative unnamed North Pacific resident subspecies (and Southern Resident DPS) are genetically isolated, Pilot *et al.* (2010) show that they are not."

The 2004 BRT did not claim that the ecotypes were completely isolated, merely that there was a "… high degree of contemporary reproductive isolation…" (Krahn *et al.* 2004 p. 16). The petition's claims to the contrary, the Pilot *et al.* (2010) results show that there is at most rare and episodic contemporary gene flow between the transient and offshore ecotypes and no evidence of contemporary gene flow between the resident and offshore ecotypes or the resident and transient ecotypes. Using model fitting methods to estimate historical gene flow, Pilot *et al.* (2010) estimate that there has been low (generally < 1%) rates of gene flow among the ecotypes historically (see Table 5 of Pilot *et al.* 2010). These rates are consistent with the BRT's interpretation of a high degree of reproductive isolation, and are also consistent with the information available to the 2004 BRT when it made its evaluation (see Tables 4 and 5 of Hoelzel 2004).

p. 30 – "The significance of the findings of Pilot *et al.* (2010) is threefold.
First, they demonstrate with data that social interactions among killer whale pods do occur in the wild and they occur more frequently than has been reported (i. e., many interactions are simply "missed" by human observers who cannot watch a vast area of ocean to take note of killer whale pod interactions, 24 hours a day, 7 days a week, year round)."

Actually, Pilot *et al.* (2010) only studied patterns of genetic data, and contained no data or analysis of social interactions.

p. 30 – "The genetic data provide evidence that these inter-pod social interactions occur, and that they can and do result in mating among individuals in different pods, including mating among individuals of different ecotypes (i.e., between resident and transient killer whales)."

As we explain above, Pilot *et al.* (2010) found no direct evidence at all of mating between resident and transient killer whales (see Appendix S3 of Pilot *et al.*), and their indirect (model fitting) methods indicated that rates of gene flow between residents and transients were less than one half a percent (Table 5 of Pilot *et al.*). Pilot *et al.* did find somewhat higher rates of gene flow among resident populations (ie, within the resident ecotype), but even these were very low for all pairs of populations except between Russia and the Bering Sea and Bering Sea and Alaska: "In residents, very high gene flow rates were revealed from RU to BS (0.28) and from BS to AR (0.14), and much lower rates (ranging from 0.005 to 0.024) between other pairs of resident populations." (p. 26).

p. 33 – "Therefore, if only mtDNA is considered in an analysis, the loss of mtDNA variation in populations (also referred to as lineage sorting) can give an erroneous appearance of populations (and putative species) being genetically isolated because they are trying to maintain taxonomic differences (i.e., Morin *et al.* 2010) while at the same time ecotypes and populations are not isolated for nuclear genetic variation. This is precisely the case with killer whales, a fact the Service did not acknowledge in its 2005 listing of the killer whale DPS, or in its 2011 status review of the population."

There are multiple inaccuracies with this statement and the discussion of mtDNA patterns that surrounds it in the Petition. First, the BRT explicitly discussed the strengths and limitations of mitochondrial (maternal) and nuclear genetic markers (see pp. 22-23 of Krahn *et al.* 2002 and p. 16 of Krahn *et al.* 2004). Second, the statement seems to imply that North Pacific killer whales ecotypes and populations are not strongly differentiated at nuclear loci. This is simply not correct: Hoelzel *et al.* (2007), Pilot *et al.* (2010), Morin *et al.* (2010), and Parson *et al.* (2013) all describe patterns of microsatellite (nuclear) variation among populations, and all find significant levels of divergence consistent with generally low rates of gene flow (typically < 1 migrant/generation among ecotypes and very much less for some analyses). A preliminary version of one of these analyses (Hoelzel 2004) was discussed extensively by the 2004 BRT (Krahn *et al.* 2004 pp. 11-13).

With regard to 'lineage sorting' of mtDNA, this phenomena was explicitly considered by the BRT (see Krahn *et al.* 2002 p. 23 paragraph 3), who ultimately concluded that much of mtDNA variation among populations was in fact random and due to stochastic events. That conclusion, although reasonable at the time, must now be updated based on the new whole mitogenome data of Morin *et al.* (2010), which shows that when whole mitogenomes are considered patterns of mtDNA variation among killer whales are not at all random but instead are very highly correlated with ecotype. This new result, combined with the new nuclear data reported in the same paper and by Hoelzel *et al.* (2007), Pilot *et al.* (2010) and Parsons *et al.* (2013), in fact strengthens the original conclusion of the BRT that North Pacific killer whale ecotypes are highly reproductively isolated from each other.

p. 34 – "Thus, outbreeding occurs (particularly those in different ecotypes) but is limited by the frequency of interactions in the ocean, rather than by killer whales trying to maintain taxonomic or population isolation."

The implication that the only factor limiting interbreeding between resident killer whales and transient killer whales is infrequent opportunity for interactions in the ocean is not consistent with the available data. For example, both residents and transients are frequently observed in the Salish Sea, often on the same day and in the same general location but have never been observed to interact or socialize (Baird 2000). The ocean is indeed vast, but the resident and transient ecotypes have a primarily coastal distribution, have a long distance means of potentially locating each other through their acoustic calls, and are frequently sighted in the same general vicinity by human observers (see e.g. Table 2 of Zerbini *et al.* 2007). It therefore seems highly implausible that only lack of random encounters is limiting gene flow between ecotypes.

p. 35 – "Thus, the Service has erroneously attributed the patterns of genetic variation and behavior between ecotypes to genetic differences, when learned behaviors are responsible for these ecotypes."

It seems reasonable to conclude that "patterns of genetic variation" have a genetic basis. With regard to the behavioral and ecological differences among the ecotypes, the BRT never concluded that these traits were genetically based. For example, the 2004 BRT report summarized arguments for and against multiple species of North Pacific killer whales, and in the "Arguments for a single species" section noted: "Foraging specializations and other behavioral characteristics such as distinct vocalizations may be learned and therefore are not good indicators of species status (Barrett-Lennard and Heise 2004)." The BRT did consider the ecological, social and foraging differences among the ecotypes as one of several lines of evidence for subspecies status (Krahn *et al.* 2004, p. 39-40), but never claimed that these were genetically based characteristics. In discussing the factors leading to the conclusion that the southern resident killer whales are a DPS, the BRT discussed ecological setting, range, genetic differentiation, and behavioral and cultural diversity (Krahn *et al.* 2004 p. 44-45). In other words, in its DPS determination the BRT stated explicitly that it was considering behavioral and cultural factors in addition to genetic variation in assessing DPS status, consistent with USFWS and NMFS policy on DPS determination.

p. 36 – "In sum, there is no competent genetic evidence to support the designation of the North Pacific resident whale population as a subspecies."

At a minimum, this is a debatable point. Rates of contemporary gene flow have been estimated as zero between the residents and either the transient and offshore ecotypes (Pilot *et al.* 2010, Ford *et al.* 2011, Parsons *et al.* 2013). The three ecotypes can be unambiguously identified using either mtDNA or nuclear genetic data (Morin *et al.* 2010, Parsons *et al.* 2013) or photographs (Zerbini *et al.* 2007). These genetic differences are maintained in sympatry, a factor even biologists concerned about taxonomic inflation view as important evidence of taxonomic distinctiveness (Zachos *et al.* 2013). There is no question that there is some uncertainty regarding the taxonomic status of the North Pacific ecotypes and that it is possible for reasonable experts to come to somewhat different conclusions (see pp. 41 and 45 of Krahn *et al.* 2004, for example). But to conclude that there is "no competent genetic evidence" is inconsistent with the available information.

### Morphological data

p. 36 - 38 – "The Service fails to distinguish the difference between variation that is primarily due to environmental influences on development, such as body size, and variation that has a genetic basis." "In the listing decision, references to morphological differences that distinguish ecotypes are based upon studies that are anecdotal, qualitative, or pseudo-quantitative in nature (Baird & Stacey 1988; Baird 2000). There are no data to substantiate objectively actual distribution of these traits in the wild. There are no data to support the genetic basis for variation in these traits (e.g., body size, which is primarily influenced by environment rather than genetics in most mammals). Further, there are no data to support the presumption that the morphological differences in question have any functional significance (i.e., they confer a survival advantage to an ecotype). The Service's key morphological "evidence" to describe three ecotypes of killer whales in the 2005 listing rule is subjective, or involves incomplete qualitative comparisons, or both (Table 1)."

In fact, the 2004 BRT noted similar points in evaluating the morphological data (see Krahn *et al.* p. 38), and with the exception of the saddle patch pigmentation trait never claimed that the morphological differences among the ecotypes were necessarily genetically based or proven to be adaptive. Indeed, the criteria for subspecies designation suggested by Reeves *et al.* (2004) and used by the BRT do not require that morphological variation be proven to either genetically based or adaptive in order for it be used as one of several factors to delineate subspecies. It is also important to note that at the time of the status reviews in 2002-2004 (and even now) relatively little data were available for offshore killer whales.

Nonetheless, we agree with the petitioners that much of the information on morphological variation within and among the North Pacific ecotypes is qualitative in nature and would benefit from additional quantitative analysis. It is important to note, however, that the qualitative differences among the ecotypes that have been described are based on decades of field observations by biologists who have spent their entire careers studying killer whales. The BRT therefore felt comfortable including these descriptions as one of several lines of information related to potential taxonomic status. Subsequent to the 2004 BRT report, the analyses of Zerbini *et al.* (2007) indicates that at least when comparing multiple individuals of each ecotype the groups can be reliably distinguished on the basis of morphology.

p. 39 – "Saddle patches are another morphological trait used to treat the North Pacific resident whale population as a separate subspecies. Yet again there is substantial overlap among ecotypes, and the categories of patterns have been described differently by different authors. Evans *et al.* (1984) described three patterns, while Baird and Stacey (1988) described five. As shown in the line drawings from each paper on the following page (Evans *et al.* 1984; Baird and Stacey 1988), there is no overlap in the patterns, yet the Service relied on this subjective classification in its listing decision even in the absence of supporting data such as field notes, photographs, or measurements. Finally, the Service did not acknowledge another source of error in classifying saddle patch patterns: saddle patches are not always symmetrical. Therefore, different classifications can be obtained depending upon which side of the killer whale is photographed, leading to erroneous assignments."

The BRT did not use or cite the Evans *et al.* (1984) study, which was focused on patterns of killer whale pigmentation at a global scale and did not include ecotype information. The Baird and Stacey (1988) paper clearly cites the sources of the photographs they analyzed, which are from readily available publications. The publication also clearly stated that only photographs of the left side of the whales were used. The Petition speculates that right-hand-side photographs may produce different results, but provides no analysis to back up this statement.

p. 42 – "The Service fails to recognize the evolutionarily more parsimonious explanation that the behavioral traits it uses to distinguish among supposed subspecies or ecotypes are learned rather than the result of genetic differences."

As was noted above, the BRT reports never concluded that variation in vocalization or behavioral traits is genetically based.

p. 42-42 – "In a recent paper, Rehn *et al.* (2010) reported that a killer whale vocalization associated with high arousal behaviors is common to all killer whales and does not vary regardless of pod, ecotype, or location in the Pacific. Thus, this innate behavior is consistent with the killer whale's current classification as a single species"

The experimental design of the Rehn *et al.* (2010) paper was to examine isolated, non-interacting, groups of killer whales in order to find common and thus presumably innate call types. While the finding of such a call type certainly is consistent with the known evolutionarily recent common ancestry of the ecotypes, it is not strong evidence that they belong to a single species. Indeed, the Pacific ecotypes and killer whales worldwide share a great many traits due to common ancestry. For that matter, they share a great many traits in common with other delphinids. However, simply sharing traits is obviously not strong evidence that two putative taxa are conspecific or are not reproductively isolated. Humans and chimpanzees, for example, share ~99% of their genomes (Mikkelsen *et al.* 2005), but few would argue that they are not distinct species.

p. 48 – "An unbiased method would have used DNA amplification primers and reaction conditions capable of detecting types of potential prey other than just fish (i.e., marine mammals, birds, and squid). Such a method would use a pair of conserved DNA amplification primers for animals (i.e., 16sRNA), or combinations of primers that would amplify fish, marine mammals, birds, and squid, followed by application of culture independent methods (e.g., PCR, cloning of PCR products, and sequencing of the clone library). That would provide DNA sequences from virtually all animal DNAs in a sample, even if they are at low frequency. This method is widely used in microbial genomics and forensics, and is needed to detect total diversity of the prey items in the sample (Hugenholtz *et al.* 1998)."

The petition is correct that primers used in the Hanson *et al.* (2010) study were designed specifically to detect fish prey. This was in part to avoid amplifying DNA from the killer whales being sampled. However, another study (Ford *et al.* 2011b) did use 16s ribosomal DNA primers to obtain PCR amplicons from ~200 killer whale fecal samples collected from the southern resident population, including many of the same samples used in the Hanson (2010) study. These primers have been demonstrated to amplify both harbor seal and harbor porpoise, two common marine mammals preyed upon by transient killer whales. In controlled experiments in which harbor seal or harbor porpoise DNA was mixed with killer whale DNA and amplified and sequenced using these primers, the harbor porpoise and harbor seal sequences were readily detectable, along with that of killer whale. Using the same primers and methods, marine mammal sequences (other than killer whale) were not detected in any of the >200 fecal samples collected from the field (Hempelmann 2012).

## Editorial Notes

**Species Names:** The NEFSC Editorial Office's policy on the use of species names in all technical communications is generally to follow the American Fisheries Society's lists of scientific and common names for fishes, mollusks, and decapod crustaceans and to follow the Society for Marine Mammalogy's guidance on scientific and common names for marine mammals. Exceptions to this policy occur when there are subsequent compelling revisions in the classifications of species, resulting in changes in the names of species.

**Statistical Terms:** The NEFSC Editorial Office's policy on the use of statistical terms in all technical communications is generally to follow the International Standards Organization's handbook of statistical methods.

**Internet Availability:** This issue of the NOAA Technical Memorandum NMFS-NE series is being published both in hard copy and as a Web document in PDF format and can be accessed at: http://www.nefsc.noaa.gov/nefsc/publications/.

## PREFACE

The genesis of this report was a technical workshop held in Mystic, CT, on January 10-12, 2005 entitled "Workshop on Impacts to Coastal Fishery Habitat from Nonfishing Activities." The workshop and report were conceived by the Northeast Region Essential Fish Habitat Steering Committee which is composed of representatives from NOAA National Marine Fisheries Service Northeast Regional Office (NERO), NOAA National Marine Fisheries Service Northeast Fisheries Science Center (NEFSC), New England Fishery Management Council (NEFMC), Mid-Atlantic Fishery Management Council (MAFMC), and the Atlantic States Marine Fisheries Commission (ASMFC). The workshop was sponsored jointly by NOAA National Marine Fisheries Service, NEFMC and ASMFC.

The original intent of the workshop was to provide the necessary information to the NEFMC and MAFMC to assist them in updating the nonfishing impact analyses within their Fishery Management Plans as required by the Essential Fish Habitat (EFH) regulations. As work progressed, we realized that this information would be extremely useful to a much larger audience of agencies, consultants, and components of the public involved in marine and aquatic habitat assessment activities, and so this comprehensive report was developed. For this reason, the scope of impact assessment for this report was expanded to include a more general approach to coastal fishery habitat and is not limited to EFH. Our goal is to ensure that the best scientific information is available for use in making sound decisions with respect to the various environmental reviews and permitting processes conducted within the marine environment.

The comprehensive nature of this report required extensive collaboration among the authors, which includes NOAA National Marine Fisheries Service staff within the NERO Habitat Conservation Division and Headquarters Office of Habitat Conservation (OHC). We would like to thank the participants of the technical workshop who graciously provided their time and expertise towards identifying and assessing the range of impacts that threaten coastal resources in the northeast region of the United States (see appendix for list of participants). We would particularly like to thank the following individuals for their advice, time, and valuable assistance in the preparation and review of this report: Claire Steimle, Northeast Fishery Science Center (NEFSC) – Library Assistance; numerous staff of the NOAA Library; numerous reviewers, including Jen Costanza, Kathi Rodrigues, Dr. David Stevenson, and David Tomey– NOAA National Marine Fisheries Service, NERO; Jeanne Hanson – NOAA National Marine Fisheries Service, Alaska Regional Office; Joanne Delaney – NOAA National Marine Sanctuaries Program; and Ruth M. Ladd –US Army Corps of Engineers, New England District. In addition, we appreciate the advice provided by the technical and editorial reviewers at the NEFSC: Donna A. Busch, Dr. Jarita Davis, Dr. Ashok Deshpande, Dr. David Dow, Laura Garner, Dr. Jon Hare, Clyde L. MacKenzie, Jr., Donald G. McMillan, Dr. Thomas Noji, Dave Packer, and Dr. Robert Reid.

# GLOSSARY OF TERMS

| | |
|---|---|
| alevins | young salmonid fish distinguished by an attached yolk sac |
| alkalinity | the quantitative capacity of water to neutralize an acid |
| amnesic shellfish poisoning | caused by domoic acid, an amino acid, as the contaminant of shellfish |
| anadromous | migrating from the sea to fresh water to spawn |
| anoxia | complete absence of oxygen in aquatic habitats |
| anthropogenic | effects, processes, or materials that are derived from human activities |
| aquatic nuisance species | introduced (nonnative) organisms that produce harmful impacts on aquatic natural resources |
| autotrophic | a class of organism that produces organic compounds from carbon dioxide as a carbon source, by using either light or reactions of inorganic chemical compounds, as a source of energy; also known as a producer in a food chain |
| beach nourishment | the replacement of sand on an eroded beach from an outside source such as an offshore sand deposit, an inlet tidal delta, or an upland sand quarry |
| benthic | in or associated with the seafloor |
| benthos | organisms living on, in, or near the bottom of water bodies |
| bioaccumulation | the accumulation of substances, such as pesticides, methylmercury, or other organic chemicals in an organism or part of an organism |
| biocide | a chemical substance capable of killing different forms of living organisms (e.g., pesticide) |
| borrow pit | an excavation dug to provide material for fill elsewhere; used in aggregate or mineral mining and in beach nourishment |
| carcinogenic substance | cancer causing agent |
| catadromous | migrating from fresh water to the sea to spawn |
| climax community | a community of organisms the composition of which is more or less stable and in equilibrium with existing natural environmental conditions |

| | |
|---|---|
| creosote | a brownish oily liquid consisting chiefly of aromatic hydrocarbons obtained by distillation of coal tar and used especially as a wood preservative |
| cytolysis | the dissolution or destruction of a cell |
| demersal | dwelling at or near the bottom of a body of water |
| denitrification | the process of reducing nitrate and nitrite (highly oxidized forms of nitrogen available for consumption by many groups of organisms) into gaseous nitrogen |
| desalination | any of several processes that remove the excess salt and other minerals from water in order to obtain fresh water suitable for consumption or irrigation |
| diadromous | migratory between fresh and salt waters |
| diel | occurring on a daily basis, such as vertical migrations in some copepods and fish |
| dissolved oxygen | a measure of the amount of gaseous oxygen dissolved in an aqueous solution |
| echolocation | the biological sonar used by dolphins and whales for navigation and foraging |
| ecosystem | a natural unit consisting of all plants, animals, and microorganisms in an area functioning together with all the nonliving physical factors of the environment |
| endocrine disruptor | an exogenous (outside the body) agent that interferes with the production, release, transport, metabolism, binding, action, or elimination of natural hormones in the body responsible for the maintenance of homeostasis and the regulation of developmental processes |
| entrainment | the voluntary or involuntary movement of aquatic organisms from the parent water body into a surface diversion or through, under, or around screens, resulting in the loss of the organisms from the population |
| epibiota | attached plants and animals that settle and grow on natural or artificial surfaces |
| epipelagic | part of the open ocean comprising the water column from the surface down to approximately 200 meters |
| estrogenic substances | compounds that mimic female steroid hormones or inhibit male steroid hormones |

| | |
|---|---|
| eutrophication | enrichment of nutrients causing excessive plant growth that can reduce oxygen concentration and kill aquatic organisms |
| extirpate | to eliminate completely certain populations within the range of a given species |
| gas supersaturation | the overabundance of gases in turbulent water, such as at the base of a dam spillway, which can cause a fatal condition in fish |
| genotype | the genetic constituents in each cell of an organism |
| glacial till | an unsorted, unstratified mixture of fine and coarse rock debris deposited by a glacier |
| hardpan | a layer of hard subsoil or clay |
| headwater | the source of water for a river or stream |
| heterotrophic | a class of organism that requires organic substrates to get its carbon for growth and development; also known as a consumer in the food chain |
| hydrophobicity | the property of being water-repellent or tending to repel and not absorb water |
| hyperplasia | an increase in the number of the cells causing an organ or tissue to increase in size |
| hypersaline | salinity well in excess of that of sea water |
| hypertrophy | an increase in the size of an organ or in a select area of the tissue caused by an increase in the size of cells, while the number stays the same |
| hyporheic zone | saturated zone under a river or stream, composed of substrates with interstices filled with water |
| hypoxia | a low oxygen condition in aquatic habitats |
| ichthyoplankton | eggs and larvae of fish that drift in the water column |
| immunotoxicity | adverse effects on the functioning of the immune system that result from exposure to chemical substances |
| impingement | involuntary contact and entrapment of aquatic organisms on the surface of intake screens caused by the approach velocity exceeding the swimming capability of the organism |
| littoral zone | also called the intertidal zone, it lies between the high tide mark and the low tide mark |

| | |
|---|---|
| lotic | pertaining to running water, as opposed to lentic or still waters |
| macroinvertebrate | an animal lacking a backbone and visible without the aid of magnification |
| meroplankton | organisms that are planktonic for only a part of their life cycles, usually the larval stage |
| methylmercury | formed from inorganic mercury by the action of anaerobic organisms that live in aquatic systems and sediments; a bioaccumulative environmental toxin |
| mutagenic | agent causing genetic mutations |
| neurotoxic shellfish poisoning | shellfish poisoning caused by exposure to a group of polyethers called brevetoxins |
| oligohaline | brackish water with a salinity of 0.5 to 5.0 parts per thousand |
| organochlorides | a large, diverse group of organic compounds containing at least one covalently bonded chlorine atom, some of which are considered to be persistent organic pollutants and are harmful to the environment (e.g., PCB, DDT, chlordane, dioxins) |
| organometal | A member of a broad class of compounds whose structures contain both carbon and a metal (e.g., methylmercury and tetra-ethyl lead) - persistent and bioaccumulative environmental toxins |
| osmoregulation | the physiological mechanism for the maintenance of an optimal and constant fluid concentration and pressure in and around the cells |
| paralytic shellfish poisoning | caused by a group of toxins elaborated by planktonic algae (dinoflagellates, in most cases) upon which the shellfish feed |
| parr | developmental stage of young salmonid fish that follows the fry and lasts for one to three years in their native stream before becoming smolts |
| pelagic | associated with the water column |
| phytoplankton | microscopic plants that drift in the water column |
| planktivorous | feeding on plankton (e.g., most fish larvae and many pelagic fishes) |
| pycnocline | a layer of rapid change in water density with depth mainly caused by changes in water temperature and salinity |
| radionuclide | an atom with an unstable nucleus that can occur naturally but can also be artificially produced; also known as radioisotope |

| | |
|---|---|
| redd | an area in gravel where salmonids bury their eggs; also known as nests or gravel nests |
| reflective turbulence | changes in water velocity caused by wave energy reflection from solid structures in the nearshore coastal area, resulting in increased turbidity |
| riparian | land directly adjacent to a stream, lake, or estuary |
| salmonid | belonging to, or characteristic of the family salmonidae, which includes salmon, trout, and whitefish |
| sedimentation | the deposition by settling of suspended solids |
| siltation | sedimentary material consisting of very fine particles intermediate in size between sand and clay |
| smoltification | a suite of physiological, morphological, biochemical, and behavioral changes, including development of the silvery color of adults and a tolerance for seawater, that take place in young salmonid fish they prepare to migrate downstream and enter the sea |
| soil infiltration | the passage of water through the surface of the soil into the soil profile via pores or small openings |
| spermatogenesis | the process by which male gametes are formed in many sexually reproducing organisms |
| synergistic | combined effects being greater than the sum of individual effects |
| tailwater | an area immediately below a dam where the river water is cooler than normal and rich in nutrients |
| tannins | astringent, plant polyphenol compounds that bind and precipitate proteins; used in manufacturing inks and dyes |
| thermocline | a vertical temperature gradient in some layer of a body of water that is appreciably greater than the gradients above and below it |
| time-of-year restrictions | seasonal constraints for dredging to avoid or minimize impacts of sensitive periods in the life-history of an organism, such as spawning, egg development, and migration |
| tonne | sometimes referred to as a metric tonne, the measurement of mass equal to 1,000 kilograms |
| trophic level | the position that an organism occupies in a food chain |

| | |
|---|---|
| turbidity | the cloudiness or haziness of water caused by individual particles or suspended solids |
| volitional fish passage | any type of structure that provides fish passage over, through, or around an obstruction in a river or stream (e.g., dam) that can be successfully achieved under the fish's own power (as opposed to trap and truck methods) |
| xenobiotic | a chemical which is found in an organism but which is not normally produced or expected to be present in it (e.g., pollutants, such as dioxins or PCB congeners) |

# INTRODUCTION

## Report Purpose

This report stems from a workshop entitled "Technical Workshop on Impacts to Coastal Fishery Habitat from Nonfishing Activities," which was held January 10 – 12, 2005 in Mystic, CT. The workshop convened a group of experts in the field of environmental, marine habitat, and fisheries impact assessment from federal and state government agencies. The goals of the workshop were to: (1) describe known and potential adverse effects of human induced, nonfishing activities on fisheries habitats; (2) create a matrix of the degree of impacts associated with various activities in riverine, estuarine, and marine habitats; and (3) develop a suite of best management practices (BMPs) and conservation recommendations that could be used to avoid or minimize adverse impacts to fisheries habitats. Refer to Chapter One-Technical Workshop on Impacts to Coastal Fisheries Habitat from Nonfishing Activities, for a detailed summary of the technical workshop.

The general purpose and goals of this report are to:

1. Identify human activities that may adversely impact Essential Fish Habitat (EFH) and other coastal fishery habitat. As Stevenson et al. (2004) characterized the impacts to EFH from fishing activities in the northeast region, the focus of this report is on nonfishing activities.
2. Review and characterize existing scientific information regarding human-induced impacts to EFH and other coastal fishery habitat.
3. Provide BMPs and conservation measures that can be implemented for specific types of activities that avoid or minimize adverse impacts to EFH and other coastal fishery habitat.
4. Provide a comprehensive reference document for use by federal and state marine resource managers, permitting agencies, professionals engaged in marine habitat assessment activities, the regulated community, and the public.
5. Ensure that the best scientific information is available for use in making sound decisions with respect to project planning, environmental assessment, and permitting.

The National Oceanic and Atmospheric Administration's (NOAA) National Marine Fisheries Service is mandated to protect and conserve fishery resources, an activity which includes engaging in consultation with federal agencies on actions that may adversely affect NOAA's trust resources. It is anticipated that the information in this report will be used to assist federal agencies and their consultants in the preparation of impact assessments for EFH and other NOAA's trust resources. In addition, this report will assist National Marine Fisheries Service habitat specialists in: (1) reviewing proposed projects; (2) considering potential impacts that may adversely affect NOAA's trust resources; and (3) providing consistent and scientifically supported conservation recommendations. This report will also provide insight for the public and the regulated community on the issues of concern to National Marine Fisheries Service along with approaches to design and implementation of projects that avoid and minimize adverse effects to fish habitat.

## Organization of the Report

The document is organized by activities that may potentially impact EFH and other fishery habitat occurring in riverine, estuarine/coastal, and marine/offshore areas. Chapter One describes the technical workshop that was conducted and presents the results of those discussions and habitat impact evaluations. The major activities that were identified as impacting these three habitat areas include:

- coastal development
- energy-related activities
- alteration of freshwater systems
- marine transportation
- offshore dredging and disposal
- physical and chemical effects of water intake and discharge facilities
- agriculture and silviculture
- introduced/nuisance species and aquaculture
- global effects and other impacts

Each subsequent chapter characterizes impacts associated with the major activities listed above. Each chapter describes the adverse effects of various activities on fishery habitat and the species associated with those habitats, provides the scientific references to support those findings, and concludes with best management practices or conservation recommendations that could be implemented to avoid or minimize those particular adverse effects. Although the activities and effects identified in the technical workshop are reflected in the appropriate chapter, the reader may notice some minor variation in the order and content if the chapter author(s) failed to locate information in the literature on a specific topic or believed additional discussion of effects were warranted. The preparers of this report have attempted to summarize the current knowledge of impacts and effects from existing and potential activities in the coastal areas of the northeast region of the United States. However, the reader should not consider the information in the report as comprehensive for all activities and impacts on fishery habitats. For more detailed analyses and understanding, the reader should refer to the cited references and the most current literature regarding specific activities and impacts.

The BMPs and conservation measures provided in this report are designed to minimize or avoid the adverse effects of human activities on fishery habitat and to promote the conservation and enhancement of fishery habitat. The BMPs and conservation measures provided in this report reflect many of the conservation principals recommended in Hanson et al. (2003). These general principles include: (1) nonwater-dependent actions should not be located in fishery habitat if such actions may have adverse impacts on those resources; (2) activities that may result in significant adverse affects on fishery habitat should be avoided where less environmentally harmful alternatives are available; (3) if alternatives do not exist, the impacts of these actions should be minimized; and (4) environmentally sound engineering and management practices should be employed for all actions that may adversely affect fishery habitat.

The conservation measures and BMPs included with each activity present a series of practices or steps that can be undertaken to avoid or minimize impacts to fishery habitats. Not all of these suggested measures are applicable necessarily to any one project or activity that may adversely affect habitat. More specific or different measures based on the best and most current scientific information may be developed as part of the project planning or regulatory processes. The conservation recommendations and BMPs provided represent a generalized menu of the types of measures that can contribute to the conservation and protection of fishery habitat and other coastal aquatic habitats.

The final chapter contains a brief discussion of the purpose and application of compensatory mitigation used to offset adverse effects on fishery habitat. We have chosen to include a discussion on compensatory mitigation in its own chapter because its application is not generally considered a best management practice or a recommendation to conserve fishery habitat. Instead, compensatory mitigation is a method of offsetting adverse effects after they have occurred. For that reason, compensatory mitigation should be considered only after all measures to avoid and then minimize impacts have been exhausted. Compensatory mitigation should never be used as a first-line conservation measure.

Some of the impact types described in one chapter may also be found in other chapters containing similar impacts or activities. Therefore, the reader may find some redundancy in the various chapters. Because the report's focus was to describe the impacts to living marine resources and habitats associated with specific anthropogenic activities and often have similar adverse affects on living marine resources, some redundancy in the descriptions of impacts between various chapters was unavoidable.

## Characterization of Habitat in the Northwest Atlantic Ocean

The general focus of this report pertains to effects on marine, estuarine, and diadromous fishes and their habitats. However, the preparers of the report have attempted to provide a broad perspective of coastal aquatic habitat and the organisms that depend upon those habitats in an ecosystem context. Although the report often refers to "fishery habitat" or "fish," the definitions of these resources should not necessarily be limited to any particular regulatory or management mandate, such as EFH. The authors have attempted to include information on known or potential impacts that may affect the ecological functions and values for habitats for all species of fish and invertebrates. Because the focus of this report is on impacts to fish and fishery habitats, we have included only limited discussions on impacts specific to marine mammals and sea turtles.

Habitats provide living things with the basic life requirements of nourishment and shelter (Stevenson et al. 2004). According to Deegan and Buchsbaum (2005), a habitat includes the physical environment, the chemical environment, and the many organisms that compose a food web. This report employs a similarly broad definition to discuss the multitude of adverse effects on habitats in the coastal northeastern United States. For example, the quality of the water in which aquatic organisms live, feed, and reproduce is a facet of their habitat, and the presence of contaminants or alterations to the water has important implications on the health of those organisms. Habitats may also provide a broader range of benefits to the ecosystem, such as the way seagrasses physically stabilize the substrate and help recirculate oxygen and nutrients (Stevenson et al. 2004). These habitats do not exist in isolation but are linked through ecological and oceanographic processes that are a part of the larger ecosystem. For example, the movement of the water plays a major role in the interconnection of habitats by transporting nutrients, food, larvae, sediments, and pollutants among them (Tyrrell 2005).

The northwest Atlantic Ocean includes a broad range of habitats with varying physical and biological properties extending from the cold waters of the Gulf of Maine south to the more temperate climate of the Mid-Atlantic Bight. In this region, the oceanographic and physical processes interact to form a network of expansively to narrowly distributed habitat types (Stevenson et al. 2004). The offshore component of this region, also known as the Northeast US Continental Shelf Ecosystem (Sherman et al. 1996), is composed of four distinct subregions: the Gulf of Maine, Georges Bank, the Mid-Atlantic Bight, and the continental slope (Stevenson et al. 2004). In addition, the region contains freshwater rivers and streams that flow towards the sea into numerous bays and estuaries that serve as important refuge and nursery areas for marine species. This report focuses on the three major systems composing this ecosystem: riverine, estuarine/nearshore, and marine/offshore environments.

The habitat classifications described by Jury et al. (1994) and adopted by NOAA as a national standard for organizing its Estuarine Living Marine Resources (ELMR) program's database are useful because they facilitate consideration of physico-chemical interactions in water quality and habitat impacts and implications for aquatic organisms. Conveniently, this approach also aligns with ambient suspended sediment and particulate loads because maximum turbidity zones of temperate, well-mixed estuaries typically coincide with low salinity regions (Herman and Heip 1999). Accordingly, this report has used the three ELMR salinity ranges developed for coastal aquatic habitats to describe "riverine" (<0.5 ppt), "estuarine/nearshore" (0.5-25.0 ppt), and "marine/offshore" (>25.0 ppt) conditions.

## *Riverine*

Riverine habitats, located along the coast of New England and the Mid-Atlantic, provide essential habitat to anadromous and catadromous ("diadromous") fishes. These habitats include freshwater streams, rivers, streamside wetlands, and the banks and associated vegetation that may be bordered by other freshwater habitats (NEFMC 1998). Depending upon the local water velocity and other physical characteristics, riverine systems may include a variety of benthic substrates ranging from exposed bedrock, cobble, and other hard bottom types to extremely unconsolidated, soft bottom material. These features have a great bearing on the fish and invertebrate species that may be present.

Riverine habitats serve multiple purposes including migration, feeding, spawning, nursery, and rearing functions. An important component of a river system also includes the riparian corridor. The term "riparian" refers to the land directly adjacent to a stream, lake, or estuary. A healthy riparian area has vegetation supporting prey items (e.g., insects); contributes necessary nutrients; provides large woody debris that creates channel structure and cover for fish; and provides shade, which controls stream temperatures (NEFMC 1998).

## *Estuarine/nearshore*

Estuaries are the bays and inlets influenced by both the ocean and rivers that serve as the transition zone between fresh and salt water. In the northeastern United States, they also may include the substantial inland reaches of large river systems where salinities exceed 0.5 ppt. For instance, ocean tides influence the lower 153 miles of the Hudson River, and oligohaline salinities (0.5 pp – 5 ppt) can extend well inland under low flow conditions. Typically, the northernmost intrusion of brackish water does not extend past the city of Poughkeepsie, nearly 75 miles north of The Battery at the southern tip of Manhattan, NY.

Estuaries support a community of plants and animals that are adapted to the zone where fresh and salt waters mix. Estuarine habitats fulfill fish and wildlife needs for reproduction, feeding, refuge, and other physiological necessities (NEFMC 1998). Coastal and estuarine features such as salt marshes, mud flats, rocky intertidal zones, sand beaches, and submerged aquatic vegetation are critical to inshore and offshore habitats and fishery resources of the northeastern United States (Stevenson et al. 2004). For example, healthy estuaries include eelgrass beds that protect young fish from predators, provide habitat for fish and wildlife, improve water quality, and can help stabilize sediments. In addition, mud flats, high salt marshes, and saltmarsh creeks also provide productive shallow water habitat for epibenthic fishes and decapods. Inshore habitats are dynamic and heterogeneous environments that support the majority of marine and anadromous fishes at some stage of development (NEFMC 1998).

### *Marine/offshore*

The Gulf of Maine is an enclosed coastal sea, characterized by relatively cold waters and deep basins with a patchwork of various sediment types. Georges Bank is a relatively shallow coastal plateau that slopes gently from north to south and has steep submarine canyons on its eastern and southeastern edge. It is characterized by highly productive, well-mixed waters and strong currents. The Mid-Atlantic Bight is composed of the sandy, relatively flat, gently sloping continental shelf from southern New England to Cape Hatteras, NC. The continental slope begins at the continental shelf break and continues eastward with increasing depth until it becomes the continental rise. It is fairly homogenous, with exceptions at the shelf break, some of the canyons, the Hudson Shelf Valley (offshore New York), and areas of glacially rafted hard bottom (Stevenson et al. 2004).

The offshore benthic habitat features include sand waves, shell aggregates, gravel beds, boulder reefs, and submerged canyons which provide nursery areas for many fish species (NEFMC 1998). Many marine organisms inhabit the stable offshore environment for multiple stages of their life history.

## Essential Fish Habitat

In 1996, the US Congress declared that "one of the greatest long-term threats to the viability of the commercial and recreational fisheries is the continuing loss of marine, estuarine, and other aquatic habitats. Habitat considerations should receive increased attention for the conservation and management of fishery resources of the United States" (Magnuson-Stevens 1996, sec. 2.a.9.). Along with this declaration, Congress added new habitat conservation provisions to the Magnuson-Stevens Fishery Conservation and Management Act (MSA), the federal law that governs US marine fisheries management. The MSA requires that fishery management plans describe and identify essential fish habitat, minimize adverse effects on habitat caused by fishing, and identify other actions to encourage the conservation and enhancement of such habitat. Essential fish habitat has been defined as "those waters and substrate necessary to fish for spawning, breeding, feeding, or growth to maturity" (Magnuson-Stevens 1996, sec. 3.10.).

The MSA also requires federal agencies to consult with the Secretary of Commerce, acting through the NOAA's National Marine Fisheries Service, on all actions authorized, funded or undertaken, or proposed to be authorized or undertaken by the agency, that may adversely affect EFH. The process developed for conducting these EFH consultations is described in the EFH regulations (50 CFR §600.905 – 920). In summary, federal agencies initiate consultation by preparing and submitting an EFH assessment to the National Marine Fisheries Service that describes the action, analyzes the potential adverse effects of the action on EFH, and provides the agency's conclusions regarding the effects of the action on EFH. In response, the National Marine Fisheries Service provides the agencies with conservation recommendations to conserve EFH by avoiding, minimizing, mitigating, or otherwise offsetting the adverse effects to EFH. Adverse effect is defined as any impact which reduces the quality and/or quantity of EFH. Adverse effects may include direct or indirect physical, chemical, or biological alterations of the waters or substrate and loss of or injury to benthic organisms, prey species, and their habitat and other ecosystem components. Adverse effects may be site-specific or habitat-wide, including individual, cumulative, or synergistic consequences of actions [50 CFR §600.910(a)]. This broad definition of adverse effects has been employed in this report to describe the various activities and sources of nonfishing impacts that can degrade fisheries habitat.

Once the National Marine Fisheries Service provides conservation recommendations, the federal action agencies must provide a detailed response in writing to the Nationial Marine Fisheries Service. The response must include measures proposed for avoiding, mitigating, or offsetting the impact of a proposed activity on EFH. If the federal action agency chooses not to adopt National Marine Fisheries Service's conservation recommendations, it must explain its reasons for not following the recommendations.

## Impacts to Habitat

Habitat alteration and disturbance occur from natural processes and human activities. Deegan and Buchsbaum (2005) placed human impacts to marine habitats into three categories: (1) permanent loss; (2) degradation; and (3) periodic disturbance. Permanent loss of habitat can result from activities such as wetland filling, coastal development, harbor dredging, and offshore mining operations (Robinson and Pederson 2005). Habitat degradation may be caused by physical changes, such as increased suspended sediment loading, overshadowing from new piers and wharves, as well as introduction of chemical contamination from land-based human activities (Robinson and Pederson 2005). Periodic disturbances are created by activities such as trawling and dredging for fish and shellfish and maintenance dredging of navigation channels.

The primary differences between these three categories are that permanent loss is irreversible, habitat degradation may or may not be reversible, and periodic disturbance is generally reversible once the source of disturbance is removed (Deegan and Buchsbaum 2005). These authors indicate that recovery times for degraded habitat depend on the nature of the agent causing the degradation and the physical characteristics of the habitat. Recovery times for periodic disturbances will vary depending on the intensity and periodicity of the disturbance and the nature of the habitat itself. Natural fluctuations in habitats, such as storms and long-term climatic changes, occur independently of anthropogenic impacts.

Deegan and Buchsbaum (2005) state that "habitat quantity is a measure of the total area available, while habitat quality is a measure of the carrying capacity of an existing habitat." Generally, activities that lead to a permanent loss of habitat reduce the quantity of habitat, whereas habitat degradation and periodic disturbances result in a loss of habitat quality. The reduced quality of habitat (e.g., siltation, eutrophication, and alteration of salinity and food webs) may be equally damaging to the biological community as a loss in habitat quantity. As Deegan and Buchsbaum (2005) have noted, "the physical structure of the habitat does not need to be directly altered for negative consequences to occur." For example, reductions in water quality can impair and limit the ability of aquatic organisms to grow, feed, and reproduce.

The end point of gradual declines in the quality of habitat can be the complete loss of habitat structure and function (Deegan and Buchsbaum 2005). Losses of habitat quantity and quality may reduce the ability of a region to support healthy and productive fish populations. From the population perspective, the loss of habitat quantity and quality creates stresses on a population. Populations that are stressed by one or more factors can be more susceptible to stresses caused by other factors (Robinson and Pederson 2005), resulting in cumulative effects. These authors call for a holistic approach to fishery management: one that considers the interactions among exploitation, contaminants, and habitat degradation on various fish stocks.

Lotze et al. (2006) show that severe depletion of marine resources (i.e., 50% reduction in abundance level) first began with the onset of European colonization. This study found that 45% of species depletions and 42% of extinctions involved multiple human impacts, mostly exploitation and habitat loss. Seventy eight percent of resource recoveries are attributed to both habitat protection and restricted exploitation, while only 22% of recoveries are attributed to reduced exploitation alone (Lotze et al. 2006). These authors also conclude that reduced exploitation, increased habitat protection, and improved water quality need to be considered together and that the cumulative effects of multiple human interventions must be included in both management and conservation strategies.

# CHAPTER ONE: TECHNICAL WORKSHOP ON IMPACTS TO COASTAL FISHERIES HABITAT FROM NONFISHING ACTIVITIES

## Introduction

A technical workshop was hosted by the Northeast Region Essential Fish Habitat Steering Committee on January 10-12, 2005 in Mystic, CT, to seek the views and recommendations of approximately 40 scientists, resource managers, and other marine resource professionals on threats to fishery habitat from nonfishing activities in the northeast coastal region. The participants of the workshop, entitled *Technical Workshop on Impacts to Coastal Fishery Habitat from Nonfishing Activities*, were federal and state environmental managers and regulators, as well as individuals from academic institutions and other organizations that have expertise and knowledge of various human-induced impacts on coastal environmental resources. A list of workshop participants and their affiliations is provided in the appendix of this report. The workshop's primary purpose was to convene marine resource professionals to review and evaluate existing information on nonfishing impacts for the purpose of updating, as necessary, fishery management plans under the New England and Mid-Atlantic Fishery Management Councils. In addition, the National Marine Fisheries Service sought to develop a nonfishing impacts reference document for use by professionals engaged in marine habitat assessment, permitting agencies, and state and federal marine resource managers. The information gathered during the workshop was used by the Northeast Region's Habitat Conservation Division staff to prepare selected chapters in the report. In general, the activities and effects contained within the various chapters of this report reflect the categories of activities and effects evaluated and discussed during the workshop.

The specific goals/tasks of the workshop included:

1. Identify all known and potential adverse effects for each category of nonfishing activity by life history strategies or stages (i.e., benthic/demersal and pelagic) and ecosystem strata (i.e., riverine, estuarine, and marine). This list of activities may also include adverse impacts to identified prey species or other specific life history requirements for species.
2. Create a matrix of nonfishing impacts for life history strategies/stages and ecosystem strata and ask the participants of the workshop to score the severity of each impact by using a relative scoring method.
3. Develop a suite of conservation measures and best management practices (BMPs) intended to avoid and minimize the adverse effects on fishery habitat and resources.
4. Identify possible information and data limitations and research needs in assessing impacts on fishery habitat or measures necessary to avoid and minimize those impacts.

Conservation measures were, to the extent possible, based on methods and technologies that have been evaluated through a scientific, peer-reviewed process. The intent was to develop recommendations that provide resource managers and regulators with specific methods and technologies yet have flexibility in their applications for various locations or project types. Ideally, providing a suite of conservation measures appropriate for various activities would give the end user several options of recommendations to consider.

Based upon the results of the workshop and effects scoring, some recommended research needs were developed. Identified research needs included basic life history requirements for some species and habitat types, physiological and biochemical responses of organisms to various physical and chemical perturbations and stressors, and technological advances in understanding or solutions to impact assessment and mitigation. Refer to the Conclusions and Recommendations chapter at the end of this report for a discussion on recommended research.

The format of the two-day workshop consisted of a series of breakout sessions, attended by the workshop participants, which represented the primary categories of nonfishing activities believed to threaten fishery resources and habitats in the northeast coast. There were ten separate breakout sessions conducted during the workshop, which are reflected in the chapters of this report. For each of the breakout sessions, a matrix of activities and known or potential adverse effects to fishery habitat, prepared by the workshop organizers, was reviewed by the workshop participants. The participants were encouraged to openly discuss and evaluate the relevance and significance for each of the activities and effects and to provide any additional activities and effects not included in the matrix. A large number of nonfishing activities occur within the coastal region and have a wide range of effects and intensities on fishery habitat. Each activity type and effect identified was evaluated in the context of life history strategies or stages (i.e., benthic and demersal) and ecosystem type or strata (i.e., riverine, estuarine/nearshore, and marine/offshore), in order to identify the importance of those factors. Following an open discussion, the participants were asked to score, by life history strategies/stages and ecosystem strata, the various activities and adverse effects on the impact matrix. In addition, participants were asked to include specific and relevant "conservation recommendations" and BMPs to avoid and minimize adverse effects to fishery habitat and resources.

On the last day of the workshop, the participants engaged in an informal discussion on the significance of cumulative effects and how multiple and additive effects can influence impacts to fishery habitat and resources. While the discussions were general in nature and few specifics of cumulative effects were discussed, there was a general agreement that cumulative effects are important and should play a larger role in assessment of habitat impacts. We found that the scores provided by the participants in the impact matrices for most breakout sessions to be relatively consistent throughout. While the variability in scores for some impact categories was high, we believe that the mean and median values for most effects' scores provide an accurate reflection of professional judgment by the participants. The relatively high variability in the scores of some activity types and effects may be due to varying interpretations of ecosystem strata and life history strategies or stages by the participants.

## Effects Scoring System

Because one workshop goal was to assess the severity or degree of threat for known and potential impacts to fishery habitats, the workshop organizers strived to develop a semiquantitative scoring system that could measure the relative impacts for each activity and effect based upon the professional judgment of the participants. Developing defined values for measuring the significance of adverse effects for an activity is difficult and can depend upon the type of habitat being affected; the characteristic, intensity, and duration of the activity and disturbance; and a number of natural physical, chemical, and biological processes that may be occurring in the area and at the time of the activity. For this reason, the workshop organizers chose a semiquantitative scoring system with a range from 0 to 5, with a 1 being the lowest impact and a 5 being the highest impact. A "0" was used if an impact is not expected to occur or is not applicable, and a "UN" (unknown) was used if the participant does not know the degree of impact for a particular activity.

We believe that a relative scoring method that allows for flexibility and professional judgment in assigning a value for an effect is better than an absolute scoring system that has discreet and predefined values. Using a relative scoring range of 0 through 5 provided the participants a choice from a continuum of impact values for each effect and avoids the difficulty in finding consensus for the definition of predefined values. We then calculated the mean and median values of each effect and assigned a qualitative value of the threat for each effect by using the following criteria:

If either the mean or median value was greater than or equal to 4.0, a “high” index score was assigned; if the mean value was between 2.1 and 3.9, a “medium” index score was assigned; and if the mean value was less than or equal to 2.0, a “low” index score was assigned.

Note: We defined the “high” index score to include either mean or median values in order to be risk averse in identifying activities that are known to be or may be a potentially high threat. Only mean values were used in assessing “medium” and “low” index scores.

## Workshop Summary

The results of the workshop scoring in each session are listed in Table 1 through 10. “High,” “medium,” and “low” index scores are notated as H, M, and L, respectively. As might be expected, there were positive correlations between the highest scoring effects and the ecosystem types in which those activities generally occur. For example, the high scoring effects in the alteration of freshwater systems and agriculture and silviculture sessions were generally all in the riverine ecosystem. Except for the offshore dredging and disposal session, there were fewer effects that were scored high in the marine/offshore ecosystem compared to the riverine and estuarine/nearshore ecosystems. This suggests the participants viewed the intensity of effects from nonfishing impacts to decrease as the distance from the activity increases. As one might expect, many of the far field effects that scored high were those activities that affect the water column (e.g., ocean noise, impacts to water quality) or effects that are capable of being transported by currents (oil spills or drilling mud releases). In addition, the global effects and other impacts session had high scores more evenly distributed across all ecosystems because of the nature of the impacts discussed in this session (e.g., climate change, atmospheric deposition, ocean noise). The number of activities and threats identified in the coastal development session were greater than other sessions because of the cross cutting nature of activities associated with human coastal development. Because of this, some activity types and effects assessed in the coastal development session were discussed to some degree in other sessions.

Some sessions had index scores with relatively high variability. For example, the scores for all activity types of the offshore dredging and disposal session had relatively low mean values and high standard deviations for effects in the estuarine/nearshore ecosystem. About half of the participants in this session either did not provide a score for impacts in the riverine or estuarine/nearshore ecosystems, or they marked them as “not-applicable.” Participants who provided a score for these two ecosystems generally scored them relatively high. This suggests a difference in participants’ interpretation of where “offshore” activities are located. Specifically, some individuals may consider the “offshore” area to be within close enough proximity of the nearshore and estuarine environments to adversely affect these areas, while others may perceive the “offshore” area to be too far removed to have a noticeable effect. There were activities in other sessions, such as beach nourishment in coastal development, with scores with high standard deviations. The high variability in perceived threats may be a reflection of regional perspectives. While the majority of the participants involved in this workshop were from the New England region, about one-quarter of the participants were from the mid-Atlantic or southeast regions where beach nourishment projects are much more common. The associated impacts to benthic habitats from beach nourishment are also generally thought to be greater in the New England (where cobble or hard bottom habitats may be present) and south Atlantic (where live bottom habitats may be present) regions than in the mid-Atlantic. However, because the responses of the workshop participants were anonymous, it was not possible to test this hypothesis.

Many of the effects that were scored as high in the workshop sessions were those that are well documented in the literature as having adverse effects on coastal resources. For example, nutrient enrichment and siltation/sedimentation effects were scored as high in nearly all workshop sessions, demonstrating the widely accepted views that these impacts translate to general reductions in the quality and quantity of fishery resources and habitats. Some of the more unexpected results of the workshop session scores are those effects that had high mean and/or median values but may be a topic that does not have a wealth of research documenting those impacts. Some of these results may be based upon a collective judgment by the participants that these activities or effects require additional scientific investigations to resolve the perceived risks and concerns. In several of these effects or activities, the authors of the associated report chapters were unable to locate information in the scientific literature regarding those threats. For example, release of pharmaceuticals and endocrine disruptors were two effects that were scored high in the workshop session, and yet the potential scope and intensity of adverse effects that these chemicals have on fishery resources has not been thoroughly investigated.

Those activities and effects considered by the workshop participants to have “high” threats to fishery habitat warrant further investigations, including research in characterizing and quantifying these impacts on fishery resources, as well as investigating methods for avoiding and/or minimizing the impacts. Refer to the Conclusions and Recommendations chapter for further discussions regarding the workshop results.

**Table 1. Habitat impact categories in coastal development workshop session (N=14)**

| Activity Type | Potential Effects | Habitat Impact Categories | | | | | |
|---|---|---|---|---|---|---|---|
| | | Life History/Ecosystem Type | | | | | |
| | | Benthic/Demersal Stages | | | Pelagic Stages | | |
| | | Riverine | Estuarine/ Nearshore | Marine/ Offshore | Riverine | Estuarine/ Nearshore | Marine/ Offshore |
| Nonpoint Source Pollution and Urban Runoff | Nutrient loading/eutrophication | H | H | M | H | H | M |
| | Loss/alteration of aquatic vegetation | H | H | L | H | H | L |
| | Release of petroleum products | M | M | M | M | M | M |
| | Alteration of water alkalinity | M | M | L | M | M | L |
| | Release of metals | H | H | M | M | H | M |
| | Release of radioactive wastes | M | M | L | M | M | L |
| | Release of pesticides | H | H | M | H | H | M |

# CHAPTER TWO: COASTAL DEVELOPMENT

## Introduction

Urban growth and development in the United States continues to expand in coastal areas at a rate approximately four times greater than that in other areas of the country (Hanson et al. 2003). Although loss of coastal wetlands to development has decreased in the last several decades, the percentual rate of loss has remained similar to that of the 1920-1950 periods (Valiela et al. 2004). Rate of loss of coastal wetlands was estimated to be 0.2% per year from 1922-1954, while loss rates from 1982-1987 were approximately 0.18% per year (Valiela et al. 2004). The construction of urban, suburban, commercial, and industrial centers and corresponding infrastructure results in land use conversions that typically remove vegetation and create additional impervious surface. At least one study has correlated ecosystem-level changes with the addition of impervious surfaces in coastal, urbanized areas. Holland et al. (2004) found reduced abundance of stress-sensitive macroinvertebrates and altered food webs in headwater tidal creeks when impervious cover exceeded 20-30% land cover. In fact, measurable adverse changes in the physical and chemical environment were observed when the impervious cover exceeded 10-20% land cover (Holland et al. 2004). Runoff from impervious surfaces and storm sewers is the most widespread source of pollution into the nation's waterways (USEPA 1995).

This chapter discusses the various sources of anthropogenic pollution, as well as other impacts to fishery habitat associated with coastal development. This report has employed the broad definition of adverse effect provided in the essential fish habitat (EFH) regulations to include "direct or indirect physical, chemical, or biological alterations of the waters or substrate and loss of, or injury to, benthic organisms, prey species and their habitat, and other ecosystem components." (50 CFR § 600.810). For this reason, impacts to the health and physiology of the fishery resources from physical, chemical, and biological factors are included. There are a number of impacts discussed in this chapter that overlap to some degree with those in other chapters of this report. We have attempted to minimize redundant information, and references to other chapters are provided when the topic has been treated in more detail elsewhere in the report.

## Discharge of Nonpoint Source Pollution and Urban Runoff

The major threats to marine and aquatic habitats are a result of increasing human population and coastal development, which contribute to an increase in anthropogenic pollutant loads. These pollutants are released into estuarine and coastal habitats by way of point and nonpoint source discharges.

The US Environmental Protection Agency (US EPA) defines "nonpoint source" as anything that does not meet the legal definition of "point source" in section 502(14) of the Clean Water Act, which refers to "discernable, confined and discrete conveyance" from which pollutants are or may be discharged (for discussions of point source pollution and discharges, see the chapters on Chemical Effects: Water Discharge Facilities and Physical Effect: Water Intake and Discharge Facilities). Nonpoint source (NPS) pollution comes from many diffuse sources. Land runoff, precipitation, atmospheric deposition, seepage, and hydrologic modification are the major contributors to NPS pollution. The general categories of NPS pollution are: sediments, nutrients, acids and salts, metals, toxic chemicals, and pathogens. While all pollutants can become toxic at high enough levels, a number of compounds can be toxic at relatively low levels. The US EPA has identified and designated these compounds as "priority pollutants." Some of these "priority pollutants" include: (1) metals, such as cadmium, copper, chromium, lead, mercury, nickel, and zinc that arise from industrial operations, mining, transportation, and agriculture use; (2) organic compounds, such as pesticides, polychlorinated biphenyl (PCB) congeners, solvents, petroleum hydrocarbons, organometallic compounds, phenols, formaldehyde, and biochemical methylation of metals in aquatic sediments; (3) dissolved gases, such as chlorine and ammonium; (4) anions, such as cyanides, fluorides, sulfides, and sulphates; and (5) acids and alkalis (USEPA 2003a).

While our understanding of the individual, cumulative, and synergistic effects of all contaminants on the coastal ecosystem are incomplete, pollution discharges may cause organisms to be more susceptible to disease or impair reproductive success (USEPA 2005). Although the effects of NPS pollution are usually lower in severity than are those of point source pollution, they may be more widespread and damaging to fish and their habitats in the long term. NPS pollution may affect sensitive life stages and processes, is often difficult to detect, and its impacts may go unnoticed for a long time. When population impacts are finally detected, they may not be tied to any one event or source, and they may be difficult to correct, clean up, or mitigate. Increasing human populations and development within coastal regions generally leads to an increase in impervious surfaces, including but not limited to roads, residential and commercial development, and parking lots. Impervious surfaces cause greater volumes of run-off and associated contaminants in aquatic and marine waters.

Urban runoff is generally difficult to control because of the intermittent nature of rainfall and runoff, the large variety of pollutant source types, and the variable nature of source loadings (Safavi 1996). The 2000 National Water Quality Inventory (USEPA 2002) reported that runoff from urban areas is the leading source of impairment in surveyed estuaries and the third largest source of impairment in surveyed lakes. Urban areas can have a chronic and insidious pollution potential that one-time events such as oil spills do not.

It is important to note that the affects of pollution on coastal fishery resources may not necessarily represent a serious, widespread threat to all species and life history stages. The severity of the threat that individual pollutants may represent for aquatic organisms depends upon the type and concentration of the chemical compound and the length of exposure for a particular species and its life history stage. For example, species that spawn in areas that are relatively deep with strong bottom currents and well-mixed water may not be as susceptible to pollution as species that inhabit shallow, inshore areas near or within enclosed bays and estuaries. Similarly, species whose egg, larval, and juvenile life history stages utilize shallow, inshore waters and rivers may be more prone to coastal pollution than are species whose early life history stages develop in offshore, pelagic waters.

### *Nutrient loading and eutrophication*

In the northeastern United States, highly eutrophic conditions have been reported in a number of estuarine and coastal systems, including Boston Harbor, MA, Long Island Sound, NY/CT, and Chesapeake Bay, MD/VA (Bricker et al. 1999). While much of the excess nutrients within coastal waters originates from sewage treatment plants, nonpoint sources of nutrients from municipal and agricultural run-off, contaminated groundwater and sediments, septic systems, wildlife feces, and atmospheric deposition from industry and automobile emissions contribute significantly (Hanson et al. 2003; USEPA 2005). Failing septic systems contribute to NPS pollution and are a negative consequence of urban development. The US EPA estimates that 10-25% of all individual septic systems are failing at any one time, introducing feces, detergents, endocrine disruptors, and chlorine into the environment (Hanson et al. 2003). Sewage waste contains significant amounts of organic matter that cause a biochemical oxygen demand, leading to eutrophication of coastal waters (Kennish 1998) (see also the chapter on Chemical Effects: Water Discharge Facilities). O'Reilly (1994) found that extensive hypoxia in the northeastern United States has been more chronic in river-estuarine systems from Chesapeake Bay to Narragansett Bay, RI, than in systems to the north, except for episodic low dissolved oxygen in Boston Harbor/Charles River, MA, and the freshwater portion of the Merrimack River, MA/NH. The US EPA's National Coastal Condition Report II (USEPA 2004) reported similar trends in northeast coast estuaries and also noted signs of degraded water quality in estuaries north of Cape Cod, MA. Although the US EPA report found much of the Acadian Province (i.e., Maine and New Hampshire) to have good water quality conditions, it identified Great Bay, NH, as only having fair to poor conditions (USEPA 2004).

Severely eutrophic conditions may adversely affect aquatic systems in a number of ways, including: reductions in submerged aquatic vegetation (SAV) through reduced light transmittance, epiphytic growth, and increased disease susceptibility (Goldsborough 1997); mass mortality of fish and invertebrates through poor water quality; and alterations in long-term natural community dynamics. The effect of chronic, diurnally fluctuating levels of dissolved oxygen has been shown to reduce the growth of young-of-the-year winter flounder (*Pseudopleuronectes americanus*) (Bejda et al. 1992). Short and Burdick (1996) correlated eelgrass losses in Waquoit Bay, MA, with anthropogenic nutrient loading primarily as a result of an increased number of septic systems from housing developments in the watershed. The environmental effects of excess nutrients and elevated suspended sediments are the most common and significant causes of SAV decline worldwide (Orth et al. 2006).

There is evidence that nutrient overenrichment has led to increased incidence, extent, and persistence of blooms of nuisance and noxious or toxic species of phytoplankton; increased frequency, severity, spatial extent, and persistence of hypoxia; alterations in the dominant phytoplankton species and size compositions; and greatly increased turbidity of surface waters from planktonic algae (O'Reilly 1994). Heavily developed watersheds tend to have reduced stormwater storage capacity, and the various sources of nutrient input can increase the incidence, extent, and persistence of harmful algal blooms (O'Reilly 1994). See also the chapters on Introduced/Nuisance Species and Aquaculture and Chemical Effects: Water Discharge Facilities for more information on harmful algal blooms.

### *Introduction of pathogens*

Introduction of pathogens to aquatic habitats has become more common and widespread over the last 30 years, and various factors may be responsible, including NPS pollution from highly urbanized areas (O'Reilly 1994). Urban runoff typically contains elevated levels of pathogens, including bacteria, viruses, and protozoa, often a result of introductions of bacteria from leaking septic systems, agricultural manure, domestic animals, wildlife, and other sources of NPS pollution and can lead to beach and shellfish harvesting area closures (USEPA 2005). Pathogens are generally harmful to human health through the consumption of contaminated shellfish and finfish and exposure at beaches and swimming areas (USEPA 2005). While many pathogens affecting marine organisms are associated with upland runoff, there are also naturally occurring marine pathogens that affect fish and shellfish (Shumway and Kraeuter 2000). Some naturally occurring pathogens, such as bacteria from the genus *Vibrio*, or the dinoflagellate *Pfiesteria*, can produce blooms that release toxins capable of harming fish and possibly human health under certain conditions (Buck et al. 1997; Shumway and Kraeuter 2000). Although the factors leading to the formation of blooms for these species requires additional research, nutrient enrichment of coastal waters is suspected to play a role (Buck et al. 1997).

## *Sedimentation and turbidity*

Land runoff from coastal development can result in an unnatural influx of suspended particles from soil erosion having negative effects on riverine, nearshore, and estuarine ecosystems. Impacts from this include high turbidity levels, reduced light transmittance, and sedimentation which may lead to the loss of SAV and other benthic structure (USEPA 2005; Orth et al. 2006). Other effects include disruption in the respiration of fishes and other aquatic organisms, reduction in filtering efficiencies and respiration of invertebrates, reduction of egg buoyancy, disruption of ichthyoplankton development, reduction of growth and survival of filter feeders, and decreased foraging efficiency of sight-feeders (Messieh et al. 1991; Wilber and Clarke 2001; USEPA 2005). For example, Breitburg (1988) found the predation rates of striped bass (*Morone saxatilis*) larvae on copepods to decrease by 40% when exposed to high turbidity conditions in the laboratory. De Robertis et al. (2003) found reductions in the rate of pursuit and probability of successful prey capture in piscivorous fish at turbidity levels as low as 10 nephelometric turbidity units, while the prey consumption of two species of planktivorous fish were unaffected at this turbidity level. In another laboratory study, rainbow smelt (*Osmerus mordax*) showed signs of increased swimming activity at suspended sediment concentrations as low as 20 mg/L, suggesting fish responded to increased suspended sediment concentrations with an “alarm reaction” (Chiasson 1993).

## *Release of petroleum products*

Petroleum products consist of thousands of chemical compounds that can be toxic to marine life including polycyclic aromatic hydrocarbons (PAH), which can be particularly damaging to marine biota because of their extreme toxicity, rapid uptake, and persistence in the environment (Kennish 1998). PAH have been found to be significantly higher in urbanized watersheds when compared to nonurbanized watersheds (Fulton et al. 1993). By far, the largest amount of petroleum released through human activity comes from the use of petroleum products (e.g., cars, boats, paved urban areas, and two-stroke engines) (ASMFC 2004). Most of the petroleum consumption activities are land-based; however, rivers and storm and wastewater streams carry the petroleum to marine environments such as estuaries and bays. Although individual petroleum product releases are small, they are widespread and common and when combined, they contribute nearly 85% of the total petroleum pollution from human activities (ASMFC 2004).

Petroleum products can be a major stressor on inshore fish habitats. Short-term impacts include interference with the reproduction, development, growth, and behavior (e.g., spawning, feeding) of fishes, especially early life-history stages (Gould et al. 1994). PAH can degrade aquatic habitat, consequently interfering with biotic communities and may be discharged into rivers from nonpoint sources, including municipal run-off and contaminated sediments. Oil has been shown to disrupt the growth of vegetation in estuarine habitats (Lin and Mendelssohn 1996). Although oil is toxic to all marine organisms at high concentrations, certain species are more sensitive than others and, in general, the early life stages (i.e., eggs and larvae) of organisms are most sensitive (Gould et al. 1994; Rice et al. 2000).

Oil spills may cover and degrade coastal habitats and associated benthic communities or may produce a slick on the surface waters which disrupts the pelagic community. The water column may be polluted with oil as a result of wave action and currents dispersing the oil. Benthic habitat and the shoreline can be covered and saturated with oil, leading to the protracted damage of aquatic communities, including the disruption of population dynamics. Oil can persist in sediments for decades after the initial contamination, causing disruption of physiological and metabolic processes of demersal fishes (Vandermeulen and Mossman 1996). These changes may lead to disruption of community organization and dynamics in affected regions and permanently diminish fishery habitat. Carcinogenic and mutagenic properties of oil compounds have been identified (Larsen 1992; Gould et al. 1994). For more detail on oil spills, see the chapter on Energy-related Activities.

### *Alteration of water alkalinity*

Fishery resources are known to be sensitive to changes in water alkalinity. Rivers and the brackish waters of estuaries are especially sensitive to acidic effluents because of the lower buffering capacity of freshwater as compared to that of salt water. The influx of pH altering flows to aquatic habitats can hinder the sustainability of fisheries. Municipal run-off, contaminated groundwater, and atmospheric deposition are potential nonpoint sources of acid influx to aquatic habitats. Acidification may disrupt or prevent reproduction, development, and growth of fish (USFWS and NMFS 1999). Osmoregulatory problems in Atlantic salmon (*Salmo salar*) smolts have been demonstrated to be related to habitats with low pH (Staurnes et al. 1996). Low pH in estuarine waters has been shown to cause cellular changes in the muscle tissues of Atlantic herring (*Clupea harengus*), which may lead to a reduction in swimming ability (Bahgat et al. 1989).

### *Alteration of temperature regimes*

Alteration of natural temperature regimes can occur in riverine and estuarine ecosystems because of land runoff from urbanized areas. Radiant heating from impervious surfaces, such as concrete and asphalt can increase the water temperature of streams, rivers, and bays. The removal of shoreline and riparian vegetation can reduce shading effects and raise the water temperature of creeks and ponds that drain into larger water bodies. Temperature influences biochemical processes, behavior (e.g., migration), and physiology of aquatic organisms (Blaxter 1969), and long-term thermal pollution may change natural community dynamics.

Because warmer water holds less oxygen than colder water does, increased water temperatures reduce the dissolved oxygen concentration in bodies of water that are not well mixed. This may exacerbate nutrient-enrichment and eutrophication conditions that already exist in many estuaries and marine waters in the northeastern United States. In addition, increased water temperatures in the upper strata of the water column can increase water column stratification, which inhibits the diffusion of oxygen into deeper water leading to reduced (hypoxic) or depleted (anoxic) dissolved oxygen concentrations in estuaries with excess nutrients (Kennedy et al. 2002). Stratification could also affect primary and secondary productivity by suppressing nutrient upwelling and mixing in the upper regions of the water column, potentially altering the composition of phytoplankton and zooplankton. Impacts to the base of the food chain would not only affect fisheries but could impact entire ecosystems.

### *Release of metals*

Metal contaminants are found in the water column and can persist in the sediments of coastal habitat, including urbanized areas, as well as fairly uninhabited regions, and are a potential environmental threat (Larsen 1992; Readman et al. 1993; Buchholtz ten Brink et al. 1996). High levels of metals, such as mercury, copper, lead, and arsenic, are found in the sediments of New England estuaries because of past industrial activity (Larsen 1992) and may be released into the water column during navigation channel dredging or made available to organisms as a result of storm events. Some activities associated with shipyards and marinas have been identified as sources of metals in the sediments and surface waters of coastal areas (Milliken and Lee 1990; USEPA 2001; Amaral et al. 2005). These include copper, tin, and arsenic from boat hull painting and scraping, hull washing, and wood preservatives. Treated wood used for pilings and docks releases copper compounds that are applied to preserve the wood (Poston 2001; Weis and Weis 2002). These chemicals can become available to marine organisms through uptake by wetland vegetation, adsorption by adjacent sediments, or directly through the water column (Weis and Weis 2002). Refer to the Overwater Structures section of this chapter for more information on treated wood products and their effects on aquatic organisms. Urban stormwater runoff often contains metals from automobile and industrial facilities, such as mercury, lead (used in batteries), and nickel and cadmium (used in brake linings). Refer to the chapter on Marine Transportation for more information on channel dredging and storm water impacts from marinas and shipyards.

At low concentrations, metals may initially inhibit reproduction and development of marine organisms, but at high concentrations, they can directly contaminate or kill fish and invertebrates. Shifts in phytoplankton species composition may occur because of metal accumulation and may lead to an alteration of community structure by replacing indigenous producers with species of lesser value as a food source for consumers (NEFMC 1998). Metals are known to produce a number of toxic effects on marine fish species, including skeletal deformities in Atlantic cod (*Gadus morhua*) from cadmium exposure (Lang and Dethlefsen 1987), larval developmental deformities in haddock (*Melanogrammus aeglefinus*) from copper exposure (Bodammer 1981), and reduced viable hatch rates in winter flounder embryos and increased larval mortality from silver exposure (Klein-MacPhee et al. 1984). Laboratory experiments have shown high mortality of Atlantic herring eggs and larvae at copper concentrations of 30 µg/L and 1,000 µg/L, respectively, and vertical migration of larvae was impaired at copper concentrations of greater than 300 µg/L (Blaxter 1977). Copper may also bioaccumulate in bacteria and phytoplankton (Milliken and Lee 1990). Metals have been implicated in disrupting endocrine secretions of aquatic organisms, potentially disrupting natural physiological processes (Brodeur et al. 1997; Thurberg and Gould 2005). Refer to the Chemical Effects: Water Discharge Facilities chapter for a broader discussion on endocrine-disrupting chemicals. While long-term impacts do not appear significant in most marine organisms, metals can move upward through trophic levels and accumulate in fish (bioaccumulation) at levels that can eventually cause health problems in human consumers (NEFMC 1998). See also Global Effects and Other Impacts chapter for mercury loading/bioaccumulation via the atmosphere.

### *Release of radioactive wastes*

Radioactive wastes may be a potential threat to aquatic habitats used by fish and shellfish species. Fishery resources may accumulate radioactive isotopes in tissues that could lead to negative effects on the resource and consumers (ICES 1991). Potential sources of radioactive wastes are urban stormwater runoff, municipal landfills, atmospheric deposition, contaminated groundwater, and sediments (e.g., past offshore dumping locations [NEFMC 1998]).

### *Release of toxic compounds*

Many different toxic compounds, including “priority pollutants” described previously, have been found in urban runoff (USEPA 2005). The US EPA reported that at least 10% of urban runoff samples contained toxic pollutants (USEPA 2005). Organic contamination contained within urban runoff, particularly chlorinated and aromatic compounds, has been implicated in causing immuno-suppression in juvenile chinook salmon (*Oncorhynchus tshawytscha*) (Arkoosh et al. 2001). The organophosphate insecticide, malathion, has been implicated in the mass mortality of American lobsters (*Homarus americanus*) in Long Island Sound during 1999 (Balcom and Howell 2006). In addition, impairment of immune response and stress hormone production were identified as examples of the sublethal effects from exposure of this compound on American lobsters (Balcom and Howell 2006). Refer to the subsections release of metals, pesticides, and herbicides in this chapter for additional information on toxic compounds.

### *Release of pesticides and herbicides*

Although agricultural run-off is a major source of pesticide pollution in aquatic systems, residential areas are also a notable source (see Agriculture and Silviculture chapter for a discussion on agricultural runoff of pesticides). Other sources of pesticide discharge into coastal waters include atmospheric deposition and contaminated groundwater (Meyers and Hendricks 1982). Pesticides may bioaccumulate in the ecosystem by retention in sediments and detritus then ingested by macroinvertebrates, which in turn are eaten by larger invertebrates and fish (ASMFC 1992). For example, winter flounder liver tissues taken in 1984 and 1985 in Boston and Salem Harbors in Massachusetts were found to have the two highest mean concentrations of total dichlorodiphenyl trichloroethane (DDT) found in all New England sites sampled (NOAA 1991). Samples taken of soft parts from softshelled clams (*Mya arenaria*) during the same time period indicated that Boston Harbor mussels were moderately to highly contaminated with DDT when compared to nationwide sites (NOAA 1991).

There are three basic ways that pesticides can adversely affect the health and productivity of fisheries: (1) direct toxicological impact on the health or performance of exposed fish; (2) indirect impairment of the productivity of aquatic ecosystems; and (3) loss or degradation of habitat (e.g., aquatic vegetation) that provides physical shelter for fish and invertebrates (Hanson et al. 2003).

For many marine organisms, the majority of effects from pesticide exposures are sublethal, meaning that the exposure does not directly lead to the mortality of individuals. Sublethal effects can be of concern, as they impair the physiological or behavioral performance of individual animals in ways that decrease their growth or survival, alter migratory behavior, or reduce reproductive success (Hanson et al. 2003). Early development and growth of organisms involve important physiological processes and include the endocrine, immune, nervous, and reproductive systems. Many pesticides have been shown to impair one or more of these physiological processes in fish (Moore and Waring 2001; Gould et al. 1994). For example, evidence has shown that DDT and its chief metabolic by-product, dichlorodiphenyl dichloroethylene (DDE), can act as estrogenic compounds, either by mimicking estrogen or by inhibiting androgen effectiveness (Gilbert 2000). DDT has been shown to cause deformities in winter flounder eggs and Atlantic cod embryos and larvae (Gould et al. 1994). Generally, however, the sublethal impacts of pesticides on fish health are poorly understood.

The direct and indirect effects that pesticides have on fish and other aquatic organisms can be a key factor in determining the impacts on the structure and function of ecosystems (Preston 2002). This factor includes impacts on primary producers (Hoagland et al. 1996) and aquatic microorganisms (DeLorenzo et al. 2001), as well as macroinvertebrates that are prey species for fish. Because pesticides are specifically designed to kill insects, it is not surprising that these chemicals are relatively toxic to insects and crustaceans that inhabit river systems and estuaries. The use of pesticides to control mosquitoes has been suggested as a potential factor in the mass mortality of American lobsters in Long Island Sound during 1999 (Balcom and Howell 2006). Recent lab studies have shown that lobsters are considerably more sensitive to the effects of the mosquito adulticide, malathion, than are any other species previously tested. Sublethal effects (i.e., impairment of immune response and stress hormone production) occur at concentrations in parts per billion and at concentrations much lower than those observed to cause lethal effects (Balcom and Howell 2006). Lab studies have shown that American lobsters have a 96-hour LC50 (i.e., Lethal

Concentration 50- the duration and chemical concentration which causes the death of 50% of the test animals) of 33.5 ppb with immunotoxicity resulting at 5 ppb, suggesting a high sensivity in this species to both lethal and sublethal toxicity effects from malathion in seawater (De Guise et al. 2004).

Herbicides may alter long-term natural community structure by hindering aquatic plant growth or destroying aquatic plants. Hindering plant growth can have notable effects on fish and invertebrate populations by limiting nursery and forage habitat. Chemicals used in herbicides may also be endocrine disrupters, exogenous chemicals that interfere with the normal function of hormones (NEFMC 1998). Coastal development and water diversion projects contribute substantial levels of herbicides entering fish and shellfish habitat. A variety of human activities such as noxious weed control in residential development and agricultural lands, right-of-way maintenance (e.g., roads, railroads, power lines), algae control in lakes and irrigation canals, and aquatic habitat restoration results in contamination from these substances.

### *Conservation measures and best management practices (BMPs) for discharge of nonpoint source pollution and urban runoff (adapted from Hanson et al. 2003)*

1. Remove unnecessary impervious surfaces such as abandoned parking lots and buildings from riparian and shoreline areas and reestablish wetlands and native vegetation, whenever possible. Construction of new impervious surfaces should be avoided or minimized.
2. Implement BMPs for sediment control during construction and maintenance operations, including: avoiding ground disturbing activities during the wet season; minimizing the temporal and spatial extent of the disturbance; using erosion prevention and sediment control methods; maintaining natural buffers of vegetation around wetlands, streams, and drainage ways; and avoiding building activities in areas of steep slopes and areas with highly erodable soils. Whenever appropriate, recommend the use of methods such as sediment ponds, sediment traps, bioswales, or other facilities designed to slow runoff and trap sediment and nutrients (USEPA 1993).
3. Protect, enhance, and restore vegetated buffer zones along streams and wetlands that include or influence fishery habitat.
4. Manage stormwater to duplicate the natural hydrologic cycle, maintaining natural infiltration and runoff rates to the maximum extent practicable.
5. Encourage proposed residential and commercial developments to utilize municipal wastewater facilities capable of treating sewage to the maximum extent practicable. Any proposed residential developments utilizing septic systems should include modern, state of the art systems. Ensure that they are properly sited and maintained.
6. Encourage communities to implement "smart-growth" development and land-use planning that reduces urban sprawl and minimizes impervious surfaces.
7. Encourage the use of nontreated wood materials in construction near aquatic environments.
8. Incorporate integrated pest management and BMPs as part of the authorization or permitting process to ensure the reduction of pesticide contamination in fishery habitat (Scott et al. 1999).
9. Avoid the use of pesticides and herbicides in and near aquatic habitats.
10. Refrain from aerial spraying of pesticides on windy days.
11. Address nonpoint source pollution by assessing cumulative impacts of past, present, and foreseeable future development activies on aquatic habitats in the review process.

# Commercial and Domestic Water Use

Freshwater withdrawn for human use from riverine environments can alter natural current and sedimentation patterns, water quality, water temperature, and associated biotic communities (NEFMC 1998). Natural freshwater flows are subject to human alteration through water diversion for agriculture and industrial uses and modifications to the watershed. An increasing demand for potable water, combined with inefficient use of freshwater resources and natural events (e.g., droughts) have led to serious ecological damage worldwide, as well as in New England (Deegan and Buchsbaum 2005). For example, the flow of the Ipswich River in Massachusetts has been reduced to about one-half historical levels because of water withdrawals for human uses and about one-half of the native fish species on the river have been eliminated or greatly reduced (Bowling and Mackin 2003). Water withdrawal for freshwater drinking supply, power plant coolant systems, and irrigation occurs along urban and suburban areas, causing potential detrimental effects on aquatic habitats. The water withdrawal limits the amount of freshwater flowing into estuaries, which can affect the health and productivity of the ecosystem. For example, diversion of freshwater leading to increased salinities can result in oysters relocating upstream where less suitable habitat may be available and in areas subjected to higher levels of pollution (MacKenzie 2007). Urbanization leads to increases in the amount of impervious surface (e.g., roads and parking lots), which causes water to flow off the land more quickly than if the land was undeveloped and forested, reducing the natural recharge of groundwater. Alteration of the natural hydroperiod can affect circulation patterns in estuarine systems, leading to both short-term and long-term changes (Deegan and Buchsbaum 2005). In addition, the use of desalinization plants to meet industrial and municipal water needs may further alter chemical and physical environments by discharging hypersaline water into the aquatic ecosystem. Refer to the chapters on Physical Effects: Water Intake and Discharge Facilities and Alteration of Freshwater Systems for additional information on domestic and commercial freshwater usage.

### *Conservation measures and best management practices for commercial and domestic water use (adapted from Hanson et al. 2003)*

1. Ensure that the design of water diversion projects provide adequate passage, water quality, and proper timing of water flows for all life history stages of anadromous fish and that they maintain and restore adequate channel, floodplain, riparian, and estuarine conditions.
2. Incorporate juvenile and adult fish passage facilities on water diversion projects.
3. Seasonal restrictions should be used to avoid impacts to habitat during species critical life history stages (e.g., spawning and egg development periods). Recommended seasonal work windows are generally specific to regional or watershed-level environmental conditions and species requirements.

# Road Construction and Operation

The building and maintenance of roads can affect aquatic habitats by increasing rates of erosion, debris slides, landslides, sedimentation, introduction of exotic species, and degradation of water quality (Furniss et al. 1991; Hanson et al. 2003). Paved and dirt roads introduce an impervious or semipervious surface into the landscape, which intercepts rain and increases runoff, carrying soil, sand, and other sediments (Ziegler et al. 2001) and oil-based materials more quickly into aquatic habitats. Roads constructed near streams, wetlands, and other sensitive areas may cause sedimentation in these habitats and further diminish flood plain storage capacity, subsequently increasing the need for dredging in those systems. Sedimentation and the release of contaminants into aquatic habitats can be acute following heavy rain and snow and as a result of improper road maintenance activities. Even carefully designed and constructed roads can be a source of sediment and pollutants if they are not properly maintained (Hanson et al. 2003).

The effects of roads on aquatic habitat include: (1) contaminant releases; (2) increased release of sediments; (3) reduced dissolved oxygen; (4) changes in water temperature; (5) elimination or introduction of migration barriers; (6) changes in stream flow; (7) introduction of nonnative plant species; (8) altered salinity regimes; and (9) changes in channel configuration.

### *Contaminant releases*

Roads constructed near or adjacent to aquatic habitats can be a source of chemical contaminants, such as deicing chemicals, road salt, fertilizers, and herbicides to control roadside vegetation and petroleum products from vehicles or from the road asphalt itself (Furniss et al. 1991).

Nationally, an estimated 18 million tons of deicing salt, primarily sodium and calcium chlorides, are used each year and state and local governments spend approximately $10 million annually to remediate road salt contamination (USEPA 2005). Road salts dissolve and enter adjacent soils, groundwater, and surface waters through runoff, which can cause toxicity in plants, fish, and other aquatic organisms. These effects are particularly pronounced in smaller water bodies adjacent to salted areas. Stormwater runoff from roads can contain oil, grease, and other hydrocarbons from asphalt, wearing of tires, deposition from automobile exhaust, and oiling of roadsides and unpaved roads with crankcase oil (USEPA 2005). Refer to the Discharge of Nonpoint Source Pollution and Urban Runoff section of this chapter for information on impacts from stormwater runoff.

### *Sedimentation, siltation, and turbidity*

The rate of soil erosion around roads is primarily a function of storm intensity, surfacing material, road slope, and traffic levels (Hanson et al. 2003). In addition, road maintenance activities such as road sanding to prevent icing and road repair can also cause sedimentation in adjacent aquatic habitats. For roads located in steep terrain, mass soil movement triggered by roads can last for decades after roads are built (Furniss et al. 1991). Surface erosion results in increased deposition of fine sediments (Bilby et al. 1989; MacDonald et al. 2001; Ziegler et al. 2001), which has been linked to a decrease in salmon fry emergence, decreased juvenile densities, and increased predation in some species of salmon (Koski 1981).

### *Reduced dissolved oxygen*

The introduction of stormwater runoff from roads can increase the organic loads in adjacent streams and rivers, increasing the biological oxygen demand and reducing dissolved oxygen concentrations. Reduced dissolved oxygen concentrations can cause direct mortality of aquatic organisms or result in sub-acute effects such as reduced growth and reproductive success. Bejda et al. (1992) found that the growth of juvenile winter flounder was significantly reduced when dissolved oxygen (DO) levels were maintained at 2.2 mg/L or when DO varied diurnally between 2.5 and 6.4 mg/L for a period of 11 weeks.

### *Loss and alteration of vegetation and altered temperature regimes*

Roads located near streams often involve the removal of riparian vegetation for construction and safety and maintenance. Roads built adjacent to streams result in changes in water temperature and increased sunlight reaching the stream as riparian vegetation is removed and/or altered in composition (Hanson et al. 2003). Roads can also alter natural temperature regimes in riverine and estuarine ecosystems because of radiant heating effect from the road surfaces. Riparian vegetation is an important component of rearing habitat for coldwater species, such as salmonids, providing shade for maintaining cool water temperatures, food supply, and channel stability and structure (Furniss et al. 1991).

Temperature effects biochemical processes, behavior (e.g., migration), and physiology of aquatic organisms (Blaxter 1969), and long-term thermal pollution may change natural community dynamics. In addition, increased water temperatures can reduce the dissolved oxygen concentration in bodies of water that are not well mixed. This may exacerbate eutrophication conditions that already exist in many estuaries and marine waters in the northeastern United States.

### Impaired fish passage

Roads can also reduce or eliminate upstream and downstream fish passage through improperly placed culverts at road-stream crossings (Belford and Gould 1989; Clancy and Reichmuth 1990; Evans and Johnston 1980; Furniss et al. 1991). Improperly designed stream crossings adversely effect fish and aquatic organisms by blocking access to spawning, rearing, and nursery habitat because of: (1) perched culverts constructed with the bottom of the structure above the level of the stream, effectively acting as dams and physically blocking passage; and (2) hydraulic barriers to passage are created by undersized culverts which constrict the flow and create excessive water velocities (Evans and Johnston 1980; Belford and Gould 1989; Furniss et al. 1991; Jackson 2003). Smooth-bore liners made from high density plastic help meet the goal of passing water and protecting roadways from flooding, but they greatly increase flow velocities through the passage. Culverts can be plugged by debris or overtopped by high flows. Road damage, channel realignment, and extreme sedimentation from roads can cause stream flow to become too shallow for upstream fish movement (Furniss et al. 1991). Additional information on impaired fish passage is discussed in the Alteration of Freshwater Systems chapter of this report.

### Introduction of exotic invasive species

Roads can be the first point of entry for nonnative, opportunistic grass species that are seeded along road cuts or introduced from seeds transported by tires and shoes (Greenberg et al. 1997; Lonsdale and Lane 1994). Nonnative plants may be able to move away from the roadside and into aquatic sites, where they may out-compete native species and alter the structure and function of the aquatic ecosystem (see also the chapter on Introduced/Nuisance Species and Aquaculture).

### Altered hydrological regimes

Roads can result in adverse effects to hydrologic processes. They intercept rainfall directly on the road surface, in road cut banks, and as subsurface water moving down the hillslope; they also concentrate flow, either on the road surfaces or in adjacent ditches or channels (Hanson et al. 2003). Roads can divert or reroute water from flow paths that would otherwise be taken if the road were not present (Furniss et al. 1991). The hydrology of riverine and estuarine systems can be affected by fragmentation of the habitat caused by the construction of roads and culverts (Niering 1988; Mitsch and Gosselink 1993). These structures also reduce natural tidal flushing and interfere with natural sediment-transport processes, all of which are important functions that maintain the integrity of coastal wetlands (Tyrrell 2005). As discussed previously, roads can alter flood plain storage patterns. These hydrological changes may lead to increased erosion and sedimentation in adjacent streams.

Altered hydrology and flood plain storage patterns around estuaries can effect water residence time, temperature, and salinity and increase vertical stratification of the water column, which inhibits the diffusion of oxygen into deeper water leading to reduced (hypoxic) or depleted (anoxic) dissolved oxygen concentrations (Kennedy et al. 2002).

### *Altered tidal and salinity regimes*

As discussed above, roads can alter hydrologic processes by rerouting flow paths and concentrating stormwater flow towards salt marsh and tidal creeks. Together with the removal of vegetation adjacent to roads, a large and rapid influx of freshwater can alter the salinity regime and species composition of estuarine habitats. Roads and culverts can also restrict the flow in tidal creeks, lowering the head-of-tide, altering the estuarine community, and restricting the access of anadromous fish.

### *Altered stream morphology*

The geometry of a stream is affected by the amount of water and sediment that the stream carries. These factors may be altered by roads and stream crossings. Adjustments to stream morphology are usually detrimental to fish habitat (Furniss et al. 1991). Alteration of stream morphology can change stream velocity and increase sedimentation of the streambed, which can have adverse effects on spawning and migration of anadromous fish.

### *Conservation measures and best management practices for road construction and operation (adapted from Hanson et al. 2003)*

1. Roads should be sited to avoid sensitive areas such as streams, wetlands, and steep slopes.
2. Build bridges for crossing aquatic environments, rather than utilizing culverts, whenever possible. If culverts must be used, they should be sized, constructed, and maintained to match the gradient, flow characteristics, and width of the stream so as to accommodate a 100-year flood event, but equally to provide for seasonal migratory passage of adult and juvenile fish.
3. Design bridge abutments to minimize disturbances to stream banks, and place abutments outside of the floodplain whenever possible.
4. Specify erosion control measures in road construction plans.
5. Avoid side casting of road materials into streams.
6. Use only native vegetation in stabilization plantings.
7. Use seasonal restrictions to avoid impacts to habitat during species critical life history stages (e.g., spawning and egg development periods). Recommended seasonal work windows are generally specific to regional or watershed-level environmental conditions and species requirements.
8. Maintain roadway and associated stormwater collection systems properly.
9. Control the practice of roadway sanding and the use of deicing chemicals during the winter to minimize sedimentation and introduction of contaminants into nearby aquatic habitats. Sweep and remove sand after winter to reduce sediment loading in streams and wetlands.
10. Address the cumulative impacts of past, present, and foreseeable future development activities on aquatic habitats by considering them in the review process for road construction projects.

## Flood Control/Shoreline Protection

As human populations in coastal areas grow, development pressure increases and structures are often constructed along the coastline to prevent erosion and stabilize shorelines. The protection of coastal development and human communities from flooding can result in varying degrees of change in the physical, chemical, and biological characteristics of existing shoreline and riparian habitat. Attempts to protect “soft” shorelines such as beaches to reduce shoreline erosion are inevitable consequences of coastal development. Structures placed for coastal shoreline protection include breakwaters, jetties and groins, concrete or wood seawalls, rip-rap revetments (sloping piles of rock placed against the toe of the dune or bluff in danger of erosion from wave action), dynamic cobble revetments (natural cobble placed on an eroding beach to dissipate wave energy and prevent sand loss), and sandbags (Hanson et al. 2003). These structures are designed to slow or stop the shoreline from eroding, but in many cases the opposite occurs as erosion rates increase along the adjacent areas. Many shoreline “hardening” structures, such as seawalls and jetties, tend to reduce the complexity of habitats and the amount of intertidal habitats (Williams and Thom 2001). Generally, “soft” shoreline stabilization approaches (e.g., beach nourishment, vegetative plantings) have fewer adverse effects on hydrology and habitats.

Flood control measures in low-lying coastal areas include dikes, ditches, tide gates, and stream channelization. These measures are generally designed to direct water away from flood prone areas and, in the case of tide gates, prevent tidal water and storm surge from entering these areas. Adjacent aquatic habitat can become altered, and short- and long-term impacts to local fish and shellfish populations may be associated with the presence of the erosion control structures. Coastal marshes typically have a gradient of fresh to salt tolerant vegetation. These coastal wetland systems drain freshwater through tidal creeks that eventually empty into the bay or estuary. The use of water control structures can have long-term adverse effects on tidal marsh and estuarine habitats by interfering with the exchange of fresh and brackish water within the marsh habitat.

### *Altered hydrological regimes*

Water control structures within marsh habitats intercept and carry away freshwater drainage, block freshwater from flowing across seaward portions of the marsh, increase the speed of runoff of freshwater to the bay or estuary, lower the water table, permit saltwater intrusion into the marsh proper, and create migration barriers for aquatic species (Hanson et al. 2003). In deep channels where anoxic conditions prevail, large quantities of hydrogen sulfide may be produced that are toxic to marsh grasses and other aquatic life. Long-term effects of flood control on tidal marshes include land subsidence (sometimes even submergence), soil compaction, conversion to terrestrial vegetation, reduced invertebrate populations, and general loss of productive wetland characteristics (Hanson et al. 2003). Alteration of the hydrology of coastal salt marshes can reduce estuarine productivity, restrict suitable habitat for aquatic species, and result in salinity extremes during droughts and floods.

### *Altered temperature regimes*

Shoreline modifications, including the construction of seawalls and bulkheads, invariably involve the removal of shoreline vegetation which eliminates shading and can cause increased water temperatures in rivers and the nearshore intertidal zone (Williams and Thom 2001). Conversely, increased shading from seawalls and bulkheads constructed along shorelines may unnaturally reduce local light levels and primary production rates and reduce water temperatures of the water column adjacent to the structures (Williams and Thom 2001). Tide gates prevent or reduce tidal flushing to an area, causing stagnant water behind the structure and increased water temperature regimes (Williams and Thom 2001). Breakwaters and jetties can also alter hydrological processes which may result in altered fluctuations of nearshore temperature (Williams and Thom 2001).

### *Reduced dissolved oxygen*

Breakwaters and jetties affect nearshore hydrological processes, as well as river flow and tidal currents when these structures are placed at the mouth of rivers and estuaries (Williams and Thom 2001). This can alter the timing and volume of water exchange to rivers, bays, and estuaries and result in reductions in water circulation and dissolved oxygen concentrations for some areas, particularly when combined with eutrophic conditions. Flood control structures, such as tide gates, dikes, and ditches, can restrict the exchange of water within wetlands, which can create stagnant conditions and reduce dissolved oxygen concentrations (Spence et al. 1996; Williams and Thom 2001).

### *Altered sediment transport and increased erosion/accretion*

As discussed above, shoreline stabilization structures such as breakwaters, jetties, and groins affect nearshore hydrological processes which can alter wave energy and current patterns that, in turn, can affect littoral drift and longshore sediment transport (Williams and Thom 2001). In comparisons between natural and seawalled shorelines, Bozek and Burdick (2005) found no statistically significant effects on several salt marsh processes in Great Bay, NH. However, at high-energy sites, the authors found trends indicating greater sediment movement and winnowing of fine grain sediments adjacent to seawalls (Bozek and Burdick 2005).

These structures can also impact sediment budgets in estuaries and rivers. Alterations to sediment transport can affect bottom habitats, beach formation, and sand dune size (Williams and Thom 2001). Hardened shorelines, from the construction of seawalls, groins, and revetments, directly affect nearshore sediment transport by impounding natural sediment sources. Shoreline structures can cause beach erosion and accretion in adjacent areas. Long-term, chronic impacts may result in a reduction of intertidal habitat, bottom complexity, and associated soft-bottom plant and animal communities (Williams and Thom 2001). In tidal marshes, floodgates and dikes restrict sediment transport which is a natural part of the marsh accretion process. The use of these structures can result in subsidence of the marsh and loss of salt marsh vegetation.

### *Alteration and loss of benthic and intertidal habitat*

As discussed above, breakwaters, jetties, and groins can affect nearshore hydrological processes, such as wave energy and current patterns and, in turn, can have detrimental impacts on benthic habitats. Increased sedimentation as a result of reflective turbulence (changes in water velocity caused by wave energy reflection from solid structures in the nearshore coastal area) and turbidity can reduce or eliminate vegetated shallows (Williams and Thom 2001). In addition, these structures can alter the geomorphology of existing habitats, resulting in a large-scale replacement of soft-bottom, deepwater habitat with shallow and intertidal, hard structure habitats (Williams and Thom 2001). Alterations to the shoreline as a result of bulkhead and other hard shoreline structures can increase wave energy seaward of the armoring, causing scouring of bottom sediments and loss of salt marsh vegetation.

### *Altered stream morphology*

Flood and erosion control structures such as bulkheads, levees, and dikes built along streams and rivers, as well as the canalization of streams and rivers, result in simplified riverine habitat and a reduction in pools and riffles that provide habitat for fish (Spence et al. 1996). In addition, altered stream hydrology and morphology can change sediment grain size and reduce the organic matter available to small organisms that serve as prey for larger species in the food web (Williams and Thom 2001).

### *Impacts to riparian habitat*

As discussed above, shoreline modifications such as the construction of seawalls and bulkheads, involve the removal of shoreline vegetation which eliminates shading and can cause increased water temperatures in rivers and the nearshore, intertidal zone (Williams and Thom 2001). The loss of riparian vegetation reduces the forage and cover for aquatic organisms and the input of large woody debris and smaller organic detritus, including leaves (Spence et al. 1996).

### *Impaired fish passage*

Tide gates and other flood control structures can eliminate or restrict access of fish to salt marshes. Tide gates can create physical barriers for estuarine fish species that utilize salt marsh wetlands for feeding and early development. High flow rates at tide gates or culvert openings can prevent small fish from accessing critical marsh and freshwater habitat. In some cases, fish can become trapped behind tide gates, preventing them from accessing deeper water and potentially stranding them during periods of low water (Williams and Thom 2001).

### *Alteration of natural communities*

Armoring of shorelines to prevent erosion and maintain or create shoreline real estate simplifies habitats, reduces the amount of intertidal habitat, and negatively affects nearshore processes and the ecology of coastal species (Williams and Thom 2001). For example, Chapman (2003) found a paucity of mobile species associated with seawalls in a tropical estuary, compared with surrounding areas. In that study, approximately 50% of taxa found on natural rocky shorelines were absent on constructed seawall, and seawalls were found to have a diminished proportion of rare taxa. Alterations to the shoreline from hydraulic action include increased energy seaward of the armoring from reflected wave energy, narrowing of the dry beach, coarsening of the substrate, steepening of the beach slope, reduction of sediment storage capacity, a loss of organic debris, and a reduction of downdrift sediment (Williams and Thom 2001). Bozek and Burdick (2005) found no statistically significant effects of seawalls on salt marsh processes in Great Bay, NH; however, their data indicated seawalls tended to eliminate the high-diversity vegetative zones at the upper border of the salt marsh. Installation of breakwaters and jetties can result in community changes, including burial or removal of resident biota, changes in the habitat structure, alteration in prey and predator interaction, and physical obstructions that can alter the recruitment patterns of larvae (Williams and Thom 2001).

### *Reduced ability to counter sea-level rise*

The effect of shoreline erosion and land subsidence will likely be exacerbated by sea-level rise because of global climate change. Sea level rose 10-20 cm (4-8 inches) in the 20$^{th}$ century and may rise another 18-59 cm (7-23 inches) by 2100 (IPCC 2007). As sea levels continue to rise, salt marshes, mudflats, and coastal shallows must be able to shift horizontally without interruption from natural or manmade barriers (Bigford 1991). Hard structures, such as seawalls, bulkheads, and jetties may inhibit the shoreward migration of marsh wetlands (Kelley 1992) and SAV beds (Orth et al. 2006). In addition, global climate change is expected to cause greater precipitation and more intense storms in the mid-high latitudes in the northern hemisphere (Nedeau 2004). Along with rising sea levels, these factors may exacerbate coastal erosion and increase the apparent need for shoreline protection. See Global Effects and Other Impacts chapter for more information on global climate change.

### *Conservation measures and best management practices for flood control/shoreline protection (adapted from Hanson et al. 2003)*

1. Avoid or minimize the loss of coastal wetlands as much as possible, including encouraging coastal wetland habitat preservation. Preservation of coastal upland buffers between buildings and wetlands may allow for the inland migration of wetlands as sea levels rise.
2. Avoid the diking and draining of tidal marshlands and estuaries, whenever possible.
3. Use "soft" approaches (such as beach nourishment, vegetative plantings, and placement of large woody debris), in lieu of "hard" shoreline stabilization and modifications (such as concrete bulkheads and seawalls, concrete or rock revetments), whenever possible.
4. Ensure that the hydrodynamics and sedimentation patterns are properly modeled and that the design avoids erosion to adjacent properties when "hard" shoreline stabilization is deemed necessary.
5. Include efforts to preserve and enhance fishery habitat (e.g., provide new gravel for spawning or nursery habitats; remove barriers to natural fish passage; and use of weirs, grade control structures, and low flow channels to provide the proper depth and velocity for fish) to offset impacts from proposed riparian habitat and stream modifications.
6. Construct a low-flow channel to facilitate fish passage and help maintain water temperature in reaches where water velocities require armoring of the riverbed.
7. Replace in-stream fish habitat by installing boulders, rock weirs, and woody debris and by planting riverine aquatic cover vegetation to provide shade and habitat.
8. Avoid installing new water control structures in tidal marshes and freshwater streams. If the installation of new structures cannot be avoided, ensure that they are designed to allow optimal fish passage and natural water circulation.
9. Ensure water control structures are monitored for potential alteration of water temperature, dissolved oxygen concentration, and other parameters.
10. Use seasonal restrictions to avoid impacts to habitat during species critical life history stages (e.g., spawning, egg, and larval development periods). Recommended seasonal work windows are generally specific to regional or watershed-level environmental conditions and species requirements.
11. Address the cumulative impacts of past, present, and foreseeable future development activities on aquatic habitats by considering them in the review process for flood control and shoreline protection projects.

## Beach Nourishment

Beach nourishment, the process of mechanically or hydraulically placing sediments (i.e., sand and gravel) directly on an eroding shore to restore or form a protective or desired recreational beach, has been steadily increasing along the eastern US coastline since the 1960s (Greene 2002). Beaches and shorelines are dynamic, constantly eroding and accreting because of exposure to waves, currents, and wind. Beach nourishment serves as a "soft," sacrificial barrier to protect the beach and property along the coast from storm and flood damage. Between 1923 and 2004, it is estimated that approximately 515 million cubic yards of beach sediment have been deposited on the

US east coast barrier island shoreline from Maine to Florida, including 966 instances of beach nourishment at 343 locations (Valverde et al. 1999; PSDS 2005).

Beach nourishment as a protective measure against coastal flooding and storm damage may be considered less of an impact to marine organisms and fishery habitat than are most "hard" structure solutions discussed in the previous section. However, beach nourishment can have a number of short- and long-term impacts on fishery resources, including displacing benthic organisms during and after nourishment, interference with respiration and feeding in finfish and filter feeding invertebrates, temporary removal of benthic prey, burial of habitat that serves as foraging and shelter sites, potential burial of demersal and benthic species, and mortality of species at vulnerable life stages, such as eggs, larvae, and juveniles (Greene 2002). Sand or cobble material needed for beach nourishment is generally dredged from offshore areas, referred to as borrow or mining sites, and either hydraulically pumped through pipes or loaded onto barges for transfer and placement on the beach. Fish and invertebrates in and around the borrow site can be subjected to entrainment, sedimentation, and increased turbidity during the dredging and transport of the beach material. In addition, the creation of borrow pits may alter the bottom topography and sediment transport processes in offshore habitats and form depressions with low-dissolved oxygen. Nourished beaches seldom last as long as natural beaches, and natural coastal processes erode the replenished sand, requiring additional nourishment of those beaches (Pilkey and Dixon 1996). The life span of a nourished beach can be highly variable and primarily dependent upon storm intensity and frequency following the completion of a project. According to Pilkey and Dixon (1996), the life span of most nourished beaches is 2-5 years. Beach nourishment projects are often conducted at a high economic cost, and they can represent a long-term and cumulative impact on the marine biological community.

Increased global precipitation, more intense storms, and sea level rise predicted for the mid-high latitudes in the northern hemisphere because of global climate change will likely exacerbate erosional forces on beaches (Nedeau 2004) and increase the frequency of beach renourishment to protect eroding shoreline. See Global Effects and Other Impacts chapter for more on global climate change.

### *Altered hydrological regimes*

Sand removed from borrow sites can potentially affect the geomorphology of offshore sand bars and shoals that absorb incoming waves, causing greater wave energy and/or change refraction patterns (Greene 2002). This may increase the erosion rate at the nourished beach and adjacent, nonnourished beaches. In addition, nourished beaches tend to have altered sediment grain size, shape, and distribution across the beach, which can lead to changes in the hydrodynamic patterns in the intertidal beach zone (Pilkey and Dixon 1996; Greene 2002).

In addition, the conditions in deeply excavated borrow pits can become anaerobic during certain times of the year. The dissolved oxygen concentration within these deep pits can be depressed to a level that adversely affects the ability of fish and invertebrates to utilize the area for spawning, feeding, and development (Pacheco 1984). For example, construction grade aggregate removal in Raritan Bay, NJ, Long Island Sound, and the intercoastal waterway in New Jersey have left deep pits and large depressions that are more than twice the depth of the surrounding area. The pits have remained chemically, physically, and biologically unstable with limited biological diversity for more than five decades. These borrow pits in Raritan Bay were found to possess depressed benthic communities and elevated levels of highly hydrated and organically enriched sediments (Pacheco 1984).

### *Altered sediment transport*

Longshore transport of sediments may be affected by the creation of borrow pits, which can be deep depressions taking several years to refill and can alter the nearshore sediment budget (Greene 2002). Longshore sediment transport may also be affected in the nearshore environment if material placed on the beach is not compatible with natural or historic material. In addition, nearshore rock groins are sometimes constructed in order to reduce erosion of the nourished beach, which alters the downdrift of sediment and may starve adjacent beaches of sand.

### *Alteration/loss of benthic habitat*

Sand infauna and sessile benthic organisms in the path of dredging equipment at the borrow site are generally removed and killed during mining. In addition, some mobile organisms, such as crustaceans and larval and juvenile fish, can be entrained by the dredge equipment. Following mining, species diversity of benthic infaunal organisms within borrow pits drops precipitously, but recolonization in sandy sediments typically occurs through larval transport and migration of postsettlement life-stages (i.e., juveniles and adults) (Greene 2002).

Benthic fauna at the beach site will be killed by burial following nourishment unless an organism is capable of burrowing through the overburden of sand (Greene 2002). Several factors determine survival of beach invertebrate fauna, including the ability for vertical migration through the sand overburden and the recruitment potential of larvae, juveniles, and adult organisms from adjacent areas (Greene 2002). Peterson et al. (2000) found an 86-99% reduction in the abundance of dominant species of beach macro-invertebrates ten weeks after nourishment on a North Carolina beach. These observations were made between the months of June and July, when the abundances of beach macro-invertebrates are typically at their maximum and providing the important ecosystem service of feeding abundant surf fishes and ghost crabs (Peterson et al. 2000).

### *Alteration of natural communities*

The recovery of the benthic infauna at a borrow site is dependent upon a number of factors, including the amount of material removed, the fauna present at the site and surrounding area prior to dredging, and the degree of sedimentation that occurs following dredging (Greene 2002). For sand habitats, the recovery time of benthic infauna within borrow sites has been reported to be as rapid as less than one year, while other studies have indicated recovery may take greater than five years (Greene 2002). Some differences in recovery time may be attributed to the fact that most benthic infauna recolonization studies look at abundance of individuals but fail to measure trophic level changes and the life history of individuals in the samples (Greene 2002). The postdredging benthic community may function very differently than does the predredging community. The borrow pits may require several years to refill with sediment and may contain a greater silt content than do the surrounding areas (Greene 2002). Generally, the degree of alteration of the sediment composition appears to be the largest factor in determining long-term impact at a borrow site (Greene 2002). The dissolved oxygen concentration within borrow pits can be depressed to a level that adversely affects the ability of fish and invertebrates to utilize the area for spawning, feeding, and development (Pacheco 1984).

Similar to the findings on the recovery of benthic infauna at borrow sites, results of studies assessing the recovery of organisms at nourished beaches are highly variable (Greene 2002). While some studies conclude that beach infauna populations may recover to predredging levels between two to seven months, other studies suggest recovery times are much longer (Greene 2002). Peterson et al. (2000) found a large reduction in prey abundance and body size of benthic macroinvertebrates at a nourished intertidal beach that likely translated to trophic level impacts on surf zone fishes and shorebirds.

### *Increased sedimentation/turbidity*

High turbidity in the water column and sedimentation on adjacent benthic habitats can result from resuspension of sediment at the discharge pipe and from sediment winnowing from the nourished beach into the surf zone. In addition, turbidity can also increase between the borrow site and the target beach when sand is lost during hopper loading, from leaks in the pipelines carrying sand to the beach, and from the dredging activity at the borrow site itself. High turbidity and suspended sediments can be persistent in the nearshore waters long after a beach is nourished if mud balls, silt, and clays are present in the mined sediment (Greene 2002).

Generally, the severity of the effects of suspended sediments on aquatic organisms increases as a function of sediment concentration and the duration of exposure (Newcombe and Jensen 1996). Some of the effects of suspended sediments on marine organisms can include altered foraging patterns and success (Breitburg 1988), gill abrasion and reduced respiratory functions, and death (Wilber and Clark 2001). The sensitivity of species to suspended sediments is highly variable and dependent upon the nature of the sediment and the life history stage of the species. The eggs and larval stages of marine and estuarine fish are generally highly sensitive to suspended sediment exposures compared to some freshwater taxa studied (Wilber and Clark 2001). Sedimentation from beach nourishment may also have adverse effects on invertebrates that serve as prey for fish (Greene 2002). Refer to the Marine Transportation and Offshore Dredging and Disposal chapters for more information regarding turbidity and sedimentation impacts on aquatic organisms.

### *Conservation measures and best management practices for beach nourishment (adapted from Hanson et al. 2003)*

1. Avoid sand mining in areas containing sensitive marine benthic habitats (e.g., spawning and feeding sites, hard bottom, cobble/gravel substrate, shellfish beds).
2. Avoid beach nourishment in areas containing sensitive marine benthic habitats adjacent to the beach (e.g., spawning and feeding sites, hard bottom, cobble/gravel substrate).
3. Conduct beach nourishment during the winter and early spring, when productivity for benthic infauna is at a minimum; this may minimize the impacts for some beach sites.
3. Assess source material for compatibility with that of material to be placed on beach (e.g., grain size and shape, color). Slope of nourished beach should mimic the natural beach profile.
4. Use upland beach material sources, if compatible, to avoid impacts associated with offshore sand mining.
5. Preserve, enhance, or create beach dune and native dune vegetation in order to provide natural beach habitat and reduce the need for nourishment.
6. Monitor turbidity during operations, and cease operations if turbidity exceeds predetermined threshold levels at the beach and borrow sites.
7. Implement seasonal restrictions to avoid impacts to habitat during species critical life history stages (e.g., spawning season, egg, and larval development period). Recommended seasonal work windows are generally specific to regional or watershed-level environmental conditions and species requirements.
8. Address the cumulative impacts of past, present, and foreseeable future development activies on aquatic habitats by considering them in the review process for beach nourishment projects.

## Wetland Dredging and Filling

The dredging and filling of coastal wetlands for commercial and residential development, port, and harbor development directly removes important wetland habitat and alters the habitat surrounding the developed area. Even development projects that appear to have minimal individual wetland impacts can have significant cumulative effects on the aquatic ecosystem. This section discusses the impacts on fishery habitat from dredging and filling freshwater and tidal wetlands for development purposes. Additional information on dredging and filling in freshwater wetlands and rivers and streams is provided in the chapter on Alteration of Freshwater Systems, and dredging and disposal of dredge material in subtidal habitats (e.g., navigation channel dredging and marine mining) have been addressed in the chapters on Marine Transportation and Offshore Dredging and Disposal. The primary impacts to fishery habitat from the introduction of fill material in or adjacent to wetlands include: (1) physical loss of habitat; (2) loss or impairment of wetland functions; and (3) changes in hydrologic patterns.

The discharge of dredge and fill materials are regulated under Section 404 of the Clean Water Act (CWA) of 1972 for all "waters of the United States," which include both freshwater and tidal wetlands. Some of the types of discharge of fill material covered under Section 404 of the CWA include: (1) placement of fill that is necessary to the construction of a structure or impoundment; (2) site development fills for recreational, industrial, commercial, or residential uses; (3) causeway or road fills, dams, or dikes; (4) artificial islands; (5) property protection and/or reclamation devices such as riprap, groins, seawalls, breakwaters, and revetments; (6) beach nourishment; (7) levees; (8) fill for structures such as sewage treatment facilities, intake and outfall pipes associated with power plants and subaqueous utility lines; and (9) artificial reefs.

### *Loss and alteration of wetland vegetation*

Salt marsh wetlands serve as habitat for early life history stages of many fish species, as well as shellfish, crabs, and shrimp, which use the physical structure of the marsh grasses as refuge from predators (Tyrrell 2005). Smaller fish, such as mummichog (*Fundulus heteroclitus*), Atlantic silverside (*Menidia menidia*), sticklebacks (*Gasterosteids*, spp.), and sheepshead minnow (*Cyprinidon variegates*), rely on salt marshes for parts of their life cycles. These species form the prey base of many larger, commercially important species such as a number of flounder species, black sea bass (*Centropristis striata*), and bluefish (*Pomatomus saltatrix*) (Collette and Klein-MacPhee 2002).

Filling wetlands removes productive habitat and eliminates the important functions that both aquatic and many terrestrial organisms depend upon. For example, the loss of wetland habitats reduces the production of detritus, an important food source for aquatic invertebrates; alters the uptake and release of nutrients to and from adjacent aquatic and terrestrial systems; reduces wetland vegetation, an important source of food for fish, invertebrates, and water fowl; hinders physiological processes in aquatic organisms (e.g., photosynthesis, respiration) caused by degraded water quality and increased turbidity and sedimentation; alters hydrological dynamics, including flood control and groundwater recharge; reduces filtration and absorption of pollutants from uplands; and alters atmospheric functions, such as nitrogen and oxygen cycles (Niering 1988; Mitsch and Gosselink 1993).

### *Altered hydrological regimes*

The discharge of dredged or fill material into aquatic habitats can modify current patterns and water circulation by obstructing the flow or by changing the direction or velocity of water flow and circulation. As a result, adverse changes can occur in the location, structure, and dynamics of aquatic communities; shoreline and substrate erosion and deposition rates; the deposition of suspended particulates; the rate and extent of mixing of dissolved and suspended components of the water body; and water stratification (Hanson et al. 2003). Altering the hydrology of wetlands can affect the water table, groundwater discharge, and soil salinity, causing a shift in vegetation patterns and quality of the habitat. Hydrology can be affected by fragmenting the habitat caused by the construction of roads and residential development or by building bulkheads, dikes, levees, and other structures designed to prevent or remove floodwater from the land around the wetlands (Niering 1988; Mitsch and Gosselink 1993). These structures also reduce natural tidal flushing and interfere with natural sediment-transport processes, all of which are important functions that maintain the integrity of the marsh habitat (Tyrrell 2005). Altered hydrodynamics can affect estuarine circulation, including short-term (diel) and longer term (seasonal or annual) changes (Deegan and Buchsbaum 2005). Alteration of the hydrology and soils of salt marsh wetlands has led to the invasion of an exotic haplotype of the common reed (*Phragmites australis*), which has spread dramatically and degraded salt marsh habitats along the Atlantic coast (Posey et al. 2003; Tyrrell 2005).

### *Loss of flood storage capacity*

Coastal wetlands absorb and store rain and urban runoff, buffering upland development from floods. In addition, coastal marshes provide a physical barrier that protects upland development from storm surge. As a result, the loss and alteration of coastal wetlands can cause upland development to be more prone to flooding from storms and heavy rains. Furthermore, altering the hydrological regimes of wetlands through construction of dikes, levees, and tide gates can redirect floodwater towards rivers and estuaries and bypass the natural flood storage functions of coastal wetlands.

### *Altered current patterns*

Replacing wetlands with roads, buildings, and other impervious surfaces increases the volume and intensity of storm water runoff, which can accelerate the rate of coastal erosion. Placing dredge material onto intertidal mud habitats can dramatically alter tidal flow. These effects can change the geomorphology and current patterns of rivers and estuaries and adversely affect habitat suitability for certain species. For example, counter current flows set up by freshwater discharges into estuaries are important for larvae and juvenile fish entering those estuaries. Behavioral adaptations of marine and estuarine species allow larvae and early juveniles to concentrate in estuaries (Deegan and Buchsbaum 2005).

### *Altered temperature regimes*

The loss of riparian and salt marsh vegetation can increase the amount of solar radiation reaching streams and rivers and results in an increase in the water temperatures of those water bodies (Moring 2005). Replacing coastal wetlands with impervious surfaces such as asphalt, which absorb more solar radiation than does vegetation, tends to raise the water temperature in adjacent aquatic environments. Altered temperature regimes have the ability to affect the distribution; growth rates; survival; migration patterns; egg maturation and incubation success; competitive ability; and resistance to parasites, diseases, and pollutants of aquatic organisms (USEPA 2003b). In freshwater habitats of the northeastern United States, the temperature regimes of cold-water fish such as salmon, smelt, and trout may be exceeded, leading to local extirpation of these species (Moring 2005). The removal of riparian vegetation can also have the effect of lowering water temperatures during winter, which can increase the formation of ice and delay the development of incubating fish eggs and alevins in salmonids (Hanson et al. 2003).

### *Release of rutrients/eutrophication*

When functioning properly, riparian and tidal wetlands support denitrification of nitrate-contaminated groundwater. While sediment particles can bind to some nutrients, resuspension of sediments following a disturbance tends to cause a rapid release of nutrients to the water column (Lohrer and Wetz 2003). Coastal wetlands reduce the risk of eutrophication in estuaries and nearby coastal waters (Tyrrell 2005) by absorbing nutrients in groundwater and storm water. Eliminating or degrading coastal wetlands through dredge and fill activities can eliminate these important wetland functions and adversely affect estuarine and marine ecosystems.

### *Release of contaminants*

The removal of wetlands eliminates an important wetland function: pollution filtration (Niering 1988; Mitsch and Gosselink 1993). Wetlands are capable of absorbing metals, pesticides, excess nutrients, oxygen-consuming substances, and other pollutants that would otherwise be transported directly to aquatic environments. In addition, dredging and filling of wetlands can release contaminants that have accumulated in the sediments into adjacent aquatic habitats.

### *Increased sedimentation/turbidity*

When functioning properly, riparian and tidal wetlands filter sediment and runoff from floodplain development. Siltation, sedimentation, and turbidity impacts on riverine and estuarine habitats can be worsened by the loss and replacement of wetlands with impervious surfaces. Suspended sediments in aquatic environments reduce the availability of sunlight to aquatic plants, cover fish spawning areas and food supply, interfere with filtering capacity of filter feeders, and can clog and harm the gills of fish (USEPA 2003b).

### *Loss of fishery productivity*

Hydrological modifications from dredge and fill activities and general coastal development are known to increase the amount of run-off entering the aquatic environment and may contribute to the reduced productivity of fishery resources. Many wetland dependent species, such as mummichog, Atlantic silverside, sticklebacks, and sheepshead minnow, are important prey for larger, commercially important species such as a number of flounder species, black sea bass, and bluefish (Collette and Klein-MacPhee 2002). Although there have been sharp declines or collapses of many estuarine-dependent fisheries in the United States, attributing reductions in fishery productivity directly to losses of wetland habitat can be complicated (Deegan and Buchsbaum 2005). Recent wetland losses can be quantified for discrete regions and the nation as a whole; however, a number of other factors, such as overfishing, cultural eutrophication, and altered input of freshwater caused by flood control structures, probably all contribute to a reduction in the productivity of fisheries. Since the implementation of the Clean Water Act in 1972, the major problems for coastal habitats have changed from outright destruction to more subtle types of degradation, such as cultural eutrophication (Deegan and Buchsbaum 2005).

### *Introduction of invasive species*

A nonnative haplotype of the common reed, *Phragmites australis,* has expanded its range along the entire east coast of the United States, primarily in wetland habitats disturbed by nutrient loading and hydrological alterations of salt marsh wetlands (Posey et al. 2003). *Phragmites* is tolerant of low-salinity conditions in salt marshes, which can occur with tidal restrictions from the construction of tide gates, bulkheads, and dikes. Under these conditions, *Phragmites* can out-compete native salt marsh vegetation such as *Spartina* sp. (Burdick et al. 2001; Deegan and Buchsbaum 2005). Salt marshes that are dominated by *Phragmites* may have reduced function and productivity compared to that of salt marshes consisting of native marsh vegetation (Tyrrell 2005).

### *Conservation measures and best management practices for wetland dredging and filling (adapted from Hanson et al. 2003)*

1. Apply a sequence of measures to avoid, minimize, and mitigate adverse impacts in wetlands to all proposed dredging projects. Dredging and filling within wetlands should be avoided to the maximum extent practicable.
2. Consider only "water-dependent" dredge and fill projects in wetlands and only after upland alternatives have been investigated.
3. Do not dispose dredge material in wetlands, and ensure that these materials meet or exceed applicable state and/or federal water quality standards.
4. Identify and characterize fishery habitat functions/services in the project areas prior to any dredge and fill activities.
5. Identify the direct and indirect affects of wetland fills on fishery habitat during proposed project reviews, including alterations of hydrology and water quality as a result of the proposed project.
6. Assess the cumulative impact from past, current, and all reasonably foreseeable future dredge and fill operations that impact aquatic habitats via federal, state, and local resource management and permitting processes.
7. Use seasonal restrictions to avoid impacts to habitat during species critical life history stages (e.g., spawning and egg development periods). Recommended seasonal work windows are generally specific to regional or watershed-level environmental conditions and species requirements.
8. Undertake activities in wetlands, if required, using only low ground pressure vehicles.
9. Address the cumulative impacts of past, present, and foreseeable future development activities on aquatic habitats by considering them in the review process for wetland dredge and fill projects.

## Overwater Structures

With increasing coastal development comes a concomitant interest in the construction and operation of waterfront facilities, the use of coastal waterways, and the environmental implications of these activities (Barr 1993). Overwater structures include commercial and residential piers and docks, floating breakwaters, moored barges, rafts, booms, and mooring buoys. These structures are typically located from intertidal areas to areas of water depths approximately 15 m below mean low water (i.e., the shallow subtidal zone). Light, wave energy, substrate type, depth, and water quality are the primary factors controlling the plant and animal assemblages found at a particular site. Overwater structures and associated use activities can alter these factors and interfere with key ecological functions such as spawning, rearing, and the use of refugia. Site-specific factors (e.g., water clarity, current, depth) and the type and use of a given overwater structure determine the occurrence and magnitude of these impacts (Hanson et al. 2003).

### *Shading impacts to vegetation*

Overwater structures create shade which reduces the light levels below the structure. Shading from overwater structures can reduce prey organism abundance and the complexity of the habitat by reducing aquatic vegetation and phytoplankton abundance (Haas et al. 2002). The size, shape, and intensity of the shadow cast by a particular structure are dependent upon its height, width, construction materials, and orientation. In field studies conducted in Massachusetts, the most significant factors affecting shading impacts on eelgrass were the height of the structure above vegetation, orientation of the dock, and dock width (Burdick and Short 1999). High and narrow piers and docks produce narrower and more diffuse shadows than do low and wide structures. Increasing the numbers of pilings used to support a pier increases the shade cast by pilings on the under-pier environment. In addition, less light is reflected underneath structures built with light-absorbing materials (e.g., wood) than from structures built with light-reflecting materials (e.g., concrete or steel). Under-pier light levels have been found to fall below threshold amounts for the photosynthesis of diatoms, benthic algae, eelgrass, and associated epiphytes and other autotrophs. Eelgrass and other macrophytes can be reduced or eliminated, even through partial shading of the substrate, and have little chance to recover (Kenworthy and Hauners 1991). Structures that are oriented north-south produce a shadow that moves across the bottom throughout the day, resulting in a smaller area of permanent shade than those that are oriented east-west (Burdick and Short 1999; Shafer 1999). In a report investigating effects of residential docks in south Florida, Smith and Mezich (1999) found approximately 40% of the docks surveyed had additions fixed to them (e.g., boat lifts and cradles, floating docks, finger piers). These structural additions increased the dock area (and seagrass impacts) and ranged from 16-77%, and contributed to mean seagrass impacts of 47% beyond the footprint of the dock.

Similar shading impacts to salt marsh vegetation from docks and piers have been reported. A study in Connecticut measuring the density and average plant height of salt marsh vegetation below docks and adjacent areas found a reduction in vegetative reproductive capacity caused by the presence of docks (Kearney et al. 1983). This study concluded that the height of the dock was a strong determining factor in the effects to salt marsh vegetation.

### *Altered hydrological regimes*

Alterations to wave energy and water transport from overwater structures can impact the nearshore detrital foodweb by altering the size, distribution, and abundance of substrate and detrital materials (Hanson et al. 2003). The disruption of longshore transport can alter substrate composition and can present potential barriers to the natural processes that build spits and beaches and provide substrates required for plant propagation, fish and shellfish settlement and rearing, and forage fish spawning (Hanson et al. 2003).

### *Contaminant releases*

Kennish (2002) identified a number of contaminants associated with overwater structures that can be released into the aquatic environment, including detergents, petroleum products, and copper. Treated wood used for pilings and docks releases contaminants into the aquatic environment. Creosote-treated wood pilings and docks commonly release PAH and other chemicals, such as ammoniacal copper zinc arsenate (ACZA) and chromated copper arsenate (CCA), which are applied to preserve the wood (Poston 2001; Weis and Weis 2002). These chemicals can become available to marine organisms through uptake by wetland vegetation, adsorption by adjacent sediments, or directly through the water column (Weis and Weis 2002). The presence of CCA in the food chain can also cause a localized reduction in species richness and diversity (Weis and Weis 2002). These preservatives are known to leach into marine waters after installation, but the rate of leaching is highly variable and dependent on many factors, including the age of the treated wood. Concrete or steel, on the other hand, are relatively inert and do not leach contaminants into the water.

### *Benthic habitat impacts*

Additional impacts associated with overwater structures may include damage to seagrasses and substrate scour from float chains and anchors (Kennish 2002). Docks located in intertidal areas that are exposed during low tides result in vessels resting on the substrate, which may impact shellfish beds, SAV, and intertidal mudflats. Vessels operating in shallow water to access docks may cause a resuspension of bottom sediments and may physically disrupt aquatic habitats, such as bank and shoreline (Barr 1993) and SAV through "prop dredging" (Burdick and Short 1999). Barr (1993) identified a number of potential impacts to aquatic ecosystems from resuspension of sediments caused by vessel activity, including reductions in primary productivity (e.g., phytoplankton and SAV), alteration of temperature, dissolved oxygen and pH of the water, abrasion and clogging of fishes gill filaments, and reductions in egg development and the growth of some fishes and invertebrates. Glasby (1999) found that epibiota on pier pilings at marinas subject to shading were markedly different than those in surrounding rock reef habitats. Shading by overwater structures may be responsible for the observed reductions in juvenile fish populations found under piers and the reduced growth and survival of fishes held in cages under piers, when compared to open habitats (Able et al. 1998; Duffy-Anderson and Able 1999).

### *Increased erosion/accretion*

Pilings can alter adjacent substrates with increased deposition of sediment from changes in current fields or shell material deposition from piling communities. Changes in substrate type can alter the nature of the flora and fauna native to a given site. Kearney et al. (1983) found that docks and pier walkways cause shading impacts to salt marsh vegetation, reduce plant root mat, and may lead to soil erosion in the area of the structures. In the case of pilings, native dominant communities typically associated with sand, gravel, mud, and eelgrass substrates may be replaced by communities associated with shell hash substrates (Penttila and Doty 1990; Nightingale and Simenstad 2001; Haas et al. 2002). In addition to impacts to eelgrass habitat from overwater structures, Penttila and Doty (1990) found that changes to current fields around structures caused altered sediment distribution and topography that created depressions along piling lines.

### *Changes in predator/prey interaction*

Fish use visual cues for spatial orientation, prey capture, schooling, predator avoidance, and migration. The reduced-light conditions found under an overwater structure limit the ability of fish, especially juveniles and larvae, to perform these essential activities (Hanson et al. 2003). In addition, the use of artificial lighting on docks and piers creates unnatural nighttime conditions that can increase the susceptibility of some fish to predation and interfere with predator/prey interactions (Nightingale and Simenstad 2001).

### *Cumulative effects*

While the effect of some individual overwater structures on fishery habitat may be minimal, the overall impact may be substantial when considered cumulatively. For example, although shading impacts on seagrasses may affect a relatively small area around overwater structures, fragmentation of seagrass beds along a highly developed shoreline or within a bay can be considerable. Fragmentation of seagrass habitat can lower the integrity of the remaining seagrass beds, leaving it more susceptible to other impacts (Burdick and Short 1999). The additive effect of these structures increases the overall magnitude of impact, reduces the ability of the habitat to support native plant and animal communities, and makes the habitat more susceptible to damage from storms and disease.

### *Conservation measures and best management practices for overwater structures (adapted from Hanson et al. 2003)*

1. Use upland boat storage whenever possible to minimize need for overwater structures.
2. Locate overwater structures in sufficiently deep waters to avoid intertidal and shade impacts, to minimize or preclude dredging, to minimize groundings, and to avoid displacement of SAV, as determined by a preconstruction survey.
3. Design piers, docks, and floats to be multi-use facilities serving multiple homeowners in order to reduce the overall number of such structures and the nearshore habitat that is impacted.
4. Incorporate measures that increase the ambient light transmission under piers and docks. Some of these measures include: maximizing the height of the structure and minimizing the width of the structure to decrease shade footprint; grated decking material; using the fewest number of pilings necessary to support the structures to allow light into under-pier areas and minimize impacts to the substrate; and aligning piers, docks, and floats in a north-south orientation to allow the path of the sun to cross perpendicular to the length of the structure and reduce the duration of shading.
5. Encourage seasonal use of docks and off-season haul-out.
6. Avoid placing floating docks in areas supporting SAV. Locate floats in deep water to avoid light limitation and grounding impacts to the intertidal zone, and ensure that adequate water depth is available between the substrate and the bottom of the float throughout all tide cycles.
7. Incorporate float stops in dock proposals when it is impracticable or impossible to avoid placing floating docks in water deep enough to avoid contact with the bottom to avoid mechanical and/or hydraulic damage to the substrate from the float during low tides. Float stops should be designed to provide a minimum of 2 ft of clearance between the float and substrate to prevent hydraulic disturbances to the bottom. Greater clearances may be necessary in higher energy environments that experience strong wave action.
8. Conduct in-water work during the time of year when managed species and prey species are least likely to be impacted.
9. Avoid the use of treated wood timbers or pilings to the extent practicable. The use of alternative materials such as untreated wood, concrete, or steel is recommended. Concrete and steel pilings are generally considered to be less damaging, since they help reflect light under docks and generally do not release contaminants into the aquatic environment.
10. Orient artificial lighting on docks and piers such that illumination of the surrounding waters at night is avoided.
11. Address the cumulative impacts of past, present, and foreseeable future development projects on aquatic habitats by considering them in the review process for overwater structure projects.

## Pile Driving and Removal

Pilings provide support for the decking of piers and docks; they function as fenders and dolphins to protect structures, support navigation markers, and are used to construct breakwaters and bulkheads. Materials used in pilings include steel, concrete, wood (both treated and untreated), plastic or a combination thereof, and they are usually driven into the substrate with impact hammers or vibratory hammers (Hanson et al. 2003). Impact hammers consist of a heavy weight that is repeatedly dropped onto the top of the pile, driving it into the substrate. Vibratory hammers utilize a combination of a stationary, heavy weight and vibration, in the plane perpendicular to the long axis of the pile, to force the pile into the substrate. While impact hammers are able to drive piles into most substrates (e.g., hardpan, glacial till), vibratory hammers are limited to softer, unconsolidated substrates (e.g., sand, mud, gravel). Piles can be removed by using a variety of methods, including vibratory hammer, direct pull, clamshell grab, or cutting/breaking the pile below the mudline. Vibratory hammers can be used to remove all types of pile, including wood, concrete, and steel. Broken stubs are often removed with a clamshell and crane. In other instances, piles may be cut or broken below the mudline, leaving the buried section in place (Hanson et al. 2003).

### *Sound energy impacts*

Pile driving with impact hammers can generate intense underwater sound pressure waves that may adversely affect fish species and their habitats. These pressure waves have been shown to injure and kill fish (CalTrans 2001; Longmuir and Lively 2001). Injuries directly associated with pile driving include rupture of the swimbladder and internal hemorrhaging, but these have been poorly studied (CalTrans 2001).

### *Benthic habitat impacts*

The extraction of piles can result in altered sediment composition and depressions in the bottom, which may cause erosion and loss of sediment. Bottom depressions may fill in with fine sediments and silt, changing the characteristics of the benthic habitat. Removal of piles may cause sediments to slough off and elevate the suspended sediment concentrations at the work area (Hanson et al. 2003). The subsequent sedimentation and turbidity can impact adjacent sensitive habitats, such as SAV.

### *Increased sedimentation/turbidity and contaminant releases*

The primary adverse effect of removing piles is the suspension of sediments, which may result in harmful levels of turbidity and release of contaminants contained in those sediments. Contaminants contained within the sediments in the area of pilings can become available to aquatic plants and animals when pilings are extracted from the substrate. Sediment plumes may also be created around the pilings when they are installed, although it is usually much less than the turbidity created during removal. Some turbidity may be generated when piles are installed or removed with hydraulic jets, although this technique may not be widely used in the northeast coastal region. Vibratory pile removal tends to cause the sediments to slough off, resulting in relatively low levels of suspended sediments and contaminants (Hanson et al. 2003). Vibratory removal of piles may be preferable in some circumstances because it can be used on all types of piles, providing that they are structurally sound. Breaking or cutting the pile below the mudline may suspend only small amounts of sediment, providing the stub is left in place and little digging is required to access the pile. Direct pull or use of a clamshell to remove broken piles, however, may suspend large amounts of sediment and contaminants. When the piling is pulled from the substrate with these two methods, sediments clinging to the piling will slough off as it is raised through the water column, producing a potentially harmful plume of turbidity and/or contaminants. The use of a clamshell may suspend additional sediment if it penetrates the substrate while grabbing the piling (Hanson et al. 2003). For more information on turbidity and sedimentation, consult the chapters on Physical Effects: Water Intake and Discharge Facilities and Marine Transportation. Additional information on contaminant releases can be reviewed in the Chemical Effects: Water Discharge Facilities chapter.

### *Conservation measures and best management practices for pile driving and removal (adapted from Hanson et al. 2003)*

1. Drive piles during low tide periods when substrates are exposed in intertidal areas.
2. Use a vibratory hammer to install piles, when possible. Under those conditions where impact hammers are required for reasons of seismic stability or substrate type, it is recommended that the pile be driven as deep as possible with a vibratory hammer prior to the use of the impact hammer.
3. Implement measures to attenuate the sound or minimize impacts to aquatic resources during piling installation. Methods to mitigate sound impacts include, but are not limited to, the following:
    a. Surround the pile with an air bubble curtain system or dewatered cofferdam.
    b. Drive piles during low water conditions for intertidal areas.
    c. Utilize appropriate work windows that avoid impacts during sensitive times of year (e.g., anadromous fish runs and spawning, larval, and juvenile development periods).
4. Remove creosote-coated piles completely rather than cutting or breaking off if the pile is structurally sound.
5. Minimize the suspension of sediments and disturbance of the substrate when removing piles. Measures to help accomplish this include, but are not limited to, the following:
    a. Remove piles with a vibratory hammer when practicable, rather than with the direct pull or clamshell method.
    b. Remove the pile slowly to allow sediment to slough off at or near the mudline.
    c. Hit or vibrate the pile first to break the bond between the sediment and pile to minimize the potential for the pile to break, as well as reduce the amount of sediment sloughing off the pile during removal.
    d. Encircle the pile or piles with a silt curtain that extends from the surface of the water to the substrate.
6. Fill all holes left by the piles with clean, native sediments, if possible.
7. Place piles on a barge equipped with a basin to contain all attached sediment and runoff water after removal. Creosote-treated timber piles should be cut into short lengths to prevent reuse, and all debris, including attached, contaminated sediments, should be disposed of in an approved upland facility.
8. Drive broken/cut stubs with a pile driver sufficiently below the mudline to prevent release of contaminants into the water column as an alternative to their removal.
9. Use seasonal restrictions to avoid impacts to habitat during species critical life history stages (e.g., spawning and egg development periods). Recommended seasonal work windows are generally specific to regional or watershed-level environmental conditions and species requirements.
10. Address the cumulative impacts of past, present, and foreseeable future development activities on aquatic habitats by considering them in the review process for pile driving projects.

## Marine Debris

Marine debris is a chronic problem along much of the US coast, resulting in littered shorelines and estuaries and creating hazards for marine organisms. Marine debris consists of a large variety of anthropogenic materials such as generic litter, hazardous wastes, and discarded or lost fishing gear and can have varying degrees of negative effects on the coastal ecosystem (Hanson et al. 2003). It generally enters waterways indirectly through rivers and storm drains or by direct ocean dumping. Several laws and regulatory programs exist to prevent or control the disposal of industrial wastes and the release of marine debris from ocean sources, including commercial merchant vessels (e.g., galley waste and other trash), recreational boaters and fishermen, offshore oil and gas exploration and facilities, military and research vessels, and commercial fishing vessels (Cottingham 1988). Despite these laws and regulations, marine debris continues to adversely impact our waters (Hanson et al. 2003). See the Marine Transportation chapter for more information on marine debris.

Land-based sources of marine debris account for approximately 80% of the marine debris on the beaches and in the waters of the Gulf of Maine (Hoagland and Kite-Powell 1997), as well as other coastal areas of the United States (Hanson et al. 2003). Land-based debris can originate from a wide variety of sources, including combined sewer overflows and storm drains; storm-water runoff; landfills; solid waste disposal; manufacturing facilities; poorly maintained garbage bins; floating structures (i.e., docks and piers); and general littering of beaches, rivers, and open waters (Cottingham 1988; Hanson et al. 2003). Plastics account for 50-60% of marine debris collected from the Gulf of Maine (Hoagland and Kite-Powell 1997).

### *Entanglement and ingestion*

Entanglement and ingestion of marine debris by marine species is known to affect individuals of at least 267 species worldwide, including 86% of all sea turtle species, 44% of all seabird species, and 43% of all marine mammal species (Laist 1997). Plastic debris may be ingested by seabirds, fish and invertebrates, sea turtles, and marine mammals, which can obstruct the animal's intestinal tract and cause infections and death (Cottingham 1988). A study of marine debris ingestion by seabirds in the southern Atlantic Ocean found that 73% of all birds sampled had ingested some type of marine debris, and plastics composed 66% of all debris occurrences (Copello and Quintana 2003).

### *Introduction of invasive species*

Marine debris discarded from commercial cargo and recreational vessels are one of the primary methods of transporting nonindigenous marine life around the world, some of which have become invasive species that can alter the structure and function of aquatic ecosystems (Valiela 1995; Carlton 2001; Niimi 2004). Refer to the chapters on Marine Transportation, and Introduced/Nuisance Species and Aquaculture for more information on invasive species.

### *Contaminant releases and introduction of pathogens*

The type of debris from land-based sources can include raw or partially treated sewage, litter, hazardous materials (e.g., PAH, paint, solvents), and discarded trash. The typical floatable debris from combined sewer overflows includes street litter, sewage containing viral and bacterial pathogens, pharmaceutical by-products from human excretion, and pet wastes. It may contain condoms, tampons, and contaminated hypodermic syringes, all of which can pose physical and biological threats to fishery habitat (Hanson et al. 2003). Toxic substances in plastics, for example, can persist in the environment and bioaccumulate through the food web and can kill or impair fish and invertebrates that use habitat polluted by these materials.

### *Conversion of habitat*

Because of the wide range and diversity of sources and materials contributing to marine debris, the effects on aquatic habitats are likewise wide-ranging and diverse. Floating or suspended trash can directly affect fish and invertebrates that may consume or are entangled by the debris. Debris that settles to the bottom of rivers, estuaries, and open ocean areas may continue to cause environmental problems. Plastics and other materials with a large surface area can cover and suffocate sessile animals and plants. Debris can be transported by currents to other areas where it can become snagged and attached to benthic reefs, damaging these sensitive habitats.

### *Conservation measures and best management practices for marine debris (adapted from Hanson et al. 2003)*

1. Require all existing and new commercial construction projects near the coast (e.g., marinas and ferry terminals, recreational facilities, boat building and repair facilities) to develop and implement refuse disposal plans.
2. Encourage proper trash disposal in coastal and ocean settings.
3. Provide resources to the public on the impact of marine debris and guidance on how to reduce or eliminate the problem.

# CHAPTER THREE: ENERGY-RELATED ACTIVITIES

## Petroleum Exploration, Production, and Transportation

### *Introduction*

The exploration, production, and transportation of petroleum have the potential to impact riverine, estuarine, and marine environments on the northeastern US coast. Petroleum exploration, production, and transportation are a particular concern in areas such as the Gulf of Maine and Georges Bank, which support important fishery resources and represent significant value to the US economy. Although petroleum exploration and production do not currently occur within the northeast coastal and offshore region, the transportation of oil and gas (i.e., pipelines and tankers) and the associated infrastructure are widespread. It is expected that issues relating to petroleum development will continue to gain importance as world energy costs and demands rise. The Energy Policy Act of 2005 (Pub. L. 109-58, § 357, 42 U.S.C. §15912) authorizes the Minerals Management Service (MMS) to perform surveys (exploration) for petroleum reserves on the Outer Continental Shelf (OCS) of the United States. The OCS is the submerged lands, subsoil, and seabed lying between the United States' seaward jurisdiction and the seaward extent of federal jurisdiction.

Petroleum exploration involves seismic testing, drilling sediment cores, and test wells in order to locate potential oil and gas deposits. Petroleum production includes the drilling and extraction of oil and gas from known reserves. Oil and gas rigs are placed on the seabed and as oil is extracted from the reservoirs, it is transported directly into pipelines. While rare, in cases where the distance to shore is too great for transport via pipelines, oil is transferred to underwater storage tanks. From these storage tanks, oil is transported to shore via tanker (CEQ 1977). According to the MMS, there are 21,000 miles of pipeline on the United States OCS. According to the National Research Council (NRC), pipeline spills account for approximately 1,900 tonnes per year of petroleum into US OCS waters, primarily in the central and western Gulf of Mexico (NRC 2003).

The major sources of oil releases as a result of petroleum extraction include accidental spills and daily operational discharges. The NRC estimates the largest anthropogenic source of petroleum hydrocarbon releases into the marine environment is from petroleum extraction-related activities. Approximately 2,700 tonnes per year in North America and 36,000 tonnes per year worldwide are introduced to the marine environment as a result of "produced waters" (NRC 2003). "Produced waters" are waters that are pumped to the surface from oil reservoirs which cannot be separated from the oil. Produced waters are either injected back into reservoirs or discharged into the marine environment (NRC 2003). Over 90% of the oil released from extraction activities is from produced water discharges which contain dissolved compounds (i.e., polycyclic aromatic hydrocarbons, PAH) and dispersed crude oil (NRC 2003). These compounds stay suspended in the water column and undergo microbial degradation or are sorbed onto suspended sediments and are deposited on the seabed. Elevated levels of PAH in sediments are typically found up to 300 m from the discharge point (NRC 2003).

While petroleum extraction and transportation can result in impacts to the marine environment, it is important to note that natural seeps contribute to approximately 60% of all petroleum hydrocarbons that are released into the marine environment (NRC 2003). In addition, land-based runoff and discharges by two–stroke recreational boating engines account for nearly 22% of the total petroleum released into the marine environment in North America (NRC 2003).

## *Underwater noise*

Oil and gas activities generate noise from drilling activities, construction, production facility operations, seismic exploration, and supply vessel and barge operations that can disrupt or damage living marine resources. The effects of oil exploration-related seismic energy may cause fish to disperse from the acoustic pulse with possible disruption to their feeding patterns (Marten et al. 2001). Larvae and young fish are particularly sensitive to noise generated from underwater seismic equipment. Noise in the marine environment may adversely affect marine mammals by causing them to change behavior (e.g., movement and feeding), interfering with echolocation and communication, or injuring hearing organs (Richardson et al. 1995). Noise issues related to petroleum tanker traffic can adversely affect fishery resources within the marine environment, particularly within estuarine areas which host much of the nation's petroleum land-based port activities. Refer to the chapters on Marine Transportation and Global Effects and Other Impacts for information regarding impacts to fishery resources from underwater noise.

## *Habitat conversion and loss*

Petroleum extraction and transportation can lead to a conversion and loss of habitat in a number of ways. Activities such as vessel anchoring, platform or artificial island construction, pipeline laying, dredging, and pipeline burial can alter bottom habitat by altering substrates used for feeding or shelter. Disturbances to the associated epifaunal communities, which may provide feeding or shelter habitat, can also result. The installation of pipelines associated with petroleum transportation can have direct and indirect impacts on offshore, nearshore, estuarine, wetland, beach, and rocky shore coastal zone habitats. The destruction of benthic organisms and habitat can occur through the installation of pipelines on the sea floor (Gowen 1978). Benthic organisms, especially prey species, may recolonize disturbed areas, but this may not occur if the composition of the substrate is drastically changed or if facilities are left in place after production ends.

The discharge of drilling cuttings (i.e., crushed sedimentary rock) during petroleum extraction operations can result in varying degrees of change to the sea floor and affect feeding, nursery, and shelter habitat for various life stages of marine organisms. Cuttings may adversely affect bottom-dwelling organisms at the site by burial of immobile forms or forcing mobile forms to migrate. The accumulation of drill cuttings on the ocean floor can alter the benthic sedimentary environment (NRC 2003).

Physical damage to coastal wetlands and other fragile areas can be caused by onshore infrastructure and pipelines associated with petroleum production and transportation. Physical alterations to habitat can occur from the construction, presence, and eventual decommissioning and removal of facilities such as islands or platforms, storage and production facilities, and pipelines to onshore common carrier pipelines, storage facilities, or refineries. For additional information regarding impacts of pipelines associated with petroleum production, refer to the section on Cables and Pipelines in this chapter of the report.

## *Contaminant discharge*

A variety of contaminants can be discharged into the marine environment as a result of petroleum extraction operations. Waste discharges associated with a petroleum facility include drilling well fluids, produced waters, surface runoff and deck drainage, and solid-waste from wells (i.e., drilling mud and cuttings) (NPFMC 1999). In addition to crude oil spills, chemical, diesel, and other contaminant spills can occur with petroleum-related activities (NPFMC 1999).

Produced waters contain finely dispersed oil droplets that can stay suspended in the water column or can settle out into sediments. Produced waters are generally more saline than seawater and contain elevated concentrations of radionuclides, metals, and other contaminants. Elevated levels of contaminated sediments typically extend up to 300 m from the discharge point (NRC 2003). In estuarine waters, higher saline produced waters can affect the salt wedge and form dense saltwater plumes.

The discharge of oil drilling mud can change the chemical and physical characteristics of benthic sediments at the disposal site by introducing toxic chemical constituents. The addition of contaminants can reduce or eliminate the suitability of the water column and substrate as habitat for fish species and their prey. The discharge of oil-based drill cuttings are currently not permitted in US waters; however, where oil-based drill cuttings have been discharged, there is evidence that sediment contamination and benthic impacts can occur up to 2 km from the production platform (NRC 2003).

The petroleum refining process converts crude oil into gasoline, home heating oil, and other refined products. The process of refining crude oil into various petroleum products produces effluents, which can degrade coastal water quality. Oil refinery effluents contain many different chemicals at different concentrations including ammonia, sulphides, phenol, and hydrocarbons. Toxicity tests have shown that most refinery effluents are toxic, but to varying extents. Some species are more sensitive and the toxicity may vary throughout the life cycle. Experiments have shown that not only can the effluents be lethal, but they can often have sublethal effects on growth and reproduction (Wake 2005). Field studies have shown that oil refinery effluents often have an adverse impact on aquatic organisms (i.e., an absence of all or most species), which is more pronounced in the area closest to the outfall (Wake 2005).

The operation of oil tankers can discharge contaminants into the water column and result in impacts to pelagic and benthic organisms. Older tankers that do not have segregated ballast tanks (i.e., completely separated from the oil cargo and fuel systems) can discharge ballast water containing contaminants (NRC 2003).

### *Discharge of debris*

Petroleum extraction and transportation can result in the discharge of various types of debris, including domestic wastewater generated from offshore facilities, solid-waste from wells (i.e., drilling mud and cuttings), and other trash and debris from human activities associated with the facility (NPFMC 1999). Debris, either floating on the surface, suspended in the water column, covering the benthos, or along the shoreline can have deleterious impacts on fish and shellfish within riverine habitat, as well as in benthic and pelagic habitats in the marine environment (NEFMC 1998). Debris from petroleum extraction and transportation activities can be ingested by fish (Hoagland and Kite-Powell 1997). Reduction and degradation of habitat by debris can alter community structure and affect the sustainability of fisheries.

### *Oil spills*

In even moderate quantities, oil discharged into the environment can affect habitats and living marine resources. Accidental discharge of oil can occur during almost any stage of exploration, development, or production on the OCS and in nearshore coastal areas and can occur from a number of sources, including equipment malfunction, ship collisions, pipeline breaks, other human error, or severe storms (Hanson et al. 2003). Oil spills can also be attributed to support activities associated with product recovery and transportation and can also involve various contaminants including hazardous chemicals and diesel fuel (NPFMC 1999).

Oil, characterized as petroleum and any derivatives, can be a major stressor to inshore fish habitats. Oil can kill marine organisms, reduce their fitness through sublethal effects, and disrupt the structure and function of the marine ecosystem (NRC 2003). Short-term impacts include interference with the reproduction, development, growth and behavior (e.g., spawning and feeding) of fishes, especially at early life-history stages (Gould et al. 1994). Petroleum compounds are known to have carcinogenic and mutagenic properties (Larsen 1992). Various levels of toxicity have been observed in Atlantic herring (*Clupea harengus*) eggs and larvae exposed to crude oil in concentrations of 1-20 ml/L (Blaxter and Hunter 1982). Oil spills may cover and degrade coastal habitats and associated benthic communities or may produce a slick on the surface waters which disrupts the pelagic community. These impacts may eventually lead to disruption of community organization and dynamics in affected regions. Oil can persist in sediments for years after the initial contamination (NRC 2003), interfering with physiological and metabolic processes of demersal fishes (Vandermeulen and Mossman 1996).

Oil spills can have adverse effects to both subtidal and intertidal vegetation. Direct exposure to petroleum can lead to die off of submerged aquatic vegetation (SAV) in the first year of exposure. Certain species which propagate by lateral root growth rather than seed germination may be less susceptible to oil in the sediment (NRC 2003). Oil has been demonstrated to disrupt the growth of vegetation in estuarine habitats (Lin and Mendelssohn 1996). Kelp located in low energy environments can retain oil in their holdfasts for extended periods of time. Oil spills are known to cause severe and long-term damage to salt marshes through the covering of plants and contamination of sediments. Lighter and more refined oils such as No. 2 fuel oil are extremely toxic to smooth cordgrass (*Spartina alterniflora*) (NRC 2003). Impacts to salt marsh habitats from oil spills depend on type, coverage, and amount of oil. Oil spills within salt marshes will likely have a greater impact in the spring growing season, compared to the dormant periods in the fall and winter.

Habitats that are susceptible to damage from oil spills include the low-energy coastal bays and estuaries where heavy deposits of oil may accumulate and essentially smother intertidal and salt marsh wetland communities. High-energy cobble environments are also susceptible to oil spills, as oil is driven into sediments through wave action. For example, many of the beaches in Prince William Sound, AK, with the highest persistence of oil following the *Exxon Valdez* oil spill were high-energy environments containing large cobbles overlain with boulders. These beaches were pounded by storm waves following the spill, which drove the oil into and well below the surface (Michel and Hayes 1999). Oil contamination in sediments may persist for years. For example, subsurface oil was detected in beach sediments of Prince William Sound twelve years after the *Exxon Valdez* oil spill, much of it unweathered and more prevalent in the lower intertidal biotic zone than at higher tidal elevations (Short et al. 2002).

Oil can have severe detrimental impacts on offshore habitats, although the effects may not be as acute as in inshore, sheltered areas. Offshore spills or wellhead blowouts can produce an oil slick on surface waters which can disrupt entire pelagic communities (i.e., phytoplankton and zooplankton). The disruption of plankton communities can interfere with the reproduction, development, growth, and behavior of fishes by altering an important prey base.

Physical and biological forces act to reduce oil concentrations (Hanson et al. 2003). Generally, the lighter fraction aromatic hydrocarbons evaporate rapidly, particularly during periods of high wind and wave activity. Heavier oil fractions typically pass through the water column and settle to the bottom. Suspended sediments can adsorb and carry oil to the seabed. Hydrocarbons may be solubilized by wave action which may enhance adsorption to sediments, which then sink to the seabed and contaminate benthic sediments (Hanson et al. 2003). Tides and hydraulic gradients allow movement of soluble and slightly soluble contaminants (e.g., oil) from beaches to surrounding streams in the hyporheic zone (i.e., the saturated zone under a river or stream, comprising substrate with the interstices filled with water) where pink salmon (*Oncorynchus* *gorbuscha*) eggs incubate (Carls et al. 2003). Oil can reach nearshore areas and affect productive nursery grounds, such as estuaries that support high densities of fish eggs and larvae. An oil spill near a particularly important hydrological zone, such as a gyre where fish or invertebrate larvae are concentrated, could also result in a disproportionately high loss of a population of marine organisms (Hanson et al. 2003). Epipelagic biota, such as eggs, larvae and other planktonic organisms, would be at risk from an oil spill. Planktonic organisms cannot actively avoid exposure, and their small size means contaminants may be absorbed quickly. In addition, their proximity to the sea surface can increase the toxicity of hydrocarbons several-fold and make them more vulnerable to photo-enhanced toxicity effects (Hanson et al. 2003).

Many factors determine the degree of damage from a spill, including the composition of the petroleum compound, the size and duration of the spill, the geographic location of the spill, and the weathering process present (NRC 2003). Although oil is toxic to all marine organisms at high concentrations, certain species and life history stages of organisms appear to be more sensitive than others. In general, the early life stages (i.e., eggs and larvae) are most sensitive, juveniles are less sensitive, and adults least so (Rice et al. 2000). Some marine species may be particularly susceptible to hydrocarbon spills if they require specific habitat types in localized areas and utilize enclosed water bodies, like estuaries or bays (Stewart and Arnold 1994).

Small but chronic oil spills may be a particular problem to the coastal ecosystem because residual oil can build up in sediments. Low-levels of petroleum components from such chronic pollution have been shown to accumulate in fish tissues and cause lethal and sublethal effects, particularly at embryonic stages. Effects on Atlantic salmon (*Salmo salar*) from low-level chronic exposure to petroleum components and byproducts (i.e., polycyclic aromatic hydrocarbons [PAH]) have been shown to increase embryo mortality, reduce growth (Heintz et al. 2000), and lower the return rates of adults returning to natal streams (Wertheimer et al. 2000).

As spilled petroleum products become weathered, the aromatic fraction of oil is dominated by PAH as the lighter aromatic components evaporate into the atmosphere or are degraded. Because of its low solubility in water, PAH concentrations probably contribute little to acute toxicity (Hanson et al. 2003). However, lipophilic PAH (those likely to be bonded to fat compounds) may cause physiological injury if they accumulate in tissues after exposure (Carls et al. 2003; Heintz et al. 2000). Even concentrations of oil that are diluted sufficiently to not cause acute impacts in marine organisms may alter certain behavior or physiological patterns. For example, “fatty change,” a degenerative disease of the liver, can occur from chronic exposure to organic contaminants such as oil (Freeman et al. 1981).

Sublethal effects that may occur with exposure to PAH include impairment of feeding mechanisms for benthic fish and shellfish, growth and development rates, energetics, reproductive output, juvenile recruitment rates, increased susceptibility to disease and other histopathic disorders (Capuzzo 1987), and physical abnormalities in fish larvae (Urho and Hudd 1989). Effects of exposure to PAH in benthic species of fish include liver lesions, inhibited gonadal growth, inhibited spawning, reduced egg viability and reduced growth (Johnson et al. 2002). Gould et al. (1994) summarized various toxicity responses to winter flounder (*Pseudopleuronectes americanus*) exposed to PAH and other petroleum-derived contaminants, including liver and spleen diseases, immunosuppression responses, tissue necrosis, altered blood chemistry, gill tissue clubbing, mucus hypersecretion, altered sex hormone levels, and altered reproductive impairments. For Atlantic cod (*Gadus morhua*) exposed to various petroleum products, responses included reduced growth rates, gill hyperplasia, increased skin pigmentation, hypertrophy of gall bladder, liver disease, delayed spermatogenesis, retarded gonadal development and other reproductive impairments, skin lesions, and higher parasitic infections (Gould et al. 1994).

## *Oil spill clean-up activities*

There are a number of oil spill response and cleanup methods available. Chemical dispersants are used primarily in open water environments. Dispersants contain surfactant chemical that under proper mixing conditions and concentrations attach to oil molecules and reduce the interfacial tension between oil molecules (NOAA 1992). This allows oil molecules to break apart and thus break down the oil slick. Depending on the environmental conditions and biological resource present, dispersants can result in acute toxicity. Exposure to high concentrations of oil dispersants has been shown to block the fertilization of eggs and induce rapid cytolysis of developing eggs and larvae in Atlantic cod (Lonning and Falk-Petersen 1978). Other methods of cleanup for open water spills include in-situ burning and nutrient and microbial remediation. In each case, impacts are dependent on the resources present in the particular location. Other forms of shoreline cleanup include the use of sorbents, trenching, sediment removal, and water flooding/pressure washing. Sediment removal and pressure washing will result in direct impact to the benthos. Trampling and cutting of salt marsh vegetation during cleanup activities can be severe, causing damage to plants and forcing oil into the sediments. However, impacts associated with the cleanup activities need to be weighed against the impacts created by the the spill itself.

## *Siltation, sedimentation, and turbidity*

Exploratory and construction activities may result in resuspension of fine-grained mineral particles, usually smaller than silt, in the water column. Fish and invertebrate habitat may be adversely affected by elevated levels of suspended particles (Arruda et al. 1983), which can result in both lethal and sublethal impacts to marine organisms (Newcombe and MacDonald 1991; Newcombe and Jensen 1996). Short-term impacts from increases in suspended particles may include high turbidity, reduced light, and sedimentation which may lead to the loss or complexity of benthic habitat (USFWS and NMFS 1999). Suspended particles can reduce light penetration and lower the rate of photosynthesis and the primary productivity of the aquatic area, especially if the turbidity is persistent (Gowen 1978). Groundfish and other fish species can suffer reduced feeding ability and limited growth if high levels of suspended particles persist in the water column. Other problems associated with suspended solids include disrupted respiration and water transport rates in marine organisms, reduced filtering efficiencies in invertebrates, reduced egg buoyancy, disrupted ichthyoplankton development, reduced growth and survival of filter feeders, and decreased foraging efficiency of sight-feeders (Gowen 1978; Messieh et al. 1991; Barr 1993). Demersal eggs of fish and invertebrates can be adversely impacted by sediment deposition and suffocation. For example, hatching is delayed for striped bass (*Morone saxatilis*) and white perch (*Morone americana*) exposed to sediment concentrations as low as 100 mg/L for 1 day (Wilber and Clarke 2001). Berry et al. (2004) reported a decreased hatching success for winter flounder eggs with increasing depth of burial by sediment. No hatching occurred at burial depths of approximately 2 mm. Breitburg (1988) found the predation rates of striped bass larvae on copepods to decrease by 40% when exposed to high turbidity conditions in the laboratory. Anadromous fish passage in estuarine and riverine environments can also be adversely impacted by increased turbidity. For example in laboratory experiments, rainbow smelt (*Osmerus mordax*) showed signs of increased swimming activity at suspended sediment concentrations as low as 20 mg/L, suggesting fish responded to increased sediment concentrations with an “alarm reaction” (Chiasson 1993).

Shallow water environments, rocky reefs, nearshore and offshore rises, salt and freshwater marshes (wetlands), and estuaries are more likely to be adversely impacted than are open-water habitats. This is due, in part, to their higher sustained biomass and lower water volumes, which decrease their ability to dilute and disperse suspended sediments (Gowen 1978).

### *Conservation recommendations and best management practices for petroleum exploration, production, and transportation (adapted from Hanson et al. 2003)*

1. Conduct preconstruction biological surveys in consultation with resource agencies to determine the extent and composition of biological populations or habitat in the proposed impact area. Construction should be sited to minimize impacts to fishery resources.
2. Avoid the discharge of produced waters into marine and estuarine environments. Reinject produced waters into the oil formation whenever possible.
3. Avoid discharge of drilling mud and cuttings into the marine, estuarine, and riverine environment.
4. Avoid placing roads and bridges and structures associated with petroleum exploration and production in the nearshore marine environment. Particular care should be made to avoid SAV, intertidal flats, and salt marsh habitat.
5. Use methods to transport oil and gas that limit the need for handling in sensitive fishery habitats.
6. Use horizontal directional drilling for installation of pipelines in areas containing sensitive habitats, whenever possible.
7. Provide for monitoring and leak detection systems at oil extraction, production, and transportation facilities that preclude oil from entering the environment.
8. Evaluate impacts to habitat during the decommissioning phase, including impacts during the demolition phase.
9. Schedule dredging and excavation activities when the fewest species and least vulnerable life stages are present. Appropriate work windows can be established based on the multiple season biological sampling. Recommended seasonal work windows are generally specific to regional or watershed-level environmental conditions and species requirements.
10. Ensure that oil extraction, production, and transportation facilities have developed and implemented adequate oil spill response plans. Assist government agencies responsible for oil spills (e.g., US Coast Guard, state and local resource agencies) in developing response plans and protocols, including identification of sensitive marine habitats and development and implementation of appropriate oil spill-response measures.
11. Potential adverse impacts to marine resources from oil spill clean-up operations should be weighed against the anticipated adverse affects of the oil spill itself. The use of chemical dispersants in nearshore areas where sensitive habitats are present should be avoided.
12. Address the cumulative impacts of past, present, and foreseeable future development projects on aquatic habitats by considering them in the review process for petroleum exploration, production, and transportation projects.

## Liquefied Natural Gas (LNG)

### *Introduction*

Liquefied Natural Gas (LNG) is expected to provide a large proportion of the future energy needs in the northeastern United States. In recent years there has been an increase in proposals for new LNG facilities, including both onshore and offshore facilities from Maine to Delaware. In the northeastern United States, there are currently onshore LNG facilities operating in Everett, MA, and Cove Point, MD, and two offshore LNG facilities have been approved to operate in Massachusetts Bay.

The LNG process cools natural gas to its liquid form at approximately -260 degrees Fahrenheit (F). This reduces the volume of natural gas to approximately 1/600$^{th}$ of its gaseous state volume, making it possible for economical transportation with tankers. Upon arrival at the destination, the LNG is either regasified onshore or offshore and sent out into an existing pipeline infrastructure, or transported onshore for storage and future regasification. The process of regasification occurs when LNG is heated and converted back to its gaseous state. LNG facilities can utilize either "open loop," "closed loop," or "combined loop" systems for regasification. Open loop systems utilize warm seawater for regasification, and closed loop systems generally utilize a recirculating mixture of ethylene glycol for regasification. Combined loop systems utilize a combination of the two systems.

Onshore LNG facilities generally include a deepwater access channel, land-based facilities for regasification and distribution, and storage facilities. Offshore facilities generally include some type of a deepwater port with a regasification facility and pipelines to transport natural gas into existing gas distribution pipelines or onshore storage facilities. Deepwater ports require specific water depths and generally include some form of exclusion zone for LNG vessel and/or port facility security.

### *Habitat conversion and loss*

The conversion of habitat and/or the loss of benthic habitats can occur from the construction and operation of LNG facilities. The placement of pipelines and associated structures on the seafloor can impact benthic habitats from physical occupation and conversion of the seafloor. The installation of pipelines can impact shellfish beds, hard-bottomed habitats, and SAV (Gowen 1978). Plowing or trenching for pipeline installation and side-casting of material can lead to a conversion of substrate and habitat. Placement of anchors for the construction of the deepwater port facilities can have direct impact to the substrate and benthos.

Because of the large size of LNG tankers, dredging may need to occur in order to access onshore terminals. The deepening of channel areas and turning basins can result in permanent and temporary dredging impacts to fishery habitat, including the loss of spawning and juvenile development habitat caused by changes in bathymetry, suitable substrate type, and sedimentation. Disruption of the areas from dredging and sedimentation may cause spawning fish to leave the area for more suitable spawning conditions. Dredging, as well as the equipment used in the process such as pipelines, may damage or destroy other sensitive habitats such as emergent marshes and SAV, including eelgrass beds (Mills and Fonseca 2003) and macroalgae beds. The stabilization and hardening of shorelines for the development of upland facilities can lead to a direct loss of SAV, intertidal mudflats, and salt marshes that serve as important habitat for a variety of living marine resources. See the Marine Transportation, Offshore Dredging and Disposal, and Coastal Development chapters for more detailed information on impacts from dredging.

### *Discharge of contaminants*

Discharge of contaminants can occur as a result of spills during offloading procedures associated with either onshore or offshore facilities. There is limited information and experience regarding the aquatic impacts resulting from an LNG spill; however, because of the toxic nature of natural gas, acute impacts to nearby resources and habitats can be expected.

Biocides (e.g., copper and aluminum compounds) are often utilized in the hydrostatic testing of pipelines. LNG tankers utilize large amounts of seawater for regasification purposes (i.e., open-loop system), for engine cooling, and for ship ballast water. Biocides are commonly utilized to prevent pipeline and engine fouling from marine organisms and are subsequently discharged into surrounding waters. Laboratory experiments have shown high mortality of Atlantic herring eggs and larvae at copper concentrations of 30 µg/L and 1,000 µg/L, respectively, and vertical migration of larvae was impaired at copper concentrations of greater than 300 µg/L (Blaxter 1977). The release of contaminants can reduce or eliminate the suitability of water bodies as habitat for fish species and their prey. In addition, contaminants, such as copper and aluminum, can accumulate in sediments and become toxic to organisms contacting or feeding on the bottom.

### *Discharge of debris*

LNG facilities can result in the discharge of debris, including domestic waste waters generated from the offshore facility, and other trash and debris from human activities associated with the facility (NPFMC 1999). Impacts from the discharge of debris from LNG are similar to those described in the Petroleum Exploration, Production, and Transportation section of this chapter.

### *Siltation, sedimentation, and turbidity*

LNG construction activities may result in increased suspended sediment in the water column caused by dredging, the installation of pipelines, anchors and chains, and the movement of vessels through confined areas, and upland site development. Impacts from siltation and sedimentation from LNG are similar to those described in the Petroleum Exploration, Production, and Transportation section of this chapter.

### *Entrainment and impingement*

Intake structures for traditional power plants can result in impingement and entrainment of marine organisms through the use of seawater for cooling purposes (Enright 1977; Helvey 1985; Callaghan 2004). Likewise, intake structures utilized for the LNG regasification process can result in impingement and entrainment of living marine resources. "Open-loop" LNG regasification systems utilize seawater for warming into a gaseous state and are typically utilized when ambient water temperatures are greater than about 45°F. In addition, "combined loop" systems can utilize seawater for partial regasification. Depending on the geographic location and the water depth of the intake pipe, phytoplankton, zooplankton, and fish eggs and larvae can be entrained into the system. Juvenile fish can also be impinged on screens of water intake structures (Hanson et al. 1977; Hanson et al. 2003). Normal ship operations utilize intake structures for ballast water and engine cooling and can result in additional impingement and entrainment of resources, as well.

The entrainment and impingement impacts on aquatic organisms from LNG facilities have the potential to be substantial. For example, an assessment of impacts of a proposed LNG facility in the Gulf of Mexico determined that an open-loop regasification system could utilize 176 million gallons of water per day, which may entrain 1.6 billion fish and 60 million shrimp larvae per year, 3.3 billion fish eggs per year, and 500 billion zooplankton per year (R. Ruebsamen, pers. comm.). Additional entrainment and impingement impacts were expected for vessel ballast and cooling water uses. In the northeastern United States, an offshore LNG regasification facility approved in Massachusetts Bay with a closed-loop system has estimated annual mortality rates caused by vessel ballast and cooling water for the eggs and larvae for Atlantic mackerel (*Scomber scombrus*), pollock (*Pollachius virens*), yellowtail flounder (*Limanda ferruginea*), and Atlantic cod of 8.5 million, 7.8 million, 411,000, and 569,000, respectively (USCG 2006).

### *Alteration of temperature regimes*

The operation of LNG facilities can result in the alteration of temperature regimes. Discharge of water from engine cooling operations can be at temperatures up to 10°F higher than surrounding waters. Water utilized for the purposes of regasification could be discharged at temperatures colder than the surrounding water by about 10-15°F. Changes in water temperatures can alter physiological functions of marine organisms, including respiration, metabolism, reproduction, and growth. In riverine and estuarine environments, changes to water temperatures can impact the egg and juvenile life stages of Atlantic salmon (USFWS and NMFS 1999). Thermal effluent in inshore habitat can cause severe problems by directly altering the benthic community or adversely affecting marine organisms, especially egg and larval life stages (Pilati 1976; Rogers 1976). For example, the seaward migration of juvenile American shad (*Alosa sapidissima*) are cued to water temperatures (Richkus 1974; MacKenzie et al. 1985), and temperature influences biochemical processes of the environment and the behavior (e.g., migration) and physiology (e.g., metabolism) of marine organisms (Blaxter 1969; Stanley and Colby 1971).

### *Alteration of hydrological regimes*

The operation of LNG facilities can affect the hydrology of confined waterbodies, waterbodies with limited flows such as streams and rivers, and estuaries fed by streams and rivers. Depending upon the characteristics of the waterbody and the nature of the water intake and discharge, altered stream flow can result in reductions in stream flow and subsequent degradation of ecosystem functions (Reiser et al. 2004).

### *Alteration of salinity regimes*

The operation of LNG tankers can result in the alteration of hydrological regimes caused by the discharge of brine from onboard desalination operations. For example, the operation of LNG tankers within riverine and estuarine environments can impact anadromous fish by altering salinity regimes (Dodson et al. 1972; Leggett and O'Boyle 1976) and affecting the ability of fish to access migration corridors.

### *Underwater noise*

Underwater noise sources generate sound pressure that can disrupt or damage marine life. LNG activities generate noise from construction, production facility operations, and tanker traffic. Larvae and young fish are particularly sensitive to noise generated from underwater seismic equipment. It is also known that noise in the marine environment may adversely affect marine mammals by causing them to change behavior (e.g., movement, feeding), interfering with echolocation and communication or injuring hearing organs (Richardson et al. 1995). Noise issues related to LNG tanker traffic may adversely affect fishery resources in the marine environment, particularly in estuarine areas where some LNG port activities are located or proposed. A more thorough review of underwater noise can be found in the chapter on Global Effects and Other Impacts.

### *Exclusion zones*

Because of security concerns, LNG tankers and terminals include safety and exclusion areas. Different types of restrictions are put in place based on the distance from the facility. However, restrictions on commercial and recreational fishing activities around the LNG facilities can lead to a displacement of fishing effort to other/adjacent areas. This in turn, may increase fishing effort and habitat impacts to more ecologically sensitive areas.

## *Introduction of invasive species*

Introductions of nonnative invasive species into marine and estuarine waters are a significant threat to living marine resources in the United States (Carlton 2001). Nonnative species can be released unintentionally when ships release ballast water (Hanson et al. 2003; Niimi 2004). Hundreds of species have been introduced into United States waters from overseas and from other regions around North America, including finfish, shellfish, phytoplankton, bacteria, viruses, and pathogens (Drake et al. 2005). LNG tankers entering US waters are generally loaded with cargo and do not need to release large amounts of ballast water. However, even small amounts of released ballast water have the potential to contain invasive exotic species. In addition, as vessels are unloaded and ballast is taken on in US waters, the water may contain species that are potentially invasive to other locations. The transportation of nonindigenous organisms to new environments can have severe impacts on habitat (Omori et al. 1994), change the natural community structure and dynamics, lower the overall fitness and genetic diversity of natural stocks, and pass and/or introduce exotic lethal disease. Refer to the chapters on Marine Transportation and Introduced/Nuisance Species and Aquaculture for more information on invasive species and shipping.

## *Conservation recommendations and best management practices for LNG facilities*

1. Conduct preconstruction biological surveys in consultation with resource agencies to determine the extent and composition of biological populations or habitat in the proposed impact area.
2. Recommend the use of "closed loop" systems, which minimize the volume of water utilized for regasification, over "open loop" systems. This will serve to minimize the level of impingement and entrainment of living marine resources.
3. Locate facilities that use surface waters for regassification and engine cooling purposes away from areas of high biological productivity, such as estuaries.
4. Design intake structures to minimize entrainment or impingement.
5. Regulate discharge temperatures (both heated and cooled effluent) such that they do not appreciably alter the temperature regimes of the receiving waters, which could cause a change in species assemblages and ecosystem function. Strategies should be implemented to diffuse the heated effluent.
6. Avoid the use of biocides (e.g., aluminum, copper, chlorine compounds) to prevent fouling where possible. The least damaging antifouling alternatives should be implemented.
7. Implement operational monitoring plans to analyze impacts resulting from intake and discharge structures and link them to a plan for adaptive management.
8. Provide for monitoring and leak detection systems at natural gas production and transportation facilities that preclude gas from entering the environment.
9. Schedule dredging and excavation activities when the fewest species and least vulnerable life stages are present. Appropriate work windows can be established based on the multiple season biological sampling. Recommended seasonal work windows are generally specific to regional or watershed-level environmental conditions and species requirements.
10. Address cumulative impacts of past, present, and foreseeable future development projects on aquatic habitats by considering them in the project review process of LNG facilities construction and operations. Based on evaluation of the foreseeable impacts to fishery habitats, a determination can be made regarding the most suitable location and operational procedures for LNG facilities. Ideally, such an analysis would be done at the regional or national level based on natural gas usage and need.

11. Ensure that gas production and transportation facilities have developed and implemented adequate gas spill response plans. Assist government agencies responsible for gas spills (e.g., US Coast Guard, state and local resource agencies) in developing response plans and protocols, including identification of sensitive marine habitats and development and implementation of appropriate gas spill-response measures.

## Offshore Wind Energy Facilities

### *Introduction*

Offshore wind energy facilities (windmills) convert wind energy into electricity through the use of turbines. An offshore facility generally consists of a series of wind turbine generators, an inner-array of submarine electric cables that connect each of the turbines, and a single electric service platform (ESP). Electricity is transmitted from the ESP to an onshore facility through one or a series of submarine cables.

While there are no operating offshore wind facilities in the United States at the writing of this report, there is an increasing number of proposals to develop offshore wind facilities within the northeast region. The construction and operation of offshore wind facilities has the potential to adversely affect fishery habitats.

### *Habitat conversion and loss*

The construction of offshore wind turbines and support structures can result in benthic habitat conversion and loss because of the physical occupation of the natural substrate. Scour protection around the structures, consisting of rock or concrete mattresses, can also lead to a conversion and loss of habitat. For example, the total seafloor area occupied by 130 wind turbines, ESP and associated scour mats for an offshore wind farm proposed in Nantucket Sound, MA, is expected to be approximately 3.21 acres (USACE 2004). Should scour around cables and the base of structures occur, subsequent substrate stabilization activity would lead to additional impact on benthic habitat. Likewise, the burial and installation of submarine cable arrays can impact the benthic habitat through temporary disturbance from plowing and from barge anchor damage. In some cases, plowing or trenching for cable installation can permanently convert benthic habitats when top layers of sediments are replaced with new material. The installation of cables and associated barge anchor damage can adversely affect SAV, if those resources are present in the project area. Cable maintenance, repairs, and decommissioning can also result in impacts to benthic resources and substrate.

### *Siltation, sedimentation, and turbidity*

The construction of wind turbine and support structures can cause increased turbidity in the water column and sedimentation impacts on adjacent benthic habitats. Likewise, the subsurface installation of underwater cables can result in similar impacts. Most of these impacts are relatively short-term and should subside after construction is completed. Maintenance and repairs of wind turbines and submarine electric cables can be expected to persist during the operation of the wind generator facilities. Increased sedimentation and turbidity during the decommissioning of wind energy facilities could be greater than the construction impacts if all submarine structures were to be removed. Siltation, sedimentation, and turbidity impacts related to the construction and maintenance activities from offshore wind energy projects are similar to those described in the Petroleum Exploration, Production, and Transportation section of this chapter.

## *Alteration of hydrological regimes*

The placement of wind energy facilities, especially large arrays or "farms," in marine and estuarine habitats may affect hydrological regimes by altering tidal and current patterns. Altered current patterns could affect the distribution of eggs and larvae and the distribution of species within estuaries and bays, as well as the migration patterns of anadromous fishes.

## *Alteration of electromagnetic fields*

Background direct current electric fields originate from the metallic core of the Earth and the electric currents flowing in the upper layer of the Earth's crust. The strength of this geomagnetic field is highest at the magnetic poles and the lowest at the equator. Marine fishes, such as elasmobranches and anadromous fishes, utilize natural electromagnetic fields (EMFs) for navigation and migratory behavior (Gill et al. 2005). Studies have shown sharks and rays are capable of detecting artificial EMFs (Meyer et al. 2005), and some species have a remarkable sensitivity to electric fields in seawater (Kalmijn 1982). Some species of fish have shown sensitivity to underwater EMFs, including several species of sharks (i.e., *Scyliorhinus canicula, Mustelus canis,* and *Prionace glauca)* and thornback skate (*Raja clavata*) (Kalmijn 1982); and sea lamprey (*Petromyzon marinus*), eels (*Anguilla sp.*), Atlantic cod, plaice (*Pleuronectes platessa*), yellowfin tuna (*Thunnus albacares*) and Atlantic salmon (Gill et al. 2005). Electrical cables associated with offshore wind energy facilities produce EMFs (and induced electric fields) which could interfere with fish behavior. However, at the present time there is no conclusive evidence that EMFs have an adverse effect on marine species (Gill et al. 2005).

## *Underwater noise*

Underwater noise during construction of turbines may have impacts to hearing in fish and may cause fish to disperse with possible disruption to their feeding and spawning patterns. Underwater noise from the operation of wind turbines may decrease the effective range for sound communication in fish and mask orientation signals (Wahlberg and Westerberg 2005). Atlantic salmon and cod have been shown to detect offshore windmills at a maximum distance of about .04 km to 25 km at high wind speeds (i.e., >13 m/s), and noise from turbines can lead to permanent avoidance by fish within ranges of about 4 m (Wahlberg and Westerberg 2005). Noise from construction of wind farms (e.g., pile driving) could have significant effects on fish (Hoffmann et al. 2000). It is also known that noise in the marine environment may adversely affect marine mammals by causing them to change behavior (e.g., movement, feeding), interfering with echolocation and communication or injuring hearing organs (Richardson et al. 1995). A more thorough review of underwater noise can be found in the chapter on Global Effects and Other Impacts.

## *Alteration of community structure*

Offshore wind energy facilities have the potential to alter the local community structure of the marine ecosystem. There is significant debate as to whether the presence of underwater vertical structures (e.g., oil platforms) contribute to new fish production by providing additional spawning and settlement habitat or simply attract and concentrate existing fishes (Bohnsack et al. 1994; Pickering and Whitmarsh 1997; Bortone 1998). The aggregation of fish in the vicinity of the wind turbine structures may subject certain species to increased fishing. Additive and synergistic effects of multiple stressors, such as the presence of electric cables on the seafloor and underwater sound generated by the turbines, could have cumulative effects on marine ecosystem and community dynamics (e.g., predator-prey population densities, migration corridors).

### *Discharge of contaminants*

An ESP serves as a connection point for the inner-array of cables as well as a staging area for maintenance activities. Hazardous materials that may be stored at the ESP include fluids from transformers, diesel fuel, oils, greases and coolants for pumps, fans and air compressors. Discharge of these contaminants into the water column can affect the water quality in the vicinity of the offshore wind facility. Further information regarding the impacts of oil spills and contaminants can be found in the Petroleum Exploration, Production, and Transportation section of this chapter, and the chapters on Coastal Development and Chemical Affects: Water Discharge Facilities of the report.

### *Conservation recommendations and best management practices for offshore wind energy facilities*

1. Conduct preconstruction biological surveys in consultation with resource agencies to determine the extent and composition of biological populations or habitat in the proposed impact area.
2. Avoid placing cables associated with offshore wind facilities near sensitive benthic habitats, such as SAV.
3. Use horizontal directional drilling to avoid impacts to sensitive habitats, such as salt marshes and intertidal mudflats.
4. Make contingency plans and response equipment available to respond to spills associated with service platforms.
5. Use scour protection for turbines and associated structures and cables to the minimum practicable in order to avoid alteration and conversion of benthic habitat.
6. Bury cables to an adequate depth in order to minimize the need for maintenance activities and to reduce conflicts with other ocean uses.
7. Time construction of facilities to avoid impacts to sensitive life stages and species. Recommended seasonal work windows are generally specific to regional or watershed-level environmental conditions and species requirements.
8. Address the cumulative impacts of past, present, and foreseeable future development activities on aquatic habitats in the review process for offshore wind energy facilities construction and operations.

## Wave and Tidal Energy Facilities

### *Introduction*

Wave power facilities involve the construction of stationary or floating devices that are attached to the ocean floor, the shoreline, or a marine structure like a breakwater with exposure to adequate "wave climate." Ocean wave power systems can be utilized in the offshore or nearshore environments. Offshore systems can be situated in deep water, typically in depths greater than 40 m (131 ft). Some examples of offshore systems include the Salter Duck, which uses the bobbing motion of the waves to power a pump that creates electricity. Other offshore devices use hoses connected to floats that move with the waves. The rise and fall of the float stretches and relaxes the hoses, which pressurizes the water, which in turn rotates a turbine. In addition, some seagoing vessels can be built to capture the energy of offshore waves. These floating platforms create electricity by funneling waves through internal turbines.

Wave energy can be utilized to generate power from the nearshore area in three ways:

1. Floats or pitching devices generate electricity from the bobbing or pitching action of a floating object. The object can be mounted to a floating raft or to a device fixed on the ocean floor. A

similar device, the pendulor, is a wave-powered device consisting of a rectangular box, which is open to the sea at one end. A flap is hinged over the opening and the action of the waves causes the flap to swing back and forth. The motion powers a hydraulic pump and a generator.

2. Oscillating water columns generate electricity from the wave-driven rise and fall of water in a cylindrical shaft. The rising and falling water column drives air into and out of the top of the shaft, powering an air-driven turbine.
3. Wave surge or focusing devices, also called "tapered channel" or "tapchan" systems, rely on a shore-mounted structure to channel and concentrate the waves, driving them into an elevated reservoir. Water flow out of this reservoir is used to generate electricity by using standard hydropower technologies (USDOE 2003).

Tidal energy facilities are designed to generate power in tidal estuaries through the use of turbines. A barrage, or dam, can be placed across a tidal river or estuary. This design utilizes a build-up of water within a headpond to create a differential on either side (depending on the tide), and then the water is released to turn the turbines. While less efficient, tidal power facilities can also utilize water currents to turn turbines. Turbines can be designed in a number of ways and include the "helical-type" turbines, as well as the "propeller-type" turbines. Turbines are generally placed within areas of fast moving water with strong currents to take advantage of both ebb and flow tides. For impacts associated with conventional hydropower facilities, refer to the chapter on Alteration of Freshwater Systems.

### *Habitat conversion and loss*

The construction of tidal and wave energy facilities includes the placement of structures within the water column, thus converting open water habitat to anthropogenic structure. The placement of support structures, transmission lines, and anchors on the substrate will result in a direct impact to benthic habitats which serve as feeding or spawning habitats for various species. Large-scale tidal power projects which utilize a barrage can cause major changes in the tidal elevations of the headpond which can affect intertidal habitat. Alterations in the range and duration of tide flow can adversely affect intertidal communities that rely on specific hydrological regimes. Mud and sand flats may be converted to subtidal habitat, while high saltmarsh areas that may be normally flooded only on the highest spring tides can become colonized by terrestrial vegetation and invasive species (Gordon 1994).

### *Siltation, sedimentation, and turbidity*

Construction of tidal facilities in riverine and estuarine areas can result in increased sedimentation. Structures placed within riverine and estuarine habitats can reduce the natural transport of sediments and cause an accretion of silt and sediments within impoundments. Deposition of sediments can adversely impact benthic spawning habitats of various anadromous fish species, including riffle and pool complexes. Clean gravel substrates, which are preferred by rainbow smelt and Atlantic salmon, can be subjected to increased siltation from alterations in the sediment transport. Shallow water environments, rocky reefs, nearshore and offshore rises, salt, and freshwater marshes (wetlands), and estuaries are more likely to be adversely impacted than open-water habitats. This is due, in part, to their higher sustained biomass and lower water volumes, which decrease their ability to dilute and disperse suspended sediments (Gowen 1978). Impacts from siltation and sedimentation from wave and tidal power facilities are similar to those described in the Petroleum Exploration, Production, and Transportation section of this chapter.

## Alteration of hydrological regimes

Water circulation patterns and the tidal regimes can be altered during the operation of a barrage-type tidal facility. This can result in poor tidal flushing of the headwaters of estuaries and rivers and can lead to decreased water quality and increases in water temperature (Rulifson and Dadswell 1987). Altered current patterns could affect the distribution of eggs and larvae and the distribution of species within estuaries and bays as well as the migration patterns of anadromous fishes. Hydrological regimes may also be impacted by flows passing through and around tidal turbines and support structures.

## Entrainment, impingement, and other impacts to migration

Water control structures, such as dams, alter the flow, volume, and depth of water within impoundments and below the structures. Water impoundments tend to stratify the water column, increasing water temperatures and decreasing dissolved oxygen levels. Projects operating as "store and release" facilities can drastically affect downstream water flow and depth, resulting in dramatic fluctuations in habitat accessibility, acute temperature changes and an overall decline in water quality (NEFMC 1998). The construction of dams, with either inefficient or nonexistent fish bypass structures, has been a major cause of the population decline of US Atlantic salmon (USFWS and NMFS 1999). Tidal energy facilities located within estuaries or riverine environments have the potential to directly impact migrating fish (Dadswell et al. 1986). Dadswell and Rulifson (1994) reported various physical impacts to fish traversing low-head, tidal turbines in the Bay of Fundy, Canada, including mechanical strikes with turbine blades, shear damage, and pressure- and cavitation-related injuries/mortality. They found between 21-46% mortality rates for tagged American shad passing through the turbine. The physical presence of tidal power facilities can impact the return of diadromous fishes to natal rivers (Semple 1984). Refer to the chapter on Alteration of Freshwater Systems for further information on impacts from water control structures.

## Alteration of electromagnetic fields

Electrical distribution cables associated with ocean wave-power facilities produce EMFs similar to offshore wind energy facilities and may interfere with fish behavior (Gill et al. 2005). Refer to the discussion under the Offshore Wind Energy Facilities in this chapter for information on the affects of EMFs.

## Conservation recommendations and best management practices for wave and tidal energy facilities

1. Do not permit the construction of barrage-type tidal energy facilities because of the potential for large impacts to the ecosystem and migratory fishery resources.
2. Require preconstruction assessments for analysis of potential impacts to fishery resources for all projects. Assessments should include comprehensive monitoring of the timing, duration, and utilization of the area by diadromous and resident species, potential impacts from the project, and contingency planning using adaptive management.
3. Do not site projects in areas that may result in adverse effects to sensitive marine and estuarine resources and habitats.
4. Avoid project siting of any wave or tidal energy facility within riverine, estuarine, and marine ecosystems utilized by diadromous species.
5. Time construction of facilities to avoid impacts to sensitive life stages and species. Recommended seasonal work windows are generally specific to regional or watershed-level environmental conditions and species requirements.

6. Include impacts associated with the decommissioning and/or dismanteling of wave or tidal energy facility as part of the environmental analyses. Contingency for removal of structures should be required as part of any permits or licenses.
7. Address the cumulative impacts of past, present, and foreseeable future development activities on aquatic habitats in the review process for wave and tidal facilities construction and operations.

# Cables and Pipelines

## *Introduction*

With the continued development of coastal regions comes greater demand for the installation of cables, utility lines for power and other services, and pipelines for oil and gas. The installation of pipelines, utility lines, and cables can have direct and indirect impacts on the offshore, nearshore, estuarine, wetland, beach, and rocky shore coastal zone habitats.

## *Habitat conversion and loss*

The installation of cables and pipelines can result in the loss of benthic habitat from dredging and plowing through the seafloor. This can result in a direct loss of benthic organisms, including shellfish. Construction impacts can result in long-term or permanent damage, depending on the degree and type of habitat disturbance and best management practices employed for a project. The installation of pipelines can impact shellfish beds, hard-bottomed habitats, and SAV (Gowen 1978). Cables can damage complex habitats containing epifaunal growth during installation, if allowed to "sweep" along the bottom while being positioned into the correct location. Shallow water environments, rocky reefs, nearshore and offshore rises, salt and freshwater marshes (wetlands), and estuaries are more likely to be adversely impacted than are open-water habitats. This is due to their higher sustained biomass and lower water volumes, which decrease their ability to dilute and disperse suspended sediments (Gowen 1978). Benthic organisms, especially prey species, may recolonize disturbed areas, but this may not occur if the composition of the substrate is drastically changed or if pipelines are left in place after production ends.

Pipelines installed on the seafloor or over coastal wetlands can alter the environment by causing erosion and scour around the pipes, resulting in escarpments on coastal dune and salt marshes, and on the seafloor. Alterations to the geomorphology of coastal habitats from pipelines can exacerbate shoreline erosion and fragment wetlands. Because vegetated coastal wetlands provide forage and protection to commercially important invertebrates and fish, marsh degradation caused by plant mortality, soil erosion, or submergence will eventually decrease productivity.

Pipelines are generally buried below ground by digging trenches or canals. Digging trenches may change the coastal hydrology by: (1) facilitating rapid drainage of interior marshes during low tides or low precipitation; (2) reducing or interrupting freshwater inflow and associated littoral sediments; and (3) allowing saltwater to move farther inland during periods of high tides (Chabreck 1972). Saltwater intrusion into freshwater marsh often causes a loss of salt-intolerant emergent plants and SAV (Chabreck 1972; Pezeshki et al. 1987). Soil erosion and a net loss of organic matter may also occur (Craig et al. 1979).

Conversion of benthic habitat can occur if cables and pipelines are not buried sufficiently within the substrate. Conversion of habitats can also occur in areas where a layer of fine sediment is underlain with coarser materials. Once these materials are plowed for pipeline/cable installation, they can be mixed with underlying coarse sediment, and thus, alter the substrate composition. This can adversely affect the habitat of benthic organisms which rely on soft sand or mud habitats. The armoring of pipeline with either rock or concrete can result in permanent habitat alterations if placed within soft substrate. The placement of cables and pipelines often necessitates removal of hard bottom or rocky habitats in the pipeline corridor. These habitats are removed by using explosives or mechanical fracturing and can result in a reduction of available hard bottom substrate and habitat complexity.

Subsea pipelines that are placed on the substrate have the potential to create physical barriers to benthic invertebrates during migration and movement. In particular, the migration of American lobster (*Homarus americanus*) between inshore and offshore habitats can be adversely affected if pipelines are not buried to sufficient depths (Fuller 2003). Furthermore, erosion around buried pipelines and cables can lead to uncovering of the structure and the formation of escarpements. This, in turn, can interfere with the migratory patterns of benthic species.

### *Siltation, sedimentation, and turbidity*

The installation of cables and pipelines can lead to increased turbidity and subsequent sedimentation, caused by either the plowing or jetting method of installation. Elevated siltation and turbidity during cable and pipeline installation is typically short-term and restricted to the area surrounding the cable and pipeline corridor. However, pipelines that are left unburied and exposed can cause erosion of the substrate and cause persistent siltation and turbidity in the surrounding area. Maintenance activities related to cables and pipelines, as well as removal for decommissioned cables and pipelines, can release suspended sediments into the water column. Long-term effects of suspended sediment include reduced light penetration and lowered photosynthesis rates and the primary productivity of the area (Gowen 1978). Impacts from siltation, sedimentation, and turbidity from cables and pipelines are similar to those described in the Petroleum Exploration, Production, and Transportation section of this chapter.

### *Release of contaminants*

Petroleum products can be released into the environment if pipelines are broken or ruptured by unintentional activities, such as shipping accidents or deterioration of pipelines. A review of impacts from petroleum spills can be found in the Petroleum Exploration, Production, and Transportation section of this chapter. In addition, resuspension of contaminants in sediments, such as metals and pesticides, during pipeline installation can have lethal and sublethal effects to fishery resources (Gowen 1978). Contaminants may have accumulated in coastal sediments from past industrial activities, particularly in heavily urbanized areas. Metals may initially inhibit reproduction and development of marine organisms, but at high concentrations they can directly or indirectly contaminate or kill fish and invertebrates. The early life-history stages of fish are the most susceptible to the toxic impacts associated with metals (Gould et al. 1994). The release of contaminants can reduce or eliminate the suitability of water bodies as habitat for fish species and their prey. In addition, contaminants, such as copper and aluminum, can accumulate in sediments and become toxic to organisms contacting or feeding on the bottom.

Impacts to sensitive wetland and subtidal habitats can be avoided during pipeline and cable installation using horizontal directional drilling techniques, which allow the pipe or cable to be installed in a horizontal drill hole below the substrate. "Frac-outs" (i.e., releases of drilling mud or other lubricants, such as bentonite mud) can occur during the drilling process, and material can escape through fractures in the underlying rock. This typically happens when the drill hole encounters a natural fracture in the rock or when insufficient precautions are taken to prevent new fractures from occurring. Fishery habitats can be adversely affected if a "frac-out" occurs during the installation process and discharges drilling mud or other contaminants into the surrounding area.

Cranford et al. (1999) found that chronic intermittent exposure to sea scallops (*Placopecten magellanicus*) of dilute concentrations of operational drilling wastes, characterized by acute lethal tests as practically nontoxic, can affect growth, reproductive success, and survival.

Maintenance of cables and pipelines can also result in subsequent impacts to the aquatic environment. The maintenance of pipelines includes the "pigging" of pipelines to clean out residual materials from time-to-time. The release of these materials into the surrounding environment can lead to water quality impacts and contamination of adjacent benthic habitats. For example, biocides (e.g., copper and aluminum compounds) are often utilized in the hydrostatic testing of pipelines and are subsequently discharged into surrounding waters. Laboratory experiments have shown high mortality of Atlantic herring eggs and larvae at copper concentrations of 30 µg/L and 1,000 µg/L, respectively, and vertical migration of larvae was impaired at copper concentrations of greater than 300 µg/L (Blaxter 1977).

### *Alteration of electromagnetic fields*

Underwater electrical distribution cables produce EMFs that may interfere with fish behavior (Gill et al. 2005). However, at the present time there is no conclusive evidence that EMFs have an adverse effect on marine species (Gill et al. 2005). See also the discussion of underwater EMFs in the Offshore Wind Energy Facilities section of this chapter and the Global Effects and Other Impacts chapter of the report.

### *Underwater noise*

The installation of cables and pipelines can produce underwater noise that may disrupt or damage fishery resources. Noise from construction activities (e.g., pile driving) can have significant effects on fish (Hoffmann et al. 2000). Larvae and young fish are particularly sensitive to noise generated from underwater explosives during blasting. It is also known that noise in the marine environment may adversely affect marine mammals by causing them to change behavior (movement, feeding), interfering with echolocation and communication, or injuring hearing organs (Richardson et al. 1995).

### *Alteration of community structure*

The construction of pipelines and other underwater structures has the potential to alter the local community structure of the marine ecosystem. There is significant debate as to whether the presence of underwater vertical structures (e.g., oil platforms) contribute to new fish production by providing additional spawning and settlement habitat or simply attract and concentrate existing fish within an area (Bohnsack et al. 1994; Pickering and Whitmarsh 1997; Bortone 1998). Underwater pipelines are anthropogenic structures that could have similar attraction and production issues relating to fishery management. As with wind turbines and offshore LNG facilities, aggregation of fishes in the vicinity of pipeline structures may subject certain species to increased fishing pressure. By altering the age and species composition in the area around pipelines, predator/prey interactions and reproduction can be altered, and these changes may have community-level affects on fisheries.

### *Conservation recommendations and best management practices for cables and pipelines (adapted from Hanson et al. 2003)*

1. Align crossings along the least environmentally damaging route. Sensitive habitats such as hard-bottom (e.g., rocky reefs), SAV, oyster reefs, emergent marsh, and mud flats should be avoided.

2. Use horizontal directional drilling where cables or pipelines would cross sensitive habitats, such as intertidal mudflats and vegetated intertidal zones, to avoid surface disturbances. Measures should be employed to avoid/minimize impacts to sensitive fishery habitats from potential frac-outs, including:
    a. The use of nonpolluting, water-based lubricants should be required.
    b. Drill stem pressures should be monitored closely so that potential frac-outs can be identified.
    c. Drilling should be halted, if frac-outs are suspected.
    d. Above ground monitoring should be employed to identify potential frac-outs.
    e. Spill clean-up plan and protocols should be developed, and clean-up equipment should be on-site to quickly respond to frac-outs.
3. Avoid construction of permanent access channels since they disrupt natural drainage patterns and destroy wetlands through excavation, filling, and bank erosion.
4. Backfill excavated wetlands with either the same or comparable material capable of supporting similar wetland vegetation. Original marsh elevations should be restored.
5. Use existing rights-of-way whenever possible to lessen overall encroachment and disturbance of wetlands.
6. Bury pipelines and submerged cables where possible. Unburied pipelines or pipelines buried in areas where scouring or wave activity eventually exposes them can result in impacts to invertebrate migratory patterns.
7. Use silt curtains or other types of sediment control in order to protect sensitive habitats and resources.
8. Limit access for equipment to the immediate project area avoid access through sensitive resources.
9. Avoid the use of open trenching for installation. Methods in which the trench is immediately backfilled reduce the impact duration and should therefore be employed when possible.
10. Conduct construction during the time of year that will have the least impact on sensitive habitats and species. Appropriate work windows can be established based on the multiple season biological sampling. Recommended seasonal work windows are generally specific to regional or watershed-level environmental conditions and species requirements.
11. Evaluate impacts to habitat during the decommissioning phase, including impacts during the demolition phase and impacts resulting from permanent habitat losses.
12. Address the cumulative impacts of past, present, and foreseeable future development activities on aquatic habitats in the review process for cable and pipeline construction and operations.
13. Ensure that oil and gas pipeline systems include leak detection capabilities to minimize potential impacts from spills.

# CHAPTER FOUR: ALTERATON OF FRESHWATER SYSTEMS

## Introduction

Freshwater riverine and riparian habitats located in the northeastern coastal United States provide important habitat for the growth, survival, and reproduction of diadromous fishes and are critical to maintaining healthy estuarine ecosystems. Some of the diadromous fish (species that migrate between freshwater and saltwater for specific life history functions) inhabiting the Northeast include Atlantic salmon (*Salmo salar*), striped bass (*Morone saxatilis*), alewife (*Alosa pseudoharengus*), blueback herring (*Alosa aestivalis*), American shad (*Alosa sapidissima*), rainbow smelt (*Osmerus mordax*), Atlantic sturgeon (*Acipenser oxyrinchus*), shortnose sturgeon (*Acipenser brevirostrum*), and American eel (*Anguilla rostrata*). Not only are diadromous fishes subject to environmental impacts in the marine environment, but they also encounter dams, pollution, effects of urbanization, and habitat changes in freshwater (Moring 2005). In addition, some forage species that are important prey for marine fisheries depend upon freshwater habitats for portions of their life cycle. The health and availability of freshwater systems and the preservation and maintenance of associated functions and values are vital to the diversity, health, and survival of marine fisheries.

Free flowing rivers, ponds, and lakes act as migratory corridors, spawning, nursery, and rearing areas and provide forage and refuge for life stages of these species. Riverine and riparian corridors, and palustrine and lacustrine wetlands provide important functions and values for resident and migratory fish, freshwater mussels, reptiles, amphibians, and insects (Chabreck 1988). Riparian corridors provide shade, nutrients, and habitat enhancing debris in riverine systems (Bilby and Ward 1991), which are essential elements necessary for these aquatic resources to thrive. In addition to supporting aquatic resources, freshwater wetlands perform important and broad ecological functions by reducing erosion, attenuating floodwater velocity and volume, improving water quality by the uptake of nutrients, and reducing sediment loads (Howard-Williams 1985; De Laney 1995; Fletcher 2003). Freshwater habitats are intricately connected to terrestrial and coastal ecosystems, making them vulnerable to a wide array of anthropogenic disturbances that can alter the functions, values, quantity, and accessibility of freshwater wetlands used by migratory fish (Beschta et al. 1987; Naiman 1992).

Biological, chemical, and physical threats to freshwater environments from terrestrial and aquatic sources have led to habitat fragmentation and degradation (Bodi and Erdheim 1986; Wilbur and Pentony 1999; USEPA 2000; Kerry et al. 2004). In particular, nonfishing activities, such as mining, dredging, fill placement, dam construction and alterations of hydrologic regimes, thermal discharges, and nonpoint source pollution have degraded and eliminated freshwater habitats (Zwick 1992; Wilbur and Pentony 1999; Hanson et al. 2003). Examples of nonpoint source pollution include urban stormwater and agricultural runoff (e.g., petroleum products, metals, pesticides, fertilizers, and animal wastes). Refer to the Coastal Development and Agriculture and Silviculture chapters for more detailed discussion on nonpoint source pollution. The federal Clean Water Act (CWA) has eliminated certain types of disposal activities, limited fill activities, and otherwise resulted in improved protection of the nation's wetlands and waterways. Despite these and other regulations to protect aquatic habitat, anthropogenic impacts continue, dramatically affecting fish habitat, including prey species and fisheries (Wilson and Gallaway 1997; Bodi and Erdheim 1986; Hanson et al. 2003; Ormerod 2003; Kerry et al. 2004).

## Dam Construction and Operation

The history and effects of dam construction on passage and habitat is well documented (Larinier 2001; Heinz Center 2002). Among the major identified causative factors of the population demise of Atlantic salmon, dam construction and operation may be the most dramatic (NEFMC 1998; Parrish et al. 1998; USFWS and NMFS 1999). In the United States, 76,000 dams have been identified in the National Inventory of Dams by the US Army Corps of Engineers and the Federal Emergency Management Agency (Heinz Center 2002). This number may be as high as 2 million when small-scale dams are included (Graf 1993). Dam construction and operation in the northeastern United States have occurred for centuries to provide power generation, navigation, fire and farm ponds, reservoir formation, recreation, irrigation, and flood control. Important for the local economy when originally constructed, today many of these structures are obsolete, unused, abandoned, or decaying. Fish passages in any given river system may not be consistent or effective throughout, limiting the ability for Atlantic salmon and many other migratory and resident species to reach necessary habitat. Sections 18 and 10j of the Federal Power Act require fish passage and protection and mitigation for damages to fish and wildlife, respectively, at hydroelectric facilities.

The effects of dam construction and operation on fisheries and aquatic habitat include: (1) complete or partial upstream and downstream migratory impediment; (2) water quality and flow patterns alteration; (3) thermal impacts; (4) alterations to the floodplain, including riparian and coastal wetland systems and associated functions and values; (5) habitat fragmentation; (6) alteration to sediment and nutrient budgets; and (7) limitations on gene flow within populations.

### *Impaired fish passage*

The construction of dams with either no fish passage or ineffective passage was the primary agent of the population decline of US Atlantic salmon (USFWS and NMFS 1999; NEFMC 1998). By 1950, less than 2% of the original habitat for Atlantic salmon in New England was accessible because of dams (Buchsbaum 2005). Dams physically obstruct passage and alter a broad range of habitat characteristics essential for passage and survival. Without any mechanism to get around a dam, there is no upstream passage to spawning and nursery habitat. Fish that gather at the base of the dam will either spawn in inadequate habitat, die, or return downstream without spawning. The presence of a fish passage structure does not necessarily ensure access to upstream habitat. Even with a structure in place, passage is contingent on many factors, including water-level fluctuations, altered seasonal and daily flow regimes, elevated temperatures, reduced water velocities, and discharge volumes (Haro et al. 2004).

Safe, timely, and effective downstream passage by fish is also hindered by dams. The time required for downstream migration is greatly increased because of reduced water flows within impoundments (Raymond 1979; Spence et al. 1996; PFMC 1999). This delay results in greater mortality associated with predation and the physiological stress associated with migration. Downstream passage for fish is hindered or prevented while passing over spillways and through turbines (Ruggles 1980; NEFMC 1998) and by entrainment or impingement on structures associated with a hydroelectric facility. Dadswell and Rulifson (1994) reported on the physical impacts observed in fish traversing low-head, tidal turbines in the Bay of Fundy, Canada, which included mechanical strikes with turbine blades, shear damage, and pressure- and cavitation-related injuries/mortality. They found 21-46% mortality rates for experimentally tagged American shad passing through the turbine.

Fragmentation of aquatic habitat caused by dams can result in a loss of genetic diversity and spawning potential that may make populations of fish more vulnerable to local extirpation and extinctions, particularly for species functioning as a metapopulation (Morita and Yamamoto 2002).

### Altered hydrologic, salinity, and temperature regimes

Dams and dam operations alter flow patterns, volume, and depth of water within impoundments and below the dam. These hydrological alterations tend to increase water temperatures, stratify the water column, and decrease dissolved oxygen concentrations in the water impoundments. Projects operating as "store and release" facilities can drastically affect downstream water flow and depth, resulting in dramatic fluctuations in habitat accessibility, acute temperature changes, and overall water quality. Although large, impounding dams have the ability to alter the hydrology of large segments or entire rivers, smaller, run-of-the river dams that do not contain impoundments generally have little or no ability to alter downstream hydrology (Heinz Center 2002).

Reductions in river water temperatures are common below dams if the intake of the water is from lower levels of the reservoir. Stratification of reservoir water not only affects temperature but can create oxygen-poor conditions in deeper areas and, if these waters are released, can degrade the water quality of the downstream areas (Heinz Center 2002).

By design, dams often reduce peak flows as flood control measures. However, reductions of peak flows can decrease the physical integrity of the downstream river because the floodplains (including side channels, islands, bars, and beaches) are not as extensively connected to the river (Heinz Center 2002). In addition, dams can also reduce low flows during periods of drought and when dam operators reduce water releases in order to maintain water levels in the impoundments (Heinz Center 2002).

Dams with deep reservoirs have high hydrostatic pressures at the bottom and can force atmospheric gases into solution. If these waters are released below the dam, either by water spilling over dams or through turbines, it can cause dissolved gas supersaturation, resulting in injury or death to fish traversing the dam (NEFMC 1998; Heinz Center 2002).

Tidal fresh habitat is limited to a narrow zone in river systems where the water is tidally influenced, yet characteristically fresh (i.e., < 0.5 ppt salinity). This narrow habitat type may be altered or lost because of dam construction and operations.

### Alteration of stream bed and stream morphology

The construction of a dam fragments habitat, altering both upstream and downstream biogeochemical processes and resulting in a wide array of direct and indirect cumulative impacts (Poff et al. 1997; Heinz Center 2002). Multiple habitat variables are affected by dams, principally streambed properties (Spence et al. 1996), the transport of sediments and large woody debris (Spence et al. 1996; PFMC 1999), and overall stream morphology.

Dams typically reduce peak flows as a flood control measure and can reduce low flows when water releases are reduced to save water during drought. As the range of flows in the river are decreased, the width of the active portion of the watershed is reduced and the river channel shrinks (Heinz Center 2002).

### Altered sediment/large woody debris transport

Dams affect the physical integrity of watersheds by fragmenting the lengths of rivers, changing their hydrologic characteristics, and altering their sediment regimes by trapping most of the sediment entering the reservoirs and disrupting the sediment budget of the downstream landscape (Heinz Center 2002). Because water released from dams is relatively free of sediment, downstream reaches of rivers may be altered by increased particle size, erosion, channel shrinkage, and deactivation of floodplains (Heinz Center 2000).

Large woody debris (LWD) and other organic matter are often removed from rivers containing dams, as well as for other reasons, such as aesthetics, road and bridge maintenance, and commercial and recreational uses. Organic debris provides habitat for a variety of aquatic organisms, such as Atlantic salmon, by promoting habitat complexity, including the formation of pool and riffle complexes and undercut banks (Montgomery et al. 1995; Abbe and Montgomery 1996; Spence et al. 1996). Removing organic debris may change the structure, function, and value of the river system. From a broader perspective, removal of LWD from a river system disrupts a link between the forest and the sea (Maser and Sedell 1994; NRC 1996; Collins et al. 2002; Collins et al. 2003).

### *Riparian zone development and alteration of wetlands*

Riparian wetlands may be lost to water level increases upstream and flow alterations downstream of the dam. Generally, the greater the storage capacity of a dam, the more extensive are the downstream geomorphological and biological impacts (Heinz Center 2002). Lost wetlands result in a loss of floodplain and flood storage capacity, and thus a reduced ability to provide flood control during storm events. A healthy riparian corridor is well vegetated, harbors prey items, contributes necessary nutrients, provides LWD that creates channel structure and cover for fish, and provides shade, which controls stream temperatures (Bilby and Ward 1991; Hanson et al. 2003). When vegetation is removed from riparian areas, water temperatures tend to increase and LWD is less common. The result is less refuge for fish, fundamental changes in channel structure (e.g., loss of pool habitats), instability of stream banks, and alteration of nutrient and prey sources within the river system (Hanson et al. 2003). Riparian zone development can be considered a secondary effect of dam construction. Residential, recreational, and commercial development may result from the associated impoundment.

### *Changes to native aquatic communities*

Impoundments can concentrate predators and disease carrying organisms and disrupt fish development, thereby altering the community structure at various trophic levels and potentially changing the natural habitat and fishery dynamics of the aquatic habitat. In addition, the loss of wetlands by the increased impoundment level and reduction of freshwater input and sediments below the dam can have potentially serious impacts on both fish and invertebrate populations (NEFMC 1998).

Impoundments also create an opportunity for nonnative species to become established. Common carp (*Cyprinus carpio*), northern pike (*Esox lucius*), and walleye (*Sander vitreus*) are a few examples. These species have the ability to dramatically alter local habitats and aquatic communities. In some instances, introduced species such as smallmouth bass (*Micropterus dolomieu*) become managed as a sport fish to the exclusion of native species. Over time, these introduced species become accepted as part of the "natural" condition. Like the changes associated with creating an impoundment, these introduced species can change the community dynamics of the riverine system.

### *Conservation measures and best management practices for dam construction and operation (adapted from Hanson et al. 2003 and PFMC 1999)*

1. Avoid the construction of new dam facilities, where possible.
2. Retrofit existing dams with efficient and functional upstream and downstream fish passage structures.
3. Construct and design facilities with efficient and functional upstream and downstream adult and juvenile fish passage which ensures safe, effective, and timely passage.
4. Construct dam facilities with the lowest hydraulic head practicable for the project purpose. Site the project at a location where dam height can be reduced.
5. Consider all upstream passage types, including natural-like bypass channels, denil-type and vertical slot fishways, Alaskan steeppass, fishlifts, etc. Volitional passage is preferable to trap and truck methods.
6. Downstream passage should prevent adults and juveniles from passing through the turbines and provide sufficient water downstream for safe passage.
7. Operate facilities to create flow conditions that provide for passage, water quality, proper timing of life history stages, and properly functioning channel conditions, and to avoid strandings and redd (i.e., spawning nest) dewatering. Run-of-river, such that the volume of water entering an impoundment exits the impoundment with minimal fluctuation of the headpond, is the preferred mode of operation for fishery and aquatic resource interests. Water flow monitoring equipment should be installed upstream and downstream of the facility. Generally, fluctuations in headpond water levels should be kept between 6 and 12 inches.
8. Coordinate maintenance and operations which require drawdown of the impoundment with state and federal resource agencies to minimize impacts to aquatic resources.
9. Use seasonal restrictions for construction, maintenance, and operations of dams to avoid impacts to habitat during species' critical life history stages (e.g., spawning and egg development periods). Recommended seasonal work windows are generally specific to regional or watershed-level environmental conditions and species requirements.
10. Develop water and energy conservation guidelines for integration into dam operation plans and into regional and watershed-based water resource plans.
11. Encourage the preservation of LWD, whenever possible. If possible, relocate debris as opposed to removing it completely. Remove LWD only to prevent damage to property or threats to human health and safety.
12. Address the cumulative impacts of past, present, and foreseeable future development activities on aquatic habitats by considering them in the review process for dam construction and operation.
13. Consider the removal of a dam when it is feasible (see the following section on dam removal).

## Dam Removal

A number of factors may be considered in determining the efficacy of removing a dam, including habitat restoration, safety, and economics (Babbitt 2002; Heinz Center 2002). Dam removal provides overall environmental benefits to freshwater habitats and aquatic resources. The recovery of some anadromous species, such as Atlantic salmon and rainbow smelt, may be dependent on targeted dam removals, principally those dams blocking passage to high quality spawning and rearing habitat. Dam removal reconnects previously fragmented habitat, allowing the natural flow of water, sediment, nutrients, and the genetic diversity of fish populations and reestablishes floodplains and riparian corridors (Morita and Yokota 2002; Nislow et al. 2002).

The Heinz Center (2002) provides a thorough overview of environmental, economic, and social issues to consider when evaluating dam removal. Because there are a number of concerns and interests surrounding dams and their use, the overall benefits of dam removal must be weighed against all potential adverse impacts. It is important to bear in mind that although the removal of a dam may reverse most of the undesirable changes, it is unlikely to restore completely the natural conditions because of other dams on the river and the other anthropogenic effects on streams, such as channel control and land use management (Heinz Center 2002).

For many local residents, the impoundments created by these dams define a way of life for the community. Changing the existing conditions may not necessarily be perceived as good for all parties. For example, an impoundment may contain stocked game fish which provide recreational opportunities for the community. Dam removal may eliminate these species or bring about interactions with formerly excluded diadromous species. However, because dams alter sediment and nutrient transport processes and raise water levels upstream of the structure, dam removal can result in short and long-term impacts upstream and downstream.

The effects of dam removal on fisheries and aquatic habitat include: (1) release of contaminants; (2) short-term water quality degradation; (3) flow pattern alteration; (4) loss of benthic and sessile invertebrates; and (5) alterations of the riparian landscape and associated functions and values.

### *Release of contaminated sediments and short-term water quality degradation*

Dam removal typically results in an increased transfer of sediments downstream of the dam, while the spatial and temporal extent of sediment transfer depends on the size of the dam and total sediment load. Sediments accumulated behind dams can bind and adsorb contaminants that when remobilized after the removal of a dam have the potential to adversely affect aquatic organisms including the eggs, larvae, and juvenile stages of finfish, filter feeders, and other sedentary aquatic organisms (Heinz Center 2002). For example, a reduction in macroinvertebrate abundance, diatom richness, and algal biomass has been attributed to the downstream transport of fine sediments previously stored within a dam impoundment (Thomson et al. 2005). However, as fine sediment loads are reduced and replaced by coarser materials in the streambed, macroinvertebrate and finfish assemblages should recover from the disturbance (Thomson et al. 2005). Dam removal can impact overall water quality during and after the demolition phase, although these are typically temporary effects that generally do not result in chronic water quality degradation (Nechvatal and Granata 2004; Thomson et al. 2005).

### *Flow pattern alteration*

Dam removal generally changes downstream conditions by increasing the water and sediment discharges which tend to decrease channel gradients and increase stream depths and widths (Heinz Center 2002). In addition, flood events may increase; reactivate the floodplain; and reconnect side channels, islands, bars, and beaches. Reconnecting and increasing the active floodplain may help reduce low flow conditions in a river. Removal of a dam restores the natural timing of peak and low flows, which have important consequences for the biological components of the ecosystem. For example, seed production among native trees and spawning migrations of anadromous fish species often coincides with peak flows in the spring (Heinz Center 2002).

### *Loss of benthic and sessile invertebrates*

As discussed above, remobilized sediments after the removal of a dam have the potential to adversely affect aquatic organisms including benthic and sessile invertebrates. However, although water quality often is degraded immediately following removal, the abundance and diversity of aquatic invertebrates should increase as the sediment budget and hydrology of the river approaches a natural equilibrium (Heinz Center 2002).

## *Alteration of wetlands*

Lowering the water level will alter the wetland structure upstream of the old dam site and the associated wildlife assemblage. Lowering of impoundments can result in the alteration of existing wetlands (Nislow et al. 2002). As water levels recede, fringing wetlands may be lost while new wetlands are formed along the new riparian border. Newly exposed stream banks may need armoring or other erosion control methods to protect them. The history of the project, geomorphology of the watershed, and location in the river system, among other factors, will dictate the types of environmental issues dam removal will present. Geomorphic effects of downstream sediment transport may have long-term implications (Pizzuto 2002). However, many of these impacts are short-term, dissipating with time as the river system comes to a natural equilibrium (Bushaw-Newton et al. 2002; Thomson et al. 2005).

## *Conservation measures and best management practices for dam removal (adapted from Hanson et al. 2003)*

1. Conduct a comprehensive evaluation of the historic and existing hydrology, hydraulics, and sediment transport prior to the decision to remove a dam to assess possible adverse and cumulative effects of the removal of the structure on the watershed. Dam removal assessments should adopt a watershed scale of analysis.
2. Conduct an assessment of the biotic component of the effected area, particularly if anadromous fish restoration is one of the objectives of the dam removal. For example, the assessment may include characterization of the historic distribution and abundance of fish species, their various life history habitat requirements, and their limiting environmental factors. The assessment should also evaluate the predicted physical and chemical conditions following dam removal to determine if additional restoration may be necessary.
3. Conduct sufficient testing to evaluate the type, extent, and level of contamination upstream of the dam prior to the decision to remove a dam. Contaminated sediments, if extensively present, may require mechanical or hydraulic removal prior to the removal of the dam.
4. Conduct sufficient evaluation of the streambed within the impoundment to plan for any necessary streambed modifications.
5. Consider the possible necessity for removal of the dam in stages to control the release of sediments, if sediments are expected to be released downstream.
6. Schedule dam removal during the less sensitive time of year for aquatic resources, particularly outside the expected migratory period. Recommended seasonal work windows are generally specific to regional or watershed-level environmental conditions and species requirements.
7. Plan for revegetating the newly exposed stream bank with native vegetation.
8. Establish a contingency plan in the event that the stream channel needs modification (addition of riffle and pool complex, added features to create habitat complexity, meanders, etc.) to facilitate fish passage and habitat functions.
9. Establish a monitoring protocol to evaluate success of the restoration for fish passage and utilization.
10. Conduct outreach to the public to provide an understanding of the benefits of dam removal.

## Stream Crossings

Stream crossings are characterized as any structure providing access over a stream, river, or other water body for transportation purposes (e.g., roads, utilities). The feasibility of effective fish passage at stream crossings may be complex. Land ownership, utility crossing, flood protection for low-lying properties, and safety along the transportation corridor must be considered. Unfortunately, many transportation corridors interact and interfere with fisheries corridors (i.e., streams and rivers). These transportation corridors require structures for crossing rivers, streams, and other water bodies. If improperly designed, stream crossings can alter, degrade, fragment or eliminate aquatic habitat and potentially impede, or eliminate, passage for resident and migratory species (Evans and Johnston 1980; Belford and Gould 1989; Clancy and Reichmuth 1990; Furniss et al. 1991; USGAO 2001; Jackson 2003). Until recently, the primary concerns related to designing these structures were cost, designed load capacity, and hydraulics. Furthermore, common practice for repairing deficient structures often resulted in maintaining inadequate stream crossing conditions (e.g., "slip-lining" with smaller diameter pipe, lining of culvert with concrete, or replacing the structure in-kind).

Some American states and Canadian provinces have recognized the concerns relating to fish passage and stream crossings. For example, the Maine Department of Transportation and Commonwealth of Massachusetts Riverways Program, among others, have independently published guidelines for addressing fish passage at stream crossings (MEDOT 2004; MRP 2005). These and similar documents provide extensive information regarding fish and aquatic organism passage, habitat continuity, and wildlife passage requirements for environmentally-sound and safe transportation across streams, rivers, and other waterbodies.

The construction, maintainance, and operation of roadways at stream crossings can also affect aquatic habitats by increasing rates of erosion, debris slides or landslides and sedimentation, introduction of exotic species, and degradation of water quality (Furniss et al. 1991; Hanson et al. 2003). However, the focus of this chapter is the design and operation of the fish passage structure. Refer to the Coastal Development chapter in this report for information pertaining to impacts associated with roadways and vehicular traffic at stream crossings.

### *Impacts to fish passage*

Improperly designed stream crossings can block fish and aquatic organism passage in a variety of ways, including: (1) perched culverts constructed with the bottom of the structure above the level of the stream effectively act as a dam and physically block passage; and (2) hydraulic barriers to passage are created by undersized culverts which constrict the flow and create excessive water velocities (Evans and Johnston 1980; Belford and Gould 1989; Furniss et al. 1991; Jackson 2003). Smooth-bore liners made from high density plastic help meet the goal of passing water and protecting roadways from flooding, but they greatly increase flow velocities through the passage. Conversely, oversized culverts with large, flat bottom surfaces reduce water depth. Insufficient water depths may also be another hydraulic impediment to passage (Haro et al. 2004). In situations where water velocities are not physically limiting and water depths are sufficient, the impediments to passage may be a lack of resting pools. Many stream crossings, particularly longer culverts, are placed over wide stretches of river. Fish may not be capable of burst speeds and sustained swimming throughout the length of the crossing. Under such conditions, migrating fish are unable to reach spawning habitat.

### *Alteration of hydrologic regimes*

Undersized and/or improperly placed stream crossings can also affect water quality. Undersized structures can act as dams, impounding water and increasing water temperature. In extreme cases, if flows are sufficiently reduced and the impounded area deep enough, increased surface temperatures can create thermal stratification and reduce dissolved oxygen. In addition, as water flows through the structure the temperature of the water can rise, affecting aquatic organisms downstream. Undersized culverts can also cause flooding upstream of the crossing, affecting upland and riparian habitat.

### *Conservation measures and best management practices for stream crossings*

1. Design stream crossings for the target finfish species and various age classes. Other aquatic species, such as amphibians, reptiles, and mammals, should also be considered in the designs, as they play a role in healthy ecosystems.
2. Design structures to provide safe and timely passage to minimize injury and limit excessive predation.
3. Design and install new structures in a manner not to interfere with fish and aquatic organism passage and that complies with all applicable regulations.
4. Design structures to provide sufficient water depth and maintain suitable water velocities for target species during the migration season. Consider seasonal headwater and tailwater levels and how variations in them could affect passage of all aquatic life stages. Design considerations may include constructing a low flow channel, weir structure, energy dissipation pools, and designing structures for bank full width.
5. Consider the presence of nonnative, invasive aquatic species in fish passage design for stream crossings, particularly where the crossing may present an existing barrier to passage.
6. Design the structure to maintain or replicate natural stream channel and flow conditions to the greatest extent practicable. An open bottom arch or bridge is preferred. The structure should be able to pass peak flows in accordance with state and federal regulations. Ensure sufficient hydrologic data have been collected.
7. Bury culverts and pipes sufficiently to replicate a natural streambed. Doing so will also provide habitat functions, such as resting pools and reduced water velocities for longer structures.
8. Match the gradient of the stream crossing with the natural stream channel grade. Perched culverts should be removed, wherever practicable.
9. Maintain or stabilize upstream and downstream channel and bank conditions if the stream crossing structure causes erosion or accretion problems. Use of native vegetation should be required for erosion control and sediment stabilization.
10. Ensure the location and overall design of the fish passage structure and the stream crossing are compatible with local stream conditions and stream geomorphology.
11. Ensure that materials for the fish passage structure are nontoxic to fish and other aquatic organisms. Pressure treated lumber should be avoided.
12. Develop construction design and methods for repairing and replacing stream crossings that take into account fish passage requirements.
13. Conduct in-water construction activities during a time of year that would have the least environmental impacts to aquatic species (e.g., low flow seasons). Temporary diversions and coffer dams may be suitable alternatives with proper planning. Recommended seasonal work windows are generally specific to regional or watershed-level environmental conditions and species requirements.

14. Address the cumulative impacts of past, present, and foreseeable future development activities on aquatic habitats by considering them in the review process for stream crossing projects.

## Water Withdrawal and Diversion

Freshwater is becoming limited because of natural events (e.g., droughts), increasing commercial and residential demand of potable water, and inefficient use. Freshwater is diverted for human use from groundwater, lakes, and riverine environments or is stored in impoundments. The withdrawal or impoundment of water can alter natural current and sedimentation patterns, water quality, water temperature, and associated biotic communities (NEFMC 1998). Natural freshwater flows are subject to alteration through water diversion and use and modifications to the watershed such as deforestation, dams, tidal restrictions, and stream channelization (Boesch et al. 1997). Water withdrawal for freshwater drinking supply, power plant cooling systems, and irrigation occurs along urban and agricultural areas and may have potentially detrimental effects on aquatic habitats. Increased water diversion is associated with human population growth and development (Gregory and Bisson 1997). Water diversion is not only associated with water withdrawal and impoundment, but it also represents water discharges, which alter the flow and velocity and have associated water quality issues (Hanson et al. 2003). Water withdrawal in freshwater systems can also affect the health of estuarine systems. Refer to the Physical Effects: Water Intake and Discharge Facilities and Coastal Development chapters for additional information on the affects of water withdrawal on estuarine systems.

The effects of water withdrawal and diversion on freshwater fishery habitat can include: (1) entrainment and impingement; (2) impaired fish passage; (3) alteration of flow and flow rates, and processes associated with proper flows; (4) degradation of water quality (e.g., water temperature, dissolved oxygen) associated with proper water depth, drainage, and sedimentation patterns; (5) loss and/or degradation of riparian habitat; and (6) loss of prey and forage.

### *Entrainment and impingement*

The diversion of water for power plant cooling and other reservoirs results in entrainment and impingement of invertebrates and fishes (especially early life-history stages of fish) (NEFMC 1998). Fish and invertebrate populations may be adversely affected by adding this source of mortality to the early life stage which often determines recruitment and strength of the year-class. Important habitat for aquatic organisms around water intakes may become unavailable for recruitment and settlement (Travnichek et al. 1993).

### *Impaired fish passage and altered hydrologic regimes*

Water diversion and the withdrawal or discharge of water can result in a physical barrier to fish passage (Spence et al. 1996). Excessive water withdrawal can greatly reduce the usable river channel. Rapid reductions or increases in water flow, associated with dam operations for example, can greatly affect fish migratory patterns. Depending on the timing of reduced flows, fish can become stranded within the stream channel, in pools, or just below the river in an estuary system.

### *Water quality degradation*

The release of water with poor quality (e.g., altered temperatures, low dissolved oxygen, and the presence of toxins) affects migration and migrating behavior. The discharge of irrigation water into a freshwater system can degrade aquatic habitat (NRC 1996) by altering currents, water quality, water temperature, depth, and drainage and sedimentation patterns. Both water quantity and quality can greatly affect the usable zone of passage within a channel (Haro et al. 2004). Altered temperature regimes have the ability to affect the distribution; growth rates; survival; migration patterns; egg maturation and incubation success; competitive ability; and resistance to parasites, diseases, and pollutants of aquatic organisms (USEPA 2003). In freshwater habitats of the northeastern United States, the temperature regimes of cold-water fish such as salmon, smelt, and trout may be exceeded leading to extirpation of the species in an area. Some evidence indicates that elevated water temperatures in freshwater streams and rivers in the northeastern United States may be responsible for increased algal growth, which has been suggested as a possible factor in the diminished stocks of rainbow smelt (Moring 2005).

### *Release of contaminants*

Irrigation discharges are often associated with contaminants and toxic materials (e.g., metals, pesticides, fertilizers, salts, and nutrients) and possibly introduced pathogens, all of which stress the habitat and aquatic organisms (USEPA 2003). Studies evaluating pesticides in runoff and streams generally find that concentrations can be relatively high near the application site and soon after application but are significantly reduced further downstream and with time (USEPA 2003). However, some pesticides used in the past (e.g., dichlorodiphenyl trichloroethane [DDT]) are known to persist in the environment for years after application.

Soil transported from irrigated croplands and rangelands usually contains a higher percentage of fine and less dense particles, which tend to have a higher affinity for adsorbing pollutants such as insecticides and herbicides (Duda 1985; USEPA 2003). In addition, irrigation water has a natural base load of dissolved mineral salts, and return flows convey the salt to the receiving streams or groundwater reservoirs. If the amount of salt in the return flow is low in comparison to the total stream flow, water quality may not be degraded to the extent that aquatic functions are impaired. However, if the process of water diversion and the return flow of saline drainage water is repeated many times along a stream or river, downstream habitat quality can become progressively degraded (USEPA 2003).

### *Siltation and sedimentation*

Water diversions can alter sediment and nutrient transport processes (Christie et al. 1993; Fajen and Layzer 1993), which can hinder benthic processes and communities. Suspended sediments in aquatic environments can reduce the availability of sunlight to aquatic plants, interfere with filtering capacity of filter feeders, and clog and harm the gills of fish (USEPA 2003). Increased suspended sediments may degrade or eliminate spawning and rearing habitats, impede feeding, negatively affect the food sources of fishes, severely alter the aquatic food web, and thus negatively affect the growth and survival of diadromous fish. Fine sediments are potentially detrimental to Atlantic salmon development and survival during all life stages. For example, sediments can fill interstitial spaces, embedding the substrate and preventing oxygenated water from reaching the incubating eggs within redds and inhibiting the removal of waste metabolites; eliminate refuge utilized by fry and parr to avoid predators; create a homogeneous environment which can lead to lower fish densities; reduce macroinvertebrate abundance; and decrease the depth and area of pools utilized by juveniles and adults (Danie et al. 1984; Fay et al. 2006). In addition, Breitburg (1988) found the predation rates of striped bass larvae on copepods to decrease by 40% when exposed to high turbidity conditions in the laboratory.

## *Loss of wetlands and flood storage*

Healthy riparian corridors are well vegetated, support abundant prey items, maintain nutrient fluxes, provide LWD that creates channel structure and cover for fish, and provide shade, which controls stream temperatures (Bilby and Ward 1991; Hanson et al. 2003). Riparian wetland vegetation can be affected by long-term or frequent changes in water levels caused by water withdrawals and diversions. Removal of riparian vegetation can impact fish habitat by reducing cover and shade, by reducing water temperature fluctuations, and by affecting the overall stability of water quality characteristics (Christie et al. 1993). As river and stream water levels recede because of withdrawals, fringing wetlands may be lost and armoring or other erosion control methods may be needed to protect newly exposed stream banks. The results are less refuge for fish, fundamental changes in channel structure (e.g., loss of pool habitats), instability of stream banks, and alteration of nutrient and prey sources within the river system (Hanson et al. 2003). The changes to the natural habitat caused by irrigation water discharges can potentially lead to large-scale aquatic community changes. Changes in flow patterns may affect the availability of prey and forage species. In conjunction with anthropogenic watershed changes, water diversions and associated riparian impacts have been associated with the increase in some harmful algal blooms (Boesch et al. 1997), which further impact an array of aquatic habitat characteristics. Lost wetlands correlate to a loss of floodplain and flood storage capacity, and thus a reduced ability to act as flood control during storm events.

For additional information on water diversion impacts, refer to the Physical Affects: Water Intake and Discharge Facilities, Chemical Affects: Water Discharge Facilities, and Agriculture and Silviculture chapters in this report.

## *Conservation measures and best management practices for water withdrawal/ diversion (adapted from Hanson et al. 2003)*

1. Design projects to create flow conditions adequate to provide for passage, water quality, proper timing for all life history stages, and avoidance of juvenile stranding and redd (i.e., spawning nest) dewatering, as well as to maintain and restore properly functioning channel, floodplain, riparian, and estuarine conditions.
2. Use seasonal restrictions to avoid impacts to habitat during species' critical life history stages (e.g., spawning and egg development periods). Recommended seasonal work windows are generally specific to regional or watershed-level environmental conditions and species requirements.
3. Establish adequate instream flow conditions for anadromous fish.
4. Design intakes with minimal flows to prevent impingement/entrainment (e.g., ≤0.5 feet per second).
5. Screen water diversions on fish-bearing streams, as needed.
6. Design thermal discharges such that ambient stream temperatures are maintained or a zone of passage is provided to maintain suitable temperatures for fish passage.
7. Incorporate juvenile and adult fish passage facilities on all water diversion projects.
8. Whenever possible, contaminants and sediments should be removed from water discharge prior to entering rivers and other aquatic habitats.
9. Address the cumulative impacts of past, present, and foreseeable future development activities on aquatic habitats by considering them in water withdrawal project review processes.

## Dredging and Filling

The dredging and filling of riparian and freshwater wetlands directly remove potentially important habitat and alter the habitat surrounding the developed area. Expansion of navigable waterways is associated with economic growth and development and generally adversely affects benthic and water-column habitats. Routine dredging is required to maintain the desirable depth as the created channel fills with sediment. Direct removal of riverine habitat from dredge and fill activities may be one of the biggest threats to riverine habitats and anadromous species (NEFMC 1998).

Dredge and fill activities in riverine and riparian habitats can affect fisheries habitat in a number of ways, including: (1) reducing the ability of the wetland to retain floodwater; (2) reducing the uptake and release of nutrients; (3) decreasing the amount of detrital food source, an important food source for aquatic invertebrates (Mitsch and Gosselink 1993); (4) converting habitats by altering water depth or the substrate type (i.e., substrate conversion); (5) removing aquatic vegetation and preventing natural revegetation; (6) hindering physiological processes to aquatic organisms (e.g., photosynthesis, respiration) caused by increased turbidity and sedimentation (Arruda et al. 1983; Cloern 1987; Dennison 1987; Barr 1993; Benfield and Minello 1996; Nightingale and Simenstad 2001); (7) directly eliminating sessile or semimobile aquatic organisms via entrainment or smothering (Larson and Moehl 1990; McGraw and Armstrong 1990; Barr 1993; Newall et al. 1998); (8) altering water quality parameters (i.e., temperature, oxygen concentration, and turbidity); (9) releasing contaminants such as petroleum products, metals, and nutrients (USEPA 2000); (10) reducing dissolved oxygen through reduced photosynthesis and through chemical processes associated with the release of reactive compounds in the sediment (Nightingale and Simenstad 2001).

Filling wetlands removes productive habitat and eliminates the important functions that both aquatic and many terrestrial organisms depend upon. For example, the loss of wetland habitats reduces the production of detritus, an important food source for aquatic invertebrates; alters the uptake and release of nutrients to and from adjacent aquatic and terrestrial systems; reduces wetland vegetation, an important source of food for fish, invertebrates, and water fowl; hinders physiological processes in aquatic organisms (e.g., photosynthesis, respiration) because of degraded water quality and increased turbidity and sedimentation; alters hydrological dynamics, including flood control and groundwater recharge; reduces filtration and absorption of pollutants from uplands; and alters atmospheric functions, such as nitrogen and oxygen cycles (Mitsch and Gosselink 1993).

### *Flood storage capacity*

Impervious surfaces decrease the capacity of a watershed to absorb pulses of freshwater input (e.g., heavy rain, snowmelt). Similarly, stormwater drain systems decrease the storage by directing water directly into a nearby wetland or river system. The rate and volume of stormwater runoff from land into rivers and streams is greater in watersheds with high percentages of impervious surface cover and extensive drainage systems, which reduce the stormwater storage capacity (American Rivers 2002). Measurable adverse changes in the physical and chemical environment were observed when the impervious cover exceeded 10-20% of the land cover (Holland et al. 2004). Flashy, high-velocity pattern of flows and associated pulse of contaminants from upland sources can have long-term, cumulative impacts on freshwater wetlands and riverine, estuarine, and marine ecosystems. As development continues throughout the region, the ability to minimize loss of flood storage capacity and mitigate consequences of increasing coverage of impervious surfaces will be significant planning issues (American Rivers 2002). Refer to the Coastal Development chapter for additional information on stormwater runoff and nonpoint source pollution.

Impacts associated with dredging and filling of aquatic habitats and wetlands are discussed in greater detail in the Offshore Dredging and Disposal Activities, Marine Transportation, and Coastal Development chapters of this report.

### *Conservation measures and best management practices for dredging and filling (adapted from Hanson et al. 2003)*

1. Avoid the filling of wetlands and riparian habitat whenever possible. Ensure proposed dredge and fill projects in wetlands are water-dependent.
2. Utilize best management practices (BMPs) to limit and control the amount and extent of turbidity and sedimentation. Standard BMPs may include constructing silt fences, coffer dams, and operational modification (e.g., hydraulic dredge rather than mechanical dredge).
3. Require the use of multiple-season biological sampling data (both pre- and post-construction) when appropriate to assess the potential and resultant impacts on habitat and aquatic organisms.
4. Test sediment compatibility for open-water disposal per the US Environmental Protection Agency (US EPA) and US Army Corps of Engineers requirements for inshore and offshore, unconfined disposal.
5. Plan dredging and filling activities to avoid submerged aquatic vegetation and special aquatic sites. This may include the placement of pipes for hydraulic dredging and anchoring of barges and other vessels associated with the dredging project.
6. Design the dredge footprint to avoid littoral zone habitat, and appropriate buffers should be in place to protect these areas from wind driven waves and boat wakes.
7. Schedule dredging activities when the fewest species and least vulnerable life stages are present. Appropriate work windows can be established based on the multiple season biological sampling. Recommended seasonal work windows are generally specific to regional or watershed-level environmental conditions and species requirements.
8. Reference all dredging projects in a geographical information system (GIS) compatible format for long-term evaluation.
9. Identify sources of sedimentation within the watershed that may exacerbate repetitious maintenance activities. Implement appropriate management techniques to control these sources.
10. Address cumulative impacts of past, present, and foreseeable future dredging operations on aquatic habitats by considering them in the review process.

## Mining

Most modern mining operations in the northeast US region involve bulk mineral commodities (aggregates such as sand, gravel, and crushed stone), but the region has a long history of mineral mining for mica, feldspar, copper, iron, gold, silver, and coal, as well as peat (Lepage et al. 1991; Boudette 2005; VADMME 2007). While some mineral mining continues in this region, many operations have ceased entirely (Lepage 1991). Some of these abandoned mines have become a source of groundwater or surface water contamination and have been identified by the US EPA's Superfund Program (USEPA 2007) and other nonfederal programs for cleanup. Currently, the US EPA Superfund Program lists cleanup sites on the Susquehanna River in Pennsylvania from coal mining and tributaries leading to East Penobscot Bay in Maine and the Connecticut River in Vermont from copper and other metal mining.

Few active mining sites in the northeast US region currently affect fishery resources as they generally are not located adjacent to or in rivers that support didromous fish. In addition, because access for diadromous fish to historic spawning grounds has been adversely affected by dams and poor water quality throughout the region (Moring 2005), the potential adverse effects of mining operations on these species have been reduced in recent times. Nonetheless, some sand and gravel extraction projects occur within rivers and their tributaries of the northeast US region. Although limited information is available on this subject, it appears the number of active sand and gravel operations that may adversely affect diadromous fish in the northeast US region is relatively small compared to other regions of the United States. However, considering the potential direct and indirect effects from historic and current mining activities on long-term water quality and health of diadromous species, a brief discussion on this topic is warranted in this section.

Mining within riverine habitats may result in direct and indirect chemical, biological, and physical impacts to habitats within the mining site and surrounding areas during all stages of operations (NEFMC 1998). On-site mining activities include exploration, site preparation, mining and milling, waste management, decommissioning and reclamation, and abandonment. Mining operations often occur in urban settings or around existing or historic mining sites; however, mining in remote settings where human activity has caused little disruption and aquatic resources are most productive may cause significant impacts (NRC 1999). Existing state and federal regulations have been established to restrict various environmental impacts associated with mining operations. However, the nature of mining will always result in some alteration of habitat and natural resources (NRC 1999).

Some of the impacts associated with the extraction of material from within or near a stream or river bed include: (1) disruption of preexisting balance between sediment supply and transporting capacity, leading to channel incision and bed degradation; (2) increased suspended sediment, sediment transport, turbidity, and gravel siltation; (3) alteration in the morphology of the channel and decreased channel stability; (4) direct impacts to fish spawning and nesting habitats (redds), juveniles, and prey items; (5) alteration of the channel hydraulics during high flows caused by material stockpiled or left abandoned; (6) removal of instream roughness, including LWD; (7) reduced groundwater elevations and stream flows caused by dry pit or wet pit mining; and (8) destruction of the riparian zone during extraction operations (Pearce 1994; Packer et al. 2005). In addition, structures used in mining extraction and transportation often cause additional impacts to wetland and riverine habitats (Starnes and Gasper 1996). Other impacts include fragmentation and conversion of habitat, alteration of temperature regimes, reduction in oxygen concentration, and the release of toxic materials.

### *Mineral mining*

Although there is a long history of mining in the northeast region of the United States, few active mineral mining operations remain that are located in or adjacent to streams or rivers in this region, and even fewer mineral mining operations occur in streams and rivers utilized by diadromous fish. Nonetheless, mineral mining has occurred in the northeast US region in the past, as evidenced by a number of completed and ongoing remediation sites in areas that have supported or historically supported diadromous fish (USEPA 2007). A brief discussion on the potential impacts to aquatic habitats is provided below.

The effects of mineral mining on riverine habitat depend on the type, extent, duration, and location of the mining activity. Surface mining typically involves suction dredging, hydraulic mining, panning, sluicing, strip mining, and open-pit mining. Surface mining has a greater potential impact on riverine habitat than does underground or shaft mining, depending on other aspects of the mining activities, including processing and degree of disturbance (Spence et al. 1996; Hanson et al. 2003). Elimination of vegetation, topographic alterations, alteration of soil and subsurface geological structure and alteration of surface and groundwater hydrologic regimes are potential effects of surface mining (Starnes and Gasper 1996). Soil erosion and sediment runoff may be the greatest impact of surface mining, contributing a greater sediment load per area of disturbance compared with other activities because of the degree of soil, topographic, and vegetation disturbance (Nelson et al. 1991).

### *Sand and gravel mining*

Sand and gravel are the most valuable and extensively exploited nonfuel mineral resources in the eastern US region and are mined in all states from Virginia to Maine (Bolen 2007). According to Starnes and Gasper (1996), sand and gravel extraction is the least regulated of all mining industries, and approximately 80% of this resource is extracted under jurisdiction of state and local laws only. These authors state that sand and gravel mining is "widely used in large US rivers and can increase the sediment bed load through resuspension, physically eliminate benthic organisms, and destroy fish spawning and nursery areas, all of which ultimately change aquatic community composition" (Starnes and Gasper 1996); however, they do not identify specific rivers that are affected or state whether the rivers support diadromous fish species. The Virginia Department of Mines, Minerals and Energy states, "Sand and gravel are extracted from coastal sand pits, river terraces or dredged from the rivers themselves" (VADMME 2007). In 2005, over 15,000 tons of sand were mined from two operations along the Roanoke River in Virginia (VADMME 2007). In addition, a dredge and fill permit was granted by the US Army Corps of Engineers to allow sand extraction in the St. John River, ME, for use in road sanding operations (USACE 2005). Although sand and gravel mining may not be a significant threat to diadromous fish in the northeast US region at this time, at least some activity is currently taking place, and any increase in activity represents potential future threat.

Gravel and sand mining operations can involve wet-pit mining (i.e., removal of material below the water table); dry pit mining on beaches, exposed bars, and ephemeral streambeds; or subtidal mining. Impacts associated with sand and gravel mining in riverine environments are similar to mineral mining impacts and include: turbidity plumes and resuspension of sediment and nutrients, removal of spawning habitat, and alteration of stream channel morphology. These physical perturbations often lead to alteration of migration patterns, physical and thermal barriers to upstream and downstream migration, increased fluctuation in water temperature, decrease in dissolved oxygen, high mortality of early life stages, increased susceptibility to predation, and loss of suitable habitat (Packer et al. 2005). For information pertaining to impacts associated with mining and dredging in marine habitats refer to the chapter on Offshore Dredging and Disposal Activities.

### *Peat mining*

Peat is mined in the United States primarily for horticultural and industrial purposes, including a filtration medium to remove toxic materials and a fuel/oil absorbent (Jasinski 2007). Peat mining occurs in a number of states in the northeast US region, although at relatively small scales. In Maine, at least one peat mining operation exists in the Narraguagus River watershed, which burns mixtures of peat and wood chips to generate electricity (Lepage et al. 1991; USFWS and NMFS 1999).

The impacts associated with peat mining include the release of contaminants (i.e., peat fiber, arsenic residues, and other toxic chemicals), siltation, increased stormwater runoff from roads and other unvegetated areas, and altered hydraulic flow regimes (NEFMC 1998; USFWS and NMFS 1999). Peat mining has been associated with acidic conditions in eastern Maine watersheds, such as Narraguagus River, and has been identified as a potential contributor to Atlantic salmon declines (USFWS and NMFS 1999).

### *Alteration of stream bed and stream morphology*

Surface mining can alter channel morphology by making the stream channel wider and shallower and removing the natural sediment load. Consequently, the suitability of stream reaches as rearing habitat may decrease, especially during summer low-flow periods when deeper waters are important for survival. Gravel bar skimming or "scalping," which involves the removal of the surface from gravel bars without excavating below the low water flow level, can significantly impact aquatic habitat (Packer et al. 2005). Bar skimming creates a wide, flat cross section in the stream channel, which eliminates confinement of the low flow channel. A reduction in pool frequency may adversely affect migrating adults that require holding pools (Spence et al. 1996). Changes in the frequency and extent of bedload movement and increased erosion and turbidity can also remove spawning substrates, scour redds, result in a direct loss of eggs and young, or reduce their quality by deposition of increased amounts of fine sediments. These changes can affect the early life stages of Atlantic salmon, which exhibit an affinity for specific habitat types (Fitzsimons et al. 1999; Hedger et al. 2005). Extraction of sand and gravel in riverine ecosystems can directly eliminate the amount of gravel available for spawning if the extraction rate exceeds the deposition rate of new gravel in the system. Gravel excavation also reduces the supply of gravel to downstream habitats. The extent of suitable spawning habitat may be reduced where degradation reduces gravel depth or exposes bedrock (Spence et al. 1996). Associated with stream morphology alterations are resultant increased temperatures from a reduction in summer base flows; altered width to depth ratios; decreased riparian vegetation; decreased dissolved oxygen concentration as water temperatures increase; decreased nutrients from loss of floodplain connection and riparian vegetation; and decreased food production (e.g., loss of invertebrate prey populations) (Spence et al. 1996).

### *Sedimentation and siltation*

Sedimentation effects of mining may be immediate or delayed. During gravel extraction, for example, fine material can travel long distances downstream in the form of turbidity plumes. Silt can also be released during peat mining operations (USFWS and NMFS 1999). Sedimentation may be a delayed effect because gravel removal typically occurs at low flow when the stream has the least capacity to transport fine sediments out of the system. Increased sedimentation results when the spring freshet inundates an extraction area that is less stable than before mining operations. The extent and duration of sedimentation and siltation is likely to be higher than normal as unstable sediment washes freely into the system during higher rates of flow, acting as a migratory barrier to anadromous fish, such as Atlantic salmon, and increasing entrainment of sediment in downstream habitat. The result can be a degradation or loss of spawning and rearing habitat within the system (Spence et al. 1996).

### *Release of contaminants*

Peat mining can negatively impact diadromous fish, including Atlantic salmon, from the discharge of low pH water containing peat silt and dissolved metals and pesticides (USFWS and NMFS 1999). However, only one peat mining operation has been identified on the Narraguagus

River in Maine, and monitoring efforts at the site suggests that impacts are being controlled (USFWS and NMFS 1999).

Although current mineral mining operations in the northeast region of the United States are not a significant threat to rivers supporting diadromous fish, the effects of historic mining operations continue to be remediated (USEPA 2007). Harmful or toxic materials can be released directly from mining operations, including processing and machinery. Mining can introduce high levels of metals, sulfuric acid, mercury, cyanide, arsenic, and processing reagents into waterways. Water pollution by metals and acids is associated with mineral mining because ores, rich in sulfides, are commonly mined to extract gold, silver, copper, zinc, and lead (NRC 1999). In combination with anoxic conditions, sulfur-containing sediments can create additional levels of toxicity in addition to acid conditions (Brouwer and Murphy 1995). The improper handling or discharge of tailings and settling ponds can result in a direct loss of living aquatic resources as a result of decreased water quality and increased concentration levels of toxic substances. Locating settling ponds in unstable or landslide prone upland sites makes them prone to dangerous, instantaneous releases of large quantities of toxins. Groundwater and surface water may be incidentally contaminated by leaching of toxic substances from upland settling ponds.

### *Conservation measures and best management practices for mining (adapted from Hanson et al. 2003 and Packer et al. 2005)*

1. Use upland aggregate sources before beginning any mining activities in active channels or floodplains.
2. Avoid mining operations in rivers and streams identified as important migratory pathways, spawning, and nursery habitat for anadromous fish.
3. Conduct a thorough assessment and characterization of aquatic resources, sediments, and potential sources of point and nonpoint contaminants prior to gravel removal.
4. Design, manage, and monitor sand and gravel mining operations to minimize potential direct and indirect impacts to riverine habitat if operations cannot be avoided. This includes, but is not limited to, migratory corridors, foraging and spawning areas, and stream/river banks.
5. Minimize the spatial extent and the depth of mine extraction operation to the maximum extent practicable.
6. Schedule necessary in-water activities when the fewest species and least vulnerable life stages are present. Seasonal restrictions should be used to avoid impacts to habitat during species critical life history stages (e.g., spawning and egg development periods). Recommended seasonal work windows are generally specific to regional or watershed-level environmental conditions and species requirements.
7. Identify upland or off-channel (where channel will not be captured) gravel extraction sites as alternatives to gravel mining in or adjacent to rivers and streams identified as important pathways for anadromous fish, if possible.
8. Utilize best management practices to avoid spills of dirt, fuel, oil, toxic materials, and other contaminants. Prepare a spill prevention plan and maintain appropriate spill containment and water repellent/oil absorbent cleanup materials on the project location.
9. Treat wastewater (e.g., acid neutralization, sulfide precipitation, reverse osmosis, electrochemical, or biological treatments) and recycle onsite to minimize discharge to streams. Treat wastewater before discharge for compliance with state and federal clean water standards.
10. Reclaim mining wastes that contain contaminants such as metal, acids, arsenic, or other substances if leachate could enter aquatic habitats through surface or groundwater.

11. Use best management practices to minimize opportunities for sediment to enter streams and waterways. Methods such as contouring, mulching, silt curtains, and settling ponds should be part of the operations plan. Monitor turbidity during operations and alter operations if turbidity levels reach or exceed a predetermined level.
12. Address the cumulative impacts of past, present, and foreseeable future development activities on aquatic habitats by considering them in mining project review processes.

## Emerging Issues for Freshwater Systems

### *Endocrine disruptors, pharmaceuticals, and nanoparticles*

Growing concerns have mounted in response to the effects of endocrine-disrupting chemicals on humans, fish, and wildlife (Kavlock et al. 1996; Kavlock and Ankley 1996). These chemicals act as "environmental hormones" that may mimic the function of the sex hormones androgen and estrogen (Thurberg and Gould 2005). One of the sources of endocrine disrupting compound is the effluent of residential and commercial wastewater treatment facilities, as well as agricultural runoff (USGS 2002). Some of the chemicals shown to be estrogenic include polychlorinated biphenyl (PCB), dieldrin, DDT, phthalates, and alkylphenols (Thurberg and Gould 2005), which have had or still have applications in agriculture and may be present in irrigation water. Metals have also been implicated in disrupting endocrine secretions of marine organisms, potentially disrupting natural biotic processes (Brodeur et al. 1997). Adverse effects include reduced or altered reproductive functions, which could result in population-level impacts. Refer to the Chemical Effects: Water Discharge Facilities chapter for more information on endocrine disruptors. In addition to endocrine disrupting compounds, recent studies have found municipal wastewater effluent entering streams and rivers containing human and veterinary pharmaceuticals, including antibiotics and natural and synethetic hormones (USGS 2002).

Other recent concerns are the release of substances referred to as nanoparticles into the aquatic environment. Nanoparticles, such as fullerenes (e.g., 60-carbon molecules often referred to as "buckyballs") may have great potential for use in the pharmaceutical, lubricant, and semiconductor industries, as well as applications in energy conversion. However, the micro-fine particulate waste generated from the production and use of nanoparticles may adversely affect the distribution, feeding, ecology, respiration, and nutrient regeneration of microorganisms, such as bacterivorous and herbivorous protozoa, protists, and phagotrophic or mixotrophic microalgae (Colvin 2003).

### *Harmful algal blooms*

Impervious surfaces and stormwater drain systems can increase the rate and volume of stormwater runoff into rivers and streams. This direct flushing of water generates large pulses of runoff into rivers and streams, carrying with it nutrients and a wide-range of pollutants that flow into estuaries and coastal areas. Nutrient-rich waters have been associated with harmful algal blooms (HABs), which can deplete the oxygen in the water during bacterial degradation of algal tissue and can result in hypoxic or anoxic "dead zones" and large-scale fish kills in rivers, estuaries, and coastal areas (Deegan and Buchsbaum 2005; MDDNR 2007). For example, HABs have been responsible for fish kills in the freshwater portions of the Potomac River in Virginia and the Corsica River in Maryland, as well as in the Potomac and Chesapeake Bay estuaries (MDDNR 2007). HABs affecting Gulf of Maine waters have resulted in shellfish bed closures and mortalities to endangered marine mammals (NOAA 2008; WHOI 2008). While the causes of HABs in coastal waters of New England are unclear, large pulses of freshwater rivers and streams in the region as a result of elevated rainfall and snowmelt in the spring are being examined as contributing factors in creating conditions favorable for algal growth (NOAA 2008). Refer to the Coastal Development and Introduced/Nuisance Species and Aquaculture chapters for more information on HABs.

### *Introduced and nusiance species*

Introductions of nonnative nuisance species are a significant threat to freshwater and coastal ecosystems in the United States (Carlton 2001). Nonnative species may be released intentionally (i.e., fish stocking and pest control programs) or unintentionally during industrial shipping activities (e.g., ballast water releases), aquaculture operations, recreational boating, biotechnology, or from aquarium discharge (Hanson et al. 2003; Niimi 2004). For example, increased competition for food sources between the invasive exotic zebra mussel (*Dreissena polymorpha*) and open-water commercial and recreational species have altered the trophic structure in the Hudson River estuary, NY, by withdrawing large quantities of phytoplankton and zooplankton from the water column, thus increasing competition with planktivorous fish (Strayer et al. 2004). Refer to the Introduced/Nuisance Species and Aquaculture chapter for information on introduced and nuisance species.

# CHAPTER FIVE: MARINE TRANSPORTATION

## Introduction

The demand for increased capacity of marine transportation vessels, facilities, and infrastructure is a global trend that is expected to continue in the future. This demand is fueled by a need to accommodate growing vessel operations for cargo handling activities and human population growth in coastal areas. As coastal areas continue to grow, there is a concomitant increase in the demand for water transportation services and recreational opportunities.

It is also important to note that coastal areas under high developmental pressure are often located adjacent to productive and sensitive aquatic environments. Historically, human settlements in the northeastern United States were probably established on the basis of availability to food resources and marine transportation. Coastal features such as estuaries and embayments satisfied these needs as they are highly productive ecosystems ideal for fishing, farming, or hunting and are sheltered waters that provide access to rivers and the ocean for transportation purposes. Today, urban growth and development in coastal areas are growing at a rate approximately five times that of other areas of the country and over one-half of all Americans live within 50 miles of the coast (Markham 2006). The continued demand on the coast today is likely attributed to the highly desirable aesthetic quality and recreational opportunities, including access to fishing, beaches, and boating.

The expansion of port facilities, vessel operations, and commercial and recreational marinas can have adverse impacts on fishery habitat. The growth of the marine transportation industry is accompanied by land-use changes, including over-water or in-water construction, filling of aquatic habitat and wetlands, and increased maintenance activities. Although some categories of habitat impacts resulting from activities related to port and marina construction and maintenance and vessel operations may be minimal and site specific, the cumulative effects of these activities over time can have substantial impacts on habitat.

The construction of new ports and marinas typically involves the removal of sediments by dredging from intertidal and subtidal habitats in order to create navigational channels, turning basins, anchorages, and berthing docks for the size and types of vessels expected to use the facilities. For existing ports and marinas, dredging is generally conducted on a routine basis in order to maintain the required depths as sediment is transported and deposited into the channels, basins, anchorages, and docks. The construction of new ports and marinas, or the expansion of existing facilities, is often referred to as “improvement” dredging; whereas, dredging existing ports and marinas in order to maintain an assigned or authorized depth is generally referred to as “maintenance” dredging. Because the chemical, physical, and biological impacts associated with both “improvement” and “maintenance” dredging are similar in nature, both types of dredging are discussed in the Navigation Dredging section of this chapter. Other impacts associated with newly constructed and expanded ports and marinas are covered under the Construction and Expansion of Ports and Marinas section of this chapter.

## Construction and Expansion of Ports and Marinas

Construction of ports and marinas can change physical and chemical habitat parameters such as tidal prism, depth, water temperature, salinity, wave energy, sediment transport, and current velocity. Alterations to physical characteristics of the coastal ecosystems can cause adverse effects to biological parameters, such as the composition, distribution, and abundance of shellfish and submerged aquatic vegetation (SAV). These changes can impact the distribution of nearshore habitats and affect aquatic food webs.

### Loss and conversion of habitat

Port and marina facilities are typically located in areas containing highly productive intertidal and subtidal habitats, including saltmarsh wetlands and SAV. Coastal wetlands provide a number of important ecological functions, including foraging, spawning/breeding, protection from predators, as well as nutrient uptake and release and retention of storm and floodwaters. Vegetated wetlands and intertidal habitats are some of the most highly productive ecosystems in the world, and support one or more life stages of important commercial and recreational fishery resources in the United States (Dahl 2006). One of the most obvious habitat impacts related to the construction of a port or marina facility is alteration or loss of physical space taken up by the structures required for such a facility. The construction of ports and marinas can alter or replace salt marsh, SAV, and intertidal mud flat habitat with "hardened" structures such as concrete bulkheads and jetties that provide relatively few ecological functions. Boston Harbor, MA, exemplifies a northeastern coastal port transformed by expansive dredging and filling of former shallow estuarine waters and salt marsh wetlands. Between 1775 and 1980, wetland filling within the harbor extensively altered the shoreline, with the airport alone amounting to 2,000 acres of filled intertidal salt marsh wetlands (Deegan and Bushbaum 2005).

Over-water structures, such as commercial and residential piers and docks, floating breakwaters, barges, rafts, booms, and mooring buoys are associated with port and marina facilities and are constructed over both subtidal and intertidal habitats. Although they generally have less direct physical contact with benthic habitats than in-water structures, float, raft, and barge groundings at low tides and the scouring of the substrate by the structures and anchor chains can be substantial. Piles and other in-water structures can alter the substrate below and adjacent to the structures by providing a surface for encrusting communities of mussels and other sessile organisms, which can create shell deposits and shift the biota normally associated with sand, gravel, mud, and eelgrass substrates to those communities associated with shell hash substrates (Penttila and Doty 1990; Nightingale and Simenstad 2001a).

Shoreline armoring is an in-water activity associated with the construction and operation of marinas and ports, intended to protect inland structures from storm and flood events and to prevent erosion that is often a result of increased boat traffic. Armoring of shorelines to prevent erosion and maintain or create shoreline development simplifies habitats, reduces the amount of intertidal habitat, and affects nearshore processes and the distribution of aquatic communities (Williams and Thom 2001). Hydraulic effect alterations to the shoreline include increased energy seaward of the armoring from reflected wave energy, which can exacerbate erosion by coarsening the substrate and altering sediment transport (Williams and Thom 2001). Installation of breakwaters and jetties can also result in community changes, including burial or removal of resident biota, changes in cover, preferred prey species, predator interaction, and the movement of larvae (Williams and Thom 2001). Chapman (2003) found a paucity of mobile species associated with seawalls in a tropical estuary, compared with surrounding areas.

### Altered light regimes and loss of submerged aquatic vegetation

Alteration of the light regimes in coastal waters can affect primary production, including the distribution and density of SAV, as well as the feeding and migratory behavior of fish. Over-water structures shade the surface of the water and attenuate the sunlight available to the benthic habitat under and adjacent to the structures. The height, width, construction materials used, and the orientation of the structure in relation to the sun can influence how large a shade footprint an over-water structure may produce and how much of an adverse impact that shading effect may have on the localized habitat (Fresh et al. 1995; Burdick and Short 1999; Shafer 1999; Fresh et al. 2001). High, narrow piers and docks produce more diffuse shadows which have been shown to reduce shading impacts to SAV (Burdick and Short 1999; Shafer 1999).

The density of pilings can also determine the amount of light attenuation created by dock structures. Piling density is often higher in larger, commercial shipping ports than in smaller recreational marinas, as larger vessels and structures often require a greater number of support structures such as fenders and dolphin piles. Light limitations caused by pilings can be reduced through adequate spacing of the pilings and the use of light reflecting materials (Thom and Shreffler 1996; Nightingale and Simenstad 2001a). In addition, piers constructed over solid structures, such as breakwaters or wooden cribs, would further limit light transmittance and increase shading impacts on SAV.

Although shading impacts are greatest directly under a structure, the impacts on SAV may extend to areas adjacent to the structure as shadows from changing light conditions and adjacent boats or docks create light limitations (Burdick and Short 1999; Smith and Mezich 1999). A decrease in SAV and primary productivity can impact the nearshore food web, alter the distribution of invertebrates and fish, and reduce the abundance of prey organisms and phytoplankton in the vicinity of the over-water structure (Kahler et al. 2000; Nightingale and Simenstad 2001a; Haas et al. 2002).

The sharp light contrasts created by over-water structures because of shading during the day and artificial lighting at night can alter the feeding, schooling, predator avoidance, and migratory behaviors of fish (Nightingale and Simenstad 2001a; Hanson et al. 2003). Fish, especially juveniles and larvae, rely on visual cues for these behaviors. Shadows create a light-dark interface which may increase predation by ambush predators and increase starvation through limited feeding ability (Able et al. 1999; Hanson et al. 2003). In addition, the migratory behavior of some species may favor deeper waters away from shaded areas during the day and lighted areas may affect migratory movements at night, contributing to increased risk of predation (Nightingale and Simenstad 2001a).

### *Altered temperature regimes*

Shoreline modifications, including the construction of seawalls and bulkheads, can alter nearshore temperature regimes and natural communities. Modified shorelines invariably contain less shoreline vegetation than do natural shorelines, which can reduce shading in the nearshore intertidal zone and cause increases in water temperatures (Williams and Thom 2001). Conversely, seawalls and bulkheads constructed along north facing shorelines may unnaturally reduce light levels and reduce water temperatures in the water column adjacent to the structures (Williams and Thom 2001).

### *Siltation, sedimentation, and turbidity*

The construction of a new port or marina facility is usually associated with profound changes in land use and in-water activities. Because a large proportion of the shoreline associated with a port is typically replaced with impervious surfaces such as concrete and asphalt, stormwater runoff is exacerbated and can increase the siltation and sedimentation loads in estuarine and marine habitats. The upland activities related to building roads and buildings may cause erosion of topsoil which can be transported through stormwater runoff to the nearshore aquatic environment, increasing sedimentation and burying benthic organisms. Construction and expansion of ports and marinas generally include dredging channels, anchorages, and berthing areas for larger and greater numbers of vessels, which contribute to localized sedimentation and turbidity. In addition, the use of underwater explosives to construct bulkheads, seawalls, and concrete docks may temporarily resuspend sediments and cause excessive turbidity in the water column and impact benthic organisms. Refer to the section on Navigation Dredging later in this chapter for information on channel dredging.

Impacts associated with increased suspended particles in the water column include high turbidity levels, reduced light transmittance, and sedimentation which may lead to reductions or loss of SAV and other benthic habitats. Elevated suspended particles have also been shown to adversely affect the respiration of fish, reduce filtering efficiencies and respiration of invertebrates, reduce egg buoyancy, disrupt ichthyoplankton development, reduce the growth and survival of filter feeders, and decrease the foraging efficiency of sight-feeders (Messieh et al. 1991; Barr 1993).

Structures such as jetties and groins may be constructed to reduce the accretion of sediment in navigable channels, so by design they alter littoral sediment transport and change sedimentation rates. These structures may reduce sand transport, cause beach and shoreline erosion to down drift areas, and may also interfere with the dispersal of larvae and eggs along the coastline (Williams and Thom 2001). Substrate disturbance from pile driving and removal can increase turbidity, interfere with fish respiration, and smother benthic organisms in adjacent areas (Mulvihill et al. 1980). In addition, contaminants in the disturbed sediments may be resuspended into the water column, exposing aquatic organisms to potentially harmful compounds (Wilbur and Pentony 1999; USEPA 2000; Nightingale and Simenstad 2001b). Refer to the Coastal Development chapter for a more detailed discussion on impacts related to pile driving and removal.

### *Contaminant releases*

The construction of ports and marinas can alter natural currents and tidal flushing and may exacerbate poor water quality conditions by decreasing water circulation. Bulkheads, jetties, docks, and pilings can create water traps that accumulate contaminants or nutrients washed in from land based sources, vessels, and facility structures. These conditions may create areas of low dissolved oxygen, dinoflagellate blooms, and elevated toxins.

Contaminants can be released directly into the water during construction activities associated with new ports and marinas or indirectly through storm water runoff from land-based operations. Accidental and incidental spills of petroleum products and other contaminants, such as paint, degreaser, detergents, and solvents, can occur during construction operations of a facility. Large amounts of impervious surfaces at ports and marinas can increase, and in some cases direct, stormwater runoff and contaminants into aquatic habitats. The use of certain types of underwater explosives to construct bulkheads, seawalls, and concrete docks may release toxic chemicals (e.g., ammonia) in the water column that can impact aquatic organisms.

Wood pilings and docks used in marina and port construction are often treated with chemicals such as chromated copper arsenate, ammoniacal copper zinc, and creosote to help extend the service of the structures in the marine environment. These preservatives can leach harmful chemicals into the water that have been shown to produce toxic affects on fish and other organisms (Weis et al. 1991). Creosote-treated wood for pilings and docks has also been used in marine environments and has been shown to release polycyclic aromatic hydrocarbons (PAH) continuously and for long periods of time after installation or treatment; whereas other chemicals that are applied to the wood, such as ammoniacal copper zinc arsenate (ACZA) and chromated copper arsenate (CCA), tend to leach into the environment for shorter durations (Poston 2001). Affects from exposure of aquatic organisms to PAH include carcinogenesis, phototoxicity, immunotoxicity, and disturbance of hormone regulation (Poston 2001). The rate and duration that these preservatives can be leached into marine waters after installation are highly variable and dependent on many factors, including the length of time since the treatment of the wood and the type of compounds used in the preservatives. The toxic effects of metals such as copper on fish are well known and include body lesions, damage to gill tissue, and interrupted cellular functions (Gould et al. 1994). These chemicals can become available to marine organisms through uptake by wetland vegetation, adsorption by adjacent sediments, or directly through the water column (Weis and Weis 2002). The presence of CCA in the food chain may cause localized reductions in species richness and diversity (Weis and Weis 2002). Concrete, steel, or nontreated wood are relatively inert and generally do not leach contaminants into the water.

Dredging and filling of intertidal and subtidal habitats can resuspend sediments into the water column that may have been contaminated by nearby industrial activities. Information on contaminant releases from dredging can be found in the Navigation Dredging section of this chapter and the Chemical Effects: Water Discharge Facilities chapter of the report.

### *Altered tidal, current, and hydrologic regimes*

One of the primary functions of a marina or port is to shelter and protect boats from wave energy. In-water structures of ports and marinas such as bulkheads, breakwaters, jetties, and piles result in localized changes to tidal and current patterns. These alterations may exacerbate poor water quality conditions in these facilities by reducing water circulation. In addition, in-water structures interfere with longshore sediment transport processes resulting in altered substrate amalgamation, bathymetry, and geomorphology. Changing the type and distribution of sediment may alter key plant and animal assemblages, starve nearshore detrital-based foodwebs, and disrupt the natural processes that build spits and beaches (Nightingale and Simenstad 2001a; Hanson et al. 2003).

The protected, low energy nature of marinas and ports may alter fish behavior as juvenile fish show an affinity to structure and may congregate around breakwaters or bulkheads (Nightingale and Simenstad 2001a). These alterations in behavior may make them more susceptible to predation and may interfere with normal migratory movements.

### *Underwater blasting and noise*

Noise from underwater blasting and in-water construction generates intense underwater sound pressure waves that may adversely affect marine organisms. These pressure waves have been shown to injure and kill fish (Caltrans 2001; Longmuir and Lively 2001; Stotz and Colby 2001). Fish are known to use sound for prey and predator detection as well as social interaction (Richard 1968; Myrberg 1972; Myrberg and Riggio 1985; Hawkins 1986; Kalmijn 1988), and underwater blasting and noise may alter the their distribution and behavior (Feist et al.1996).

Generally, aquatic organisms that possess air cavities (i.e., lungs and swim bladders) are more susceptible to underwater blasts than those without (Keevin et al. 1999). In addition, smaller fish are more likely to be impacted by the shock wave of underwater blasts than are larger fish, and the eggs and embryos tend to be particularly sensitive; however, fish larvae tend to be less sensitive to blasts than eggs or post-larvae fish, probably because the larvae stages do not yet possess air bladders (Wright 1982; Keevin et al. 1999).

Blasting may be used for dredging new navigation channels and boat basins or expanding existing channels in areas containing rock substrates, boulders, and ledges. The construction of new in-water structures, such as bulkheads, seawalls, and concrete docks also may involve blasting. Blasting represents a single point of disturbance with a restricted, and often predictable, mortality zone. In addition, blasting engineers purposefully focus the blast energy towards fracturing rock substrate and prevent excess energy from being released into the water column (Keevin et al. 1999). Techniques used to prevent blasting damage to structures in the vicinity of a project, such as bubble curtains, may be effective mitigation measures for reducing blasting impacts on aquatic biota (Keevin et al. 1999). Although the use of bubble curtains have been shown to be effective at minimizing pressure wave impacts on fish (Keevin et al. 1997; Longmuir and Lively 2001), the difficulty of deploying bubble curtains in field conditions may reduce the efficacy of this technology in mitigating these effects (Keevin et al. 1997).

Unlike blasting, pile driving is a repeating sound disturbance that can last for extended periods of time during construction. There are several factors which affect the type and intensity of sound pressure waves during pile driving, including the size and material of the piling, the firmness of the substrate, and the type of pile-driving hammer that is used (Hanson et al. 2003). Wood and concrete piles produce lower sound pressures than do steel piles. Pile driving in firmer substrate, which requires more energy, will produce more intense sound pressures (Hanson et al. 2003). Both impact hammers and vibratory hammers are commonly used when driving pilings into the substrate. Vibratory hammers produce sounds with more energy in the lower frequencies (15-26 Hz), compared to higher frequency noise generated by impact hammers (100-800 Hz) (Carlson et al. 2001). The behavioral response elicited by fish differs in these two ranges of sound frequencies. Fish respond to sounds similar to vibratory hammers by consistently displaying an avoidance response and not habituating to the sound despite repeated exposure (Dolat 1997; Knudsen et al. 1997; Sand et al. 2000). In contrast to vibratory hammers, fish may be initially startled by an impact hammer but eventually become habituated and no longer respond to the stimuli. Acclimation to the sound may place fish in more danger as they remain in range of potentially harmful sound pressure waves (Dolat 1997). Refer to the chapter on Global Effects and Other Impacts for additional information on underwater noise impacts to aquatic organisms.

### *Conservation recommendations and best management practices for construction and expansion of ports and marinas*

1. Encourage federal, state, and local authorities to assist port authorities and marinas in developing management plans that avoid and minimize impacts to the coastal environment and that are consistent with coastal zone management plans.
2. Encourage implementation of environmental management systems for ports and marinas that incorporate strong operational controls and best management practices (BMPs) into existing job descriptions and work instruction.
3. Encourage marinas to participate in NOAA/US EPA's Coastal Nonpoint Program and the Clean Marina Initiative.
4. Explore alternative port developments such as satellite ports and offshore terminals, which may decrease some impacts associated with traditional inshore port facility developments.
5. Conduct site suitability analyses for new or proposed expansion of port and marina facilities to reduce and avoid habitat degradation or loss. Some of the analyses that should be conducted include identifying alterations to current and circulation patterns, water quality, bathymetric and topographic features, fisheries utilization and species distributions, and substrate features.
6. Conduct pre- and post-project biological surveys over multiple growing seasons to assess impacts on submerged and emergent aquatic vegetation communities.
7. Site new or expansions of port and marina facilities in deep-water areas to the maximum extent practicable to avoid the need for dredging. Areas that are subject to rapid shoaling or erosion will likely require more frequent maintenance dredging and should be avoided.

8. Avoid areas identified as supporting high abundance and diversity of species (e.g., SAV beds, intertidal mudflats, emergent wetlands, fish spawning areas) when locating new or expanded port and marina facilities.
9. Encourage the use of preproject surveys by qualified biologists/botanists to identify and map invasive plants within the proposed project area, and develop and implement an eradication plan for nonnative species.
10. Consider excavating uplands as a less-damaging alternative for new or expanded port and marina facilities instead of dredging intertidal or shallow subtidal habitat. However, water quality modeling should be conducted to evaluate potential impacts associated with enclosed and poorly flushed marinas.
11. Retain and preserve marine riparian buffers to maintain intertidal microclimate, flood and stormwater storage capacity, and nutrient cycle.
12. Consider low-wake vessel technology and appropriate vessel routes in the facility design and permitting process to minimize impacts to shorelines and shallow water habitats. Vessel speeds should be adapted to minimize wake damage to shorelines, and no-wake zones should be considered in highly sensitive areas, such as fish spawning habitat and SAV beds.
13. Do not locate new port and marina facilities in areas that have reduced tidal exchange and/or shallow water habitats, such as enclosed bays, salt ponds, and tidal creeks.
14. Implement construction designs for new ports and marinas to facilitate good tidal exchange and surface water movement and provide an adequate migratory corridor for fish. When possible, structures that impede tidal exchange and that may interfere with the movement of marine organisms, such as solid breakwaters, should be avoided.
15. Ensure that new ports and marinas incorporate BMPs in the construction operation plans that prevent and minimize the release of contaminants and debris caused by construction equipment and activities. The plan should include a spill response plan and training, and spill response equipment should be installed and maintained properly on-site.
16. Implement seasonal restrictions when necessary to avoid construction-related impacts to habitat during species' critical life history stages (e.g., spawning and egg development periods).
17. For structures located over SAV, the amount of light reaching vegetation below the dock should be maximized by providing adequate height over the water, minimizing the width of the dock, and orienting the length of the dock in a north-south direction.
18. The use of wood preservatives, such as creosote, ACZA and CCA should be avoided, where possible. If CCA treated wood must be used, the wood can be presoaked for several weeks or the wood can be coated with plastic sheath to reduce/eliminate leaching. Concrete and steel pilings are generally considered to be less damaging, since they reflect light more than wood docks and generally do not release contaminants into the aquatic environment. However, concrete pilings and docks generally increase the overall size of the overwater structure and may not be preferable in areas containing SAV.
19. Site floating docks, which limit light transmittance more than elevated structures, only in nonvegetated areas. When used, floating docks should either be located in areas of adequate depth so that adequate clearance between the float and the bottom is maintained, or fitted with structures (i.e., float stops) that prevent the float from contacting the bottom. Float stops should be designed to provide a minimum of 2 feet of clearance between the float and substrate to prevent hydraulic disturbances to the bottom. Greater clearances may be necessary in higher energy environments that experience strong wave action.
20. Orient night lighting such that illumination of the surrounding waters is avoided.

21. Reduce sound pressure impacts during pile installation by using wood or concrete piles, rather than hollow steel piles which produce intense, sharp spikes of sound that are more damaging to fish.
22. Use technologies that have been designed to reduce the adverse effects of underwater sound pressure waves such as air bubble curtains and metal or fabric sleeves to surround the pile. Air bubble systems must have adequate airflow, and the pile should be fully contained to ensure that sound attenuation is successful.
23. Conduct pile driving during low tides in intertidal and shallow subtidal areas.
24. Employ vibratory hammers when removing old piles to help minimize the release of suspended sediments, silt, and contaminants into the water column; these may be preferable over direct pull or the use of a clamshell dredge.
25. Reduce or eliminate the amount of sediment released into the water column by cutting the pile off below the mudline and leaving the stub in place when removing old piles.
26. Mitigate impacts to marine organisms, particularly those with air cavities (i.e., swim bladders and lungs), from underwater blasting by employing BMPs such as focusing the blast energy towards a solid rock substrate rather than towards the water column; installing noise attenuating devices such as air curtains; conducting the blasting during periods of low-water or low-tide; using delayed blasts that produce sequenced, lesser-charged explosions that reduce the shockwave; stemming (capping) the charge bore hole with material that contains the blast; and repelling charges that frighten fish from the blast area prior to blasting (Keevin 1998).
27. Consult federal and state resource agencies prior to work that involves blasting to assess the marine resource utilization of the area. Biological surveys may be required to assess the presence of fishery resources. Time-of-year restrictions should be employed to avoid impacting sensitive species and life history stages that use the area. Recommended seasonal work windows are generally specific to regional or watershed-level environmental conditions and species requirements.
28. Integrate measures to reduce nonpoint source (NPS) pollution, such as a stormwater management plan into the design, maintenance, and operation of a port or marina. Some examples of BMPs for stormwater management include (adapted from Amaral et al. 2005):
    a. Minimize the amount of impervious surfaces surrounding the port or marina facility and maintain a buffer zone between the coastal zone and upland facilities.
    b. Implement runoff control strategies to decrease the amount of contaminants entering marine waters from upland sources. This can be accomplished by using alternative surface materials such as crushed gravel, decreasing the slope of surfaces towards the waters' edge, and installing filtering systems or settling ponds.
    c. Designate specific enclosed areas for maintenance activities such as sanding, painting, engine repairs. Use tarp enclosures or spray booths for abrasive blasting to prevent residue from reaching surface waters.
    d. Provide and maintain appropriate storage, transfer, containment, and disposal facilities for liquid hazardous material, such as solvents, antifreeze, and paints.
29. Address the cumulative impacts of past, present, and foreseeable future development activities on aquatic habitats by considering them in port and marina review processes.

## Operation and Maintenance of Ports and Marinas

Existing ports and marinas can be a source of impacts to fishery resources and habitat that may differ from those relating to construction and expansion of new facilities. These impacts may be associated with the operation of the facilities, equipment impacts, and stormwater runoff. Examples of port or marina impacts include chronic pollution releases, underwater noise, altered light regimes, and repeated physical disturbances to benthic habitats.

### *Contaminant release and storm water runoff*

Ports and marinas can be a source of contaminants directly associated with facility activities and by stormwater runoff from the facility and the surrounding urbanized areas. The long-term operation of a marina or port can provide a chronic presence of contaminants to the localized area that can have an adverse effect on the quality of fishery habitat and population dynamics (Wilbur and Pentony 1999).

The oil and fuel that accumulates on dock surfaces, facilities properties, adjacent parking lots, and roadways may enter coastal waters through stormwater runoff and snowmelt. Oil and fuel contains PAH and other contaminants that are known to bioaccumulate in marine organisms and impact the marine food web (Nightingale and Simenstad 2001a; Amaral et al. 2005). In addition, these contaminants can persist in bottom sediments where they can be resuspended through a variety of activities such as propeller scouring and dredging. Marina activities such as vessel refueling, engine repair, and accidental vessel sinking may increase the risk of fuel and oil contamination of the surrounding environment (Amaral et al. 2005).

Marina facilities such as storage areas for paint, solvents, detergents, and other chemicals may pose a risk of introducing additional contaminants to the marine environment resulting in both acute and chronic toxicity to marine biota (Amaral et al. 2005). These products are often a routine and essential part of marina or port operations, and if handled and stored improperly they can increase the risk of accidental spillage. Various port and vessel maintenance activities may contribute to metal contamination to the surrounding waters. For example, elevated levels of copper are often associated with ports and marinas, especially those with a high density of recreational boats because of the type of antifouling paints used on those boats. A number of other metals have been detected in the sediments and surface waters of marinas, including arsenic (used in paints and wood preservatives), zinc (leached from anodes used to reduce corrosion of boat hulls and motors), mercury (used in float switches for bilge and other storage tank pumps), lead (used in batteries), nickel, and cadmium (used in brake linings) (USEPA 2001). However, stormwater runoff may be the primary source of copper in most marinas in urban areas (Warnken et al. 2004).

Wooden pilings and docks in marinas and ports are typically treated with some type of preservative, such as chromated copper arsenate, ammoniacal copper zinc, and creosote. These preservatives can leach harmful chemicals into the water that have been shown to have toxic effects on fish and other organisms (Weis et al. 1991). Concrete, steel, or nontreated wood are relatively inert and do not leach contaminants into the water. Refer to this chapter's section on Construction and Expansion of Ports and Marinas and the Coastal Development chapter for more information on the affects of copper and other wood preservatives on aquatic resources.

Because marinas and ports typically contain large areas of impervious surfaces and are located at the interface between land and water, stormwater runoff can be greater at these facilities compared with other types of land uses. The organic particulates that are washed into marine waters from the surrounding surfaces can add nutrients to the water and cause eutrophication in bays and estuaries. A number of sources of organic matter from ports and marinas can degrade water quality and reduce dissolved oxygen concentrations, including sewage discharges from recreational and commercial boats, trash tossed overboard, fish wastes disposed of into surface waters, pet wastes, fertilizers, and food wastes (USEPA 2001). Eutrophication often leads to abnormally high phytoplankton populations, which in turn can reduce the available light to SAV beds. Changes in water quality caused by eutrophication can sometimes have a more severe impact on seagrass populations than shading from over-water structures or physical uprooting by vessel and float groundings (Costa et al. 1992; Burdick and Short 1999).

### *Release of debris*

Solid waste is another problematic issue associated with port and marina operations. A great deal of solid waste is generated through daily operations of a commercial port as well as the recreational activities of a marina. This waste may include plastics such as fishing line, bottles, tarps, food containers, and shopping bags, or paper products and other materials, which can be released as debris into the surface waters through accidental loss from vessels or through stormwater runoff from upland facilities. Activities such as sanding, pressure washing, sand blasting, and discarding rags and oil/fuel filters can contribute to marine debris if improper handling and disposal is allowed (USEPA 2001). If this waste is collected and disposed of properly the impacts to the environment can be minimized (Amaral et al. 2005). Plastics are a large component of the trash released into marine waters, accounting for 50-60% of marine debris collected from the Gulf of Maine (Hoagland and Kite-Powell 1997). Plastics contain toxic substances that can persist in the environment and bioaccumulate through the food web, impairing metabolic functions in fish and invertebrates that use habitats polluted by plastic debris. Some chemicals found in plastics, known as “endocrine disruptors,” may interfere with the endocrine system of aquatic organisms (Kavlock et al. 1996; Kavlock and Ankley 1996). These chemicals act as “environmental hormones” that may mimic the function of the sex hormones androgen and estrogen (Thurberg and Gould 2005). Adverse effects include reduced or altered reproductive functions, which could result in population-level impacts.

Marine debris can directly affect fish and invertebrates that may consume or become entangled by the debris. Plastic debris may be ingested by seabirds, fish and invertebrates, sea turtles, and marine mammals, which can cause infections and death of the animal (Cottingham 1988). Debris can be transported by currents to other areas where it can become snagged and attached to benthic habitat, damaging sensitive reef habitat. Additional information on impacts associated with marine debris can be found under Operation and Maintenance of Vessels section of this chapter and in the Coastal Development chapter of this report.

### *Underwater noise*

The ambient noises emanating from ports and marinas are from a combination of boat propellers, engines, pumps, generators, and other equipment within vessels and shore-side equipment. In coastal areas the sounds of cargo and tanker traffic are multiplied by complex reflected paths from scattered and reverberated noises caused by littoral geography. Commercial and private fishing boats, pleasure craft, personal watercraft (i.e., jet skis), industrial vessels, public transport ferries, and shipping safety and security services such as tugs boats, pilot boats, enforcement vessels, and coastal agency support craft generate sounds that can impact marine organisms, particularly fish and marine mammals. Exposure to continuous noise may also create a shift in hearing thresholds for marine organisms resulting in hearing losses at certain frequency ranges (Jasny et al. 1999). Refer to the Global Effects and Other Impacts chapter and the Operation and Maintenance of Vessels and the Construction and Expansion of Ports and Marinas sections in this chapter for more information on underwater noise.

## *Derelict structures*

Increased vessel activity in and around port and marina operations increase the probability of the grounding of vessels, which may not always be removed immediately from the aquatic environment. In addition to being public health and navigational hazards, derelict or abandoned vessels can cause various impacts to coastal habitats. Grounded vessels can physically damage and smother benthic habitats, create changes in wave energy and sedimentation patterns, and scatter debris across sensitive habitats (Precht et al. 2001; Zelo and Helton 2005). However, the most common environmental threat of a derelict or abandoned vessel is the release of oil or other pollutants. These hazardous materials may be part of a vessel's cargo, fuel and oil related to vessel operations, or chemicals contained within the vessel's structure which may be released over time through decay and corrosion. Refer to the Operation and Maintenance of Vessels section of this chapter for more information on impacts associated with derelict structures and grounded vessels.

## *Mooring and floating dock impacts*

Vessel mooring impacts, although localized, can reduce habitat quality and complexity. Accidental vessel groundings can smother or crush shellfish, scour vegetation, and disturb substrates (Nightingale and Simenstad 2001a). Disturbance of substrates can lead to increased turbidity, reduced light penetration, decreased dissolved oxygen levels, and the possible resuspension of contaminants. In addition, moored vessels contacting the bottom during low tides can cause the bottom habitat in the area of the mooring to be unavailable for fish and other marine biota during the time the vessel is resting on the bottom. Vessels that contact the bottom can create scouring of the substrate and result in permanent alteration or loss of benthic habitats, such as eelgrass. Demersal eggs (e.g., Atlantic herring [*Clupea harengus*]) and larvae that utilize an area can also be destroyed from the impact of the vessel or shading. Floating piers and docks may also alter wave energy, current patterns, and longshore sediment transport, especially in areas that experience strong current velocities (Nightingale and Simenstad 2001a).

Depending upon the type and configuration, the mooring tackle itself may cause impacts to substrate and benthos, including SAV. Typical vessel moorings consist of an anchor connected to a surface buoy by a long length of heavy chain. In most moorings, some portion of the anchor chain drags and often scours the bottom and forms a depression in the sediment surface (Walker et al. 1989). In areas influenced strongly by tides and currents or wind, the bottom scouring takes on a circular or "V" configuration when the anchor chain is allowed to drag along the bottom as the vessel or buoy swings with the tide or wind (Nightingale and Simenstad 2001a). The resulting scour holes allow further erosion and loss of the physical integrity of the habitat, which can lead to fragmentation of seagrass meadows (Walker et al. 1989; Hastings et al. 1995). Hastings et al. (1995) attributed an approximate 18% direct loss of seagrass habitat from boat moorings in one bay in Western Australia. Refer to the Coastal Development chapter of this report for a more detailed discussion on impacts from overwater structures.

## *Alteration of light regimes*

As discussed in other sections of this chapter, overwater structures shade the surface of the water and attenuate the light available to benthic habitat under and adjacent to the structures. The height, width, construction materials used, and orientation of the structure in relation to the sun can influence how large a shade footprint an over-water structure may produce and how much of an adverse impact that shading effect may have on the benthic habitat (Burdick and Short 1999; Shafer 1999; Fresh et al. 2001; Nightingale and Simenstad 2001a). Refer to the chapter on Coastal

Development and the Construction and Expansion of Ports and Marinas section of this chapter for more information on docks structures and light attenuation.

### *Conservation recommendations and best management practices for the operation and maintenance of ports and marinas (adapted from Amaral et al. 2005; Hanson et al. 2003)*

1. Consider environmental impacts through port development and operations plans, including:
   a. assess all activities at facility and identify potential environmental impacts
   b. determine compatibility with port environmental practices and assess available control technologies
   c. evaluate and monitor effectiveness of control technologies
   d. develop and implement environmental management
2. Encourage marinas to participate in NOAA/US EPA's Coastal Nonpoint Program and the Clean Marina Initiative.
3. Ensure that marina and port facility operations have an oil spill response plan in place, which has been shown to improve the response and recovery times of oil spills.
4. Ensure that marina or port facilities have adequate oil spill response equipment accessible and clearly marked. Oil spill response equipment may include oil booms, absorbent pads, and oil dispersant chemicals.
5. Use dispersants that remove oils from the environment, rather than those that simply move them from the surface to the ocean bottom.
6. Install automatic shut-off nozzles at fuel dispensing sites and require the use of fuel/air separators on air vents or tank stems of inboard fuel tanks to reduce the amount of fuel oil spilled into surface waters by vessels using fuel stations.
7. Promote the use of oil-absorbing materials in the bilge areas of all boats with inboard engines.
8. Place containment berms around fixed pieces of machinery that use oil and gas within the facility.
9. Encourage public education and signage to promote proper disposal of solid debris and polluting materials.
10. Encourage the proper disposal of materials produced and used by the operation, cleaning, maintenance, and repair of boats to limit the entry of solid and contaminated waste into surface waters.
11. Recommend the placement of garbage containers to supervised areas and use containers that have lids in order to reduce the potential for litter to enter the marine environment.
12. Promote the use of pumpout facilities and restrooms at marinas and ports to reduce the release of sewage into surface waters. Ensure that these facilities are maintained and operational, and provide these services at convenient times, locations, and reasonable cost. In addition, promote the use of these facilities through public education and signage.
13. Develop a harbor management plan which addresses the maintenance and operation of pumpout facilities.
14. Prevent the disposal of fish waste or other nutrient laden material in marina or port basins through the use of public education, signage, and by providing alternate fish waste management practices.
15. Ensure that measures to reduce NPS pollution, such as a stormwater management plan, are integrated into the maintenance and operation of a port or marina.

16. Recommend site-specific solutions to NPS pollution by considering the frequency of marina operations and potential pollution sources. Management practices should be tailored to the specific issues of each marina.
17. Encourage the removal of unnecessary impervious surfaces surrounding the port or marina facility and maintain a buffer zone between the aquatic zone and upland facilities.
18. Ensure that stormwater runoff from parking lots and other impervious surfaces is collected and treated to remove contaminants prior to delivery to any receiving waters. This can be accomplished by using alternative surface materials such as crushed gravel, decreasing the slope of surfaces towards the water's edge, and installing filtering systems or settling ponds.
19. Recommend that specific, enclosed areas are designated for maintenance activities such as sanding, painting, engine repairs. Using tarp enclosures or spray booths for abrasive blasting will also prevent residue from reaching surface waters.
20. Ensure that facilities provide for appropriate storage, transfer, containment, and disposal facilities for harmful liquid material, such as solvents, antifreeze, and paints.
21. Recommend that facilities provide a containment system and a filtering and treatment system for vessel wash down wastewater.
22. Ensure that floating structures, including barges, mooring buoys, and docks are located in adequate water depths to avoid propeller scour and grounding of vessel and floating structures. When floating docks cannot be located in adequate depth to avoid contact on the bottom at low tides, recommend that float stops (structural supports to prevent the float from resting on the bottom) are installed. Float stops should be designed to provide a minimum of 2 feet of clearance between the float and substrate to prevent hydraulic disturbances to the bottom. Greater clearances may be necessary in higher energy environments that experience strong wave action.
23. Recommend anchoring techniques and mooring designs that avoid scouring from anchor chains. For example, anchors that do not require chains (e.g., helical anchors) or moorings that use subsurface floats to prevent anchor chains from dragging the bottom are some designs that should be considered.
24. When moorings with anchor chains cannot be avoided, recommend that areas prone to high current and wind velocity be avoided, where the sweep of the anchor chain on the bottom can cause the greatest damage.
25. Recommend the use of concrete, nontreated wood or steel dock materials to avoid the leaching of contaminants associated with wood preservatives.

## Operation and Maintenance of Vessels

Vessel activity in coastal waters is generally proportional to the degree of urbanization and port and harbor development within a particular area. Benthic, shoreline, and pelagic habitats may be disturbed or altered by vessel use, resulting in a cascade of cumulative impacts in heavy traffic areas (Barr 1993). The severity of boating-induced impacts on coastal habitats may depend on the geomorphology of the impacted area (e.g., water depth, width of channel or tidal creek), the current velocity, the sediment composition, the vegetation type and extent of vegetative cover, as well as the type, intensity, and timing of boat traffic (Yousef 1974; Karaki and vanHoften 1975; Barr 1993). Recreational boating activity mainly occurs during the warmer months which coincide with increased biological activity in east coast estuaries (Stolpe and Moore 1997; Wilbur and Pentony 1999). Similarly, frequently traveled routes such as those traveled by ferries and other transportation vessels can impact fish spawning, migration, and recruitment behaviors through noise and direct disturbance of the water column (Barr 1993).

Other common impacts of vessel activities include vessel wake generation, anchor chain and propeller scour, vessel groundings, the introduction of invasive or nonnative species, and the discharge of contaminants and debris (Hanson et al. 2003).

### *Impacts to benthic habitat*

Vessel operation and maintenance activities can have a wide range of impacts to benthic habitat, ranging from minor (e.g., shading of SAV) to potentially large-scale impacts (e.g., ship groundings and fuel or toxic cargo spills). Direct disturbances to bottom habitat can include propeller scouring and vessel wake impacts on SAV and other sensitive benthic habitats and direct contact by groundings or by resting on the bottom at low tides while moored. Propeller scarring can result in a loss of benthic habitat, decrease productivity, potentially fragment SAV beds, and lead to further erosion and degradation of the habitat (Uhrin and Holmquist 2003). Eriksson et al. (2004) found that boating activities can have direct and indirect impacts on SAV, including drag and tear on plant tissues resulting from increased wave-action, reduction in light availability caused by elevated turbidity and resuspension of bottom sediments, and altered habitat and substrate that causes plants to be uprooted and can inhibit recruitment. The disturbance of sediments and rooted vegetation decreases habitat suitability for fish and shellfish resources and can effect the spatial distribution and abundance of fauna (Nightingale and Simenstad 2001a; Uhrin and Holmquist 2003; Eriksson et al. 2004).

### *Resuspension of bottom sediments/turbidity*

The degree of sediment resuspension and turbidity that is produced in the water column from vessel activity is complex but is generally dependent upon the wave energy and surge produced by the vessel, as well as the size of the sediment particles, the water depth, and the number of vessels passing through an area (Karaki and vanHoften 1975; Barr 1993). These activities typically increase turbidity and sedimentation on SAV and other sensitive benthic habitats (Klein 1997; Barr 1993; Nightingale and Simenstad 2001a; Eriksson et al. 2004). Studies investigating sedimentation impacts on eelgrass have found that experimental burial of 25% of the plant height can result in greater than 50% mortality (Mills and Fonseca 2003). Klein (1997) reported that turbidity generated by boats operating in shallow waters can exceed safe levels by up to 34-fold.

The resuspension of sediments can affect habitat suitability for fish and shellfish resources and effect the spatial distribution and abundance of fauna (Nightingale and Simenstad 2001a; Uhrin and Holmquist 2003; Eriksson et al. 2004). The egg and larval stages of marine and estuarine fish are generally highly sensitive to suspended sediment exposures (Wilber and Clark 2001), and juvenile fish may be susceptible to gill injury when suspended sediment levels are high (Klein 1997). Sedimentation and turbidity impacts associated with boating may be more pronounced in areas that contain shallow water habitat where the bottom is composed of fine sediments (Klein 1997).

### *Shoreline erosion*

Wave energy caused by industrial and recreational shipping and transportation can have substantial impacts on aquatic shoreline and backwater areas which can eventually cause the loss and disturbance of shoreline habitats (Karaki and vanHoften 1975; Barr 1993; Klein 1997). Vessel wakes along frequently traveled routes can cause shoreline erosion, damage aquatic vegetation, disturb substrate, and increase turbidity. Wave energy and surge produced by vessels are dependent upon a number of factors, including the size and configuration of the vessel hull, the size of the vessel, and the speed of the vessel (Karaki and vanHoften 1975; Barr 1993). The degree of erosion on shorelines caused by vessels is complex, but it is generally dependent upon the wave energy and surge produced by the vessel and the slope of the shoreline, the type of sediment (e.g., clay, sand), and the type and amount of shoreline vegetation, as well as the characteristics of the water body (e.g., water depth and bottom topography) and distance between the vessel and shoreline (Karaki and vanHoften 1975; Barr 1993).

### *Contaminant spills and discharges*

A variety of substances can be discharged or accidentally spilled into the aquatic environment, such as gray water (i.e., sink, laundry effluent), raw sewage, engine cooling water, fuel and oil, vessel exhaust, sloughed bottom paint, boat washdown water, and other vessel maintenance and repair materials that may degrade water quality and contaminate bottom sediments (Cardwell et al. 1980; Cardwell and Koons 1981; Krone et al. 1989; Waite et al. 1991; Hall and Anderson 1999; Hanson et al. 2003).

Industrial shipping and recreational boating can be sources of metals such as arsenic, cadmium, copper, lead, and mercury (Wilbur and Pentony 1999). Metals are known to have toxic effects on marine organisms. For example, laboratory experiments have shown high mortality of Atlantic herring eggs and larvae at copper concentrations of 30 µg/L and 1,000 µg/L, respectively, and impairment of vertical migration for larvae at copper concentrations greater than 300 µg/L (Blaxter 1977). Copper may also bioaccumulate in bacteria and phytoplankton (Milliken and Lee 1990). Metals may enter the water through various vessel maintenance activities such as bottom washing, paint scraping, and application of antifouling paints (Amaral et al. 2005). For example, elevated copper concentrations in the vicinity of shipyards have been associated with vessel maintenance operations such as painting and scraping of boat hulls (Milliken and Lee 1990). Studies have shown a positive relationship between the number of recreational boats in a marina and the copper concentrations in the sediments of that marina (Warnken et al. 2004). Copper and an organotin, called tributyltin (TBT), are common active ingredients in antifouling paints (Milliken and Lee 1990). The use of TBT is primarily used for large industrial vessels to improve the hydrodynamic properties of ship's hulls and fuel consumption, while recreational vessels typically use copper-based antifouling paints because of restrictions introduced in the Organotin Antifouling Paint Control Act of 1988 (33 U.S.C. 2401), which bans its use on vessels less than 25 m in length (Milliken and Lee 1990; Hofer 1998).

Herbicides are also used in some antifouling paints to inhibit the colonization of algae and the growth of seaweeds on boat hulls and intake pipes (Readman et al. 1993). Similar to copper, the highest concentrations of herbicides in nearshore waters are associated with recreational marinas, which may be because of a higher frequency of use of these types of antifouling paints for pleasure boats compared to commercial vessels (Readman et al. 1993). The leaching of these chemicals into the marine environment could affect community structure and phytoplankton abundance (Readman et al. 1993).

Fuel and oil spills can affect animals directly or indirectly through the food chain. Fuel, oil, and some hydraulic fluids contain PAH which can cause acute and chronic toxicity in marine organisms (Neff 1985). Toxic effects of exposure to PAH have been identified in adult finfish at concentrations of 5-50 ppm and the larvae of aquatic species at concentrations of 0.1-1.0 ppm (Milliken and Lee 1990). Small, but chronic oil spills are a potential problem because residual oil can build up in sediments and affect living marine resources. Even though individual releases are small, they are also frequent and when combined they contribute nearly 85% of the total input of oil into aquatic habitats from human activities (ASMFC 2004). Incidental fuel spills involving small vessels are probably common events, but these spills typically involve small amounts of material and may not necessarily adversely affect fishery resources. Larger spills may have significant acute adverse affects, but these events are relatively rare and usually involve small geographic areas.

Outboard engines, as opposed to inboard engines that are generally used for larger, commercial vessels, are unique in that their exhaust gases cool rapidly and leave some hydrocarbon components condensed and in the water column rather than being released into the atmosphere (Moore and Stolpe 1995). Outboard engine pollution, particularly from two-cycle engines, can contribute to the concentrations of hydrocarbons in the water column and sediment (Milliken and Lee 1990). Two-cycle outboard engines accomplish fuel intake and exhaust in the same cycle and tend to release unburned fuel along with the exhaust gases. In addition, two-cycle engines mix lubricant oil with the fuel, so this oil is released into the water along with the unburned fuel. There are over 100 hydrocarbon compounds in gasoline, including additives to improve the efficiency of the fuel combustion (Milliken and Lee 1990). Once discharged into the water, petroleum hydrocarbons may remain suspended in the water column, concentrate on the surface, or settle to the bottom (Milliken and Lee 1990).

Any type of fuel or oil spill has the potential to cause impacts to organisms and habitats in the water column, on the bottom, and on the shoreline, but it is unknown to what extent these effects are individually or cumulatively significant. Effects on fish from low-level chronic exposure may increase embryo mortality, reduce growth, or alter migratory patterns (Heintz et al. 2000; Wertheimer et al. 2000). For more details on the impacts of oil or fuel spills, see the chapter on Energy-related Activities.

Gray water and sewage discharge from boats may impact water quality by increasing nutrient loading and biological oxygen demand of the local area and through the release of disease causing organisms and toxic substances (Thom and Shreffler 1996; Klein 1997). Positive correlations between boating activity levels and elevated levels of fecal coliform bacteria in nearshore coastal waters have been reported (Milliken and Lee 1990). Although the Clean Water Act (CWA) of 1972 makes it illegal to discharge untreated wastes into coastal waters and the Federal Water Pollution Control Act requires recreational boats be equipped with marine sanitation devices (MSDs), it is legal to discharge treated wastes, and illegal discharges of untreated waste may be common (Milliken and Lee 1990; Amaral et al. 2005). Despite these laws, many vessels may not be equipped with MSDs and on-shore pumpout stations are not common (Amaral et al. 2005). Impacts from vessel waste discharges may be more pronounced in small, poorly flushed waterways where pollutant concentrations can reach unusually high levels (Klein 1997).

### *Underwater noise*

The noise generated by vessel operations is usually concentrated in ports, marinas, and heavily used shipping lanes or routes and may impact fish spawning, migration, and recruitment behaviors (Hildebrand 2004). Exposure to continuous noise may also create a shift in hearing thresholds for marine organisms resulting in hearing losses at certain frequency ranges (Jasny et al. 1999). Reducing vessel noise is a difficult task because of the economic incentives that encourage the expansion of commercial shipping and the lack of alternatives for efficient global transport of large and high tonnage material (Hildebrand 2004).

Small craft with high-speed engines and propellers (e.g., recreational boats with outboard engines) typically produce higher frequency noise than do larger vessels that generate substantial low-frequency noise because of their size and large, slow-speed engines and propellers (Kipple and

Gabriele 2004). A noise study of three size-classes of vessels (i.e., small, 17-30 feet; medium, 50-100 feet; and large, >100 feet) in Glacier Bay, AK, found that, on average, overall sound levels were higher for the larger vessel categories (Kipple and Gabriele 2004). However, vessel sound levels in this study were generally measured at vessel speeds less than 10 knots, and the investigators found increasing sound levels with greater vessel speed (Kipple and Gabriele 2004). Scholik and Yan (2002) reported significant elevation of the auditory threshold of the fathead minnow (*Pimephales promelas*), after exposure to noise from an idling 55 horsepower outboard motor. Furthermore, the frequencies of the noise from the outboard engine corresponded to the frequencies of the fish's auditory threshold shifts, specifically in this species' most sensitive hearing range (1.0-2.0 kHz).

Commercial shipping vessels are a major source of low frequency (5-500 Hz) noise in the marine environment and may be one of the most pervasive sources of anthropogenic ocean noise (Jasny et al. 1999; Stocker 2002; Hildebrand 2004). Low frequencies travel long distances in the marine environment, which is probably why these frequencies are also used by marine mammals for communication (Jasny et al. 1999). Ship noise is generated from the use of engines and other on-board mechanical devices such as pumps, cooling systems, and generators, as well as movement of water across the hull and propellers (Stocker 2002; Hildebrand 2004). These sounds are amplified and transferred to the water through the ship's hull (Stocker 2002). The size and frequency of use for commercial vessels traversing the ocean and nearshore waters may explain why they are considered a major source of noise impacts compared to the more numerous fishing and pleasure craft found in coastal waters (Hildebrand 2004).

There are several factors which influence sound attenuation in shallow coastal waters including temperature variations or thermoclines, bottom geography, and sediment composition. Vessel noise may reverberate or scatter off geological features and anthropogenic structures in the water (Stocker 2002).

Sonar is another source of anthropogenic noise attributed to vessel operation. It is used for various purposes such as depth sounding and fish finding and can vary in range depending on the use (15-200 kHz for commercial navigation, 1-20 kHz for other positioning and navigation, and 100-3,000 Hz for long range sonar) (Stocker 2002). Refer to the Global Effects and Other Impacts chapter of this report for more information on ocean noise.

### *Release of debris*

As discussed in the Operation and Maintenance of Ports and Marinas section of this chapter, the release of solid waste in coastal waters is a considerable concern. Billions of pounds of debris are dumped into the oceans each year (Milliken and Lee 1990), and vessel traffic is a significant source of this waste because of accidental loss, routine practices of dumping waste, and illegal dumping activities (Cottingham 1988). Entanglement in or ingestion of this debris can cause fish, marine mammals, and sea birds to become impaired or incapacitated, leading to starvation, drowning, increased vulnerability to predators, and physical wounds (Milliken and Lee 1990). Marine debris can also cause direct physical damage to habitat features through smothering or physical disturbance.

Plastics are an especially persistent form of solid waste. Plastics tend to concentrate along coastal areas because they float on the surface and can be transported by ocean currents (Milliken and Lee 1990). Commercial fishing, merchant vessel, cruise ship, and recreational boats are major contributors to marine plastic debris (Cottingham 1988; Milliken and Lee 1990). Cottingham (1988) estimated that merchant vessels are the primary source of plastic refuse in New England. Refer to the Operation and Maintenance of Ports and Marinas section in this chapter for information on plastic debris and the Coastal Development chapter of this report for more information on general marine debris.

### *Abandoned and derelict vessels*

Derelict or abandoned vessels can cause a variety of impacts to habitats and are public health and navigational hazards. Grounded vessels may physically damage and smother benthic habitats, create changes in wave energy and sedimentation patterns, and scatter debris across sensitive habitats (Precht et al. 2001; Zelo and Helton 2005). The potential impact footprint of a grounded vessel can be much larger than the vessel itself as vessels move or break up during storm events, which can scour bottom habitat, amplify impacts, and complicate removal (Zelo and Helton 2005). The physical impacts of a grounded vessel can be greater in shallow water since the wreck is more likely to be unstable and move, may break up more rapidly because of wave and current forces, and is more likely to need urgent removal because of navigation concerns which may lead to additional resource impacts (Michel and Helton 2003). Refer to the Offshore Dredging and Disposal Activities chapter of this report for information regarding intentional sinking of vessels for disposal and creation of artificial reefs.

The most common environmental threat of a derelict or abandoned vessel is the release of oil or other pollutants. These hazardous materials may be part of a vessel's cargo, fuel and oil related to vessel operations, or chemicals contained within the vessel's structure which may be released through decay and corrosion over time. Rusting vessel debris can also cause iron enrichment in enclosed areas, which has been associated with harmful algal blooms (Helton and Zelo 2003; Michel and Helton 2003).

The historical focus of laws regarding derelict or abandoned vessels was the protection of the property rights of shipowners and the recovery of cargo (Michel and Helton 2003). Existing federal laws and regulations do not provide clear authority or funding to any single agency for the removal of grounded or abandoned vessels that harm natural resources but which are not otherwise obstructing or threatening to obstruct navigation or threatening a pollution discharge (Helton and Zelo 2003). In many cases vessels are abandoned and are left to continually damage the marine environment because a responsible party cannot be identified or a funding source for removal cannot be secured (Zelo and Helton 2005). Physical impacts, in particular, can persist for decades when vessels are left in the marine environment, and in some cases simply removing a vessel is enough to allow natural recolonization of benthic organisms (Zelo and Helton 2005).

Removal of a derelict vessel will ensure that the vessel does not become a navigation hazard to other ships and that hazardous materials are not released during storms which can damage the wreckage further. It also ensures that abandoned vessels do not become illegal dumpsites for oil, industrial waste, and other hazardous materials, including munitions (Helton and Zelo 2003). Salvage and wreck removal activities can result in unintended habitat impacts. For example, fuel spillage may occur during salvage operations of a wrecked vessel. The potential for collateral impacts should be considered when planning a salvage operation (Michel and Helton 2003). Wrecks in shallow water are often removed and scuttled in deep water to prevent further damage to more vulnerable, nearshore benthic habitats and to avoid the risks involved in bringing an unstable vessel into port (Michel and Helton 2003).

Although many of the habitat impacts described above can be averted if derelict vessels are removed while still afloat, abandoned and neglected floating vessels can also create habitat impacts (Zelo and Helton 2005). These vessels may shade seagrass beds, scour subtrates with anchor chains, or release pollutants from decaying hull materials and paints (Sunda 1994; Negri et al. 2002; Smith et al. 2003; Zelo and Helton 2005).

## *Nonnative and invasive species*

Nonnative species, some of which are invasive, have been introduced to coastal areas through industrial shipping and recreational boating (Omori et al. 1994; Wilbur and Pentony 1999; Hanson et al. 2003; Pertola et al. 2006). These introductions can be in the form of fouling organisms on the bottom of vessels as they are transported between water bodies or through the release of ballast water from large commercial vessels. Modern ships can carry 10 to 200 thousand tons of ballast water at a time and transport marine organisms across long distances and in relatively short time periods (Hofer 1998). This expeditious travel increases the risk that the organisms taken up in ballast water will be viable when introduced into a distant port or marina during deballasting (Wilbur and Pentony 1999). Pertola et al. (2006), in an investigation of dinoflagellates and other phytoplankton from the ballast tank sediments of ships at ports in the northeastern Baltic Sea, found a large assemblage of germinated dinoflagellate cysts in 90% of all ships and at all ports sampled. Ship traffic can transport, in large numbers, nonnative and invasive species of phytoplankton that can be harmful to native aquatic species (Pertola et al. 2006). The nonnative green algae (*Codium fragile*), is an example of a species that has invaded the northeastern US coast, the eastern Atlantic Ocean, Mediterranean Sea, and New Zealand and has displaced native species of *Codium* (Walker and Kendrick 1998; Tyrrell 2005). Shipping has been implicated as the major agent of spread of this species (Walker and Kendrick 1998), as well as of the zebra mussel (*Dreissena polymorpha*) (Strayer et al. 2004). This invasive species has been shown to have had an adverse effect on the populations of some native species of fish (e.g., *Alosa* spp.), as well as phytoplankton, zooplankton, aquatic vegetation, water chemistry, and zoobenthos (Strayer et al. 2004).

Introduced species can adversely impact habitat qualities and functions by altering the community structure, competing with native species, and introducing exotic diseases (Omori et al. 1994; Wilbur and Pentony 1999; Carlton 2001). Additional discussion of the effects of introduced species can be found in the chapters on Introduced/Nuisance Species and Aquaculture and Physical Effect: Water Intake and Discharge Facilities.

## *Conservation recommendations and best management practices for vessel operation and maintenance*

1. Encourage marinas to participate in NOAA/US EPA's Coastal Nonpoint Program and the Clean Marina Initiative.
2. Ensure that commercial ships and port facilities have oil-spill response plans in place which improve response and recovery in the case of accidental spillage.
3. Ensure that commercial ships and or port facilities have adequate oil-spill response equipment accessible and clearly marked.
4. Use dispersants that remove oils from the environment rather than dispersants that simply move them from the surface to the ocean bottom.
5. Promote the use of oil-absorbing materials in the bilge areas of all boats with inboard engines.
6. Promote the use of fuel/air separators on air vents or tank stems of inboard fuel tanks to reduce the amount of fuel and oil spilled into surface waters during fueling of boats.
7. Encourage recreational boats to be equipped with marine sanitation devices (MSDs) to prevent untreated sewage to be pumped overboard.
8. Encourage ship designs that include technologies capable of reducing noise generated and transmitted to the water column, such as the use of muffling devices already required for land-based machinery that may help reduce the impacts of vessel noise.

9. The effects of proposed and existing vessel traffic and associated underwater noise should be assessed for potential impacts to sensitive areas such as migration routes and spawning areas for marine animals.
10. Exclude vessels or limit specific vessel activities such as high intensity, low-frequency sonar, to known sensitive marine areas if evidence indicates that these activities have a substantial adverse effect to marine organisms.
11. Promote education and signage on all vessels to encourage proper disposal of solid debris at sea.
12. Encourage the use of innovative cargo securing and stowing designs that may reduce solid debris in the marine environment from the transportation of commercial cargo.
13. Use appropriate equipment and techniques to salvage and remove grounded vessels and follow all necessary state and federal laws and regulations. If possible, avoid using the propulsion systems of salvage tugs that can cause propeller wash and scour the bottom. Instead, moor the tugs and use a ground tackle system to provide maneuvering and pull.
14. Minimize additional seafloor damage when a derelict vessel has to be dragged across the seafloor to deep water by following the same ingress path. Alternatively, identify the least sensitive, operationally feasible towpath. Dismantling derelict vessels in place when stranded close to shore may cause less environmental impact than dredging or dragging a vessel across an extensive shallow habitat.
15. Reduce the risk of a sudden release of the entire cargo when a submerged derelict vessel contains hazardous aqueous solutions that pose limited environmental risks, such as mild acids and bases, by allowing the release of the cargo under controlled conditions. The controlled release plan can include water-quality monitoring to validate the calculated dilution rates and plume distance assumptions. All applicable state and federal laws and regulations regarding the release of chemicals into the water should be followed.
16. Develop a contingency plan for uncontrolled releases during vessel salvage operations. The salvage plan should include a risk assessment to determine the most likely release scenarios and use the best practices of the industry.
17. Schedule nonemergency salvage operations while including environmental considerations to minimize potential impacts on natural resources. Environmental considerations include periods when few sensitive species are present, avoidance of critical reproductive periods, and weather patterns that influence the trajectory of potential releases during operations
18. Choose a scuttling site for a derelict vessel in a deep-water location in federal or Exclusive Economic Zone (EEZ) waters that does not contain any sensitive resources or geological hazards. Ensure that all proposed disposal of vessels in the open ocean adheres to state and federal guidance and regulations, including section 102(a) of the Marine Protection, Research, and Sanctuaries Act (Ocean Dumping Act), and under 40 CFR § 229.3 of the US EPA regulations. Refer to the Offshore Dredging and Disposal Activities chapter for additional recommendations and BMPs for the disposal of vessels.

# Navigation Dredging

## *Introduction*

Channel dredging is a ubiquitous and chronic maintenance activity associated with port and harbor operation and vessel activity (Barr 1987; NEFMC 1998). Navigational dredging occurs in rivers, estuaries, bays, and other areas where ports, harbors, and marinas are located (Messieh and El-Sabh 1988). The locations of these facilities often coincide with sensitive aquatic habitats that are vital for supporting fishery production (Newell et al. 1998).

For the purposes of navigation, dredging can be generally classified as either creating new or expanded waterways with greater profiles, depths, and scope or as maintenance of existing waterways for the purpose of maintaining established profiles, depths, and scope. Although the latter category represents the most common dredging scenario, new construction, or "improvement" dredging as it is sometimes called, has become increasingly common at larger ports and harbors throughout the United States. Several corresponding factors have likely led to greater need for navigational "improvements" and increases in the operating depths and the sizes of existing ports and harbors, including: (1) increased demand for marine cargo and transportation; (2) expansion of commercial fleets; (3) increased demand for larger capacity commercial and recreational vessels; and (4) increased urbanization and infrastructure development along the coast (Messieh et al. 1991; Wilbur and Pentony 1999; Nightingale and Simenstad 2001b). In particular, this demand for larger capacity commercial cargo vessels has led to an increased competition among the major coastal ports to provide facilities to accommodate these vessels. Improvement dredging may occur in areas that have not previously been subjected to heavy vessel traffic and dredging activities, such as new commercial marinas or the creation of a new channel or turning basin in an existing port or marina facility. Because improvement dredging is often conducted in areas that have been less affected by previous dredging and vessel activities, the impacts are generally more severe than the impacts associated with regular maintenance dredging activities unless the sediments involved in the maintenance dredging contain high levels of contaminants (Allen and Hardy 1980).

Maintenance dredging is generally required in most navigation channels and port and marina facilities because of the continuous deposition of sediments from freshwater runoff or littoral drift. Navigation channels require maintenance dredging to remove accumulated sediments, typically conducted on a temporal scale of one to ten years (Nightingale and Simenstad 2001b). Alterations in sedimentation patterns of estuaries resulting from increased coastal development and urbanization often increases the sediment influx and the frequency for maintaining existing channels and ports. Dredging for other purposes, such as aggregate mining for sand and gravel, conveyance of flood flows, material for beach nourishment, and removal of contaminated sediments or construction of subtidal confined disposal of contaminated sediments, may be done separately or in conjunction with navigation dredging (Nightingale and Simenstad 2001b). Refer to the Offshore Dredging and Disposal Activities chapter of this report for more information on offshore aggregate mining and to the Coastal Development chapter of this report contains information on the affects of beach nourishment and other coastal development activities.

There is a variety of methods and equipment used in navigation dredging, and a detailed explanation and assessment is beyond the scope of this report. However, one can categorize dredging activities as either using hydraulic or mechanical equipment. The type of equipment used for navigation dredging primarily depends on the nature of the sediments to be removed and the type of disposal required. Some of the factors that determine the equipment type used are the characteristics of the material to be dredged, the quantities of material to be dredged, the dredging depth, the distance to the disposal area, the physical environmental factors of the dredging and disposal area, the contamination level of sediments, the methods of disposal, the production (i.e., rate of material removed) required, and the availability of the dredge equipment (Nightingale and Simenstad 2001b).

Hydraulic dredging involves the use of water mixed with sediments that forms a slurry, which is pumped through a pipeline onto a barge or a hopper bin for off-site disposal. To increase the productivity of the dredging operation (i.e., maximizing the amount of solid material transported to the disposal site), some of the water in the sediment slurry may be allowed to overflow out of the hopper which can increase the turbidity in the surrounding water column. If the disposal site is relatively close to the dredge site, the slurry may be pumped through a pipeline directly to the disposal site (e.g., beach disposal).

Mechanical dredging typically involves the use of a clamshell dredge, which consists of a bucket of hinged steel that is suspended from a crane. The bucket, with its jaws open, is lowered to the bottom and as it is hoisted up, the jaws close and carry the sediments to the surface. The sediments are then placed in a separate barge for transport to a disposal site. Bucket dredges tend to increase the suspended sediment concentrations compared to hydraulic dredges because of the resuspension created as sediment spills through the tops and sides of the bucket when the bucket contacts the bottom, during withdrawal of the bucket through the water column, and when it breaks the water's surface (Nightingale and Simenstad 2001b). Closed or "environmental" buckets are designed to reduce the sediment spill from the bucket by incorporating modifications such as rubber seals or overlapping plates and are often used in projects involving contaminated sediments.

The location and method of disposal for dredged material depends on the suitability of the material determined through chemical, and often, biological analyses conducted prior to the dredging project. Generally, sediments determined to be unacceptable for open water disposal are placed in confined disposal facilities or contained aquatic disposal sites and capped with uncontaminated sediments. Sediments that are determined to be uncontaminated may be placed in open-water disposal sites or used for beneficial uses. Beneficial uses are intended to provide environmental or other benefits to the human environment, such as shoreline stabilization and erosion control, habitat restoration/enhancement, beach nourishment, capping contaminated sediments, parks and recreation, agriculture, strip mining reclamation and landfill cover, and construction and industrial uses (Nightingale and Simenstad 2001b). Open water disposal sites can be either predominantly nondispersive (i.e., material is intended to remain at the disposal site) or dispersive (i.e., material is intended to be transported from the disposal site by currents and/or wave action (Nightingale and Simenstad 2001b). The potential for environmental impacts is dependent upon the type of disposal operation used, the physical characteristics of the material, and the hydrodynamics of the disposal site. Refer to the chapter on Offshore Dredging and Disposal Activities for more detailed information on dredge material disposal.

Dredging to deepen or maintain ports, marinas, and navigational channels involves a number of environmental effects to fishery habitats, including the direct removal or burial of demersal and benthic organisms and aquatic vegetation, alteration of physical habitat features, the disturbance of bottom sediments (resulting in increased turbidity), contaminant releases in the water column, light attenuation, releases of oxygen consuming substances and nutrients, entrainment of living organisms in dredge equipment, noise disturbances, and the alteration of hydrologic and temperature regimes. Dredging is often accompanied by a significant decrease in the abundance, diversity, and biomass of benthic organisms in the affected area and an overall reduction in the aquatic productivity of the area (Allen and Hardy 1980; Newell et al. 1998). The rate of recovery of the benthic community is dependent upon an array of environmental variables which reflect interactions between sediment particle mobility at the sediment-water interface and complex associations of chemical and biological factors operating over long time periods (Newell et al. 1998).

### *Loss or conversion of benthic habitat and substrate*

Alterations in bathymetry, benthic habitat features, and substrate types caused by navigational dredging activities may have long-term effects on the functions of estuarine and other aquatic environments. The effects of an individual project are proportional to the scale and time required for a project to be completed, with small-scale and short-term dredging activities having less impact on benthic communities than long-term and large-scale dredging projects (Nightingale and Simenstad 2001b). Dredging can have cumulative effects on benthic communities, depending upon the dredging interval, the scale of the dredging activities, and the ability of the environment to recover from the impacts. The new exposed substrate in a dredged area may be composed of material containing more fine sediments than before the dredging, which can reduce the recolonization and productivity of the benthos and the species that prey upon them.

The impacts to benthic communities vary greatly with the type of sediment, the degree of disturbance to the substrate, the intrinsic rate of reproduction of the species, and the potential for recruitment of adults, juveniles, eggs, and larvae (Newell et al. 1998). Following a dredging event, sediments may be nearly devoid of benthic infauna, and those that are the first to recolonize are typically opportunistic species which may have less nutritional value for consumers (Allen and Hardy 1980; Newell et al. 1998).

In general, dredging can be expected to result in a 30-70% decrease in the benthic species diversity and 40-95% reduction in number of individuals and biomass (Newell et al. 1998). Recovery of the benthic community is generally defined as the establishment of a successional community which progresses towards a community that is similar in species composition, population density, and biomass to that previously present or at nonimpacted reference sites (Newell et al. 1998). The factors which influence the recolonization of disturbed substrates by benthic infauna are complex, but the suitability of the postdredging sediments for benthic organisms and the availability of adjacent, undisturbed communities which can provide a recruitment source are important (Barr 1987; ICES 1992). Rates of benthic infauna recovery for disturbed habitats may also depend upon the type of habitat being affected and the frequency of natural and anthropogenic disturbances. Benthic infauna recovery rates may be less than one year for some fine-grained mud and clay deposits, where a frequent disturbance regime is common, while gravel and sand substrates, which typically experience more stability, may take many years to recover (Newell et al. 1998). Post-dredging recovery in cold waters at high latitudes may require additional time because these benthic communities can be comprised of large, slow-growing species (Newell et al. 1998).

### *Loss of submerged aquatic vegetation*

Submerged aquatic vegetation provides food and shelter for many commercially and recreationally important species, attenuates wave and current energy, and plays an important role in the chemical and physical cycles of coastal habitats (Thayer et al. 1997). The loss of vegetated shallows results in a reduction in important rearing and refugia functions utilized by migrating and resident species. Seagrass beds are more difficult to delineate and map than some other subtidal habitats because of their spatial and temporal dynamic nature, making these habitats more vulnerable to being inadvertently dredged (Thayer et al. 1997; Deegan and Buchsbaum 2005). Dredging causes both direct and indirect impacts to SAV. The physical removal of plants through dredging is a direct impact, while the reduction in light penetration and burial or smothering that is a result of the turbidity plumes and sedimentation created by the dredge are indirect impacts (Deegan and Buchsbaum 2005). While SAV may regrow in a dredged area if the exposure to excessive suspended sediments is not protracted and most of the accumulated sediments are removed by currents and tides after dredging ceases (Wilber et al. 2005), the recolonization by SAV may be limited if the bottom sediments are destabilized or the composition of the bottom sediments is altered (Thayer et al. 1997). Even when bottom sediments are stabilized and are conducive to SAV growth, channel deepening may result in the area having inadequate light regimes necessary for the recolonization of SAV (Barr 1987).

Dredge and fill operations require a permit review process which is regulated by state and federal agencies. Advancement in understanding the physical impacts of dredging on SAV and recognition of the ecological significance of these habitats has allowed special consideration for SAV beds during the permit review process. Most reviewing agencies discourage dredging activities in or near SAV beds as well as in areas that have been historically known to have SAV and areas that are potential habitats for SAV recruitment (Orth et al. 2002).

While the physical disturbance to SAV beds from dredge activities may have significant localized effects, water quality problems such as eutrophication, pollution and sedimentation have resulted in large-scale declines to SAV in some areas of the northeastern US coast (Goldsborough 1997; Deegan and Buchsbaum 2005; Wilber et al. 2005). The small, localized disturbance of SAV associated with dredging may be viewed as a significant impact in the context of diminished regional health and distribution resulting from stressors such as poor water quality and cumulative effects such as dredging, boating (propeller scour), and shoreline alteration (Goldsborough 1997; Thayer et al. 1997; Deegan and Buchsbaum 2005). The environmental effects of excess nutrients and sediments are the most common and significant causes of SAV decline worldwide (Orth et al. 2006).

### *Loss of intertidal habitat and wetlands*

Intertidal habitats (e.g., mud and sand flats) and wetlands (e.g., salt marsh) are valuable coastal habitats which support high densities and diversities of biota by supporting biological functions such as breeding, juvenile growth, feeding, predator avoidance, and migration (Nightingale and Simenstad 2001b). These valuable habitats are also some of the most vulnerable to alterations through coastal development, urbanization, and the expansion of ports and marinas.

The loss of intertidal habitat and the deepening of subtidal habitat during dredging for marina development and for navigation can alter or eliminate the plant and animal assemblages associated with these habitats, including SAV and shellfish beds (Nightingale and Simenstad 2001b; MacKenzie 2007). Dredging in intertidal habitats can alter the tidal flow, currents, and tidal mixing regimes of the dredged area as well as other aquatic habitats in the vicinity, leading to changes in the environmental parameters necessary for successful nursery habitats (Barr 1987). Dredging in tidal wetlands can also encourage the spread of nonnative invasive organisms by removing or disturbing the native biota and altering the physical and chemical properties of the habitat (Hanson et al. 2003; Tyrrell 2005).

Navigational dredging converts shallow subtidal or intertidal habitats into deeper water environments through the removal of sediments (Nightingale and Simenstad 2001b, Deegan and Buchsbaum 2005). The historical use of dredged materials was to infill wetland, salt marshes, and tidal flats in order to create more usable land. The Boston Harbor, MA, area is a prime example of this historical trend, where thousands of acres of salt marsh and intertidal wetlands have been filled over time (Deegan and Buchsbaum 2005). Filling wetlands eliminates the biological, chemical, and physical functions of intertidal habitat such as flood control, nutrient filter or sink, and nursery habitat. Although direct dredging and filling within intertidal wetlands are relatively rare in recent times, the lost functions and values of intertidal wetlands and the connectivity between upland and subtidal habitat is difficult and costly to create and restore (Nightingale and Simenstad 2001b).

### *Underwater noise*

Fish can detect and respond to sounds for many life history requirements, including locating prey and avoiding predation, spawning, and various social interactions (Myrberg 1972; Myrberg and Riggio 1985; Kalmijn 1988). The noise generated by pumps, cranes, and by the mechanical action of the dredge itself has the ability to alter the natural behavior of fish and other aquatic organisms. Feist et al. (1996) reported that pile-driving operations had an affect on the distribution and behavior of juvenile pink salmon (*Oncorhynchus gorbuscha*) and chum salmon (*Oncorhynchus keta*). Fish may leave an area for more suitable spawning grounds or may avoid a natural migration path because of noise disturbances.

The noise levels and frequencies produced from dredging depend on the type of dredging equipment being used, the depth and thermal variations in the surrounding water, and the topography and composition of the surrounding sea floor (Nightingale and Simenstad 2001b; Stocker 2002). However, dredging activities from both mechanical and hydraulic dredges produce underwater sounds that are strongest at low frequencies and because of rapid attenuation of low frequencies in shallow water, dredge noise normally is undetectable underwater at ranges beyond 20-25 km (Richardson et al. 1995). Although the noise levels from large ships may exceed those from dredging, single ships usually do not produce strong noise in one area for a prolonged period of time (Richardson et al. 1995). The noise created during dredging can produce continuous noise impacts for extended periods of time (Nightingale and Simenstad 2001b).

### *Siltation, sedimentation, and turbidity*

Dredging degrades habitat quality through the resuspension of sediments which creates turbid conditions and can release contaminants into the water column, in addition to impacting benthic organisms and habitat through sedimentation. Turbidity plumes ranging in the hundreds to thousands mg/L are created and can be transported with tidal currents to sensitive resource areas. Alterations in bottom sediments, bottom topography, and altered circulation and sedimentation patterns related to dredge activities can lead to shoaling and sediment deposition on benthic resources such as spawning grounds, SAV, and shellfish beds (Wilber et al. 2005; MacKenzie 2007). Early life history stages (eggs, larvae, and juveniles) and sessile organisms are the most sensitive to sedimentation impacts (Barr 1987; Wilber et al. 2005). Some estuarine and coastal habitats are prone to natural sediment loads and sediment resuspension because of the relatively dynamic nature of the ecosystems; therefore, most organisms adapted to these environments have tolerance to some level of suspended sediments and sedimentation (Nightingale and Simenstad 2001b).

The reconfiguration of sediment type and the removal of biogenic structure during dredging may decrease the stability of the bottom and increase the ambient turbidity levels (Messieh et al. 1991). This increased turbidity and sedimentation can reduce the light penetration of the water column which then can adversely affect SAV and reduce primary productivity (Cloern 1987; Dennison 1987; Wilbur and Pentony 1999; Mills and Fonseca 2003; Wilbur et al. 2005). The combination of decreased photosynthesis and the interaction of the suspended material with dissolved oxygen in the water may result in short-term oxygen depletion (Nightingale and Simenstad 2001b).

If suspended sediment loads remain high, fish may experience respiratory distress and reduced feeding ability because of sight limitations, while filter feeders may suffer a reduction in growth and survival (Messieh et al.1991; Barr 1993; Benfield and Minello 1996; Nightingale and Simenstad 2001b). Prolonged exposure to suspended sediments can cause gill irritation, increased mucus production, and decreased oxygen transfer in fish (Nightingale and Simenstad 2001b; Wilber et al. 2005). Reduced dissolved oxygen concentrations and increased water temperatures may be cumulative stressors that exacerbate the effects of respiratory distress on fish from extended exposure to suspended sediments (Nightingale and Simenstad 2001b). In addition, mobile species may leave an area for more suitable feeding or spawning grounds, or avoid migration paths because of turbidity plumes created during navigational dredging.

Increased turbidity and sedimentation may also bury benthic organisms and demersal fish eggs. The depth of burial and the density of the substrate may limit the natural escape response of some organisms that are capable of migrating vertically through the substrate (Barr 1987; Wilber et al. 2005). In addition, anoxic conditions in the disturbed sediments may decrease the ability of benthic organisms to escape burial (Barr 1987). Short-term burial, where sediment deposits are promptly removed by tides or storm events, may have minimal effects on some species (Wilber et al. 2005). However, even thin layers of fine sediment have been documented to decrease gas exchange in fish eggs and adversely affect the settlement and recruitment of bivalve larvae (Wilber et al. 2005). An in-situ experiment with winter flounder (*Pseudopleuronectes americanus*) eggs exposed to sediment deposition from a navigational dredging project found a slightly lower larval survival rate compared to control sites, but the differences were not statistically significant (Klein-MacPhee et al. 2004). However, the viability of the larvae in this experiment was not monitored beyond burial escapement. Similarly, laboratory experiments with winter flounder eggs buried to various depths (i.e., control, <0.5 mm, and up to 2 mm) indicated a decreased hatch success and delayed hatch with increasing depth; but differences were not statistically significant (Berry et al. 2004). The same study also exposed winter flounder eggs to both clean, fine-grained sediment and highly contaminated, fine-grained sediment at various depths from 0.5-6.0 mm. The investigators found that eggs buried to depths of 4 mm with clean sediments did not hatch, while eggs buried to depths of 3 mm with contaminated sediments had little or no hatching success (Berry et al. 2004). Although there are clearly adverse effects to sessile benthic organisms and life stages from sedimentation from dredging activities, additional investigations are needed to assess lethal and sublethal thresholds for more species and under different sediment types and quality. In addition, better understanding about the relationship between natural and anthropogenic sources of suspended sediments and population-level effects is needed.

The use of certain types of dredging equipment can result in greatly elevated levels of fine-grained particles in the water column. Mechanical dredging techniques such as clam shell or bucket dredges usually increase suspended sediments at the dredge site more than hydraulic dredge techniques such as hopper or cutterheads, unless the sediment and water mixture (slurry) removed during hydraulic dredging is allowed to overflow from the barge or hopper and into the water column, a technique often used to reduce the number of barge trips required (Wilber and Clarke 2001). Mechanical dredges are most commonly used for smaller projects or in locations requiring maneuverability such as close proximity to docks and piers or in rocky sediments (Wilber et al. 2005), although small hydraulic dredges can be used to reduce suspended sediment concentrations in the dredging area and minimize impacts on adjacent benthic habitats, such as SAV or shellfish beds.

Seasonal or time-of-year (TOY) restrictions to dredging activities are used to constrain the detrimental affects of dredging to a timeframe that minimizes impacts during sensitive periods in the life history of organisms, such as spawning, egg development, and migration (Nightingale and Simenstad 2001b; Wilber et al. 2005). Segregating dredging impacts by life history stages provides a means for evaluating how different impacts relate to specific organisms and life history strategies (Nightingale and Simenstad 2001b). The application of TOY restrictions should be based upon the geographic location, species and life history stages present, and the nature and scope of the dredging project. Because the employment of TOY restrictions may have some negative effects, such as extending the overall length of time required for dredging and disposal, increasing the impacts on less economically valuable or poorly studied species, and increasing the economic costs of a project, the benefits of TOY restrictions should be evaluated for each individual dredging project (Wilber et al. 2005; Nightingale and Simenstad 2001b).

### Contaminant release and source exposure

Contaminated sediments are a concern because of the risk of transport of the contaminants and the exposure to aquatic organism and humans through bioaccumulation and biomagnification (Nightingale and Simenstad 2001b). Navigation dredging can create deep channels where currents are reduced and fine sediments may be trapped. Nutrients and contaminants can bind to fine particles such as those that may settle in these deep channels (Newell et al. 1998; Messiah et al. 1991). Dredging and disposal causes resuspension of the sediments into the water column and the contaminants that may be associated with the sediment particles. The disturbance of bottom sediments during dredging can release metals (e.g., lead, zinc, mercury, cadmium, copper), hydrocarbons (e.g., PAH), hydrophobic organics (e.g., dioxins), pesticides, pathogens, and nutrients into the water column and allow these substances to become biologically available either in the water column or through trophic transfer (Wilbur and Pentony 1999; USEPA 2000; Nightingale and Simenstad 2001b). Generally, the resuspension of contaminated sediments can be reduced by avoiding dredging in areas containing fine sediments. In addition, the biological and/or chemical testing requirements under the Marine Protection, Research, and Sanctuaries Act and the Clean Water Act are designed to minimize adverse effects of dredge material disposal on the environment. For additional information regarding the affects of contaminants associated with resuspended sediments, refer to the chapters on Offshore Dredging and Disposal Activities and Chemical Affects: Water Discharge Facilities in this report.

### Release of nutrients/eutrophication

Dredging can degrade water quality through resuspension of sediments and the release of nutrients and other contaminants into the water column. Nutrients and contaminants may adhere to these fine particles (Newell et al. 1998; Messieh et al. 1991). The resuspension of this material creates turbid conditions and decreases photosynthesis. The combination of decreased photosynthesis and the release of organic material with high biological oxygen demand can result in short-term oxygen depletion to aquatic resources (Nightingale and Simenstad 2001b). Long-term anoxia can occur if highly organic sediments are dredged or discharged into estuaries, particularly in enclosed or confined bodies of water. The loss of SAV is linked to poor water quality from increased turbidity and nutrient loading (Deegan and Buchsbaum 2005; Wilber et al. 2005).

### Entrainment and impingement

Entrainment is the direct uptake of aquatic organisms by the suction field created by hydraulic dredges. Benthic infauna are particularly vulnerable to entrainment by dredging, although some mobile epibenthic and demersal species such as shrimp, crabs, and fish can be susceptible to entrainment as well (Nightingale and Simenstad 2001b). Elicit avoidance responses to suction dredge entrainment has been reported for some demersal and pelagic mobile species (Larson and Moehl 1990; McGraw and Armstrong 1990). The susceptibility to entrainment for some pelagic species may be related to the degree of waterway constriction in the area of the dredging, which makes it more difficult for fish to avoid the dredge operation (Larson and Moehl 1990; McGraw and Armstrong 1990).

## Altered tidal, current, and hydrologic regimes

Large channel deepening projects can potentially alter ecological relationships through a change in freshwater inflow, tidal circulation, estuarine flushing, and freshwater and saltwater mixing (Nightingale and Simenstad 2001b). Dredging may also modify longshore current patterns by altering the direction or velocity of water flow from adjacent estuaries. These changes in water circulation are often accompanied by changes in the transport of sediments and siltation rates resulting in alteration of local habitats used for spawning and feeding (Messieh et al. 1991).

Altered circulation patterns around dredged areas can also lead to changes in sediment composition and deposition and in the stability of the seabed. The deep channels created during navigational dredging may experience reduced current flow that allows the area to become a sink for fine particles as they settle out of the water column or slump from the channel walls (Newell et al. 1998). In some cases this may change the sediment composition from sand or shell substrate to a substrate consisting of fine particles which flocculate easily and are subject to resuspension by waves and currents (Messieh et al. 1991). This destabilization of the seabed can lead to changes in sedimentation rates and a reduction in benthic resources, such as shellfish beds and SAV (Wilber et al. 2005). In addition, changes in substrate type can smother demersal eggs, affect larval settlement, and increase predation on juveniles adapted to coarser bottom substrates (Messieh et al. 1991; Wilber et al. 2005).

Navigational dredging can remove natural benthic habitat features, such as shoals, sand bars, and other natural sediment deposits. The removal of such features can alter the water depth, change current direction or velocity, modify sedimentation patterns, alter wave action, and create bottom scour or shoreline erosion (Barr 1987). Channel dredging can alter the estuarine hydrology and the mixing zone between fresh and salt water, leading to accelerated upland run-off, lowered freshwater aquifers, and greater saltwater intrusion into aquifers, as well as reduce the buffering capabilities of wetlands and shallow water habitats (Barr 1987; Nightingale and Simenstad 2001b).

Navigational channels that are substantially deeper than surrounding areas can become anoxic or hypoxic as natural mixing is decreased and detrital material settles out of the water column and accumulates in the channels. This concentration of anoxic or hypoxic water can stress nearshore biota when mixing occurs from a storm event (Allen and Hardy 1980). The potential for anoxic conditions can be reduced in areas that experience strong currents or wave energy, and sediments are more mobile (Barr 1987; Newell et al. 1998).

## Altered temperature regimes

Channel and port dredging can alter bottom topography, increase water depths, and change circulation patterns in the dredged area, which may increase stratification of the water column and reduce vertical mixing. This thermal layering of water may create anoxic or hypoxic conditions for benthic habitats. Deepened or new navigation channels may create deep and poorly flushed areas that experience reduced light penetration and water temperatures. Temperature influences biochemical processes and deep channels may create zones of poor productivity that can serve as barriers to migration for benthic and demersal species and effectively fragment estuarine habitats.

## Conservation recommendations and best management practices for navigational dredging

1. Avoid new dredging to the maximum extent practicable. Activities that would likely require dredging (such as placement of piers, docks, marinas, etc.) should instead be located in deep water or designed to alleviate the need for maintenance dredging.
2. Reduce the area and volume of material to be dredged to the maximum extent practicable.

3. Ensure that the volumes of dredge material are appropriately considered and that the identified disposal sites are adequate in containing the material. For example, the volume of material removed for the allowable over-depth dredging (usually 2 feet below the authorized or target depth) should be included in the disposal volume calculations.
4. Ensure that areas proposed for dredging are necessary in order to maintain the necessary and authorized target depths of the channel. Recent bathymetric surveys should be reviewed to evaluate the existing depths of the area proposed for dredging. Areas within the proposed dredge area that are at or deeper than the target depths should be avoided, whenever practicable.
5. Identify sources of erosion in the watershed that may be contributing to excessive sedimentation and the need for regular maintenance dredging activities. Implement appropriate management techniques to ensure that actions are taken to curtail those causes.
6. Use settling basins to act as sediment traps to prevent accretion of sediments in the navigational channel, when appropriate. This reduces the need for frequent maintenance dredging of the entire channel.
7. Consider the effects of increased boat traffic to an area when assessing a new dredging project or expanding existing channels. Increases in the speed, size, and density of boat traffic in an area may require increased frequency of maintenance dredging and produce a number of secondary impacts, such as shoreline erosion, sedimentation, and turbidity.
8. Identify the user group during the planning process to ensure that the dredging project meets the basic needs of the target user without exceeding an appropriate size and scope, or encouraging inappropriate use.
9. Consider time-of-year dredging restrictions, which may reduce or avoid impacts to sensitive life history stages, such as migration, spawning, or egg and young-of-year development. Recommended seasonal work windows are generally specific to regional or watershed-level environmental conditions and species requirements.
10. Avoid projects that involve dredging intertidal and wetland habitat.
11. Avoid dredging in areas with SAV, areas which historically supported SAV, and areas which are potential habitat for recolonization by SAV.
12. Conduct both historic surveys of the area and predredge surveys because of the spatial and temporal dynamic nature of SAV beds.
13. Avoid dredging in areas supporting shellfish beds.
14. Consider beneficial uses for uncontaminated sediments when practicable and feasible. Priority should be given to beneficial uses of material that contributes to habitat restoration and enhancement, landscape ecology approach, and includes pre- and post-disposal surveys.
15. Avoid beneficial use projects that impose unnatural habitats and features and involve habitat trade-offs (substituting one habitat type for another).
16. Ensure that sediments are tested for contaminants and meet or exceed US EPA requirements and standards prior to dredging and disposal.
17. Assess cumulative impacts for current activities in the vicinity of a proposed dredging project, as well as for activities in the past and foreseeable future.
18. Ensure that bankward slopes of the dredged area are slanted to acceptable side slopes (e.g., 3:1 ratio) to ensure that sloughing of the channel side slopes does not occur.
19. Avoid placing pipelines and accessory equipment used in conjunction with dredging operations close to algae beds, eelgrass beds, estuarine/salt marshes, and other high value habitat areas.
20. Use silt curtains in some locations to reduce impacts of suspended sediments on adjacent benthic resources.
21. Avoid dredging in fine sediments when possible to reduce turbidity plumes and the release of nutrients and contaminants which tend to bind to fine particles.

22. Include information on control sites and predredging sampling for comparison and monitoring of impacts in environmental assessments for dredging projects.
23. Ensure that disposal sites are properly sited (i.e., avoid sensitive resources and habitats) and are appropriate for the type of dredge material proposed for disposal.
24. Ensure that disposal sites are being properly managed (e.g., disposal site marking buoys, inspectors, the use of sediment capping and dredge sequencing) and monitored (e.g., chemical and toxicity testing, benthic recovery) to minimize impacts associated with dredge material.

# CHAPTER SIX: OFFSHORE DREDGING AND DISPOSAL ACTIVITIES

## Introduction

This chapter describes activities associated with offshore dredging and disposal and their potential effects on living marine resources and habitats in the northeast region of the United States. For purposes of this discussion, the "offshore" environment is defined as those waters and seabed areas considered to be "estuarine" environments and extending offshore to and occasionally beyond the edge of the continental shelf. For example, while the open waters of Chesapeake Bay, MD/VA, and Long Island Sound, NY/CT, are considered offshore for this discussion, the coves and embayments within those waters bodies are not. In addition, Raritan Bay, NY/NJ, (lower New York Harbor) and similar areas are considered offshore environments. Dredging and disposal activities within riverine habitats have been discussed in the Alteration of Freshwater Systems chapter of this report, and information on dredging within navigation channels can be reviewed in the Marine Transportation chapter of this report.

## Offshore Mineral Mining

### *Introduction*

There is an increasing demand for beach nourishment sand and a smaller, but growing, demand for construction and "stable fill" grade aggregates. As the historic landside sources of these materials have been reduced, there has been a corresponding move towards mining the continental shelf to meet this demand. It is expected that the shift to offshore mineral extraction will continue and escalate, particularly in areas where glacial movements have relocated the desired material to the continental shelf. Typically, these deposits are not contaminated because of their offshore location and isolation from anthropogenic pollution sources. Beginning in the mid-1970s, the US Geological Survey began mapping the nature and extent of the aggregate resources in coastal and nearshore continental shelf waters throughout the northeast beyond the 10-m isobath. Between 1995 and 2005, the Minerals Management Service (MMS), which oversees offshore mineral extractions, regulated the relocation of over 23 million cubic yards of sand from the Outer Continental Shelf (OCS) for beach nourishment projects (MMS 2005a). The OCS is defined as an area between the seaward extent of states' jurisdiction and the seaward extent of federal jurisdiction. Currently, the MMS, in partnership with 14 coastal states, is focusing on collecting and analyzing geologic and environmental information in the OCS in order to study sand deposits suitable for beach nourishment and wetlands protection projects and to assess the environmental impacts of OCS mining in general (Drucker et al. 2004). With the advances in marine mining and "at sea" processing, aggregate extraction can occur in waters in excess of 40 m **(**MMS 2005a**)**.

Mineral extraction is usually conducted with hydraulic dredges by vacuuming or, in some cases, by mechanical dredging with clamshell buckets in shallow water mining sites. Mechanical dredges can have a more severe but localized impact on the seabed and benthic biota, whereas hydraulic dredges may result in less intense but more widespread impact (Pearce 1994). The impacts of offshore mineral mining on living marine resources and their habitats include: (1) the removal of substrates that serve as habitat for fish and invertebrates; (2) creation of (or conversion to) less productive or uninhabitable sites such as anoxic depressions or highly hydrated clay/silt substrates; (3) release of harmful or toxic materials either in association with actual mining, or from incidental or accidental releases from machinery and materials used for mining; (4) burial of productive habitats during beach nourishment or other shoreline stabilization activities; (5) creation of harmful suspended sediment levels; and (6) modification of hydrologic conditions causing adverse impacts to desirable habitats (Pearce 1994; Wilber et al. 2003).

In addition, mineral extraction can potentially have secondary and indirect adverse effects on fishery habitat at the mining site and surrounding areas. These impacts may include accidental or intentional discharges of mining equipment and processing wastes and degradation or elimination of marine habitats from structures constructed to process or transport mined materials. These secondary effects can sometimes exceed the initial, direct consequences of the offshore mining.

### *Loss of benthic habitat types*

Offshore benthic habitats occurring on or over target aggregates may be adversely affected by mining. The mineral extraction process can disrupt or eliminate existing biological communities within the mining or borrow areas for several years following the excavation. Filling in of the borrow areas and reestablishment of a stable sediment structure is dependent upon the ability of bottom currents to transport similar sediments from surrounding areas to the mining site (ICES 1992). The principal concern noted by the International Council for the Exploration of the Sea (ICES) Working Group on the Effects of Extraction of Marine Sediments on Fisheries was dredging in spawning areas of commercial fish species (ICES 1992). Of particular concern to the ICES Working Group are fishery resources with demersal eggs (e.g., Atlantic herring [*Clupea harengus*] and sand lance [*Ammodytes marinus*]). They report that when aggregates are removed, Atlantic herring eggs are taken with them, resulting in lost production to the stock. Stewart and Arnold (1994) list the impacts on Atlantic herring from offshore mining to include the entrainment of eggs, larvae, and adults; burial of eggs; and effects of the turbidity plume on demersal egg masses. Gravel and coarse sand have been identified as preferred substrate for Atlantic herring eggs on Georges Bank and in coastal waters of the Gulf of Maine (Stevenson and Scott 2005).

### *Conversion of substrate/habitat and changes in community structure*

Disposal of residues (“tailings”) of the mining process can alter the type, as well as the functions and values, of habitats which can then alter the survival and growth of marine organisms. The tailings are often fine-grained and highly hydrated, making them very dissimilar to the natural seafloor, particularly in depths where wave energy and currents are capable of winnowing or sorting sediments and relocating them to depositional areas. It has been found that wave forces are affecting habitats in the New York Bight at depths in excess of 22 m (USACE 2005a). In laboratory experiments, benthic dwelling flatfishes (Johnson et al. 1998a) and crabs (Johnson et al. 1998b) persistently avoided sediments comprised of mine tailings.

Additionally, there can be adverse impacts from aggregate and/or mineral mining on nearby habitats associated with the removal and disturbance of substrate (Scarrat 1987). Seabed alteration can fragment habitat, reduce habitat availability, and disrupt predator/prey interactions, resulting in negative impacts to fish and shellfish populations. Not all offshore aggregate mining results in adverse impacts on seabed resources. Hitchcock and Bell (2004) conducted a detailed study of the effects from a small-scale, aggregate mining operation off the south coast of the United Kingdom and found physical impacts on the seabed to be limited to a downtide zone approximately 300 m from the dredge area. Related studies at this mining operation reported no detectable impact on the surrounding benthic communities, despite a small change in seabed particle size distribution (Hitchcock and Bell 2004).

Long-term mining can alter the habitat to such a degree that recovery may be extremely protracted and create habitat of limited value to benthic communities during the entire recovery period (van Dalfsen et al. 2000). For example, construction grade aggregate removal in Long Island Sound, Raritan Bay (lower New York Harbor) and the New Jersey portion of the intercoastal waterway have left borrow pits that are more than twice the depth of the surrounding area. The pits have remained chemically, physically, and biologically unstable with limited diversity communities for more than five decades. These pits were used to provide fill material for interstate transportation projects and have been investigated to assess their environmental impact (Pacheco 1984). Borrow pits in Raritan Bay were found to possess depressed benthic communities and elevated levels of highly hydrated and organically enriched sediments (Pacheco 1984). In one example, aggregate mining operations from the 1950s through the 1970s created a 20 m deep borrow pit in an area of Raritan Bay that, although the mining company was required to refill the pit, remains today as a rapid deposition area filling with fine-grained sediment and organic material emanating from the Hudson River and adjacent continental shelf (Pacheco 1984**)**. The highly hydrated sediments filling the depressions are of limited utility to colonizing benthic organisms.

In offshore mining operation sites, the character of the sediment which is exposed or subsequently accumulates at the extraction site is important in predicting the composition of the colonizing benthic community (ICES 1992). If the composition and topography of the extraction site resembles that which originally existed, then colonization of it by the same benthic fauna is likely (ICES 1992).

### *Changes in sediment composition*

A review of studies conducted in Europe and Great Britain found that infilling and subsequent benthic recovery of borrow areas may take from 1-15 years, depending upon the tide and current strength, sediment characteristics, the stock of colonizing species and their immigration distance (ICES 1992). Typically the reestablishment of the community appears to follow a successional process similar to those on abandoned farmlands. Germano et al. (1994) described this process, reporting that pioneering species (i.e., Stage I colonizers) usually do not select any particular habitat but attempt to survive regardless of where they settle. These species are typically filter feeders relying on the availability of food in the overlying water rather than the seafloor on which they reside. Thus, their relationship to the substrate is somewhat tenuous, and their presence is often ephemeral. However, their presence tends to provide some stability to the seafloor, facilitating subsequent immigrations by other species that bioturbate the sediment seeking food and shelter. Their arrival induces further substrate consolidation and compaction. These colonizers are usually deemed to be Stage II community species. The habitat modification activities of Stage I and II species advance substrate stability and consolidation enough for it to support, both physically and nutritionally, the largest community members (i.e., Stage III). The benthic community instability caused by dredging gives rise to one of the principal justifications for retaining benthic disturbances: the disrupted site may become heavily populated by opportunistic (i.e., Stage I) colonizer species that flourish briefly and provide motile species with an abundance of food during late summer and fall periods (Kenny and Rees 1996). However, if environmental stresses are chronic, the expected climax community may never be attained (Germano et al. 1994).

If the borrow area fails to refill with sediment similar to that which was present prior to mining, the disturbed area may not possess the original physical and chemical conditions and recovery of the community structure may be restricted or fail to become reestablished. Dredge pits that have been excavated to depths much greater than the surrounding bottom often have very slow infill rates and can be a sink for sediments finer than those of the surrounding substrate (ICES 1992).

### *Changes in bottom topography and hydrology*

The combination of rapid deposition, anomalous sediment character, and an uneven topography, as compared to the surrounding seafloor, limit recolonization opportunities for harvesting purposes (Wilk and Barr 1994). By altering bottom topography, aggregate mining can reduce localized current strength, resulting in lowered dissolved oxygen concentrations and increased accumulation of fine sediments inside borrow pits (ICES 1992). One potential benefit of some borrow pits is that they appear to provide refugia for pelagic species such as alewife (*Alosa pseudoharengus*) and scup (*Stenotomus chrysops*), as well as demersal species such as tautog (*Tautoga onitis*) and black sea bass (*Centropristis striata*) during seasonally fluctuating water temperatures (Pacheco 1984). However, it is doubtful these benefits outweigh the persistent adverse affects associated with borrow pits (Palermo et al. 1998; Burlas et al. 2001). Other consequences of aggregate mining may include alteration of wave and tidal current patterns which could affect coastal erosion (ICES 1992).

### *Siltation, sedimentation, and turbidity*

Offshore mining can increase the suspended sediment load in the water column, increasing turbidity that can then adversely affect marine organisms, particularly less motile organisms such as shellfish, tunicates, and sponges. The duration of the turbidity plume in the water column depends upon the water temperature, salinity, current speed, and the size range of the suspended particles (ICES 1992). The distance the dredged material is transported from the excavation site will be dependent upon the current strength, storm resuspension, water salinity and temperature, and the grain size of the suspended material (ICES 1992).

The life stages of the affected taxa are an important factor affecting the type and extent of the adverse impacts (Wilber and Clarke 2001). As a general rule, the severity of sedimentation and turbidity effects tends to be greatest for early life stages and for adults of some highly sensitive species (Newcombe and Jensen 1996; Wilber and Clarke 2001). In particular, the eggs and larvae of nonsalmonid estuarine fishes exhibit some of the most sensitive responses to suspended sediment exposures of all the taxa and life history stages for which data are available (Wilber and Clarke 2001). Stewart and Arnold (1994) list the impacts on Atlantic herring from offshore mining to include the effects of the turbidity plume on demersal egg masses.

### *Impacts to water quality*

The release of material into the water column during offshore mining operations can degrade water quality if the excavated material is high in organic content or clay. The effects of mixing on the water column are likely to include increased consumption of oxygen by decomposing organic matter and the release of nutrients (ICES 1992). However, mined aggregate material is typically low in organic content and clay, and any increase in the biological oxygen demand is thought to be minor and of limited spatial extent (ICES 1992).

Deep borrow pits can become anaerobic during certain times of the year. The dissolved oxygen concentration within these pits can be depressed to a level that adversely affects the ability of fish and invertebrates to utilize the area for spawning, feeding, and development (Pacheco 1984).

## *Release of contaminants*

A number of factors (i.e., environmental, geochemical, and biological) influence the potential release and bioavailability of sediment contaminants. The toxicity of such releases, in general, is primarily dependent upon the contaminant involved, its concentration in the sediments and its chemical/geochemical state. Persistent organic pollutants (POPs), such as polyaromatic hydrocarbons (PAHs), pesticides, and polychlorinated biphenyl (PCBs), are sequestered in the total organic carbon (TOC) fraction of sediments (USEPA 2003a; USEPA 2003b; USEPA 2003c). Similarly, heavy metals are sequestered by acid volatile sulfides (AVS) and the TOC fraction of marine sediments (USEPA 2005a). For POPs like PAHs, the ratio of the concentrations of these contaminants relative to those of the fractions govern bioavailability and hence toxicity (USEPA 2003a). In the case of metals, bioavailability is governed by an excess of AVS concentrations relative to the metal concentrations as normalized by TOC (USEPA 2005a). Sand and gravel sediments typically contain low TOC and AVS concentrations, and where there is a prominent source of POPs and metals, such as in highly industrialized riverways, these coarser sediments could in fact release such contaminants when disturbed or oxidized. However, the coarse-grained sediments typically targeted for aggregate mining tend to be found in high-energy environments which are not depositional areas that can be sinks for fine-grained material containing POPs and metals. Since most offshore sand and gravel deposits do not have prominent nearby sources of POPs and metals, these deposits are generally low in contaminants (ICES 1992; Pearce 1994). Thus, the mining of offshore sand and gravel material typically do not release high levels of contaminants. In addition, because of their relatively large particle size, low surface area relative to total bulk, and low surface activity (i.e., few clay or organic materials to interact chemically), there is usually little chemical interaction in the water column (Pearce 1994). However, extraction of material in estuaries or deep channels, where fine material accumulates and is subject to anthropogenic pollution deposition, may be more likely to release harmful chemicals during dredging and excavation (Pearce 1994). Refer to the chapters on Coastal Development, Marine Transportation, and Chemical Effects: Water Discharge Facilities for additional information on the release of contaminants during dredging and excavation.

## *Sediment transport from site*

Excavation at an offshore mining site that contains fine material can release suspended sediments into the water column during the excavation, as well as in the sorting or screening process. The distance the dredged material is transported from the excavation site will be dependent upon the current strength, storm resuspension, water salinity and temperature, and the grain size of the suspended material (ICES 1992). Some of the potential effects of redeposition of fines include smothering of demersal fish eggs on spawning grounds and the suffocation of filter-feeding benthos, such as shellfish and anemones (ICES 1992; Pearce 1994). Small-scale aggregate mining operations that are conducted in relatively shallow water and involving sandy, coarse-grained sediments often have relatively minimal physical and biological impacts on the surrounding seabed (Hitchcock and Bell 2004).

## *Noise impacts*

Anthropogenic sources of ocean noise appear to have increased over the past decades, and have been primarily attributed to commercial shipping, offshore gas and oil exploration and drilling, and naval and other uses of sonar (Hildebrand 2004). Offshore mineral mining likely contributes to the overall range of anthropogenic ocean noise, but little information exists regarding specific effects on marine organisms and their habitats or the importance of offshore mining relative to other sources of anthropogenic noise. The dredging equipment noise generated in offshore mining may be similar to navigation channel dredging in nearshore habitats; however, because of the greater water depths involved in offshore mining, the noise may be propagated for greater distances than in confined nearshore areas (Hildebrand 2004). Reductions in Atlantic herring catches on the Finnish coast were hypothesized to be due to disturbance to the herring movement patterns by noise and activity associated with sand and gravel mining activities (Stewart and Arnold 1994). Refer to the chapters on Global Affects and Other Impacts and Marine Transportation for additional information on noise impacts.

### *Conservation measures and best management practices for offshore mineral mining*

1. Avoid mining in areas containing sensitive or unique marine benthic habitats (e.g., spawning and feeding sites, surface deposits of cobble/gravel substrate).
2. Complete a comprehensive characterization of the borrow site and its resources prior to permit completion. Some of the components of a thorough assessment include:
    a. Determine the optimum dimensions of the borrow pit (i.e., small and deep areas or wide and shallow areas) in terms of minimizing the effects on resources.
    b. Prioritize the optimal locations of sand mining in terms of effects on resources.
    c. Assess the sand infill rates of borrow pits after completion.
    d. Assess the sediment migration patterns and rates as well as the side slope and adjacent natural seabed stability of the borrow pits after completion.
    e. Model and estimate the effect of massive and/or long-term sand mining on the surrounding seabed, shoreface (i.e., inner continental shelf), sand budgets, and resources.
    f. Assess the effect of removal (by dredging) of offshore sand banks/shoals on the surrounding natural seabed, adjacent shoreline, and the resources that use those habitats.
    g. Assess the effect of massive and/or long-term sand mining on the ecological structure of the seabed.
    h. Assess the effect of noise from mining operations on the feeding, reproduction, and migratory behavior of marine mammals and finfish.
3. Use site characterization and appropriate modeling to determine the areal extent and depth of extraction that affords expedited and/or complete recovery and recolonization times.
4. Employ sediment dispersion models to characterize sediment resuspension and dispersion during mining operations. Use model outputs to design mining operations, including "at sea" processing, to limit impacts of suspended sediment and turbidity on fishery resources and minimize the area affected.
5. Address the cumulative impacts of past, present, and foreseeable future development activities on aquatic habitats by considering them in offshore mining review processes.
6. Use seasonal restrictions when appropriate to avoid temporary impacts to habitat during species critical life history stages (e.g., spawning, and egg, embryo, and juvenile development). Recommended seasonal work windows are generally specific to regional or watershed-level environmental conditions and species requirements. Resource managers should incorporate adequate time for habitat recovery of affected functions and values to levels required by managed species.

# Petroleum Extraction

## Introduction

After some intense but unsuccessful petroleum exploration on the northeastern US continental shelf, the attention for commercial quantities of oil and gas have been directed elsewhere. Georges Bank and the continental shelf off New Jersey were thought to contain significant reserves of natural gas and several exploratory wells were drilled to locate and characterize those reserves in the late 1980s and early 1990s. At that time, few commercially viable reserves were found and the focus of petroleum exploration shifted to other regions. However, this could change in the future considering the escalating market prices and dwindling supplies of petroleum. Should renewed interest in offshore petroleum exploration and extraction in the northeast region occur, existing regulatory guidance on petroleum exploration and extraction, as well any recent research and development efforts, should be employed to ensure that marine resource impacts can be avoided, minimized, and compensated for these types of activity.

Petroleum extraction has impacts similar to mineral mining but usually with significantly less of an impact footprint (excluding spills). However, there is more risk and occurrence of adverse impacts associated with equipment operation, process related wastes and handling of byproducts (e.g., drill cuttings and spent drilling mud) which can disrupt and destroy pelagic and benthic habitats (Malins 1977; Wilk and Barr 1994). Potential releases of oil and petroleum byproducts into the marine environment may also occur as a result of production well blow-outs and spills.

Drilling muds are used to provide pressure and lubrication for the drill bit and to carry drill cuttings (crushed rock produced by the drill bit) back to the surface. Drilling muds and their additives are complex and variable mixtures of fluids, fine-grained solids, and chemicals (MMS 2005b). Some of the possible impacts associated with petroleum extraction include the dispersion of soluble and colloidal pollutants, as well as the alteration of turbidity levels and benthic substrates. Many of these impacts can be mitigated by on-site reprocessing and by transferring substances deemed inappropriate for unrestricted openwater disposal to landside disposal.

For more information on petroleum-related impacts and conservation recommendations for petroleum exploration, production, and transportation refer to the Energy-related Activities chapter of this report.

# Offshore Dredged Material Disposal

## Introduction

The disposal of dredged material in offshore waters involves environmental effects beyond those associated with the actual dredging operations. The US Army Corps of Engineers (USACE) disposes approximately 65% of its dredged material in open water, as opposed to “upland,” or land disposal (Kurland et al. 1994). Although some adverse environmental effects can be avoided with land disposal, there are a number of drawbacks including securing large tracts of land, material handling problems, overflow and runoff of polluted water, saltwater intrusion into groundwater, and costs of transporting material to land disposal sites (Kurland et al. 1994).

Disposal of dredged material is regulated under the Clean Water Act (CWA) and the Marine Protection, Research, and Sanctuaries Act (MPRSA), also known as the Ocean Dumping Ban Act (33 U.S.C. § 1251 and 1401 et seq.). The differences in the two Acts are found in the necessity and type(s) of sediment testing required by each. Generally, ocean dumping only requires biological testing if it is determined that the sediments do not meet the testing exclusion criteria as specified under the MPRSA (i.e., are contaminated). While the CWA provides for biological testing, it does not require such tests to determine whether the sediment meets the 404b testing guidelines unless specified by the USACE or the US Environmental Protection Agency (US EPA). The US EPA and the USACE are currently involved in discussions intended to combine the testing and evaluation protocols described in regulations, and in the "Greenbook" (Ocean Dumping Ban Act) and "Inland" (CWA) testing manuals. Currently, the US EPA and USACE use a tiered approach under both Acts, based upon empirical data gathered from each evaluated dredging project for determining the appropriate management options for dredge spoils (i.e., unconfined open water disposal, open water disposal with capping [CWA only], no open water disposal, or confined area disposal in harbors). Under the CWA, sediment quality guidelines or benchmarks can be used in the lower tiers to determine compliance with 404b guidelines or the need for futher testing. Although not required under the MPRSA, regulators in practice often use sediment chemistry to help determine the contaminant and sampling requirements for biological tests.

Offshore disposal sites are identified and designated by the US EPA using a combination of the MPRSA and National Environmental Policy Act (NEPA) criteria. However, the permitted use of designated disposal sites under these laws is not usually associated with the designation of the sites. To be eligible to use an offshore (i.e., federal waters) disposal site for dredged materials, project proponents must demonstrate: (1) that there are no reasonable and practical alternative disposal options available and; (2) that the sediments are compatible with natural sediments at the disposal site and are not likely to disrupt or degrade natural habitats and/or biotic communities (USEPA 2005b). Dredge material disposed at sites managed under the MPRSA must meet Ocean Dumping Ban Act criteria, which do not permit disposal of contaminated dredged material (USEPA 2005b).

### *Burial/disturbance of benthic habitat*

Studies using sidescan sonar and bottom video have been used to distinguish natural sediment character and evidence of past dumping of mud and boulders on sand bottom (Buchholtz ten Brink et al. 1996). These studies have indicated that not only have dumped materials disturbed and altered benthic habitats, but that in some cases (such as on Stellwagen Basin) the material dumped in the past was scattered far from the intended target areas (Buchholtz ten Brink et al. 1996). The discharge of dredged material disturbs benthic and pelagic communities during and after disposal. The duration and persistence of those impacts to the water column and seafloor are related to the grain size and specific gravity of the dredge spoil. Impacts to benthic communities are identified and assessed in the site designation documents (Battelle 2004; URI 2003), which may include benthic communities being buried and smothered and the physicochemical environment in which they reside being altered.

However, Rhoads and Germano (1982, 1986) and Germano et al. (1994) note that recolonization of benthic infauna at a disposal site following dumping often leads to increased occurrences of opportunistic species (Stage I), which are then heavily preyed upon by Stage II and III (e.g., target fisheries) species. According to these studies, this plethora of prey, resulting from the disturbance of the community structure, can at least temporarily increase the productivity at the disposal site. However, chronic disturbance from repeated disposal may prevent Stage III communities from establishing (Germano et al. 1994).

### *Conversion of substrate/habitat and changes in sediment composition*

Dumping dredged materials results in varying degrees of change in the physical, chemical, and biological characteristics of the substrate. The discharges can adversely affect infauna, including benthic and epibenthic organisms at and adjacent to the disposal site by burying immobile organisms or forcing motile organisms to migrate from the area. Benthic infauna species that have greater burrowing capabilities may be better able to extricate themselves from the overburden of sediment. Seasonal constraints on dredging and disposal not withstanding, it is assumed that there is a cyclical and localized reduction in the populations of benthic organisms at a disposal site. Plants and benthic infauna present prior to a discharge are unlikely to recolonize if the composition of the deposited material is significantly different (NEFMC 1998). Altered sediment composition at the disposal site may reduce the availability of infaunal prey species, leading to reduced habitat quality (Wilber et al. 2005).

### *Siltation, sedimentation, and turbidity*

Increased suspended sediment released during the discharge process and the associated increase in turbidity may hinder or disrupt activities in the pelagic zone (i.e., predator–prey relationships and photosynthesis rates). It has been estimated that less than 5% of the material in each disposal vessel is unaccounted for during and after the disposal activity (Bohlen et al. 1996), but the specific volume is influenced by both mechanical and sediment characteristics.

The discharge of dredged material usually results in elevated levels of fine-grained mineral particles, usually smaller than sand (i.e., silt/clay), and organic particles being introduced into the water column (i.e., suspended sediment plumes). The suspended particulates reduce light penetration, which affects the rate of photosynthesis and the primary productivity of an aquatic area. Typically, the suspended materials are dispersed and diluted to levels approaching ambient within 1-4 hours of the release (Bohlen et al. 1996). However, the turbidity plume resulting from a discharge can last much longer, particularly near the bottom, if the dredge material is composed of fine-grain material. In the plume field, living marine resources may experience either reduced or enhanced feeding ability as a result of the disruption of water clarity, depending upon the predator-prey relationships and the type(s) of avoidance/feeding methodologies used by the species. For instance, summer flounder (*Paralichthys dentatus*) and bluefish (*Pomatomus saltatrix*) are sight feeders and avoid areas with reduced water clarity resulting from suspended sediment such as might be found at a dredging or disposal site (Packer et al. 1999). Conversely, recent deposits of sediment at dumpsites have been reported to act as an attractant for other species of fish and crustaceans such as winter flounder (*Pseudopleuronectes americanus*) and American lobster (*Homarus americanus*) even though winnowing of fine-grained material from the excavation site or deposit mound was ongoing at the site (USACE 2001).

Generally, the severity of the effects of suspended sediments on aquatic organisms increases as a function of the sediment concentration and the duration of exposure (Newcombe and Jensen 1996). Some of the effects of suspended sediments on marine organisms can include altered foraging patterns and success (Breitburg 1988), gill abrasion and reduced respiratory functions, and death (Wilber and Clark 2001). The sensitivity of species to suspended sediments is highly variable and dependent upon the nature of the sediment and the life history stage of the species. Mortality caused by suspended sediments for estuarine species have been reported from less than 1000 mg/L for 24 hours in highly sensitive species (e.g., Atlantic silversides [*Menidia menidia*], juvenile bluefish [*Pomatomus saltatrix*]) to greater than 10,000 mg/L for 24 hours in tolerant species (e.g., mummichog [*Fundulus heteroclitus*], striped killifish [*Fundulus majalis*], spot [*Leiostomus xanthurus*], oyster toadfish [*Opsanus tau*], hogchoker [*Trinectes maculates*]) (Wilber and Clark 2001). The egg and larval stages of marine and estuarine fish exhibit some of the most sensitive responses to suspended sediment exposures of all the taxa and life history stages studied (Wilber and Clark 2001). Impacts that have been identified for demersal eggs of fish from sedimentation and suspended sediments include delayed hatching and decreased hatching success (Wilber and Clark 2001; Berry et al. 2004). The development of larvae may be delayed or altered after exposure of elevated suspended sediments, and increased mortality rates in the larvae of some species, such as striped bass (*Morone saxatilis*) and American shad (*Alosa sapidissima*), have been reported with exposure of suspended sediment concentrations less than or equal to 500 mg/L for 3 to 4 days (Wilber and Clark 2001).

The effects of sedimentation on benthic organisms can include smothering and decreased gas exchange, toxicity from exposure to anaerobic sediments, reduced light intensity, and physical abrasion (Wilber et al. 2005). Mobile benthic species that require coarse substrates, such as gravel or cobble (e.g., American lobster) may be forced to seek alternate habitat that is less optimal or compete with other species or individuals for suitable habitat (Wilber et al. 2005). Messieh et al. (1981) investigated sedimentation impacts on Atlantic herring in laboratory experiments and found increased mortality in herring eggs, early hatching and shorter hatching lengths, and reduced feeding success in herring larvae leading to stunted growth and increased mortality.

Although there is generally a consensus among scientists and resource managers that elevated suspended sediments and sedimentation on benthic habitat caused by dredging and disposal of dredge spoils result in adverse impacts to marine organisms, the specific effects on biological communities need to be better quantified. Additional research is needed to investigate dose-response models at scales appropriate for dredging and disposal and for appropriate species and life history stages (Wilber et al. 2005).

### *Release of contaminants*

Dredged material suspended in the water column can react with the dissolved oxygen in the water and result in localized depression of the oxygen level. However, research has indicated that reductions in dissolved oxygen levels during offshore sediment disposal is not appreciable or persistent in the general sediment classes found in the northeast region (USACE 1982; Fredette and French 2004; USEPA 2004).

In certain situations, trace levels of toxic metals and organics, pathogens, and viruses adsorbed or adhered to fine-grained particulates in the dredged material may become biologically available to organisms either in the water column or through food chain processes. Some of these pollutants and their concentrations are evaluated during project-specific sediment testing required under the MPRSA and CWA. Adverse chemical effects at the disposal site can be minimized through the sediment testing requirements under the MPRSA and CWA, since the discharge of potentially toxic materials are generally prohibited. Risk assessment approaches are used to further evaluate potential impacts using results from the MPRSA and CWA bioaccumulation and toxicity testing. In addition, monitoring is conducted to ensure that the biological and ecological functions and values are maintained within the site, notwithstanding the physical impacts associated with continued use of the site. However, some discharges of contaminated material may be permitted under CWA disposal regulations, if the sediments meet minimum testing criteria or the toxic affects can be managed by capping with clean material.

Fredette and French (2004) concluded that, after thirty-five years of monitoring and research, dredged material evaluated through preproject testing and deposited in properly located ocean disposal sites will remain where it is placed and have no unacceptable adverse effects on nearby marine resources. Furthermore, they concluded that the only discernible adverse impacts were near-field and short-term. These determinations were based on the magnitude of disposal activity relative to natural (e.g., storms) and other anthropogenic (e.g., outfalls) impacts (Rhoads

1994; Rhoads et al. 1995) and the low level of disposal-related impacts that have been documented (Fredette et al. 1993).

### *Changes in bottom topography, altered hydrological regimes, and altered current patterns*

A concern often raised is the stability of dredge spoil sediments placed on the seafloor. Because ocean disposal sites are typically located in low current areas with water depths in excess of the active erosion zone, the material is generally contained within the disposal site. However, before 1985, dredged material sites were occasionally located in water depths insufficient to retain materials placed there (USEPA 1986). For example, the Mud Dump Site, located in the New York Bight Apex slope area off New York Harbor, contains water depths as shallow as 15 m and the site experienced extensive erosion by a nor'easter storm in October 1992 (USEPA 1997). Reclassified as a remediation site in 1997, the site is now known as the Historic Area Remediation Site (HARS). Erosion was reported at depths of 26 m, and the winnowed sediment included grain sizes up to small cobble. Fortunately, much of the sediment was relocated into deeper portions of the site westward of the erosion field (USEPA 1997). More comprehensive evaluation protocols have been put into place since 1985 to prevent dredged or fill material discharged at authorized sites from modifying current patterns and water circulation by obstructing the flow, changing the direction or velocity of water flow and circulation, or otherwise significantly altering the dimensions of a water body.

The USACE utilizes more than twenty selected or designated offshore dredged material disposal sites in the northeast region of the United States. Several of these sites have been used because they are dispersive in nature. These sites are used, normally, to put littoral material back into the nearshore drift pattern. The containment sites have an average size of 1.15 square nautical miles in size (USACE 2005b). By law and regulation, the significant adverse effects of dredged material disposal activities must be contained within the designated or selected disposal site and even those impacts must not degrade the area's overall ecological health. There is some dispersion of fine-grained sediments and contaminants outside the sites. Each site is required to have and be managed under a dredged material monitoring and management plan that assesses the health and well-being of the site and surrounding environment. Monitoring of disposal sites is a part of these plans, which is designed to ensure that any degradation of resources or alteration in seafloor characteristics are identified and would illicit actions by permitting agencies (USEPA 2004).

### *Release of nutrients/eutrophication*

Nutrient overenrichment, or eutrophication, is one of the major causes of aquatic habitat decline associated with human activities (Deegan and Buchsbaum 2005). There are point sources of nutrients, such as sewage treatment outfalls, and nonpoint sources, such as urban storm water runoff, agricultural runoff, and atmospheric deposition, which have been discussed in other chapters of this report. Elevated levels of nutrients have undesirable effects, including: (1) increased incidence, extent, and persistence of blooms of noxious or toxic species of phytoplankton; (2) increased frequency, severity, spatial extent, and persistence of hypoxia; (3) alterations in the dominant phytoplankton species, which can reduce the nutritional and biochemical nature of primary productivity; and (4) increased turbidity levels of surface waters, leading to reductions in submerged aquatic vegetation (O'Reilly 1994).

Sediment particles can bind to some nutrients, and resuspension of sediments following dredge material disposal can cause a rapid release of nutrients to the water column (Lohrer and Wetz 2003). Ocean disposal of dredge material with high organic content can result in oxygen reduction (hypoxia) or even anaerobic conditions (anoxic) on the bottom and overlaying waters, particularly during periods when strong thermoclines are present (Kurland et al. 1994). Hypoxic and anoxic conditions can kill benthic organisms or even entire communities and lead to a proliferation of stress-tolerant species of reduced value to the ecosystem (Kurland et al. 1994). Generally, offshore waters are less sensitive to disposal of dredge material containing nutrients than inshore, enclosed water bodies.

Both the MPRSA and CWA regulations prohibit the discharge of dredge material containing high organic content and nutrient levels if the discharge results in adverse effects to the marine environment. However, prior to the stricter regulations instituted in the 1980s, the discharge of sewage sludge was permitted for decades in nearshore and offshore waters of many urbanized centers of the northeastern US coast (Barr and Wilk 1994).

### *Conservation measures and best management practices for dredge material disposal*

1. Ensure that all options for disposal of dredged materials at sea are comprehensively assessed. The consideration of upland alternatives for dredged material disposal sites must be evaluated before offshore sites are considered.
2. Ensure that adequate sediment characterizations are completed and available for making informed decisions.
3. Ensure that adequate resource assessments are completed and available during project evaluation.
4. Employ sediment dispersion models to characterize sediment resuspension and dispersion during operations. Use model outputs to design disposal operations, including measures to avoid and minimize impacts from suspended sediment and turbidity on living marine resources. Sediment dispersion models should be field-verified to various sediment and hydraulic conditions to ensure they have been calibrated appropriately to predict sediment transport and dispersion.
5. Consider "beneficial uses" of dredged material, as appropriate.
6. Ensure that the site evaluation criteria developed for selection or designation of dredged material disposal sites have been invoked and evaluated, as appropriate.
7. Avoid dredged material disposal activities in areas containing sensitive or unique marine benthic habitats (e.g., spawning and feeding sites, surface deposits of cobble/gravel substrate).
8. Employ all practicable methods for limiting the loss of sediment from the activity. Consider closed or "environmental" buckets, when appropriate.
9. Ensure that disposal sites are being properly managed (e.g., disposal site marking buoys, inspectors, the use of sediment capping and dredge sequencing) and monitored (e.g., chemical and toxicity testing, benthic recovery) to minimize impacts associated with dredge material.
10. Use sequential dredging to avoid dredging activity during specific time periods in particularly environmentally sensitive areas of large navigation channel dredging projects. This can avoid turbidity and sedimentation, bottom disruption, and noise in sensitive areas used by fishery resources during spawning, migration, and egg development.
11. Require appropriate monitoring to avoid and minimize individual and cumulative impacts of the disposal operations.
12. Use seasonal restrictions when appropriate to avoid temporary impacts to habitat during critical life history stages (e.g., spawning, egg and embryo development, and juvenile growth). Recommended seasonal work windows are generally specific to regional or watershed-level environmental conditions and species requirements. Resource managers should incorporate

adequate time for habitat recovery of affected functions and values to levels required by managed species.

# Fish Waste Disposal

## *Introduction*

Fish waste or material resulting from industrial fish processing operations from either wild stocks or aquaculture consists of particles of flesh, skin, bones, entrails, shells, or process water (i.e., liquid “stickwater” or “gurry”). The organic components of fish waste have a high biological oxygen demand and, if not managed properly, can pose environmental and health problems. Generally, the solid wastes make up 30-40% of total production, depending on the species processed (IMO 2005a). Most fish wastes degrade rapidly in warm weather and can cause aesthetic problems and strong odors as a result of bacterial decomposition if not stored properly or disposed of quickly. Because these waste streams are generally required to be pretreated and fully processed on-site, disposed at a suitable upland site, or sent through municipal sewage treatment, at sea disposal is no longer widely employed in the northeastern United States. However, these materials are sometimes discharged at sea, when appropriate.

Permitting of at sea disposal should be coordinated with appropriate federal and state agencies. Processors should contact the US EPA to determine whether federal permits are necessary for the activity. In order to determine if a federal permit applies, the US EPA must determine if the material constitutes an environmental risk or is a traditional and acceptable "fish waste" disposal defined under Section 102(d) of the Ocean Dumping Ban Act, 33 U.S.C. Part 1412(d) and the regulations promulgated at 40 C.F.R. Part 220. Generally, permits are not required for the transportation or the ocean disposal of fish waste unless: 1) disposal is proposed in harbors or other protected and enclosed waters, and the location is deemed by the EPA as potentially endangering human health, the marine environment or ecological systems; or 2) the waste contains additives or disinfectants from the processing or treatment. In these cases, National Pollutant Discharge Elimination System (NPDES) permits may be required if chlorine or other similar chemicals are used. If an environmental or human health risk is determined, the applicant may be required to submit an assessment of the disposal area and potential impacts to marine resources and follow disposal guidelines consistent with the provisions of the London Convention 1972 (IMO 2005a). Permits required for ocean disposal of fish wastes define the discharge rate of the fluids, residual tissue, and hard part pieces by using a dispersion model. Inputs to the model include discharge flow rate, tissue dimensions, mixing rates, local current patterns, and the specific gravity of the solids (USEPA 2005c). The US EPA may also consult with applicable federal and state regulatory and resource agencies and regional fisheries councils, to identify any areas of concern with respect to the disposal area and activity. Persons wishing to dispose of fish wastes in the ocean may be required to submit specific dilution modeling in support of the proposed disposal and participate in monitoring to verify the results of the modeling (USEPA 2005c).

Bivalve shells, when brought ashore and processed, are not allowed to be returned to the ocean for the purpose of waste disposal. Reuse of the shells as “cultch” in oyster farming operations is a standard, traditional fishing practice in the northeastern United States and does not require permitting, but prior to disposal the shells may be required to meet water quality criteria, principally regarding residual tissue volume.

The guidelines established by the London Convention 1972 place emphasis on progressively reducing the need to use the sea for dumping of wastes. Implementation of these guidelines and the regulations promulgated by US EPA for the disposal of fish wastes includes consideration of potential waste management options that reduce or avoid fish waste to the disposal stream. For example, applications for disposal should consider reprocessing to fishmeal, composting, production of silage (i.e., food for domestic animals/aquaculture), use in biochemical industry products, use as fertilizer in land farming, and reduction of liquid wastes by evaporation (IMO 2005a).

### *Introduction of pathogens*

Ocean disposal of fish wastes has the potential to introduce pathogens to the marine ecosystem that could infect fish and shellfish. In particular, aquaculture operations that raise nonnative species or those that provide food to animals derived from nonindigenous sources could introduce disease vectors to native species (IMO 2005a). However, the disposal guideline provisions implemented as part of the Ocean Dumping Ban Act is designed to ensure wide dispersion of the gurry and limited accumulation of soft parts waste on the sea floor. Models developed to predict the effects of authorized discharges of fish wastes were designed to avoid the accumulation of biodegradable materials on the seafloor and introduction of pathogens.

### *Release of nutrients/eutrophication*

The organic components of fish wastes have a high biological oxygen demand (BOD) and if not managed properly could result in nutrient over-enrichment and reductions in the dissolved oxygen. In ocean disposal, these affects may be seen with mounding of wastes, subsequent increases in BOD and contamination with bacteria associated with partly degraded organic wastes (IMO 2005a). However, disposal guidelines require that dumpsite selection criteria maximizes waste dispersion and consumption of the wastes by marine organisms.

### *Release of biosolids*

Generally, the solid wastes generated by fish waste disposal comprises approximately 30-40% of total production, depending upon the species processed (IMO 2005a). Biosolid waste at fish disposal sites could result in nutrient over-enrichment and reduced dissolved oxygen concentration. However, the disposal guideline provisions implemented as part of the Ocean Dumping Ban Act require wide dispersion of the gurry and limited accumulation of soft parts waste on the sea floor.

### *Alteration of benthic habitat*

Ocean disposal of fish wastes that fail to meet permit conditions and guidelines have the potential to degrade fishery habitat by adversely affecting the productivity and ecological functions of the benthic community. Concentration and mounding of wastes can increase the BOD and reduce dissolved oxygen concentration of an area resulting in reductions in the ability to support small consumer organisms such zooplankton and amphipods. This can then affect species at higher trophic levels that depend upon these consumers for food. However, disposal guidelines require dump-site selection criteria that maximize waste dispersion and consumption of the wastes by marine organisms and disposal monitoring that ensures permit conditions are met (USEPA 2005c). In addition, guidelines and permit review must consider chemical contamination of the marine environment from the waste disposal. For example, the potential presence of chemicals used in aquaculture and fish wastes subjected to chemical treatment must be assessed prior to disposal (IMO 2005a).

### *Behavioral effects*

The presence of biodegradable tissue in the water column has the potential to alter the behavior of organisms in various ways, such as causing an attractant source for scavengers. This could alter the diet of individuals and interfere with trophic-level energy dynamics and community structure. The discharge of process water and biosolid wastes should be monitored carefully to ensure conditions within state and federal permits are met.

### *Conservation measures and best management practices for disposal of fish wastes*

1. Consider the practical availability of alternative methods of disposal to reuse, recycle, or treat the waste as a comparative risk assessment involving both ocean dumping and alternatives.
2. Perform site assessments of the proposed ocean disposal location prior to dumping, including the water depths, average velocities of tidal and nontidal currents, prevailing winds throughout the year, sediment and benthic habitat types, and nature of the sea floor (depositional versus dispersive). Information collected in the site assessment will be used in predictive models developed for the waste disposal activities. Existing uses of the site should be assessed, such as commercial and recreational fishing and whale watching vessels.
3. Use predictive models for plume dispersion and waste settlement based upon physical dynamics of the disposal area, nature of the fish waste, and the method of disposal. The models should be used to assess the probability of the waste plume reaching nearshore coastal waters or other protected areas, such as marine sanctuary waters. The models should also estimate the mass flux of nitrogen and organic carbon associated with the proposed discharges on a daily and annual basis, and how this input may affect phytoplankton production and benthic communities.
4. Dispose material at a steady rate while the vessel maintains headway speed (e.g., 3 nautical miles per hour) as opposed to dumping the entire load at once in a fixed location in order to provide better dilution of fish waste.
5. Grind organic materials to appropriate sizes (e.g., 0.5 inch) prior to discharge where they will be consumed or degraded in the water column dispersion field during and subsequent to their discharge. The intent should be to avoid water quality degradation and tissue deposition and accumulation on the seafloor.
6. Ensure that the waste will be rendered biologically inert during its residence time in the water column and avoid adverse effects on water quality, including reductions in dissolved oxygen concentrations and nutrient over-enrichment.
7. Require monitoring of the waste plume during and after discharge to verify model outputs and advance the knowledge regarding the practice of at-sea disposal of fish processing wastes.

## Vessel Disposal

### *Introduction*

When vessels are no longer needed, there are several options for their disposition, including reuse of the vessel or parts of the vessel, recycling or scrapping, creating artificial reefs, and disposal on land or sea (USEPA 2006). This section discusses the potential habitat and marine fisheries impacts associated with disposal at sea.

The disposal of vessels in the open ocean is regulated by the US EPA under section 102(a) of the MPRSA (Ocean Dumping Ban Act) and under 40 CFR § 229.3 of the US EPA regulations. In part, these regulations require that (1) vessels sink to the bottom rapidly and permanently and that marine navigation is not otherwise impaired by the sunk vessel; (2) all vessels shall be disposed of in depths of at least 1,000 fathoms (6,000 feet) and at least 50 nautical miles from land; and (3) before sinking, appropriate measures shall be taken to remove to the maximum extent practicable all materials which may degrade the marine environment, including emptying of all fuel tanks and lines so that they are essentially free of petroleum and removing from the hulls other pollutants and all readily detachable material capable of creating debris or contributing to chemical pollution.

The US EPA and US Department of Transportation Maritime Administration have developed national guidance, including criteria and best management practices for the disposal of ships at sea when the vessels are intended for creation or addition to artificial reefs (USEPA 2006). Vessels disposed of to create artificial reefs have historically been designed and intended to enhance fishery resources for recreational fishermen. However, in recent years artificial reefs have been constructed for a number of nonextractive purposes such as: (1) recreational SCUBA diving opportunities; (2) socioeconomic benefits to local coastal communities; (3) increase habitat to reduce user pressure on nearby natural reefs; (4) reduce user conflicts (e.g., diving in heavily fished areas), and; (5) provide mitigation or restoration to habitat loss for commercial activities (e.g., beach nourishment, dredging, pipeline routes) (NOAA 2007). Some vessels may be sunk to provide a combination of these purposes. Vessels prepared for use as artificial reefs should: (1) be "environmentally sound" and free from hazardous and potentially polluting materials; (2) have had resource assessments for the disposal locations conducted to avoid adverse impacts to existing benthic habitats; and (3) have had stability analyses for the sinking and the ship's ultimate location conducted to ensure there is minimal expectation of adverse impacts on adjacent benthic habitats. Several guidance documents have been developed for the planning and preparation of vessels as artificial reef material, including the National Artificial Reef Plan (NOAA 2007), Coastal Artificial Reef Planning Guide (ASMFC and GSMFC 1998), the Guidelines for Marine Artificial Reef Materials (ASMFC and GSMFC 2004), and the National Guidance: Best Management Practices for Preparing Vessels Intended to Create Artificial Reefs (USEPA 2006). These documents should be consulted to ensure that conflicts with existing uses of the potential disposal site/artificial reef site are addressed and that materials onboard the vessel do not adversely impact the marine environment. Section 203 of the National Fishing Enhancement Act of 1984 (Title II of P.L. 98-623, Appendix C) established that artificial reefs in waters covered under the Act shall "be sited and constructed, and subsequently monitored and managed in a manner which will: (1) enhance fishery resources to the maximum extent practicable; (2) facilitate access and utilization by US recreational and commercial fishermen; (3) minimize conflicts among competing uses of waters covered under this title and the resources in such waters; (4) minimize environmental risks and risks to personal health and property; and (5) be consistent with generally accepted principles of international law and shall not create any unreasonable obstruction to navigation."

The appropriate siting is vital to the overall success of an artificial reef. Considerations and options for site placement and function in the environmental setting should be carefully weighed to ensure program success. Since placement of a reef involves displacement and disturbance of the existing habitat, and building the reef presumably accrues some benefits that could not exist in the absence of the reef, documentation of these effects should be brought out in the initial steps to justify artificial reef site selection. Placement of a vessel to create an artificial reef should: (1) enhance and conserve targeted fishery resources to the maximum extent practicable; (2) minimize conflicts among competing uses of water and water resources; (3) minimize the potential for environmental risks related to site location; (4) be consistent with international law and national fishing law and not create an obstruction to navigation; (5) be based on scientific information; and (6) conform to any federal, state, or local requirements or policies for artificial reefs (USEPA 2006).

The Coastal Artificial Reef Planning Guide (ASMFC and GSMFC 1998) state that when an artificial reef has been constructed, another important phase of reef management begins: monitoring and maintenance. Monitoring provides an assessment of the predicted performance of reefs and assures that reefs meet the general standards established in the Section 203 of the National Fishing Enhancement Act as listed above. It also ensures compliance with the conditions of any authorizing permits. Artificial reef monitoring should be linked with performance objectives, which ensures that NOAA National Marine Fisheries Service responsibilities to protect, restore, and manage living marine resources, and to avoid and minimize any adverse effects on these resources are fulfilled.

### *Release of contaminants*

Ships disposed of at sea, including those intended to create artificial reefs, are often military and commercial vessels which typically contain various materials that, if released into the marine environment, could have adverse effects on the marine environment. Some of the materials of concern include fuels and oil, asbestos, polychlorinated biphenyl (PCB), paint, debris (e.g., vessel debris, floatables, introduced material), and other materials of environmental concern (e.g., mercury, refrigerants) (USEPA 2006). Depending upon the nature of the contaminant and the concentration and duration of the release of contaminant(s) adverse effects to marine organisms may be acute or chronic and either lethal or sublethal. Some contaminants, such as PCB and mercury, can be persistent and bioaccumulate in the tissues of organisms resulting in more serious impacts in higher trophic level organisms. The Ocean Dumping Ban Act and the various guidance documents available for offshore disposal of vessels prohibit materials containing contaminants which may impact the marine environment. The guidance documents provide detailed best management practices regarding recommended measures to remove and abate contaminants contained within and as part of a vessel.

### *Release of debris*

Debris, including solids and floatables, are materials that could break free from a vessel during transportation to the disposal site, and during and after sinking. The release of debris can adversely affect the ecological and aesthetic value of the marine environment. Debris released from vessels is generally categorized into vessel debris (material that was once part of the vessel) and clean-up debris (material that was not part of the vessel but was brought on board the vessel during preparation for disposal).

Some debris released from vessels is not highly degradable and can be persistent in the marine environment for long periods of time, increasing the threat it poses to the environment. Some of the impacts associated with debris include: (1) entanglement and/or ingestion, leading to injury, infection, or death of marine animals that may be attracted to or fail perceive the debris in the water; (2) alteration of the benthic floral and faunal habitat structure, leading to injury or mortality or indirect impact to other species linked in the benthic food web and; (3) elevation of the risk of spills and other environmental impacts caused by impacts with other vessels (e.g., hull damage, damage to cooling or propulsion systems) (USEPA 2006). The Ocean Dumping Ban Act and the various guidance documents available for offshore disposal of vessels require all debris to be removed from vessels prior to sinking. The guidance documents provide detailed best management practices regarding recommended measures to remove vessel and clean-up debris.

### *Conversion of substrate/habitat and changes in community structure*

Vessels that are sunk for the purpose of discarding obsolete or decommissioned ships, as well as those sunk to create an artificial reef, can convert bottom habitat type and alter the ecological balance of marine communities inhabiting the area. For example, placement of vessels over sand bottom can change niche space and predator/prey interactions for species or life history stages utilizing that habitat type. Large structures such as ships tend to attract adult fish and larger predators, which may increase predation rates on smaller and juvenile fish or displace smaller fish and juveniles to other areas (USEPA 2006). Large, anthropogenic structures, such as oil and gas platforms in the Gulf of Mexico, have been shown to affect the distribution of larval and juvenile fish (Lindquist et al. 2005). In addition, large structures tend to provide proportionally less shelter for demersal fishes and invertebrates than smaller, lower profile structures, while the surfaces of steel hull vessels are less ideal for colonization by epibenthos than are natural surfaces like rock (ASMFC and GSMFC 2004). Certain types of habitat and areas may be more susceptible to physical and chemical impacts from the placement of vessels, particularly those vessels sunk as artificial reefs. Generally, vessels sunk for disposal only are located in deeper water (> 6,000 feet) and very far offshore (> 50 nautical miles from land) and may have less impacts on sensitive benthic habitats. However, vessels sunk as artificial reefs are usually located in nearshore coastal waters that also support or are frequented by marine resources that may be adversely impacted by the placement of the structure. Artificial reefs should not be sited in sensitive areas that contain coral reefs or other reef communities, submerged aquatic vegetation, or habitats known to be utilized by endangered or threatened species (USEPA 2006). The Ocean Dumping Ban Act prohibits vessel disposal in areas that may adversely effect the marine environment.

### *Changes in bathymetry and hydrodynamics*

The location of a vessel on the ocean bottom will change the bathymetry and can potentially alter the current flow of the disposal area. A proposed disposal site should be assessed as to the effects the vessel disposal and subsequent bathymetry change may have on the hydrodynamics and geomorphology of the immediate and adjacent habitats. For example, even small vessels placed on the bottom can alter currents and create turbulence around the vessel that may scour existing soft substrates and adversely affect adjacent habitats and communities. In addition, the high vertical profile may cause some vessels to be prone to movement and structural damage from ocean currents and wave surge during storm events. For example, during Hurricane Andrew, a category 5 storm, in south Florida during 1992, nearly all steel-hulled vessels sunk as artificial reefs in the area of the storm's path sustained structural damage, and a number moved 100-700 m because of the storm surge (ASMFC and GSMFC 2004). The movement of vessels after disposal can impact adjacent habitats and relocate the vessels to areas that could alter the ecological balance of marine communities in the area. In addition, reductions in navigational clearance, either as a result of the vessel being sunk in the wrong location and in an area too shallow or because later movement of the vessel from storm surge or currents may increase the potential danger to vessel navigation (e.g., hull damage, damage to cooling or propulsion systems) which may cause further damage from oil/fuel spills or groundings (ASMFC and GSMFC 2004). To minimize the risk of alterations to the bathymetry and hydrodynamics of the disposal area and vessel movement, the Ocean Dumping Ban Act and the various guidance documents available for offshore disposal of vessels require a number of evaluations prior to dumping activities, including: (1) stability analyses; (2) assessments of the seabed, including topography and geological characteristics and; (3) assessment of mean direction and velocity of currents and storm-wave induced bottom currents (ASMFC and GSMFC 2004; IMO 2005b).

### *Deployment impacts*

Some risks to the marine environment exist during the deployment (i.e., sinking) of vessels for disposal or as an artificial reef. Some potential impacts that may occur during deployment include the release of contaminants accidentally left onboard the vessel, damage to adjacent benthic habitats from anchors and cables used to maintain the vessel position as it sinks, impacts to benthic habitats from a vessel accidentally sinking in an unintended location while being towed or from movement of the ship after deployment (ASMFC and GSMFC 2004). However, careful planning during the assessment stages and adherence to operational protocols can avoid impacts during deployment.

### *Conservation measures and best management practices for disposal of vessels*

1. Require that a vessel disposal site assessment adequately characterize the physical and biological environment of the site. In addition to identifying the habitat types and species utilizing the area and targeted for enhancement, ecological investigations should include community settlement and recruitment and predator/prey dynamics and anticipated changes in competition and niche space as a result of the vessel disposal (USEPA 2006).
2. Identify the locations of any sensitive marine habitats in the area. Potential vessel disposal sites should generally not be located near any of the following marine resources: coral reefs; significant beds of aquatic vegetation or macroalgae; oyster reefs; scallop, mussel, or clam beds; existing live bottom (i.e., marine areas supporting sponges, sea fans, corals, or other sessile invertebrates generally associated with rock outcrops); and habitats of endangered or threatened species (federal and state listed) (USEPA 2006).
3. Conduct vessel stability analysis to ensure the vessel is retained in the intended location, including characterization of anticipated weather conditions, tidal dynamics, mean direction and velocity of surface and bottom drifts and storm-wave induced currents, and general wind and wave characteristics (IMO 2005b).
4. Ensure that a thorough inventory and assessment of all potential contaminants on the vessel are completed and that all preplacement cleaning and inspections are completed thoroughly and effectively.
5. Avoid the use of explosives to the extent possible in sinking vessels under 150 feet in length where alternate methods (e.g., opening seacocks, flooding with pumps, etc.) are feasible (ASMFC and GSMFC 2004).
6. Monitor the disposal operation and the placement site for adherence to permit compliance and performance objectives.
7. Ensure that physical and biological monitoring plans for vessels disposed of as artificial reefs are developed as appropriate and that monitoring and reporting requirements are met throughout the designed timeframe.

# CHAPTER SEVEN: CHEMICAL EFFECTS—WATER DISCHARGE FACILITIES

## Introduction

Disposal of various waste materials into rivers, estuaries, and marine waters is not a modern phenomenon; this practice has been used as a preferred disposal option virtually since the beginning of human civilization (Ludwig and Gould 1988; Islam and Tanaka 2004). Nevertheless, when the full spectrum of emissions from land-based activities is taken into account, the use of coastal waters as a repository for anthropogenic waste has not previously been practiced on as large or intense a global scale as in recent decades (Williams 1996). In the United States, growing human population densities in coastal communities have manifested a demonstrably adverse effect on aquatic resources. The scientific literature is replete with evidence of inorganic and organic pollutant accumulation in coastal waters from anthropogenic effluents (e.g., Ragsdale and Thorhaug 1980; Tessier et al. 1984; Phelps et al. 1985; Long E et al. 1995; Pastor et al. 1996; Smith et al. 1996; Chapman and Wang 2001; Hare et al. 2001; O'Connor 2002; Robinet and Fenteun 2002; Wurl and Obbard 2004). The federal Clean Water Act (CWA), enacted in 1972 to address many of these issues, eliminated certain types of disposal activities and otherwise induced improvements to the nation's surface water quality. Nonetheless, “despite reductions in pollution from municipal and industrial point sources more than one-third of the river miles, lake acres, and estuary square miles suffer [*sic*] some degree of impairment” (Ribaudo et al. 1999). To the extent that it may alter natural processes and natural resource communities, unabated degradation of the aquatic environment caused by a wide spectrum of human activities poses consequences for fishery resources and their habitats.

Contaminants enter our waterways through two generic vectors: point and nonpoint sources. Pollutants of nonpoint source origins tend to enter aquatic systems as relatively diffuse contaminant streams primarily from atmospheric and terrestrial sources (see Coastal Development chapter of this report for discussions on nonpoint source pollution). In contrast, point source pollutants generally are introduced via some type of pipe, culvert, or similar outfall structure. These discharge facilities typically are associated with domestic or industrial activities, or in conjunction with collected runoff from roadways and other developed portions of the coastal landscape. Waste streams from sewage treatment facilities and watershed runoff in many urbanized portions of the northeastern United States are first intermingled and then subsequently released into aquatic habitats via combined sewer overflows (CSOs). Such point discharges collectively introduce a cocktail of inorganic and organic contaminants into aquatic habitats, where they may become bioavailable to living marine resources.

While all pollutants can become toxic at high enough levels, there are a number of compounds that are toxic even at relatively low levels. The US Environmental Protection Agency (US EPA) has identified and designated more than 126 analytes as “priority pollutants.” According to the US EPA, “priority pollutants” of particular concern for aquatic systems include: (1) dichlorodiphenyl trichloroethane (DDT) and its metabolites; (2) chlorinated pesticides other than DDT (e.g., chlordane and dieldrin); (3) polychlorinated biphenyl (PCB) congeners; (4) metals (e.g., cadmium, copper, chromium, lead, mercury); (5) polycyclic aromatic hydrocarbons (PAHs); (6) dissolved gases (e.g., chlorine and ammonium); (7) anions (e.g., cyanides, fluorides, and sulfides); and (8) acids and alkalis (Kennish 1998; USEPA 2003a). While acute exposure to these substances produce adverse effects of aquatic biota and habitats, chronic exposure to low concentrations probably is a more significant issue for fish population structure and may result in multiple substances acting in "an additive, synergistic or antagonistic manner" that may render impacts relatively difficult to discern (Thurberg and Gould 2005).

Determining the eventual fate and effect of naturally occurring and synthetic contaminants in coastal environments and biota is a highly dynamic proposition that requires interdisciplinary evaluation. It is essential that all processes sensitive to pollutants be identified and that investigators realize that the resulting adverse effects may be manifested at the biochemical level in organisms (Luoma 1996) in a manner particular to the species or life stage exposed. Pollutant exposure can inhibit: (1) basic detoxification mechanisms, like production of metallothioneins or antioxidant enzymes; (2) the ability to resist diseases; (3) the ability of individuals or populations to counteract pollutant-induced metabolic stress; (4) reproductive processes including gamete development and embryonic viability; (5) growth and successful development through early life stages; (6) normal processes including feeding rate, respiration, osmoregulation; and (7) overall Darwinian fitness (Capuzzo and Sassner 1977; Widdows et al. 1990; Nelson et al. 1991; Stiles et al. 1991; Luoma 1996; Thurberg and Gould 2005).

The nature and extent of a pollutant's dispersal in our waterways are collectively dependent on a variety of factors including site-specific ecological conditions, the physical state in which the contaminant is introduced into the aquatic environment, and the inherent chemical properties of the substance in question. Soluble or miscible substances typically enter waterways in an aqueous phase and eventually become adsorbed onto organic and inorganic particles (Wu et al. 2005); however, contaminants may enter aquatic systems as either particle-borne suspensions or as solutes (Bishop 1984; Turner and Millward 2002). Dilution and settling out from such effluent streams initially are dictated by physical factors (e.g., the presence of significant currents or perhaps a strong thermocline or pycnocline) which predominantly influence the spatial extent of contaminant dispersal. In particular, turbulent mixing, or diffusion, disperses contaminant patches in coastal waters resulting in larger, comparatively diluted contaminant distributions further away from the initial point source (Bishop 1984). Biological activity and geochemical processes subsequently intercede and typically result in contaminant partitioning between the aqueous and particulate phases (Turner and Millward 2002).

While physical dispersion, biological activity, and other ecological factors clearly have important roles regarding the distribution of contaminants in aquatic habitats, contaminant partitioning is largely governed by certain ambient environmental conditions, notably salinity, pH, and the physical nature of local sediments (Turekian 1978; McElroy et al. 1989; Turner and Millward 2002; Leppard and Droppo 2003; Wu et al. 2005). Highly reactive suspended particles typically serve as important carriers of aquatic contaminants and largely are responsible for their bioavailability, transport, and ecological fate as they become dispersed in receiving waters (Turner and Millward 2002). In addition, hyporheic (i.e., the saturated zone under a river or stream, comprising substrate with the interstices filled with water) exchange between overlying water and groundwater can alter salinity, dissolved oxygen concentration, and other water chemistry aspects in ways that can influence the affinity of local sediment types for particular contaminants or otherwise affect contaminant behavior (Ren and Packman 2002).

Amendments to the CWA include important provisions to address acute or chronic water pollution emanating from discharge pipes and outfalls under the National Pollutant Discharge Elimination System (NPDES) program. Until the late 1980s, the NPDES program traditionally focused efforts on controlling industrial and municipal sewage discharges but has since expanded its purview to include storm water management (USEPA 1996). While the NPDES program has led to ecological improvements in waters of the United States, point sources continue to introduce pollutants into the aquatic environment, albeit at reduced levels. Nonetheless, studies demonstrate that particle-associated contaminants collected in coastal depositional areas are preserved in chronological strata or horizons (Huntley et al. 1995; Chillrud et al. 2003). Consequently, historically deposited contaminants may be encountered when installing new outfalls or coastal infrastructure, especially near urbanized areas. Regardless of whether these pollutants were deposited recently or decades ago, dredging incidental to construction and related activities that enhance their potential biological availability can have adverse ecological implications.

The environmental dynamics of point source wastes are complex and involve a variety of physical, chemical, and biological processes simultaneously acting on the introduced suite of contaminants and their surrounding habitat. Because of the many competing variables involved, it is difficult to predict the ultimate fate and effects of anthropogenic wastes with great precision; however, local habitat characteristics in combination with the relative solubility, degree of hydrophobicity (i.e., tending to repel and not absorb water), and chemical reactivity of the introduced substances are important determining factors at the most basic level of analysis.

To minimize redundancy, all recommended conservation measures and best management practices for sewage discharge facilities, industrial discharge facilities, and combined sewer overflows have been included at the end of this chapter.

## Sewage Discharge Facilities

### *Introduction*

Sewage treatment plants introduce a host of contaminants into our waterways primarily through discharge of fluid effluents comprising a mixture of processed "black water" (sewage) and "gray water" (all other domestic and industrial wastewater). Such municipal effluents begin as a complex mixture of human waste, suspended solids, debris, and a variety of chemicals collectively derived from domestic and industrial sources. These contaminants include an array of suspended and dissolved substances, representing both inorganic and organic chemical species (Grady et al. 1998; Epstein 2002). These substances potentially include the full spectrum of EPA priority pollutants mentioned previously and many other contaminants of anthropogenic origin. However, the five constituents that are usually the most important in determining the type of treatment that will be required are: (1) organic content (usually measured as volatile solids); (2) nutrients; (3) pathogens; (4) metals; and (5) toxic organic chemicals (USEPA 1984).

Coastal communities rely on municipal wastewater treatment to contend with potential human health issues related to sewage and also to protect surface and groundwater quality. Municipal processing facilities typically receive raw wastewater from both domestic and industrial sources, and are designed to produce a liquid effluent of suitable quality that can be returned to natural surface waters without endangering humans or producing adverse aquatic effects (Grady et al. 1998; Epstein 2002). As it is currently practiced in the United States, wastewater treatment entails subjecting domestic and industrial effluents to a series of physical, chemical, or even biological processes designed to address or manipulate different aspects of contaminant mitigation. For both logistical and economic reasons, not all municipalities expend the same level of effort removing contaminants from their wastewater before returning it to a receiving aquatic habitat. The following discussion summarizes the different levels that municipal wastewater treatment and resulting water quality benefits derived from them.

Primary treatment, also known as "screen and grit," is only marginally effective at addressing sewage contaminants and simply entails bulk removal of "settleable" solids from the wastewater by sedimentation and filtration. Sometimes total suspended solids are further reduced in the initial effluent treatment phase by implementing another level of primary treatment, which entails using chemicals to induce coagulation and flocculation of smaller particles (Parnell 2003).

The resulting bio-solids must be disposed, and their final disposition could entail composting with subsequent use in agricultural applications, placement in a landfill, disposal at sea, or even incineration (Werther and Ogada 1999). Removal and appropriate disposal of sewage present in a solid phase are important steps, if elementary, in addressing human health and aesthetic issues surrounding sewage management because doing so removes visible substances that otherwise would accumulate in the aquatic environment at or near the discharge point. Unfortunately, primary treatment of municipal wastewater alone often fails to meet overall environmental goals of supporting important water-dependent uses like fishery resource production and recreational uses featuring primary contact with the water. As a consequence, coastal communities in the northeastern region process their wastewater through one or more additional treatment levels beyond bulk solids removal to address the environmental challenges of their sewage effluents more effectively.

Following bulk sludge removal, sewage treatment plants typically pass the highly organically-enriched water emerging from primary treatment through a second process that is intended to address biological oxygen demand (BOD), an indirect measure of the concentration of biologically degradable material present in organic wastes that reflects the amount of oxygen necessary to break down those substances in a set time interval. Such secondary treatment, which is required for all municipal wastewater treatment in the United States, involves removal of much of the remaining organic material by introducing aerobic microorganisms under oxygen-enriched conditions (Parnell 2003). The resulting microbial action breaks organic substrates into progressively simpler compounds, with the final waste components predominantly released as carbon dioxide. The bacteria subsequently are removed by chlorination before the secondarily-treated effluent is released into local surface waters or the secondarily treated wastewater is directed to another part of the sewage treatment plant for additional processing. Where practiced, such effluent-polishing or advanced treatment measures use any of several techniques to remove inorganic nitrogenous or phosphorous salts to reduce the final effluent's potential to cause excessive nutrient enrichment of the receiving waters (Epstein 2002; Parnell 2003).

Because of the large expense of tertiary sewage treatment, the public sector does not implement it as a uniform municipal wastewater treatment policy. Consequently, while secondary treatment is the standard operating procedure for municipal wastewater treatment in the northeastern United States, natural resource managers cannot assume that advanced, tertiary treatment is available to meet desired environmental goals. Recent point source management policy decisions by Boston, MA, area communities are a case in point. Rather than implementing more costly advanced treatment during system upgrades, these communities chose to address local municipal wastewater challenges by implementing primary and secondary treatment combined with source reduction of certain contaminants and offshore diversion of outfalls to encourage enhanced effluent dilution (Moore et al. 2005). Despite the added expense of implementing them, both secondary and advanced treatment processes are important potential habitat protection measures, particularly because they mitigate oxygen depletion events, eutrophication, and related phenomena that can result in adverse ecological conditions.

### *Release of nutrients and eutrophication*

Particularly under lesser levels of treatment, municipal sewage facilities discharge large volumes of nutrient-enriched effluent. While some level of readily available nutrients are essential to sustain healthy aquatic habitats and ecological productivity, excess concentrations result in eutrophication of coastal habitats. Elevated nitrogen and phosphorous concentrations in municipal wastewater effluents can cause pervasive ecological responses including: exaggeration of phytoplankton and macroalgal populations; initiation of harmful algal blooms (Anderson et al. 2002); adverse affects on the physiology, growth, and survival of certain ecologically important aquatic plants (Touchette and Burkholder 2000); reduction of water transparency with accompanying adverse effects to submerged and emergent vascular plants or other disruptions to the normal ecological balance among vascular plants and algae (Levinton 1982; Cloern 2001); hypoxic or anoxic events that may cause significant fish and invertebrate mortalities; disturbances to normal denitrification processes; and concomitant decrease in local populations of fishery resources and forage species (USEPA 1994). Sewage outfalls also may become an attraction nuisance in that they may at least initially attract fish around the point of discharge until hypoxia, toxin production, and algal bloom development render the aquatic area less productive (Islam and Tanaka 2004). Collectively, adverse chemical effects may be especially significant to aquatic resources in temperate regions because strong thermoclines and persistent ice cover restrict vertical mixing and exacerbate deteriorating habitat conditions at depth.

For additional information on the mechanisms involved in denitrification of organic and inorganic compounds, Korom's (1992) review of denitrification in natural aquifers is a concise and informative compilation of heterotrophic and autotrophic denitrifiers.

### *Release of contaminants*

Municipal treatment facilities discharge large volumes of effluent into the aquatic environment. The waste stream typically contains a complex mixture of domestic and industrial wastes that contain predominantly natural and synthetic organic substances, metals, and trace elements, as well as pathogens (Islam and Tanaka 2004). Similarly, introductions of certain pharmaceuticals via municipal wastewater discharges have become causes for concern because of their potential to act as endocrine disruptors in fish and other aquatic resources. Residence time of the different contaminant classes in aquatic environments is an important habitat management consideration. Some of these substances, such as volatile organic compounds, may have a relatively short residence time in the system and other, more persistent substances, such as synthetic organometallic compounds, may linger for decades after becoming associated with the substrate or concentrated in local biota. Such pollution has been associated with mortality, malformation, abnormal chromosome division, and higher frequencies of mitotic abnormality in adult fish from polluted areas compared with those from less polluted regions of the northwest Atlantic Ocean (Longwell et al. 1992).

Increased concentrations of the various contaminant classes associated with municipal wastewater can be highly ecologically significant. For instance, exposure to contaminants within these categories have been correlated with deleterious effects on aquatic life including larval deformities in haddock (*Melanogrammus aeglefinus*) (Bodammer 1981), reduced hatching success and increased larval mortality in winter flounder (*Pseudopleuronectes americanus*) (e.g., Klein-MacPhee et al. 1984; Nelson et al. 1991), skeletal deformities in Atlantic cod (*Gadus morhua*) (Lang and Dethlefsen 1987), inhibited gamete production and maturation in sea scallops (*Placopecten magellanicus*) (Gould et al. 1988), and reproductive impairment in Atlantic cod (Thurberg and Gould 2005).

Laboratory experiments with pesticides have shown a positive relationship between malformation and survival of embryos and larvae of Atlantic cod and concentration of DDT and its breakdown product dichlorodiphenyl dichloroethylene (DDE) (Dethlefsen 1976). The proportion of fin erosion in winter flounder collected on contaminated sediments was found to be greater in fish sampled with higher concentrations of PCB in muscle, liver, and brain tissues than in fish collected in reference sites (Sherwood 1982). Studies conducted in the harbor of New Haven, CT, found high occurrences of liver lesions, blood cell abnormalities, liver DNA damage, and liver neoplasms among winter flounder with high concentrations of organic compounds, metals, and PCB in their gonads (Gronlund et al. 1991). Such pollution also has been associated with mortality, malformation, abnormal chromosome division, and higher frequencies of mitotic abnormality in adult fish from polluted areas compared with those from less polluted regions of the northwest Atlantic Ocean (Longwell et al. 1992). Observed effects of fish exposed to PAH include decrease in growth, cardiac disfunction, lesions and tumors of the skin and liver, cataracts, damage to immune systems, estrogenic effects, bioaccumulation, bioconcentration, trophic transfer, and biochemical changes (Logan 2007).

For almost a century, sewage sludge (the solids extracted from raw wastewater during sewage treatment) was disposed of at sea. In the northeastern United States, a number of designated offshore sewage sludge dumpsites existed, including one in Boston Harbor, MA, and sites in the New York Bight and the Mid-Atlantic Bight (Barr and Wilk 1994). Not surprisingly, sediments sampled in the vicinity of sewage sludge dumpsites have contained higher levels of contaminants (e.g., PCB, PAH, chlorinated pesticides, and metals) than in control sites (Barr and Wilk 1994). Sewage sludge has been demonstrated to have adverse effects on aquatic organisms. For example, early life stages of Atlantic herring (*Clupea harengus*) have shown a series of developmental abnormalities, including premature hatching accompanied by reduced viability of emerging fry; poor larval survival; smothering or incapacitation of larvae by particle flocs; and fin damage (Urho 1989; Costello and Gamble 1992). The Ocean Dumping Ban Act of 1988 prohibited sewage sludge and industrial wastes from being dumped at sea after December 31, 1991. This law is an amendment to the Marine Protection, Research, and Sanctuaries Act of 1972, which regulates the dumping of wastes into ocean waters.

In addition to these diverse contaminant classes, wastewater facilities also discharge a host of synthetic hormones or other substances that could disrupt normal endocrine function in aquatic vertebrates, as well as introduce zoonotic viruses, bacteria, and fungi that may be present in raw human sewage. These chemicals act as "environmental hormones" that may mimic the function of the sex hormones (Thurberg and Gould 2005). Adverse effects include reduced or altered reproductive functions, which could result in population-level impacts. Metals, PAHs, and other contaminants have been implicated in disrupting endocrine secretions of marine organisms (Brodeur et al. 1997; Thurberg and Gould 2005). However, the long-term effect of endocrine-disrupting substances on aquatic life is not well understood and demands serious attention by the scientific and resource policy communities. Refer to the Endocrine Disruptors subsection of this chapter for a broader discussion on this topic. Metals such as mercury are also capable of moving upward through trophic levels and can accumulate in fish (i.e., bioaccumulation) at levels which may cause health problems in human consumers.

While modern sewage treatment facilities undeniably reduce the noxious materials present in raw wastewater and some substances typical of processed effluents have their own inherent toxic effects, it also is important to recognize that secondary and advanced treatment can alter the chemistry of ordinarily benign materials in ways that initiate or enhance their toxicity. In particular, normally nonhazardous organic compounds present in wastewater potentially can be rendered toxic when raw municipal effluent is chlorinated in the sewage treatment process (NRC 1980; Epstein 2002). Other contaminants may become toxic to humans or many different aquatic resource taxa when these substances are methylated (addition of a $-CH_4$ group) or otherwise after having been chemically transformed into a harmful, biologically available molecular form.

The behavior and effects of trace chemicals in aquatic systems largely depend on the speciation and physical state of the pollutants in question. A detailed description concerning contaminant partitioning and bioavailability is beyond the scope of this technical discussion.

However, Gustafsson and Gschwend (1997) offer an excellent review of the matter in terms of how dissolved, colloidal and settling particle phases affect trace chemical fates and cycling in aquatic environments. While the observations provided by these Massachusetts Institute of Technology researchers pertain specifically to cycling of compounds in natural waters, the generic properties they discuss also would apply in the context of substances in treated wastewater since they are subject to the same physical and chemical forces. In addition, Tchobanoglous et al. (2002) may be consulted for an authoritative technical review of the environmental engineering aspects of wastewater treatment.

Exposure to potentially mutagenic or teratogenic pollutants and the resulting declines in viability at any life stage reduce the likelihood of maturation and eventual recruitment to adulthood or a targeted fishery. Literature on the aqueous and sedimentary geochemistry and physiological effects of contaminants on aquatic biota should be consulted to determine the fate of persistent compounds in local sediments and associated pore-water and the extent of acute or chronic toxic effects on affected aquatic biota (Varanasi 1989; Allen 1996; Langmuir 1996; Stumm and Morgan 1996; Tessier and Turner 1996; Paquin et al. 2003).

### *Alteration of water alkalinity*

Municipal sewage effluent that does not meet water quality standards can alter the alkalinity of riverine receiving waters. However, freshwater and low-salinity waters with low buffering capacity are more susceptible to acidification than are marine waters. Acidification of riverine habitats has been linked to the disruption of reproduction, development, and growth of anadromous fish (USFWS and NMFS 1999; Moring 2005). For example, osmoregulatory problems in Atlantic salmon (*Salmo salar*) smolts have been related to habitats with low pH (Staurnes et al. 1996). In estuarine waters, low pH has been shown to cause cellular changes in the muscle tissues of Atlantic herring which may lead to a reduction in swimming ability (Bahgat et al. 1989). However, all municipal sewage facilities are required to obtain water quality permits through the US EPA's NPDES program and must meet established pH standards for receiving waters. Acid precipitation from atmospheric sources is of concern in the northeastern United States. Refer to the Global Effects and Other Impacts chapter for more information regarding acid precipitation.

### *Impacts to submerged aquatic vegetation*

Submerged aquatic vegetation (SAV) requires relatively clear water in order to allow adequate light transmittance for metabolism and growth. Sewage effluent containing high concentrations of nutrients can lead to severely eutrophic conditions. The resulting depression of dissolved oxygen and diminished light transmittance through the water may result in local reduction or even extirpation of SAV beds that are present before habitat conditions become too degraded to support them (Goldsborough 1997). Examples of large scale SAV declines have been seen throughout the eastern coastal states, most notably in Chesapeake Bay, MD/VA, where overall abundance has been reduced by 90% during the 1960s and 1970s (Goldsborough 1997). Although a modest recovery of the historic SAV distribution has been seen in Chesapeake Bay over the past few decades, reduced light penetration in the water column from nutrient enrichment and sedimentation continues to impede substantial restoration. Primary sources of nutrients into Chesapeake Bay include fertilizers from farms, sewage treatment plant effluent, and acid rain (Goldsborough 1997). Short and Burdick (1996) correlated eelgrass losses in Waquoit Bay, MA, with anthropogenic nutrient loading primarily as a result of increased number of septic systems from housing developments in the watershed.

Eutrophication can alter the physical structure of SAV by decreasing the shoot density and blade stature, decreasing the size and depths of beds, and stimulating excessive growth of macroalgae (Short et al. 1993). An epidemic of an eelgrass wasting disease wiped out most eelgrass beds along the east coast during the 1930s, and although some of the historic distribution of eelgrass has recovered, eutrophication may increase the susceptibility of eelgrass to this disease (Deegan and Buchsbaum 2005).

### *Reduced dissolved oxygen*

The decline and loss of fish populations and habitats because of low dissolved oxygen concentrations is "one of the most severe problems associated with eutrophication in coastal waters" (Deegan and Buchsbaum 2005). The effect of chronic, diurnally fluctuating levels of dissolved oxygen has been shown to reduce the growth of young-of-the-year winter flounder (Bejda et al. 1992). High nutrient loads into aquatic habitats can cause hypoxic or anoxic conditions, resulting in fish kills in rivers and estuaries (USEPA 2003b; Deegan and Buchsbaum 2005) and potentially altering long-term community dynamics (NRC 2000; Castro et al. 2003). Highly eutrophic conditions have been reported in a number of estuarine and coastal systems in the northeastern United States, including Boston Harbor, Long Island Sound, NY/CT, and Chesapeake Bay (Bricker et al. 1999). For the southern portions of the northeast coast (i.e., Narragansett Bay, RI, to Chesapeake Bay), O'Reilly (1994) described chronic hypoxia (low dissolved oxygen) as a result of coastal eutrophication in several systems. This author reported episodic, low dissolved oxygen conditions in some of the northern portions of the northeast coast, such as in Boston Bay/Charles River and the freshwater portion of the Merrimack River, MA/NH (O'Reilly 1994). Areas particularly vulnerable to hypoxia are those that have restricted water circulation, such as coastal ponds, subtidal basins, and salt marsh creeks (Deegan and Buchsbaum 2005). While any system can become overwhelmed by unabated nutrient inputs or nutrient enrichment, the effects of these generic types of pollution when experienced in temperate regions may be especially significant in the summer. This is primarily a result of stratification of the water column and higher water temperatures and metabolic rates during summer months (Deegan and Buchsbaum 2005).

### *Siltation, sedimentation, and turbidity*

Municipal sewage outfalls, especially those that release untreated effluent from storm drains, can release suspended sediments into the water column and the adjacent benthic habitat. Increased suspended particles within aquatic habitats can cause elevated turbidity levels, reduced light transmittance, and increased sedimentation of benthic habitat which may lead to the loss of SAV, shellfish beds, and other productive fishery habitats. Other affects from elevated suspended particles include respiration disruption of fishes, reduction in filtering efficiencies and respiration of invertebrates, disruption of ichthyoplankton development, reduction of growth and survival of filter feeders, and decreased foraging efficiency of sight-feeders (Messieh et al. 1991; Barr 1993).

### *Introduction of pathogens*

Pathogens are generally a concern to human health because of consumption of contaminated shellfish and finfish and exposure at beaches and swimming areas (USEPA 2005). Microorganisms entering aquatic habitats in sewage effluents do pose some level of biological risk since they have been shown to infect marine mammals (Oliveri 1982; Bossart et al. 1990; Islam and Tanaka 2004). The degree to which anthropogenically-derived microbes may affect fish, shellfish, and other aquatic taxa remains an important research topic; however, some recently published observations concerning groundfish populations near the Boston sewage outfall into Massachusetts Bay are suggesting that appropriate management practices may address at least part of this risk (Moore et al. 2005). See also the chapters on Coastal Development and Introduced/Nuisance Species and Aquaculture for more information on the introduction of pathogens.

### *Introduction of harmful algal blooms*

Sewage treatment facilities releasing effluent with a high BOD that may enter estuarine and coastal habitats have been associated with harmful algal bloom events, which can deplete the oxygen in the water during bacterial degradation of algal tissue and result in hypoxic or anoxic "dead zones" and large-scale fish kills (Deegan and Buchsbaum 2005). There is evidence that nutrient overenrichment has led to increased incidence, extent, and persistence of nuisance and/or noxious or toxic species of phytoplankton; increased frequency, severity, spatial extent, and persistence of hypoxia; alterations in the dominant phytoplankton species and size compositions; and greatly increased turbidity of surface waters from plankton algae (O'Reilly 1994).

Algal blooms may also contain species of phytoplankton such as dinoflagellates that produce toxins. Toxic algal blooms, such as red tides, can decimate large numbers of fish, contaminate shellfish beds, and cause health problems in humans. Shellfish sequester toxins from the algae and become dangerous to consume. Toxic algal blooms could increase in the future because many coastal and estuarine areas are currently moderately to severely eutrophic (Goldburg and Triplett 1997). Heavily developed watersheds tend to have reduced stormwater storage capacity, and the high flow velocity and pulse of contaminants from freshwater systems can have long-term, cumulative impacts to estuarine and marine ecosystems. Some naturally occurring microorganisms, such as bacteria from the genus, *Vibrio*, or the dinoflagellate, *Pfiesteria*, can produce blooms that release toxins capable of harming fish and possibly human health under certain conditions (Buck et al. 1997; Shumway and Kraeuter 2000). Although the factors leading to the formation of blooms for these species will require additional research, nutrient enrichment of coastal waters is suspected to play a role (Buck et al. 1997). See also the chapter on Introduced/Nuisance Species and Aquaculture for more information on harmful algal blooms.

### *Impacts to benthic habitat*

As discussed above, treated sewage effluent containing high concentrations of nutrients can lead to severely eutrophic conditions that can reduce or eliminate SAV beds (Goldsborough 1997). In addition, municipal sewage outfalls can release suspended sediments into the water column and the adjacent benthic habitat. Increased suspended particles within aquatic habitat can cause elevated turbidity levels, reduced light transmittance, which may lead to the reduction or loss of SAV, shellfish beds and other productive benthic habitats.

### *Changes in species composition*

Treated sewage effluent can contain, at various concentrations, nutrients, toxic chemicals, and pathogens that can affect the health, survival, and reproduction of aquatic organisms. These effects may lead to alterations in the composition of species inhabiting coastal aquatic habitats and can result in community and trophic level changes (Kennish 1998). For example, highly eutrophic water bodies have been found to contain exaggerated phytoplankton and macroalgal populations that can lead to harmful algal blooms (Anderson et al. 2002). Sewage treatment facilities may initially attract fish around the point of discharge until hypoxia, toxin production, and algal bloom development render the aquatic area less productive (Islam and Tanaka 2004). Reduced light penetration in the water column from nutrient enrichment and sedimentation has been shown to contribute to the loss of eelgrass beds in coastal estuaries in southern Massachusetts, Long Island Sound, and the Chesapeake Bay (Goldsborough 1997; Deegan and Buchsbaum 2005).

### *Contaminant bioaccumulation and biomagnification*

Sewage discharges can contain metals and other substances known to be toxic to marine organisms. Not surprisingly, the bays and estuaries of highly industrialized urban areas in northeastern US coastal areas, such as Boston Harbor, Portsmouth Harbor, NH/ME, Newark Bay,NJ, western Long Island Sound, and New York Harbor, have shown relatively high metal burdens in sampled sediments (Larsen 1992; Kennish 1998; USEPA 2004a). While industrial outfalls are responsible for metal contamination in some areas, sewage has been identified as one of the primary sources. For example, although lead contamination in coastal sediments can originate from a variety of sources, sewage is believed to be the primary source of silver contamination (Buchholtz ten Brink et al. 1996). Metals may move upward through trophic levels and accumulate in fish and some invertebrates (bioaccumulation) at levels which can eventually cause health problems in human consumers (Kennish 1998; NEFMC 1998). Other chemicals are known to bioaccumulate and biomagnify in the ecosystem, including pesticides (e.g., DDT) and PCB congeners (Kennish 1998). The National Coastal Condition Report (USEPA 2004a) reported that after metals, PCB congeners and DDT metabolites were responsible for most of the contaminant criteria exceedances in northeast coast samples. For example, sediment samples collected by NOAA's National Status and Trends (NS&T) Program found in some samples very high concentrations of chlorinated hydrocarbons such as PCBs, pesticides, and dioxins from the lower Passaic River, NJ, and Newark Bay in the Hudson-Raritan estuary (Long ER et al. 1995). Other locations in this estuary containing moderately to highly toxic samples in the NS&T Program included Arthur Kill, NY/NJ, and East River, NY.

### *Release of pharmaceuticals*

Concerns have been emerging over the past few years regarding the continual exposure of aquatic organisms to the complex spectrum of active ingredients in pharmaceuticals and personal care products (PPCP), which can persist in treated effluent from sewage facilities. PPCPs comprise thousands of chemical substances, including prescription and over-the-counter therapeutic drugs, veterinary drugs, fragrances, lotions, and cosmetics (Daughton and Ternes 1999; USEPA 2007). The concentrations of PPCP in the aquatic environment are generally detected in the range of parts per thousand to parts per billion and may not pose an acute risk. However, aquatic organisms may be adversely affected because they can have continual and multigenerational exposures, exposures at high concentrations from untreated water, and they may have low dose effects (Daughton and Ternes 1999; USEPA 2007). Some of these PPCPs include steroid compounds, which may act as endocrine disruptors by mimicking the functions of sex hormones (refer to the subsection below for more information on endocrine disruptors). The effects of antibiotics and antimicrobial drugs on aquatic organisms are also of concern. Although population level effects on aquatic organisms from PPCPs are inconclusive at this time, the growing evidence on this topic suggests further investigation is warranted.

### *Endocrine disruptors*

Another recent topic of concern involves a group of chemicals, called "endocrine disruptors," which interfere with the endocrine system of aquatic organisms. Growing concerns have mounted in response to the effects of endocrine-disrupting chemicals on humans, fish, and wildlife (Kavlock et al. 1996; Kavlock and Ankley 1996). These chemicals act as "environmental hormones" that may mimic the function of the sex hormones androgen and estrogen (Thurberg and Gould 2005). Adverse effects include reduced or altered reproductive functions, which could result in population-level impacts. Several studies have implicated endocrine-disrupting chemicals with the presence of elevated levels of vitellogellin in male fish, a yolk precursor protein that is normally only found in mature female fish (Thurberg and Gould 2005). Some of the chemicals shown to be estrogenic include PCB congeners, dieldrin, DDT, phthalates, and alkylphenols (Thurberg and Gould 2005), which have had or still have applications in agriculture and may be present in irrigation water and storm water runoff. Metals have also been implicated in disrupting endocrine secretions of marine organisms, potentially disrupting natural biotic processes (Brodeur et al. 1997).

In summary, the chemical implications of sewage treatment plant effluents vary as a function of the effort taken to remove organic and inorganic contaminants collected by the wastewater treatment plant. Further complicating matters, while secondary treatment is the minimal acceptable standard treatment process in the northeastern United States, inadequately treated or even raw wastewater containing human sewage and attendant debris routinely passes into the aquatic environment from municipal processing plant outfalls when the flow and/or storage demands exceed design specifications. Such releases are commonly experienced when older sewer systems are inundated, particularly in conjunction with storm events. Accordingly, the types of treatment processes implemented, how effectively the wastewater treatment infrastructure is operating, and the salinity of the receiving waters (to the extent that it influences contaminant chemistry) are critical variables when considering the chemical implications of releasing treated wastewater into the aquatic environment.

### *Maintenance activities associated with sewage discharge facilities*

Maintenance activities associated with sewage treatment plants typically involve periodic application of chemicals to treat piping for colonization of biofouling organisms. Efforts to control fouling communities can produce larger field or even chronic disturbances that could adversely affect the aquatic environment. Under some circumstances, chemical treatments are not necessary and fouling communities may be removed mechanically using hot water under pressure. When this type of procedure is implemented, most of the direct impacts are physical. Although the use of pressurized, hot freshwater to mechanically remove fouling organisms may temporarily alter salinity and solute loads, some localized indirect thermodynamic effects that alter ambient chemistry could also occur in the dispersal plume until ambient temperature is restored. In addition, differences in the chemical composition of the source and receiving waters would be expected to have at least a minimal effect, particularly when chlorinated water is used to facilitate the removal of fouling organisms and when there is a significant difference in salinity between cleaning and receiving waters. Perhaps more typically, colonization of fouling communities is controlled through periodic use of antifouling paints, coatings, or other treatments. When conducted inappropriately, periodic applications of these substances can have chronic and potentially harmful effects in the aquatic environment.

Fortunately, application of biocides in aquatic systems is regulated under the CWA, which includes provisions to protect fishes and many invertebrate species to the extent practicable. Since local salinity ranges and diffusion rates at the outfall are important considerations in terms of eventual dispersion and relative toxicity of outfall maintenance materials, these and similar site-specific considerations often dictate which products may be used safely at a given project site. It is vital that only products designed and federally approved for use in and near aquatic habitats are deliberately allowed to enter US waterways under any circumstances.

In general, the most deleterious effects of sewage outfall maintenance probably revolve around fouling community control measures. That is because the underlying intent of such practices is to remove a large variety of plant, animal, and even bacterial populations from inhabiting the area surrounding the outfall. Biocide applications control undesirable organisms by chemical or biological means (Knight and Cooke 2002). Whether removed chemically or mechanically, the loss of these organisms at least initially may result in other forms of local ecological disturbance, such as reduced productivity and diminished prey and cover (Meffe and Carroll 1997). While outfall maintenance events individually result in an acute chemical impact to the environment and biota, it is important also to consider the cumulative effects of repeated applications over a project's maintenance cycle. Especially when undertaken regularly, the maintenance of outfall structures can create a chronic cycle of disturbance on resident biota, particularly sessile organisms.

Individual biocides and other contaminants released during outfall maintenance operations may have direct effects on local aquatic biota or they may act in an additive, synergistic, or antagonistic manner in concert with ambient physical and chemical habitat conditions. Such exposure to organic and inorganic pollutants may result in a spectrum of lethal and sublethal effects that may be discerned at every level of biological organization (Thurberg and Gould 2005). Wide distribution of contaminants, such as biocides and related outfall maintenance substances, can be facilitated through bioaccumulation in motile aquatic organisms that are capable of dispersing between riverine, estuarine, and marine habitats (Mearns et al. 1991). The pollutant-induced effects these substances engender are not limited to biochemical or physiological responses, as they may also disrupt a variety of complex behaviors which may be essential for maintaining fitness and survival (Atchison et al. 1987; Blaxter and Hallers-Tjabbes 1992; Kasumyan 2001; Scott and Sloman 2004).

In addition to measures to control fouling organisms in wastewater treatment facilities, maintenance activities also involve repairs and enhancements of structures associated with the facilities' infrastructure. Because they typically are undertaken on a relatively small scale, physical repairs of existing infrastructure usually produce impacts of lesser intensity and on a more limited spatial scale than those created during initial installation. In contrast, application of antifouling coatings or related treatments not only discourages settlement by aquatic organisms on the treated surface, but also releases biocide into the aquatic environment (Richardson 1997; Terlizzi et al. 2001). Depending on the individual case, such releases can range from very limited to extensive plumes, as measured by the volume of material emitted, and the distance broadcast away from the point source the substance may be detected in the water column.

Collectively, such releases degrade local water quality. Fortunately, chemical effects of sewage outfall maintenance in lotic coastal systems generally would be expected to dissipate relatively quickly because of dispersion by river flow or tidal action. For health and aesthetic reasons, municipal sewage outfalls should not be sited in quiescent waters. In addition, government-established protocols for biological control agents approved for applications in subaqueous discharges generally are applied in isolation within a capped pipe and are subsequently released after sufficient time has passed for the biocide properties to have abated, or more rarely after the bulk of the treating solution is siphoned off and dealt with offsite. Typically, such biocide solutions are designed to decompose into relatively benign constituent forms within hours and, when used properly, are thought not to pose a significant risk to nontarget organisms (Diderich 2002).

As is the case for initial outfall installation impacts, a variety of chemical and biological factors determine the extent to which the polluting substance affects the water column, sediments, and biota and the distance it migrates from the point source. Among them, salinity and carbonate alkalinity (i.e., carbonic acid and bicarbonate ion content) are especially important because of their respective roles in mediating chemical reactions in solution and in conferring the buffering capacity provided by marine and estuarine waters. Carbonate alkalinity, or water hardness, is an especially important property in riverine systems because the ambient carbonate concentrations regulate acid-base chemistry and other water quality parameters, which are thought to be important factors in the recovery of depleted salmonid populations in Maine (Johnson and Kahl 2005). While salmonids are particularly sensitive to degraded water quality, poor water quality is known to affect a wide variety of aquatic organisms (Tessier et al. 1984; Scott and Sloman 2004; Moore et al. 2005; Thurberg and Gould 2005).

### *Construction impacts associated with sewage discharge facilities*

The construction of municipal wastewater outfalls can have chemical effects that result from a number of activities, including releasing suspended sediments and associated pore-water in the construction zone; releasing drill mud or cuttings from a directional drilling operation; discharging substances from mechanized equipment (e.g., incidental discharges of hydrocarbons or hydraulic fluid); and introducing leachate from fresh and curing concrete, antifouling paints, and other construction materials. Contaminants initially reside in aquatic systems in either a dissolved phase in the water column or in a particulate phase when they have adsorbed onto sediments or other solids. Pollutants present in biologically-available forms subsequently become assimilated by aquatic biota and become biomagnified as they are taken up in successive trophic strata (Levinton 1982; Sigel and Sigel 2001).

While plume and sedimentation effects incidental to outfall construction do not always result in a readily observable ecological response, they commonly produce a range of direct and indirect effects to living aquatic resources and their habitats. Not all of the ecological implications of sediment resuspension and transport result in adverse effects to aquatic organisms (Blaber and Blaber 1980). These effects vary a great deal depending on which life history stages are affected (Wilber and Clarke 2001). As a general rule, however, the severity of adverse chemical effects tends to be greatest for early life stages and for adults of some highly sensitive species (Newcombe and Jensen 1996). In particular, predictive models of dose-response relationships corroborate that the eggs and larvae of nonsalmonid estuarine fishes exhibit some of the most sensitive responses to suspended sediment exposures of all the taxa and life history stages for which data are available (Wilber and Clarke 2001). Mitigative measures that limit the nature and extent of chemical impacts arising from outfall installation typically can and should be undertaken to avoid and minimize adverse construction effects.

From the standpoint of water quality, most chemical effects associated with outfall construction should be relatively acute and transitory. Adverse water quality impacts arising from outfall installation generally arise as a consequence of: (1) substances that have adsorbed onto resuspended particles; (2) pollutants that have dissolved or leached into the water column; or (3) contaminants that have been released directly by construction equipment. These pollutants may include substances that lead to nutrient enrichment; they may be chemically reduced; they may exhibit acidic or caustic properties; they may contain organometallic complexes or a variety of other natural or synthetic compounds; they may be hydrophobic or hydrophilic; or they otherwise may exhibit a diverse spectrum of chemical properties that affect their relative toxicity and dispersal in the water column.

While various physical, chemical, and biological factors come into play, the area into which such water quality impacts extend is largely dependent upon the length of time particles and solutes are held in the water column and the distance they are transported from the construction site. Grain size and ambient sediment structure characteristics have an important bearing on dispersal. As benthic material is disturbed during outfall installation and site preparation, resuspended particulate matter would settle predominantly in the immediate project vicinity. Remaining waterborne fractions subsequently would be transported over a distance and direction that are related to the grain size of disturbed sediments, the velocity of local water currents, and local wave action (Neumann and Pierson 1966). Contaminants mobilized in and subsequently deposited by the dispersal plume generated by construction activities are subject to complex biogeochemical processes that ultimately dictate their fate and ecological effects. For example, hydrogen sulfide released with pore-water from disturbed sediments depletes dissolved oxygen and results in locally hypoxic or anoxic conditions in the water column until the area engulfed within the dispersal plume becomes reoxygenated.

While important, it is essential to recognize that local sediment characteristics alone do not determine contaminant introduction or resuspension during outfall installation. The type of construction equipment used to build an outfall structure also has an important influence on the dispersion of disturbed bottom material. For traditional clamshell dredging, Tavolaro (1984) estimates a 2% loss of material through sediment resuspension at the dredge site. It is reasonable to conclude that similar losses would accrue when clamshells are used to install outfall pipes for sewage treatment facilities. In the same way, dredging methods that purposely fluidize sediments to facilitate their removal (e.g., hydraulic dredges, water jets) could result in even greater dispersion of resuspended sediment, especially when local waters are not quiescent or in situations where unfiltered return flow to the waterway is permitted. Since fine depositional sediments tend to have greater contaminant loads than do coarser sediments typical of higher energy areas, the chemical consequences of resuspending fine sediments during outfall installation are potentially greater since they are more likely to be associated with pollutants.

Likewise, water quality implications of outfall construction are not limited to sediment resuspension or releasing pore-water that contains hydrogen sulfide. Secondary vectors of chemical contamination during outfall installation include substances introduced into aquatic habitats by construction equipment and materials. Mechanized construction equipment may inadvertently or incidentally release a broad spectrum of chemicals, fuels, and lubricants into the waterway. Similarly, until the building material has completely cured or has leached out soluble contaminant fractions, subaqueous applications of wet concrete or grout, treated timber products, paints, and other construction materials would all potentially introduce pollutants into the surrounding water.

The chemical implications of constructing municipal outfalls to local substrates ultimately depend on whether (and to what extent) contaminants are released, become associated with, and accumulate in, sediments and surrounding pore-water. While sediment particles naturally exhibit cycles of exchange between the water column and bottom substrate materials (Turner and Millward 2002), dredging or outfall installation can be expected to disturb much deeper sediment horizons in a short period of time than would be expected from storms or in all but the most highly erosion prone coastal areas. As construction equipment disrupts sediment horizons at the project site, some fraction of the benthic substrate becomes resuspended into the water column (Tavolaro 1984).

Outfall construction for sewage treatment facilities can create measurable adverse impacts within the disturbed footprint, including the disruption of ambient sediment stratigraphy, cohesiveness, and geochemistry. These effects have geochemical consequences that may be particularly significant when construction activities are located in depositional or nutrient-enriched areas and where local sediments tend to be fine-grained and contain at least moderate levels of pollution. Regardless of the nature and concentration of substances adsorbed onto the sediment or sequestered in the pore-water, salinity may significantly affect local aqueous conditions, sedimentary geochemistry, and resulting ecological effects.

While it is critical to consider the impacts of outfall construction on physical habitat features, implications for resident and transitory biota also should be taken into account. Excavation and relocation of sediments, which may be performed incidental to outfall installation, would produce a sediment plume and create sedimentation effects that could result in detrimental effects on aquatic resources present in the affected area (Newcombe and Jensen 1996; Wilber and Clarke 2001; Berry et al. 2003; Wilber et al. 2005). Direct and indirect impacts related to the removal of benthic material can elicit a variety of responses from aquatic biota (Wilber and Clarke 2001) which have been addressed elsewhere in this report.

While many potential construction impacts clearly are physical in nature, the chemical effects are complex and may have important implications for biota present in the affected area. In addition to the physicochemical considerations already discussed above, the life history and ecological strategies characteristic of different species also are important considerations in assessing the potential chemical impacts of outfall installation. For instance, while highly motile adult and fish in juvenile life stages of most species could flee when construction is ongoing, those in egg and larval stages and nonmotile benthic organisms could not escape contaminant exposure. While some species like the sessile life stages of eastern oyster (*Crassostrea virginica*) have adapted to withstand some acute habitat disturbances (Galtsoff 1964; Levinton 1982), most benthic and slow-moving species would not be able to escape contaminant exposure and instead would exhibit adaptive physiological and biochemical responses to counter any pollutants present.

Contaminants released during outfall installation activities may have direct effects on local aquatic biota or they may act in an additive, synergistic, or antagonistic manner in concert with ambient physical and chemical habitat conditions. Such exposure to organic and inorganic pollutants may result in a spectrum of lethal and sublethal effects that can be discerned at the organismal, tissue, cellular, and subcellular levels of biological organization (Thurberg and Gould 2005). Wide distribution of contaminants can be facilitated through bioaccumulation in motile aquatic organisms that are capable of dispersing between riverine, estuarine, and marine habitats (Mearns et al. 1991).

Importantly, pollutant-induced effects are not limited to biochemical or physiological responses. Environmental pollutants such as metals, pesticides, and other organic compounds also have been shown to disrupt a variety of complex fish behaviors, some of which may be essential for maintaining fitness and survival (Atchison et al. 1987; Blaxter and Hallers-Tjabbes 1992; Kasumyan 2001; Scott and Sloman 2004). In particular, Kasumyan (2001) provided an excellent review of how chemical pollutants interfere with normal fish foraging behavior and chemoreception physiology, while Scott and Sloman (2004) have focused on the ways metals and organic pollutants have been shown to induce behavioral and physiological effects on fresh water and marine fishes.

## Industrial Discharge Facilities

### *Introduction*

Industrial wastewater facilities face many of the same engineering and environmental challenges as municipal sewage treatment plants. Industrial discharge facilities produce a wide variety of trace elements and organic and inorganic compounds. In the industrialized portions of the northeastern United States, such facilities include a variety of chemical plants, refineries, paper mills, defense factories, energy generating facilities, electroplating firms, mining operations, and many other high intensity industrial uses that generate large volumes of wastewater. In many situations, the sanitary and industrial process streams are intermingled and processed at the industrial facility's own treatment plant, requiring that the eventual effluent is treated to address water quality concerns from a fairly broad spectrum of contaminants. While the procedures involved are similar to those implemented at municipal treatment facilities, the specific levels and methods of wastewater treatment at industrial treatment plants vary considerably. While a detailed description of industrial wastewater engineering is well beyond the scope of this report, readers interested in specific technical information may consult portions of Tchobanoglous et al. (2002) or Perry (1997) for more information.

Like sewage plant outfalls, industrial discharge structures are point sources for a variety of environmental contaminants, particularly metals and other trace elements; nutrients; and persistent organic compounds such as pesticides and organochlorines. These substances tend to adhere to solid particles within the waste stream, become adsorbed onto finer sediment fractions once dispersed into coastal waters, and subsequently accumulate in depositional areas. Together with microbial action, local salinity and other properties of the riverine, estuarine, or marine receiving waters may alter the chemistry of these contaminant-particle complexes in ways that render them more toxic than their parent compounds. Upon entering the food web, such contaminants tend to accumulate in benthic organisms at higher concentrations than in surrounding waters (Stein et al. 1995) and may result in various physiological, biochemical, or behavioral effects (Scott and Sloman 2004; Thurberg and Gould 2005).

### *Release of metals*

Industrial discharge structures can release large volumes of effluent containing a variety of potentially harmful substances into the aquatic environment. Metals and other trace elements are common byproducts of industrial processes and as a consequence are anticipated to be components of typical industrial waste streams that may enter the aquatic environment (Kennish 1998). Metals may be grouped into transitional metals and metalloids. Transitional metals, such as copper, cobalt, iron, and manganese, are essential for metabolic function of organisms at low concentrations but may be toxic at high concentrations. Metalloids, such as arsenic, cadmium, lead, mercury, and tin, are generally not required for metabolic function and may be toxic even at low concentrations (Kennish 1998). Metals are known to produce skeletal deformities and various developmental abnormalities in marine fish (Bodammer 1981; Klein-MacPhee et al. 1984; Lang and Dethlefsen 1987). The early life history stages of fish can be quite susceptible to the toxic impacts associated with metals (Gould et al. 1994).

### *Release of organic compounds*

A variety of synthetic organic compounds are released by industrial facilities, find their way into aquatic environments and can be taken up by resident biota. These compounds are some of the most persistent, ubiquitous, and toxic pollutants known to occur in marine ecosystems (Kennish 1998). Organochlorines, such as DDT, chlordane, and PCBs, are some of the most highly toxic, persistent, and well documented and studied synthetic organic compounds. Others include dioxins and dibenzofurans that are associated with pulp and paper mills and wood treatment plants and have been shown to be carcinogenic and capable of interfering with the development of early development stages of organisms (Kennish 1998). Longwell et al. (1992) determined that dozens of different organic contaminants were present in ripe winter flounder eggs. Such accumulation can reduce egg quality and disrupt ontogenic development in ways that significantly depress survival of young (Islam and Tanaka 2004). Organic contaminants, such as PCBs, have been shown to induce external lesions (Stork 1983) and fin erosion (Sherwood 1982) and reduce reproductive success (Nelson et al. 1991) in marine fishes. In addition, suspicion is mounting that exposure to even very low levels of such persistent xenobiotic (i.e., foreign) compounds may disrupt normal endocrine function and lead to reproductive dysfunction such as reduced fertility, hatch rate, and offspring viability in a variety of vertebrates.

### Release of petroleum products

Oil, characterized as petroleum and any derivatives, consists of thousands of chemical compounds and can be a major stressor on inshore fish habitats (Kennish 1998). Industrial wastewater, as well as combined wastewater from municipal and storm water drains, contributes to the release of oil into coastal waters. Petroleum hydrocarbons can adsorb readily to particulate matter in the water column and accumulate in bottom sediments, where they may be taken up by benthic organisms (Kennish 1998). Petroleum products consist of thousands of chemical compounds that can be toxic to marine life including PAHs and water-soluble compounds, such as benzene, toluene, and xylene, which can be particularly damaging to marine biota because of their extreme toxicity, rapid uptake, and persistence in the environment (Kennish 1998). PAHs can be toxic to meroplankton, ichthyoplankton, and other pelagic life stages exposed to them in the water column (Kennish 1998). Short-term impacts include interference with the reproduction, development, growth, and behavior (e.g., spawning, feeding) of fishes, especially early life-history stages (Gould et al. 1994). Oil has been demonstrated to disrupt the growth of vegetation in estuarine habitats (Lin and Mendelssohn 1996). Although oil is toxic to all marine organisms at high concentrations, certain species are more sensitive than others. In general, the early life stages (eggs and larvae) are most sensitive, juveniles are less sensitive, and adults least so (Rice et al. 2000). Refer to the chapters on Coastal Development, Energy-related Activities, and Marine Transportation for additional information on impacts associated with petroleum products and PAH.

### Alteration of water alkalinity

A major point of departure when comparing municipal sanitary treatment outfall and industrial plant effluents concerns the ability of some industrial discharges to affect carbonate alkalinity, or buffering capacity, of receiving waters. Both riverine and estuarine strata are particularly susceptible to point source acidification because their low buffering capacity can be quickly overwhelmed by acid discharges; however, even marine habitats can be significantly and adversely affected when continual influx of acidified liquid wastewater outstrips the natural buffering capability of seawater. In riverine systems, it has been postulated that locally reduced pH may be linked to impaired Atlantic salmon recovery (Johnson and Kahl 2005) and osmoregulatory problems (NRC 2004). Oulasvirta (1990) reported periodic massive mortalities of Atlantic herring eggs from effluent containing sulfuric acid and various other metals released at a titanium-dioxide plant in the Gulf of Bothnia, Finland. Low pH in estuarine waters may lead to cellular changes in muscle tissues, which could reduce swimming ability in herring (Bahgat et al. 1989). A variety of industrial operations, ranging from mining and metal production to certain industrial manufacturing activities, is known to release acid effluents that may have adverse effects on fish, shellfish, and their habitat. Collectively, such detrimental impacts can hinder the survival and sustainability of fishery resources and their prey. Point source pollution from industrial sources is currently regulated by the states or the US EPA through the NPDES permit program, which generally does not allow discharges of low pH water into estuaries and coastal waters of the United States.

### Release of nutrients and other organic wastes

Industrial facilities that process animal or plant by-products can release effluent with high BOD which may have deleterious affects to receiving waters. Wood processing facilities, paper and pulp mills, and animal tissue rendering plants can release nutrients, reduced sulfur and organic compounds, and other contaminants through wastewater outfall pipes. For example, wood processing plants and pulp mills release effluents with tannins and lignin products containing high organic loads and BOD into aquatic habitats (USFWS and NMFS 1999). The release of these contaminants in mill effluent can reduce dissolved oxygen in the receiving waters. In addition, paper and pulp mills can release a number of toxic chemicals used in the process of bleaching pulp for printing and paper products. The bleaching process may use chlorine, sulfur derivatives, dioxins, furans, resin acids, and other chemicals that are known to be toxic to aquatic organisms (Mercer et al. 1997). These chemicals have been implicated in various abnormalities in fish, including skin and organ tissue lesions, fin necrosis, gill hyperplasia, elevated detoxifying enzymes, impaired liver functions, skeletal deformities, increased incidence of parasites, disruption of the immune system, presence of tumors, and impaired growth and reproduction (Barker et al. 1994; Mercer et al. 1997). Because of concern about the release of dioxins and other contaminants, considerable improvements in the bleaching process have reduced or eliminated the use of elemental chlorine. According to the US EPA, all pulp and nearly all paper mills in the United States have chemical recovery systems in place and primary and secondary wastewater treatment systems installed to remove particulates and BOD (USEPA 2002). Approximately 96% of all bleached pulp production uses chlorine-free bleaching technologies (USEPA 2002).

### *Construction impacts of industrial discharge facilities*

The chemical impacts associated with constructing an industrial discharge are similar to those described for sewage treatment outfalls. Generally, such discharges predominantly entail suspending sediments and releasing pore-water in the construction zone, releasing drill mud or cuttings from horizontal directional drilling equipment, incidental discharges of fuels, lubricants and other substances from mechanized construction equipment, and leachates from construction materials. Since the substances encountered and circumstances of exposure would be the same regardless of the type of outfall being installed, the Construction Impacts Associated with Sewage Discharge Facilities subsection of this chapter should be reviewed for details regarding the impacts to the water column, sediment, and aquatic biota from the construction of industrial discharge facilities.

### *Maintenance impacts of industrial discharge facilities*

The chemical impacts of maintaining industrial discharge facilities are similar to those described for sewage treatment facilities. Generally, the impacts of performing structural repairs are expected to be similar to those experienced during initial outfall installation, but on a lesser scope and magnitude. Impacts associated with the removal and treatment of fouling communities would be similar to those described for the maintenance activities of sewage treatment facilities. The reader should review the previous subsection on Maintenance Activities Associated with Sewage Discharge Facilities for details on the implications of outfall maintenance on the water column, sediment, and aquatic biota.

## Combined Sewer Overflow (CSO)

The discussion of point source discharges would be incomplete without mention of CSOs, which are ubiquitous in urban and even suburban areas in New England and the Mid-Atlantic region. For a variety of reasons, many of these municipalities operate wastewater collection systems composed of “separate” and “combined” sewers. “Separate” sewers tend to be newer or replacement installations that have distinct piping components for stormwater and sanitary sewers.

Under storm or other high runoff conditions, the separate sewer system allows excess volumes of storm water to bypass sewage treatment facilities and discharge directly into the receiving water body constraining all sanitary waste to processing at the wastewater treatment plant. This prevents the excess volume of watershed runoff from overwhelming the operating capacity of the treatment facilities. Older systems tend to be "combined" sewer systems that commingle watershed runoff and sanitary waste streams.

Typical CSOs do not discharge effluent under dry conditions but may permit unprocessed sewage under high runoff events to enter the receiving waters completely or partially untreated. This occurs when large volumes of storm water and sewage overwhelm the treatment plant and untreated sewage is discharged prematurely. Some CSO discharges violate state and/or federal water quality standards, and each municipality must develop a plan to control and eliminate these CSOs. There is no precise estimate on the number of CSOs that exist or on how much untreated sewage is discharged from them each year. However, 828 separate NPDES permits were issued by the US EPA in 2004. There were a total 9,348 authorized discharges from CSOs nationally in 2004, with approximately one half located in the northeastern United States and the remaining half in the Great Lakes region (USEPA 2002; USEPA 2004b).

The chemical implications of CSOs are that they are potential sources of very large amounts of untreated nutrients and contaminating chemicals that degrade both the aesthetic and ecological conditions of affected habitats. In addition to the adverse effects mentioned for the other outfall types, CSOs can be important point sources for pesticides, herbicides, fertilizers, and other substances commonly applied to terrestrial habitats, ranging from rural farmland and suburban yards or golf courses to highly urbanized centers. In addition, they are sources of terrestrial particulates and may be a secondary source of atmospherically-deposited pollutants that have settled anywhere in the local watershed. While impacts associated with nonpoint sources are discussed elsewhere in this report, the sanitary sewer component of CSO effluents can be construed as an extension of the preceding discussions for municipal and industrial outfalls. The net effect of permitting untreated domestic wastewater to enter the receiving waterway is to diminish the effectiveness of wastewater treatment elsewhere. In so doing, CSOs contribute to increased pollution levels and related natural resource impairments. It is not possible to measure the resulting habitat damage and accompanying aquatic resource degradation in isolation from nonpoint pollution. However, it is important that resource managers consider that CSO discharges can and will occur and account for the added pollutant loads they generate when setting permissible local effluent limits or establishing priorities for replacing outmoded urban infrastructure.

### *Construction and maintenance impacts of CSOs*

The chemical impacts associated with construction and maintenance activities in CSOs are similar to those described for sewage treatment and industrial discharge facilities. Generally, discharges associated with construction activities may include releasing contaminants associated with suspended sediments, releasing pore-water and drill mud or cuttings from directional drilling, discharges of fuels, lubricants, and other substances from construction equipment. Maintenance activities may include the removal and treatment of fouling communities and releases of contaminants similar to those described above. The reader should refer to the Construction Impacts Associated with Sewage Discharge Facilities and the Maintenance Activities Associated with Sewage Discharge Facilities subsections of this chapter for additional information on this topic.

### *Conservation measures and best management practices for sewage and industrial discharge facilities and CSOs (adapted from Hanson et al. 2003)*

1. Locate discharge points in coastal waters well away from shellfish beds, submerged aquatic vegetation, reefs, fish spawning grounds, and similar fragile and productive habitats.
2. Determine benthic productivity by sampling prior to any construction activity related to installation of new or modified facilities. Implement all appropriate best management practices to maintain habitat quality during construction including any seasonal restrictions, use of cofferdams, working in the dry at low tide, etc., as is necessary and practicable.
3. Use seasonal restrictions during construction and maintenance operations to avoid impacts to habitat during species' critical life history stages (e.g., spawning and egg development periods), when appropriate. Recommended seasonal work windows are generally specific to regional or watershed-level environmental conditions and species requirements.
4. Develop appropriate modeling studies for plume effects and other parameters of concern in cooperation with the involved resource agencies before finalizing outfall design. Any appropriate recommendations that involve agencies and developed as a consequence of the study results should be incorporated in the construction plans and operation plan for these facilities as enforceable permit conditions.
5. Institute all appropriate source control measures and/or elevate the treatment level to reduce the polluting substances in all effluents to the extent practicable. Ensure that discharge facilities obtain and adhere to NPDES program permits, as appropriate.
6. Ensure that maximum permissible discharges are appropriate for the given project setting and specify any and all operation procedures, performance standards, or best management practices that must be observed to address all reasonably foreseeable contingencies over the life of the project. Consider implementing an adaptive management plan that includes representatives from appropriate agencies to participate in future consultations for administering the management plan. Management plans should include monitoring protocols designed to measure discharge and potential impacts to sensitive resources and habitats.
7. Use best available technologies to treat discharges to the maximal effective and practicable extent, including measures that reduce discharges of biocides and other toxic substances.
8. Take precautions to mitigate the ecological damage arising from outfall maintenance activities. Facility maintenance plans should include measures such as: (a) ensuring biocides selected for a particular application are specifically designed for their intended use; (b) applying no more than the minimal effective dose, and; (c) closely following instructions for use in aquatic applications and ultimate disposal.
9. Use land treatment and upland disposal or storage for any sludge or other remaining wastes after wastewater processing is concluded. Use of vegetated wetlands as biofilters and pollutant assimilators for large-scale discharges should be limited only to circumstances where other less damaging alternatives are not available and the overall environmental suitability of such an action has been demonstrated.
10. Avoid locating pipelines and treatment facilities in wetlands and streams. Discharges should not be sited near eroding waterfronts or where receiving waters cannot reasonably assimilate the amount of anticipated discharge.
11. Ensure that the design capacity for all facilities will address present and reasonably foreseeable needs and that the best available technologies are implemented.
12. Encourage communities to reduce the volume of pollutants entering CSOs and reduce the number of CSO overflows during storm water runoff producing events. The US EPA provides recommended best management practices for communities (USEPA 1999), including: (a) reduce

and manage solid wastes streams; (b) encourage waste reduction and recycling; (c) reduce commercial and industrial pollution; (d) implement regular program of street cleaning; (e) maintain catch basins; (f) conserve water; (g) reduce unnecessary fertilizer and pesticide applications and; (h) control sediment and erosion.

# CHAPTER EIGHT: PHYSICAL EFFECTS—WATER INTAKE AND DISCHARGE FACILITIES

## Introduction

Water intake and discharge facilities are typically municipal or industrial operations that use water for some processing purpose and/or release effluent water into the aquatic environment. Increased water diversion is associated with human population growth and development (Gregory and Bisson 1997). Some examples of facilities that use and discharge water include fossil-fuel and nuclear power plants, sewage treatment facilities, industrial manufacturing facilities, and domestic and agricultural water supply facilities. The construction and operation of water intake and discharge facilities can have a wide range of physical effects on the aquatic environment including changes in the substrate and sediments, water quality and quantity, habitat quality, and hydrology. Most facilities that use water depend upon freshwater or water with very low salinity for their needs. Reductions in the quality and quantity of freshwater to bays and estuaries have led to serious damage to estuaries in the northeast US region and worldwide (Deegan and Buchsbaum 2005). This chapter discusses the physical impacts associated with water discharge and intake facilities. Refer to the chapter on Chemical Affects: Water Discharge Facilities for information on chemical impacts.

## Intake Facilities

### *Introduction*

Water intake facilities can be located in riverine, estuarine, and marine environments and can include domestic water supply facilities, irrigation systems for agriculture, power plants, and industrial process users. Nearly half of US water withdrawals are attributed to thermoelectric power facilities, and about one-third are used for agriculture irrigation (Markham 2006). In freshwater riverine systems, water withdrawal for commercial and domestic water use supports the needs of homes, farms, and industries that require a constant supply of water. Freshwater is diverted directly from lakes, streams, and rivers by means of pumping facilities or is stored in impoundments or reservoirs. Water withdrawn from estuarine and marine environments may be used to cool coastal power generating stations, as a source of water for agricultural purposes, and more recently, as a source of domestic water through desalinization facilities. In the case of power plants and desalinization plants, the subsequent discharge of water with temperatures higher than ambient levels can also occur.

Water intake structures can interfere or disrupt ecosystem functions in the source waters, as well as downstream water bodies such as estuaries and bays. The volume and the timing of freshwater delivery to estuaries have been substantially altered by the production of hydropower, domestic and industrial use, and agriculture (Deegan and Buchsbaum 2005). Long-term water withdrawal may adversely affect fish and shellfish populations by adding another source of mortality to the early life-stage, which affects recruitment and year-class strength (Travnichek et al. 1993). Water intake structures can result in adverse impacts to aquatic resources in a number of ways, including: (1) entrainment and impingement of fishes and invertebrates; (2) alteration of natural flow rates and hydroperiod; (3) degradation of shoreline and riparian habitats; and (4) alteration of aquatic community structure and diversity.

### *Entrainment and impingement*

Entrainment is the voluntary or involuntary movement of aquatic organisms from the parent water body into a surface diversion or through, under, or around screens and results in the loss of the organisms from the population. Impingement is the involuntary contact and entrapment of aquatic organisms on the surface of intake screens caused when the approach velocity exceeds the swimming capability of the organism (WDFW 1998). Most water-intake facilities have the potential to cause entrainment and impingement of some aquatic species when they are located in areas that support those organisms. Facilities that are known to entrain and impinge marine animals include power plants, domestic and agricultural water supplies, industrial manufacturing facilities, ballast water intakes, and hydraulic dredges. Some of these types of facilities need very large volumes and intake rates of water. For example, conventional 1,000-megawatt fossil fuel and nuclear power plants require cooling water rates of approximately 50 and 75 $m^3/s$, respectively (Hanson et al. 1977). Water diversion projects have been identified as a source of fish mortality and injury, and egg and larval stages of aquatic organisms tend to be the most susceptible (Moazzam and Rizvi 1980; NOAA 1994; Richkus and McLean 2000). Entrainment can subject these life stages to adverse conditions such as increased heat, antifouling chemicals, physical abrasion, rapid pressure changes, and other detrimental effects. Although some temperate species of fish are able to tolerate exposure to extreme temperatures for short durations (Brawn 1960; Barker et al. 1981), fish and invertebrates entrained into industrial and municipal water intake structures experience nearly 100% mortality from the combined stresses associated with altered temperatures, toxic effects of chemical exposure, and mechanical and pressure-related injuries (Enright 1977; Hanson et al. 1977; Moazzam and Rizvi 1980; Barker et al. 1981; Richkus and McLean 2000).

Both entrainment and impingement of fish and invertebrates in power plant and other water intake structures have immediate as well as future impacts to the riverine, estuarine, and marine ecosystems. Not only is fish and invertebrate biomass removed from the aquatic system, but the biomass that would have been produced in the future would not become available to predators (Rago 1984). Water intake structures, such as power plants and industrial facilities, are a source of mortality for managed-fishery species and play a role as one of the factors driving changes in species abundance over time (Richkus and McLean 2000).

Various physical impacts to fish traversing low-head, tidal turbines in the Bay of Fundy, Canada, were reported by Dadswell and Rulifson (1994) and included mechanical strikes with turbine blades, shear damage, and pressure- and cavitation-related injuries/mortality. They found 21-46% mortality rates for experimentally tagged American shad (*Alosa sapidissima*) passing through the turbine. NOAA (1994) reported fish diverted into power turbines experience up to 40% mortality, as well as injury, disorientation, and delay of migration. An entrainment and impingment study for a once-through cooling system of an 848-megawatt electric generating plant on the East River (NY) concluded the reduction in biomass of spawners from an unfished stock in the Long Island Sound and New York-New Jersey estuary to be extremely small (i.e., 0.01% for Atlantic menhaden [*Brevoortia tyrannus*] and 0.09% for winter flounder [*Pseudopleuronectes americanus*]) compared to fishing mortality (Heimbuch et al. 2007).

Organisms that are too large to pass through in-plant screening devices become stuck or impinged against the screening device or remain in the forebay sections of the system until they are removed by other means (Hanson et al. 1977; Langford et al. 1978; Helvey 1985; Helvey and Dorn 1987; Moazzam and Rizvi 1980). They are unable to escape because the water flow either pushes them against the screen or prevents them from exiting the intake tunnel. This can cause injuries such as bruising or descaling, as well as direct mortality. The extent of physical damage to organisms is directly related to the duration of impingement, techniques for handling impinged fish, and the intake water velocity (Hanson et al. 1977). Similar to entrainment, the withdrawal of water can entrap particular species, especially when visual acuity is reduced (Helvey 1985) or when the ambient water temperature and the metabolism of individuals are low (Grimes 1975). This condition reduces the suitability of the source waters to provide normal habitat functions necessary for subadult and adult life stages of managed living marine resources and their prey. Increased predation can also occur. Intakes can stress or disorient fish through nonlethal impingement or entrainment in the facility and by creating conditions favoring predators such as larger fish and birds (Hanson et al. 1977; NOAA 1994).

### *Ballast water and vessel operations intake*

Vessels take in and release water in order to maintain proper ballast and stability, which is affected by the variable weight of passengers and cargo and sea conditions. In addition, water is used for cooling engines and other systems. While the discharge of ballast water can cause significant impacts on the aquatic environment, particularly through the introduction of invasive species as discussed below, the intake of water for ballast and vessel cooling can also cause entrainment and impingement impacts on aquatic organisms.

Depending upon the size of the vessel, millions of gallons of water and its associated aquatic life, particularly eggs and larvae, can be transferred to the ballast tanks of a ship at a rate of tens of thousands of gallons per minute. For example, large ships, such as those constructed to transport liquefied natural gas (LNG), need to take on ballast water to stabilize the ship during offloading of the LNG. A 200,000-$m^3$ capacity LNG carrier would withdraw approximately 19.8 million gallons of water over a 10-hour period at an intake rate of 2 million gallons per hour (FERC 2005). The use of water for ballast and vessel cooling at these volumes and rates has the potential to entrain and impinge large numbers of fish eggs and larvae. For example, a proposed offshore LNG degasification facility using a closed-loop system near Gloucester, MA, would have estimated annual mortality of eggs and larvae from vessel ballast and cooling water for Atlantic mackerel (*Scomber scombrus*), pollock (*Pollachius virens*), yellowtail flounder (*Limanda ferruginea*), and Atlantic cod (*Gadus morhua*) of 8.5 million, 7.8 million, 411,000, and 569,000, respectively (USCG 2006). Refer to the chapters on Energy-related Activities and Marine Transportation for additional information on vessel entrainment and impingement impacts.

### *Alteration of hydrological regimes/flow restrictions*

Water withdrawals for industrial or municipal water needs can have a number of physical effects to riverine systems, including altering stream velocity, channel depth and width, turbidity, sediment and nutrient transport characteristics, dissolved oxygen concentrations, and seasonal and diel temperature patterns (Christie et al. 1993; Fajen and Layzer 1993). These physical changes can have ecological impacts, such as a reduction of riparian vegetation that affects the availability of fish habitat and prey (Christie et al. 1993; Fajen and Layzer 1993; Spence et al. 1996). Alteration of freshwater flows is one of the most prevalent problems facing coastal regions and has had profound effects on riverine, estuarine, and marine fisheries (Deegan and Buchsbaum 2005). For example, water in the Ipswich River in Massachusetts has been reduced to 10% of historic natural flows because of increased water withdrawals, such as irrigation water during the growing season, power plant cooling water, and potable water for a growing human population (Bowling and Mackin 2003). Approximately one-half of the 45-mile long Ipswich River was reported to have gone completely dry in 1995, 1997, 1999, and 2002, and nearly one-half of the native fish populations have either been extirpated or severely reduced in size (Bowling and Mackin 2003). Many estuarine and diadromous species, such as American eel (*Anguilla rostrata*), striped bass (*Morone* *saxatilis*), white perch (*Morone americana*), Atlantic herring (*Clupea harengus*), blue crab (*Callinectes sapidus*), American lobster (*Homarus americanus*), Atlantic menhaden (*Brevoortia tyrannus*), cunner (*Tautogolabrus adspersus*), Atlantic tomcod (*Microgadus tomcod*), and rainbow smelt (*Osmerus mordax*), depend upon the development of a counter current flow set up by freshwater discharge to enter estuaries as larvae or early juveniles; reductions in the timing and volume of freshwater entering estuaries can reduce this counter current flow and disrupt larval transport (Deegan and Buchsbaum 2005).

### *Increased need for dredging*

The alteration of the hydrological regimes and reductions in flow in riverine and estuarine systems caused by water intake structures can result in the build-up of sediments and increase the need to dredge around the intake facilities in order to prevent the sediments from negatively affecting the operations of the facility. Dredging can cause direct mortality of the benthic organisms within the area to be dredged, result in turbidity plumes of suspended particulates that can reduce light penetration, interfere with respiration and the ability of site-feeders to capture prey, impede the migration of anadromous fishes, and affect the growth and reproduction of filter feeding organisms. For more detailed discussion on the impacts of dredging, refer to the chapters on Marine Transportation and Offshore Dredging and Disposal Activities.

### *Habitat impacts*

The operation of water intake facilities can have a broad range of adverse effects on fishery habitats, including the conversion and loss of habitat and the alteration of the community structure resulting from changes in the hydrological regimes, salinities, and flow patterns. Large withdrawals of freshwater from riverine systems above the tidal water influence can cause an upstream "relocation" of the salt wedge, altering an area's suitability for some freshwater species and possibly altering benthic community structure. In addition, reductions in the volume of freshwater entering estuaries can alter vertical and longitudinal habitat structure and disrupt larval transport (Deegan and Buchsbaum 2005). Water withdrawals during certain times of the year, such as the use of irrigation water during the growing season of crops, power plant cooling water used during high energy-demand periods, or for domestic water usage during dry, summer months can severely impact the ecological health of riverine systems. For example, the water withdrawal from the Ipswich River in Massachusetts increases by two-fold or more during summer months when natural river flows are lowest (Bowling and Mackin 2003). This has led to one-half of the river going completely dry in some years and has caused fish kills and habitat degradation (Bowling and Mackin 2003).

### *Construction-related impacts*

Impacts to aquatic habitats can result from construction-related activities (e.g., dewatering, dredging) as well as routine operation and maintenance activities for water intake facilities. Generally, these impacts are similar in nature to both water intake and discharge structures and facilities. There is a broad range of impacts associated with these activities depending on the specific design and needs of the system. For example, dredging activities associated with construction of pipelines, bulkheads and seawalls, and buildings for a facility can cause turbidity and sedimentation in nearby waters, degraded water quality, noise, and substrate alterations. Filling of the aquatic habitat may also be needed for the construction of the facilities. Excavation of sediments in subtidal and intertidal habitats during construction may have at least short-term impacts, but the recovery of the aquatic habitat for spawning and egg deposition is uncertain

(Williams and Thom 2001). Many of these impacts can be reduced or eliminated through the use of various techniques, procedures, or technologies such as careful siting of the facility, timing restrictions on in-water work, and the use of directional drilling for the installation of pipelines. Some impacts may not be fully eliminated except by eliminating the activity itself.

Turbidity plume and sedimentation effects incidental to facility construction commonly produce a range of direct and indirect effects to living aquatic resources and their habitats. However, not all of the ecological implications of sediment resuspension and transport result in adverse effects to aquatic organisms (Blaber and Blaber 1980). The life history and ecological strategies characteristic of different species also are important considerations in assessing potential physical impacts from facility installation. For instance, while highly motile adult and juvenile life stages of most fishes could flee when construction is ongoing, egg and larval stages as well as nonmotile benthic organisms will likely not be able to avoid impacts. As a general rule, the severity of adverse effects tends to be greatest for early life stages and for adults of some highly sensitive species (Newcombe and Jensen 1996). The eggs and larvae of nonsalmonid estuarine fishes exhibit some of the most sensitive responses to suspended sediment exposures of all the taxa and life history stages for which data are available (Wilber and Clarke 2001). Reductions in the hatching success of white perch and striped bass eggs were reported at suspended sediment concentrations of 1,000 mg/L, and the survival of striped bass and yellow perch (*Perca flavescens*) larvae were reduced at concentrations greater than 500 mg/L and for American shad larvae at concentrations greater than 100 mg/L (Auld and Schubel 1978). Nelson and Wheeler (1997) found reduced hatching success for winter flounder eggs exposed to suspended sediment concentrations as low as 75 mg/L. While some species like the sessile life stages of eastern oyster (*Crassostrea virginica*) have adapted to withstand some acute habitat disturbances such as sedimentation and turbidity (Galtsoff 1964; Levinton 1982), most benthic and slow-moving species would not be able to escape exposure and instead would exhibit adaptive physiological and biochemical responses to counter adverse effects to water quality.

The area affected by water quality impacts from the construction of a water intake facility is largely dependent on the nature of the resuspended sediments, the duration the sediments are held in the water column, and the factors contributing to the transport of the sediments from the site. As benthic material is disturbed during facility installation and site preparation, resuspended particulate matter settles predominantly in the immediate vicinity of the project. Remaining waterborne fractions subsequently would be transported from the site and dispersed according to the grain size of disturbed sediments, the velocity of local water currents, and local wave action (Neumann and Pierson 1966).

The construction of water intake facilities can create adverse impacts within the immediate vicinity of the construction, including disrupting ambient sediment stratigraphy, cohesiveness, and geochemistry. These effects have geochemical consequences that may be particularly significant when construction activities are located in depositional or nutrient-enriched areas and where local sediments tend to be fine-grained. While important, it is essential to recognize that local sediment composition is not the only factor which affects resuspension during water intake facility installation. The type of construction equipment used to build an intake structure also has an important influence on the dispersion of dredge material. For traditional clamshell dredging, Tavolaro (1984) estimates a 2% loss of material through sediment resuspension at the dredge site. Dredge equipment that fluidizes sediments to facilitate their removal (e.g., hydraulic dredges or water jets) could result in a greater dispersion of resuspended sediment, especially when local waters are not quiescent or in situations where unfiltered return flow to the waterway is permitted. While sediment particles naturally exhibit cycles of exchange between the water column and materials composing the bottom substrate (Turner and Millward 2002), mechanized equipment used to remove sediments can reasonably be expected to disturb much deeper sediment horizons in a short period of time than would be expected from storms or in all but the most highly erosion prone coastal areas.

Additional discussions of the effects of dredging, dredged material disposal, and coastal development can be found in the Marine Transportation, Coastal Development, and Offshore Dredging and Disposal chapters.

### *Conservation measures and best management practices for water intake facilities (adapted from Hanson et al. 2003)*

1. Locate facilities that rely on surface waters for cooling or ballast in areas other than estuaries, inlets, heads of submarine canyons, rock reefs, or small coastal embayments where important fishery species or their prey concentrate for spawning and migration.
2. Design and operate facilities to create flow conditions that provide for passage, water quality, proper timing of life history stages, and properly functioning channel, floodplain, riparian, and estuarine conditions.
3. Establish adequate instream flow conditions for anadromous fish.
4. Design intake structures to minimize entrainment or impingement. Velocity caps that produce horizontal intake/discharge currents should be employed, and intake velocities across the intake screen should generally not exceed 0.5 ft/s.
5. Use closed-loop cooling systems in facilities requiring water whenever practicable, especially in areas that would impinge and entrain large numbers of fish and invertebrates.
6. Screen water diversions on fish-bearing streams, as needed. In general, 2 mm wedge wire screens are recommended on intake facilities in areas that support anadromous fishes.
7. Incorporate juvenile and adult fish passage facilities on all water diversion projects (e.g., fish bypass systems).
8. Assess existing and potential aquatic vegetation, the volume and depth of the water body, the amount and timing of freshwater inflow, the presence of upland rearing and spawning habitat, and the relative salinity of the water body.
9. Assess the hydrology of the regulated land's tolerance for increased water exchange. The assessment should account for active management of the water intake facility to allow increased water exchange during critical periods.
10. Install intake pipes and facilities during low flow periods and tidal stage; incorporate appropriate erosion and sediment control best management practices, and have an equipment spill and containment plan and appropriate materials onsite.
11. Monitor facility operations to assess impacts on water temperatures, dissolved oxygen, and other applicable parameters. Adaptive management should be designed to minimize impacts.

## Discharge Facilities

### *Introduction*

Although there are a number of potential impacts to aquatic resources from point-source discharges, it is important to be aware that not all point-source discharge results in adverse impacts to aquatic organisms or their habitats. Most point-source discharges are regulated by the US Environmental Protection Agency (US EPA) under the National Pollutant Discharge Elimination System (NPDES), and the effects on receiving waters are generally considered under this permitting program. As authorized by the Clean Water Act, the NPDES permit program controls water pollution by regulating point sources that discharge pollutants into waters of the United States.

Industrial, municipal, and other facilities must obtain permits if their discharges go directly into surface waters. In most cases, the NPDES permit program is administered by authorized state agencies.

Point source discharges may modify habitat by creating adverse impacts to sensitive areas such as freshwater, estuarine, and marine wetlands; emergent marshes; and submerged aquatic vegetation beds and shellfish beds. Extreme discharge velocities of effluent may also cause scouring at the discharge point as well as entrain particulates and thereby create turbidity plumes.

### *Habitat conversion and exclusion*

The discharge of effluent from point sources can cause numerous habitat impacts resulting from the changes in sediments, salinities, temperatures, and current patterns. These can include the conversion and loss of habitat as the salinities of estuarine areas decrease from the inflow of large quantities of freshwater or as areas become more saline through the discharge of effluent from desalinization plants. Temperature changes, increased turbidity, and the release of contaminants can also result in the reduced use of an area by marine and estuarine species and their prey and impede the migration of some diadromous fishes. Outfall pipes and their discharges may alter the structure of the habitats that serve as juvenile development habitat, such as eelgrass beds (Williams and Thom 2001). Power plants, for example, release large volumes of water at higher than ambient temperatures, and the area surrounding the discharge pipes may not support a healthy, productive community because of physical and chemical alterations of the habitat (Wilbur and Pentony 1999).

The accumulation of sediments at an outfall may alter the composition and abundance of infaunal or epibenthic invertebrate communities (Ferraro et al. 1991). These accumulated sediments can smother sessile organisms or force mobile animals to migrate from the area. If sediment characteristics are changed drastically at the discharge location, the benthic community composition may be altered permanently. This can lead to reductions in the biological productivity of the habitat at the discharge site for some aquatic resources as their prey species and important habitat types, such as aquatic vegetation, are no longer present. Outfall pipes can act as groins and interrupt sand transport, cause scour around the structures, and convert native sand habitat to larger course sediment or bedrock (Williams and Thom 2001). This can affect the spawning success of diadromous and estuarine species, many of which serve as prey species for other commercially or recreationally important species.

### *Alteration of sediment composition*

As discussed above, outfall pipes and their discharges may alter the composition of sediments that serve as juvenile development habitat through scouring or deposition of dissimilar sediments (Williams and Thom 2001). Outfalls that typically release water at high velocities may scour sediments in the vicinity of the outfall and convert the substrate to course sediments or bedrock. Conversely, outfalls that release water at lower velocities that contain fine grained, silt-laden sediments may accumulate sediments near the outfall and increase the need to dredge to remove sediment buildup (Williams and Thom 2001). This can lead to a change in the community composition because many benthic organisms are sensitive to grain size. The chronic accumulation of sediments can also bury benthic organisms that serve as prey and limit an area's suitability as forage habitat.

### *Substrate and sediment scouring*

The discharge of effluent from point sources can result in a variety of benthic habitat and water quality impacts relating to scouring of substrate and sediments at the discharge point.

Changes to the substrate from scouring may impact benthic invertebrate and shellfish community, as well as submerged aquatic vegetation, such as eelgrass (Williams and Thom 2001).

### *Turbidity and sedimentation effects*

Turbidity plumes of suspended particulates caused by the discharge of effluent, the scouring of the substrate at the discharge point, and even the repeated maintenance dredging of the discharge area can reduce light penetration and lower the rate of photosynthesis and the primary productivity of an aquatic area while elevated turbidity persists. Fish and invertebrates in the immediate area may suffer a wide range of adverse effects, including avoidance and abandonment of the area, reduced feeding ability and growth, impaired respiration, a reduction in egg hatching success, and resistance to disease if high levels of suspended particulates persist (Newcombe and MacDonald 1991; Newcombe and Jensen 1996; Wilber and Clarke 2001). Auld and Schubel (1978) reported reduced egg hatching success in white perch and striped bass at suspended sediment concentrations of 1,000 mg/L. They also found reduced survival of striped bass and yellow perch larvae at concentrations greater than 500 mg/L and for American shad at concentrations greater than 100 mg per liter (Auld and Schubel 1978). Short-term effects associated with an increase in suspended particles may include high turbidity, reduced light, and sedimentation, which may lead to the loss of benthic structure and disrupt overall productivity if elevated levels persist (USFWS and NMFS 1999; Newcombe and Jensen 1996). Other problems associated with suspended solids include reduced water transport rates and filtering efficiency of fishes and invertebrates and decreased foraging efficiency of sight feeders (Messieh et al. 1991; Wilber and Clarke 2001). Breitburg (1988) found the predation rates of striped bass larvae on copepods decreased by 40% when exposed to high turbidity conditions in the laboratory. In riverine habitats, Atlantic salmon (*Salmo salar*) fry and parr find refuge within interstitial spaces provided by gravel and cobble that can be potentially clogged by sediments, subsequently decreasing survivorship (USFWS and NMFS 1999).

### *Increased need for dredging*

The release of sediment from water discharge facilities, as well as increased turbidity and sedimentation resulting from high velocity outfall structures, can lead to a build-up of sediments. Over time this may increase the need to dredge around the discharge facility in order to prevent the sediments from negatively affecting the operations of the facility or interfering with vessel navigation. Dredging can cause direct mortality of the benthic organisms within the area to be dredged, as well as create turbidity plumes of suspended particulates that can reduce light penetration, interfere with respiration and the ability of site-feeders to capture prey, impede the migration of anadromous fishes, and affect the growth and reproduction of filter feeding organisms (Wilber and Clarke 2001). For more detailed discussion on the impacts of dredging, refer to the chapters on Marine Transportation and Offshore Dredging and Disposal Activities.

### *Reduced dissolved oxygen*

The contents of the suspended material can react with the dissolved oxygen in the water and result in oxygen depletion, which can impact submerged aquatic vegetation and benthos in the vicinity. Reduced dissolved oxygen (DO) can cause direct mortality of aquatic organisms or result in subacute effects such as reduced growth and reproductive success. Bejda et al. (1992) found that the growth of juvenile winter flounder was significantly reduced when DO levels were maintained at 2.2 mg/L or when DO varied diurnally between 2.5 and 6.4 mg/L for a period of 11 weeks.

## *Alteration of temperature regimes*

Sources of thermal pollution from water discharge facilities include industrial and power plants. Temperature changes resulting from the release of cooling water from power plants can cause unfavorable conditions for some species while attracting others. Altered temperature regimes have the ability to affect the distribution, growth rates, survival, migration patterns, egg maturation and incubation success, competitive ability, and resistance to parasites, diseases, and pollutants of aquatic organisms (USEPA 2003). Increased water temperatures in the upper strata of the water column can result in water column stratification, which inhibits the diffusion of oxygen into deeper water leading to reduced (hypoxic) or depleted (anoxic) dissolved oxygen concentrations in estuaries (Kennedy et al. 2002). Because warmer water holds less oxygen than colder water does, increased water temperatures reduce the DO concentration in bodies of water that are not well mixed. This may exacerbate nutrient-enrichment and eutrophication conditions that already exist in many estuaries and marine waters in the northeastern United States. In addition, thermal stratification could also affect primary and secondary productivity by suppressing nutrient upwelling and mixing in the upper regions of the water column, potentially altering the composition of phytoplankton and zooplankton. Impacts to the base of the food chain would not only affect fisheries, but could impact entire ecosystems.

Elevated water temperature can alter the normal migration patterns of some species or result in thermal stress and mortality in individuals should the discharges cease during colder months of the year. Thermal effluents in inshore habitat can cause severe problems by directly altering the benthic community or killing marine organisms, especially larval fish. Temperature influences biochemical processes of the environment and the behavior (e.g., migration) and physiology (e.g., metabolism) of marine organisms (Blaxter 1969). Investigations to determine the thermal tolerances of larvae of Atlantic herring, smooth flounder (*Pleuronectes putnami*), and rainbow smelt suggests that these species can tolerate elevated temperatures for short durations which are near the upper limits of cooling systems of most normally operating nuclear power plants (Barker et al. 1981). However, a number of factors affected the survival of larvae, including the salinity the individuals were acclimated to and the age of the larvae.

Long-term thermal discharge may change natural community dynamics. For example, elevated water temperature has been identified as a potential factor contributing to harmful algae blooms (ICES 1991), which can lead to rapid growth of phytoplankton populations and subsequent oxygen depletion, sometimes resulting in fish kills. Some evidence indicates that elevated water temperatures in freshwater streams and rivers in the northeastern United States caused by anthropogenic impacts may be responsible for increased algal growth, which has been suggested as a possible factor in the diminished stocks of rainbow smelt (Moring 2005).

## *Alteration of salinity regimes*

The discharge of water with elevated salinity levels from desalination plants may be a potential source of impacts to fishery resources. Waste brine is either discharged directly to the ocean or passed through sewage treatment plants. Although some studies have found desalination plant effluent to not produce toxic effects in marine organisms (Bay and Greenstein 1994), there may be indirect effects of elevated salinity on estuarine and marine communities, such as forcing juvenile fish into areas that could increase their chances of being preyed upon by other species. Conversely, treated freshwater effluent from municipal wastewater plants can produce localized reductions in salinity and could subject juvenile fish to conditions of less than optimal salinity for growth and development (Hanson et al. 2003).

### *Changes in local current patterns*

In addition to changes in temperature and salinity, local current patterns can be altered by outfall discharges or by the structures themselves. These changes can be related to changes in the rate of sedimentation around the outfall, the volume of water discharged, and the size and location of the structures.

### *Release of radioactive wastes*

Both natural and anthropogenic sources of radionuclides exist in the environment (ICES 1991). Potential sources of anthropogenic radioactive wastes include nonpoint sources, such as storm water runoff and atmospheric sources (e.g., coal-burning power plants) and point sources, such as industrial facilities (e.g., uranium mining and milling fuel lubrication) and nuclear power plant discharges (ICES 1991; NEFMC 1998). Fish exposed to radioactive wastes can accumulate radioisotopes in tissues, causing toxicity to other marine organisms and consumers (ICES 1991). The identification of radioactive wastes from industrial and nuclear power plant discharges was a focus of concern during the 1980s (ICES 1991). However, most studies since then have found trends of decreasing releases of artificial radionuclides from industrial and nuclear power plant discharges and reduced tissue-burdens in sampled fish and shellfish to levels similar to naturally occurring radionuclides (ICES 1991).

### *Ballast water discharges*

Commercial cargo-carrying and recreational vessels are the primary type of vector that transports marine life around the world, some of which become exotic, invasive species that can alter the structure and function of aquatic ecosystems (Valiela 1995; Carlton 2001; Niimi 2004). Ballast water discharges, occurring when ships take on additional cargo while at a port, are one of the largest pathways for the introduction and spread of aquatic nuisance species (ANS). The introduction of ANS can have wide reaching impacts to the aquatic ecosystem, the economy, and human health. Many ANS species are transported and released in ballast in their larval stages, become bottom-dwelling as adults, and include sea anemones, marine worms, barnacles, crabs, snails, clams, mussels, bryozoans, sea squirts, and seaweeds (Carlton 2001). In addition, some species are transported and released as adults, including diatoms, dinoflagellates, copepods, and jellyfish (Carlton 2001). Invasive, exotic species can displace native species and increase competition with native species and can potentially alter nutrient cycling and energy flow leading to cascading and unpredictable ecological effects (Carlton 2001). Additional discussion of the effects of introduced species can be found in the chapters on Introduced/Nuisance Species and Aquaculture and Marine Transportation.

### *Behavioral effects*

Discharge facility effluents have the potential to alter the behavior of riverine, estuarine, and marine species by changing the chemical and physical attributes of the habitat and water column in the vicinity of the outfall. These include attractions to the increase in flow velocity and altered temperature regimes at the discharge point and changes in predator/prey interactions. Changes in temperature regimes can artificially attract species and alter their normal seasonal migration behavior, resulting in cold shock and mortality of fishes when ambient temperatures are colder and the flow of heated water is ceased during a facility shutdown (Pilati 1976). Shorelines physically altered with outfall structures may also disrupt the migratory patterns and pathways of fish and invertebrates (Williams and Thom 2001).

## *Physiological effects*

Point-source discharges can cause a wide range of physiological effects on aquatic resources including both lethal and sublethal effects. Alteration of temperature, salinity, and dissolved oxygen concentration regimes have been shown to effect the normal physiology of marine organisms and can retard or accelerate egg and larval development and time of hatching (Blaxter 1969). Fish subjected to abnormally cold or hot temperatures from water discharges will either leave the affected area or acclimate to the change if it is within the species' thermal tolerance zone (Pilati 1976). However, a sudden change in ambient temperature can cause thermal shock and result in death to the fish, or the thermal shock may debilitate a fish and make it susceptible to predation (Pilati 1976). Temperature plays an important role in determining the survival and fitness of coldwater species, such as Atlantic salmon, and can affect the normal growth and development of eggs and fry (Blaxter 1969; Spence et al. 1996).

Water intake and outfall facilities can also have widespread chemical effects on aquatic organisms. These effects are discussed in the Chemical Effects: Water Discharge Facilities chapter.

## *Construction-related impacts of water discharge facilities*

The physical effects of constructing water discharge facilities can result from a number of activities, including releasing suspended sediments and associated pore-water in the construction zone; removal of bottom sediments and subsequent suspended sediments; turbidity and alteration of benthic habitats from dredging; releasing drill mud or cuttings from a directional drilling operation; and the loss or conversion of the existing benthic habitat and water column from placement of fill pipelines, and shoreline stabilization structures (e.g., riprap, headwalls). The impacts associated with constructing water intake and discharge structures and facilities are similar in nature and have been discussed in more detail in the Intake Facilities section of this chapter.

## *Conservation measures and best management practices for discharge facilities (adapted from Hanson et al. 2003)*

1. Conduct a thorough environmental assessment of proposed site locations for water discharge facilities prior to granting any regulatory permits. The assessments should include detailed investigations on the utilization of the aquatic environment by resident and transient species, including the migratory pathways of marine and diadromous fishes. Physical and chemical parameters of the proposed site should be included, such as sediment and substrate characteristics, hydrological dynamics of tides and currents, and temperature and salinity regimes.
2. Develop outfall design (e.g., modeling concentrations within the predicted plume or likely extent of deposition within the zone of influence) by using site specific, hydrological data with input from appropriate resource agencies.
3. Select appropriate point-source discharge locations by using information on the concentrations of living marine resources based upon site-specific, biological assessments. Sensitive and highly productive areas and habitats, such as shellfish beds, sea grass beds, hardbottom reefs should be avoided. Reduce potentially high velocities by diffusing effluent to acceptable velocities.
4. Regulate discharge temperatures (both heated and cooled effluent) such that they do not appreciably alter ambient temperatures and cause a change in species assemblages and ecosystem function in the receiving waters. Strategies should be implemented to diffuse the heated effluent.

5. Use land-treatment and upland disposal/storage techniques where possible. Use of vegetated wetlands as natural filters and pollutant assimilators for large-scale discharges should be limited to those instances where other less damaging alternatives are not available and the overall environmental and ecological suitability of such an action has been demonstrated.
6. Avoid siting pipelines and treatment facilities in wetlands and streams. Since pipeline routes and treatment facilities should not necessarily be water-dependent with regard to positioning, the priority should be to avoid their placement in wetlands or other fragile coastal habitats. Avoiding placement of pipelines within streambeds and wetlands will also reduce inadvertent infiltration into conveyance systems and retain natural hydrology of local streams and wetlands.
7. Ensure that all discharge water from outfall structures meets state and federal water quality standards. Whenever feasible, discharge pipes should extend a substantial distance offshore and be buried deep enough to not affect shoreline processes. Buildings and associated structures should be set well back from the shoreline to preclude the need for bank armoring.

# CHAPTER NINE: AGRICULTURES AND SILVICULTURE

## Croplands, Rangelands, Livestock, and Nursery Operations

### *Introduction*

Substantial portions of croplands, rangelands, and commercial nursery operations are connected, either directly or indirectly, to coastal waters where point and nonpoint pollution can have an adverse effect on aquatic habitats. According to the US Environmental Protection Agency's (US EPA) 2000 National Water Quality Inventory, agriculture was the most widespread source of pollution for assessed rivers and lakes (USEPA 2002a). In that report, agriculture was responsible for 18% of all river-mile impacts and 14% of all lake-acre impacts in the United States. In addition, 48% of all impaired river miles and 41% of all impaired lake acres were attributed to agriculture (USEPA 2002a). Impacts to fishery habitat from agricultural and nursery operations can result from: (1) nutrient loading; (2) introduction of animal wastes; (3) erosion; (4) introduction of salts; (5) pesticides; (6) sedimentation; and (7) suspended silt in water column (USEPA 2002a).

### *Release of nutrients/eutrophication*

Nutrients in agricultural land are found in several different forms and originate from various sources, including: (1) commercial fertilizers containing nitrogen, phosphorus, potassium, secondary nutrients, and micronutrients; (2) manure from animal production facilities; (3) legumes and crop residues; and (4) irrigation water (USEPA 2002a). In addition, agriculturals land are characterized by poorly maintained dirt roads, ditches, and drains that transport sediments and nutrients directly into surface waters. In many instances, headwater streams have been replaced by a constructed system of roads, ditches, and drains that deliver nutrients directly to surface waters (Larimore and Smith 1963). Worldwide, the production of fertilizers is the largest source of anthropogenic nitrogen mobilization, although atmospheric deposition exceeds fertilizer production as the largest nonpoint source of nitrogen to surface waters in the northeastern United States (Howarth et al. 2002). Human activity is estimated to have increased nitrogen input to the coastal water of the northeastern United States, specifically to Chesapeake Bay, MD/VA, by 6- to 8-fold (Howarth et al. 2002). Castro et al. (2003) estimated that the mid-Atlantic and southeast regions contained between 24-37% agricultural lands, with fertilizers and manure applications representing the highest nitrogen sources for those watersheds. The Pamlico Sound-Pungo River, NC, and Chesapeake Bay estuaries contained the highest percent of nitrogen sources coming from agriculture from the mid-Atlantic region (Castro et al. 2003). The second leading cause of pollution in streams and rivers in Pennsylvania has been attributed to agriculture, primarily nutrient loading and siltation (Markham 2006).

Nitrogen and phosphorus are the two major nutrients from agriculture sources which degrade water quality. The main forces controlling nutrient movement from land to water are runoff, soil infiltration, and erosion. Introduction of these nutrients into aquatic systems can promote aquatic plant productivity and decay leading to cultural eutrophication (Waldichuk 1993). Eutrophication can adversely affect the quality and productivity of fishery habitats in rivers, lakes, estuaries, and near-shore, coastal waters. Eutrophication can cause a number of secondary effects, such as increased turbidity and water temperature, accumulation of dead organic material, decreased dissolved oxygen, and the proliferation of aquatic vegetation. Cultural eutrophication has resulted in widespread damage to the ecology of the Chesapeake Bay, causing nuisance algal blooms, loss of productive shellfish and blue crab (*Callinectes sapidus*) habitat, and destruction of submerged aquatic vegetation (SAV) beds (Duda 1985). Nearly 80% of the nutrient loads intothe Chesapeake

Bay can be attributed to nonpoint sources, and agriculture accounted for the majority of those (USEPA 2003b). Agriculture accounts for approximately 40% and 48% of nitrogen and phosphorus loads, respectively, to the Chesapeake Bay (USEPA 2003b). Chronic eutrophication has severely impacted the historically productive recreational and commercial fisheries of the Chesapeake Bay.

While eutrophication generally causes increased growth of aquatic vegetation, it has been shown to be responsible for wide spread losses of SAV in many urbanized estuaries (Deegan and Buchsbaum 2005). By stimulating the growth of macroalgae, such as sea lettuce (*Ulva lactuca*), eutrophication can alter the physical structure of seagrass meadows, such as eelgrass (*Zostera marina*), by decreasing shoot density and reducing the size and depth of beds (Short et al. 1993; MacKenzie 2005). These alterations can result in the destruction of habitat that is critical for developing juvenile fish and can severely impair biological food chains (Hanson et al. 2003).

Groundwater is also susceptible to nutrient contamination in agricultural lands composed of sandy or other coarse-textured soil (USGS 1999). Nitrate, a highly soluble and mobile form of nitrogen, can leach rapidly through the soil profile and accumulate in groundwater, especially in shallow zones (USEPA 2003a). In the eastern United States, nitrogen contamination of groundwater is generally higher in areas that receive excessive applications of agriculture fertilizers and manure, most notably in mid-Atlantic states like Delaware, Maryland, and Virginia (i.e., the Delmarva Peninsula) (USEPA 2003a). When discharged through seeps and drains, or by direct subsurface flow to water bodies, groundwater can be a significant source of nutrients to surface waters (Hanson et al. 2003). Phosphorus from agricultural sources, such as manure and fertilizer applications and tillage, can also be a significant contributor to eutrophication in freshwater and estuarine ecosystems. Cultivation of agricultural land greatly increases erosion and with it the export of particle-bound phosphorus.

Livestock waste (manure), including fecal and urinary wastes of livestock and poultry, processing water and the feed, bedding, litter, and soil with which they become intermixed, is reported to be the single largest source of phosphorus contamination in the United States (Howarth et al. 2002). Because cattle are often allowed to graze in riparian areas, nutrients that are consumed elsewhere are often excreted in riparian zones that can impact adjacent aquatic habitats (Hanson et al. 2003). Because grazing processes remove or disturb riparian vegetation and soils, runoff that carries additional organic wastes and nutrients into aquatic habitats is accelerated (Hanson et al. 2003). Pollutants contained and processed in rangelands, pastures, or confined animal facilities can be transported by storm water runoff into aquatic environments. These pollutants may include oxygen-demanding substances such as nitrogen and phosphorus; organic solids; salts; bacteria, viruses, and other microorganisms; metals; and sediments that increase organic decomposition (USEPA 2003a). Increased nutrient levels resulting from processed water or manure causes excessive aquatic plant growth and algae. The decomposition of aquatic plants depletes dissolved oxygen in the water, creating anoxic or hypoxic conditions that can lead to fish kills. For example, six individual spills from animal waste lagoons in North Carolina during 1995 totaled almost 30 million gallons; including one spill that involved 22 million gallons of swine waste that was responsible for a fish kill along a 19-mile stretch of the New River (USEPA 2003a). Animal wastes from farms in the United States produce nearly 1.5 billion tons of nitrogen and phosphate-laden wastes each year that contribute to nutrient contamination in approximately 27,999 miles of rivers and groundwater (Markham 2006). The release of animal wastes from livestock production facilities have led to reductions in productivity of riverine, estuarine, and marine habitats because of eutrophication.

## *Introduction of pathogens*

Stormwater runoff from agriculture, particularly livestock manure, typically contains elevated levels of pathogens, including bacteria, viruses, and protozoa (USEPA 2003a). Pathogens are generally a concern to human health because of consumption of contaminated shellfish and finfish and exposure at beaches and swimming areas (USEPA 2005). While many pathogens affecting marine organisms are associated with upland runoff of fecal contamination, there are also naturally occurring marine pathogens that affect fish and shellfish (Shumway and Kraeuter 2000). Some naturally occurring pathogens, such as bacteria from the genus, *Vibrio*, or the dinoflagellate, *Pfiesteria*, can produce blooms that release toxins capable of harming fish and possibly human health under certain conditions (Buck et al. 1997; Shumway and Kraeuter 2000). Although the factors leading to the formation of blooms for these species requires additional research, nutrient enrichment of coastal waters is suspected to play a role (Buck et al. 1997). See also the chapter on Introduced/Nuisance Species and Aquaculture for more information on pathogens.

## *Reduced dissolved oxygen*

Reduced (hypoxic) or depleted (anoxic) oxygen conditions within estuarine waters as a result of cultural eutrophication may be one of the most severe problems facing coastal waters in the United States (Deegan and Buchsbaum 2005), and agriculture is a major contributing source in some areas. In general, extensive hypoxia has been more chronic in river-estuarine systems in the southern portion of the northeast coast (i.e., Narragansett Bay, RI, to Chesapeake Bay) than in the northern portion (Whitledge 1985; O'Reilly 1994; NOAA 1997). In 2001 approximately 50% of the deeper waters of the Chesapeake Bay had reduced dissolved oxygen concentrations (USEPA 2003b).

Warm temperatures, high metabolic sediment demand, and water column stratification, conditions that can be common at night during summer months, may lead to low dissolved oxygen concentrations in bottom waters (Deegan and Buchsbaum 2005). Hypoxia in estuaries north of Cape Cod, MA, are uncommon because of strong mixing and flushing characteristics of their waters in the northern New England region. However, high nutrient loads into aquatic habitats from livestock and croplands can cause hypoxic or anoxic conditions that can result in fish kills in rivers and estuaries in other areas of the northeast coast (USEPA 2003a; Deegan and Buchsbaum 2005), and they can potentially alter long-term community dynamics (NRC 2000; Castro et al. 2003). Chronic low-dissolved oxygen conditions can lower the growth and survivorship of finfish and shellfish. For example, the effect of chronic, diurnally fluctuating levels of dissolved oxygen has been shown to reduce the growth of young-of-the-year winter flounder (*Pseudopleuronectes americanus*) (Bejda et al. 1992).

## *Altered temperature regimes*

Increased siltation in shallow aquatic habitats caused by erosion from croplands and livestock operations can result in increased water temperature (Duda 1985). In addition to accelerating bank erosion, loss of riparian vegetation resulting from livestock grazing can increase the amount of solar radiation reaching streams and rivers resulting in an increase in water temperatures (Moring 2005). Altered temperature regimes have the ability to affect the distribution, growth rates, survival, migration patterns, egg maturation and incubation success, competitive ability, and resistance to parasites, diseases, and pollutants of aquatic organisms (USEPA 2003a). The temperature regimes of cold-water fish, such as Atlantic salmon (*Salmo salar*) and rainbow smelt (*Osmerus mordax*), may be exceeded in some rivers and streams of the northeastern United States and lead to local extirpation of these species. The removal of riparian vegetation can also lower water temperatures during winter, which can increase the formation of ice and delay the development of incubating fish eggs and alevins (Hanson et al. 2003). Some evidence indicates that elevated water temperatures in freshwater streams and rivers in the northeastern United States may be responsible for increased algal growth, which has been suggested as a possible factor in the diminished stocks of rainbow smelt (Moring 2005). In the watersheds of eastern Maine, blueberry and cranberry processing plants discharge processing water into rivers important to Atlantic salmon spawning and migration. These facilities are permitted to discharge water at temperatures known to be lethal to both juvenile and adult Atlantic salmon (USFWS and NMFS 1999).

### *Siltation, sedimentation, and turbidity*

As discussed above, siltation, sedimentation, and turbidity impacts related to agricultural activities are generally a result of soil erosion. Agricultural lands are also characterized by poorly maintained dirt roads, ditches, and drains that transport sediments directly into surface waters. Suspended sediments in aquatic environments reduce the availability of sunlight to aquatic plants, cover fish spawning areas and food supply, interfere with filtering capacity of filter feeders, and can clog and harm the gills of fish, and when the sediments settle they can cover oysters and shells which prevents oyster larvae from settling on them (USEPA 2003a; MacKenzie 2007). The largest source of sediment into Chesapeake Bay, for example, is from agriculture. Approximately 63% of the over 5 million pounds of sediment delivered each year to tidal waters of the Chesapeake Bay comes from agricultural sources (MacKenzie 1983; USEPA 2003b) and results in devastating impacts to shellfish and SAV. Wide-spread agricultural deforestation during the 18$^{th}$ and 19$^{th}$ centuries contributed to large sediment loads in the James,VA; York, VA; Rappahannock,VA; Potomac, WV/VA/MD/DC; Patuxent, MD; Choptank, DE/MD; and Nanticoke, DE/MD, Rivers and which may have contributed to the decline of Atlantic sturgeon (*Acipenser oxyrinchus*) populations in the Chesapeake Bay watershed (USFWS and NMFS 1998).

In addition to the affects described in greater detail within the Bank and Soil Erosion subsection of this chapter, contaminants such as pesticides, phosphorus, and ammonium are transported with sediment in an adsorbed state, such that they may not be immediately available to aquatic organisms. However, alteration in water quality, such as decreased oxygen concentration or changes in water alkalinity, may cause these chemicals to be released from the sediment (USEPA 2003a). Consequently, the impacts to aquatic organisms associated with siltation and sedimentation may be combined with the affects of pollution originating from the agricultural lands.

### *Altered hydrological regimes*

There are both direct and indirect affects of agriculture activities on the hydrology of coastal watersheds. Direct alterations of hydrology can occur from water diversion projects used for crop irrigation and livestock operations. The volume and timing of freshwater delivery to estuaries can be altered by water diversions, such as for agriculture, which in turn can increase the salinity of coastal ecosystems and diminish the supply of sediments and nutrients to estuaries (Deegan and Buchsbaum 2005). Agriculture activities use large volumes of water for irrigation, accounting for one-third of all US water withdrawals in 2000 and the second largest source of total water use after thermoelectric energy (Markham 2006).

Water withdrawal for agriculture can have adverse affects on anadromous fish, particularly Atlantic salmon, which use rivers in the Gulf of Maine for spawning and migration. Water withdrawals pose a threat to life stages of Atlantic salmon and their habitat in the Machias, Pleasant, and Narraguagus Rivers in Maine (USFWS and NMFS 1999). Freshwater was diverted from eastern Maine watersheds in the late 1990s to irrigate approximately 6,000 acres of blueberry agricultural activities, and that acreage was expected to double by the year 2005 (USFWS and NMFS 1999). The withdrawal of water may also affect the productivity of oyster beds in the eastern United States, because the distribution of oysters is largely governed by water salinity. When water is withdrawn, oyster beds are forced to move upstream and into smaller areas and often closer to cities where pollution may affect commercial marketing of the oysters (MacKenzie 2007).

Altered hydrology and flood plain storage patterns around estuaries can effect water residence time, temperature, and salinity and can increase vertical stratification of the water column, which inhibits the diffusion of oxygen into deeper water leading to reduced (hypoxic) or depleted (anoxic) dissolved oxygen concentrations (Kennedy et al. 2002). Altered hydrodynamics can affect estuarine circulation, including short-term (diel) and longer term (seasonal or annual) changes (Deegan and Buchsbaum 2005). In addition, counter current flows set up by freshwater discharges into estuaries are important for larvae and juvenile fish entering those estuaries. The diurnal behavioral adaptations of marine and estuarine species allow larvae and early juveniles to concentrate in estuaries. Reductions in freshwater flows caused by increased freshwater withdrawals can disrupt counter current flows and larval transport into estuaries (Deegan and Buchsbaum 2005). The quality and quantity of freshwater flows into estuaries are important in maintaining suitable conditions for spawning, egg, larval, and juvenile development for many estuarine-dependent species.

Indirect affects occur when sediments are transported from agricultural lands via soil erosion and are deposited in roadside ditches, streams, rivers, and navigation channels, which decrease the capacity of watersheds to attenuate the affects of flooding. The morphology of streams and rivers can be altered by eroded soil from improper livestock grazing and croplands, changing the stream width and depth and the timing and magnitude of stream flow (USEPA 2003a). In addition, sediment deposited in lakes and navigation channels reduces the storage capacity of those systems and necessitates more frequent dredging (USEPA 2003a).

### *Impaired fish passage*

Sediments transported from agricultural lands via soil erosion can change the morphology of streams and rivers. As a result, alteration of stream width and depth and the timing and magnitude of stream flow can impair the ability of anadromous fish to reach upstream spawning habitats. Roads that are constructed to access agriculture lands and for livestock may impede or prohibit migrating fish. For example, culverts constructed under roads to allow for water flow can alter the velocity and volume of water in streams and inhibit the ability of fish to migrate through the structure (Furniss et al. 1991). Additional information on fish passage impairments can be reviewed in the Alteration of Freshwater Systems chapter of this report.

### *Change in community structure and species composition*

Cropland and livestock operations can result in community-level impacts to riverine and estuarine ecosystems. As mentioned above, fertilizers applied to agricultural lands enter streams, rivers, and estuaries through stormwater runoff and groundwater sources (e.g., seeps and subsurface flows) and may result in eutrophication. Eutrophication can cause a number of secondary effects, such as increased turbidity and water temperature, accumulation of dead organic material, decreased dissolved oxygen, and the proliferation of macroalgae, such as sea lettuce (MacKenzie 2005). These alterations can then result in the destruction of habitat for small or juvenile fish and severely impair biological food chains (Hanson et al. 2003). For example, eelgrass beds growing in deeper areas of estuaries tend to be impacted more than shallower areas because those beds are very sensitive to light attenuation as a result of eutrophication (Deegan and Buchsbaum 2005). Species that depend upon eelgrass beds may be forced into shallower, potentially less desirable habitats. Declines in commercially and recreationally important finfish in Waquoit Bay, MA, have followed a concomitant decline in eelgrass beds for that area (Deegan and Buchsbaum 2005). Similarly, eelgrass wasting disease was documented to be responsible for severe declines in bay scallop (*Argopectin irradians*) landings along the east coast in the 1930s (Buchsbaum 2005).

Other impacts from agricultural activities such as soil erosion and release of fine sediments can alter aquatic communities through siltation and alteration of benthic substrates. Waldichuk (1993) identified a number of impacts to Pacific salmon (*Oncorhynchus* spp.) caused by activities related to agriculture, such as siltation in spawning, egg incubation and feeding habitats, impaired respiration and abrasion of gills from suspended particles, and failure of egg hatching resulting from low dissolved oxygen. The cumulative effect from the degradation of riverine habitats can inhibit or preclude restoration efforts of salmon populations to historic ranges by altering the community. Release of nutrients from fertilizers applied to croplands, livestock manure, and erosion of soils can reduce the dissolved oxygen levels in aquatic habitats through storm water runoff. Reduced dissolved oxygen in the water or sediments can change community composition to coastal habitats, particularly in areas with restricted water circulation such as coastal ponds, subtidal basins, and salt marsh creeks (Deegan and Buchsbaum 2005). Chronic hypoxia caused by cultural eutrophication can permanently alter the species composition and productivity of these areas.

### *Entrainment and impingement*

Water diverted and extracted for agriculture use can entrain (i.e., draw into flow system) and impinge (i.e., capture onto filter screens) aquatic organisms. Entrainment and impingement generally affects eggs, larvae, and early juvenile fish and invertebrates that cannot actively avoid the currents created at the water intake opening (ASMFC 1992). Long-term water withdrawal may adversely affect fish and invertebrate populations as well as their prey by adding another source of mortality to the early life stage which often determines recruitment and year-class strength (Hanson et al. 2003). Refer to the Physical Affects: Water Intake and Discharge Facilities chapter in this report for additional information on entrainment and impingement.

### *Bank and soil erosion*

Soil erosion in US farmland is estimated to occur seven times as fast as soil formation (Markham 2006). Soil erosion can lead to the transport of fine sediment that may be associated with a wide variety of pollutants from agricultural land into the aquatic environment. The presence of livestock in the riparian zone accelerates sediment transport rates by increasing surface soil erosion (Hanson et al. 2003), loss of vegetation caused by trampling, and streambank erosion resulting from shearing or sloughing (Platts 1991). Increased sedimentation in aquatic systems can increase turbidity and the temperature of the water, reduce light penetration and dissolved oxygen, smother fish spawning areas and food supplies, decrease the growth of SAV, clog the filtering capacity of filter feeders, clog and harm the gills of fish, interfere with feeding behaviors of certain species, cover shells on oyster beds, and significantly lower overall biological productivity (MacKenzie 1983; Duda 1985; USEPA 2003a). Soil eroded and transported from cropland usually contains a higher percentage of finer and less dense particles, which tend to have a higher affinity for adsorbing pollutants such as insecticides, herbicides, trace metals, and nutrients (Duda 1985; USEPA 2003a). One of the consequences of erosional runoff from agricultural land is that it necessitates more frequent dredging of navigational channels (USEPA 2003a), which may result in transportation to and disposal of contaminated sediments in areas important to fisheries production and other marine biota (Witman 1996). Deposition of sediments from erosional runoff can also decrease the storage capacity of roadside ditches, streams, rivers, and navigation channels, resulting in more frequent flooding (USEPA 2003a).

### *Loss and alteration of riparian-wetland areas*

Functioning riparian-wetland areas require stable interactions between geology, soil, water, and vegetation in order to maintain productive riverine ecosystems. When functioning properly, riparian-wetland areas can: (1) reduce erosion and improve water quality by dissipating stream energy; (2) filter sediment and runoff from floodplain development; (3) support denitrification of nitrate-contaminated groundwater; (4) improve floodwater retention and groundwater discharge; (5) develop root masses that stabilize banks from scouring and slumping; (6) develop ponding and channel characteristics necessary to provide habitat for fish, waterfowl, and invertebrates; and (7) support biodiversity (USEPA 2003a). Agriculture activities have the potential to degrade riparian habitats. In particular, improper livestock grazing along riparian corridors can eliminate or reduce vegetation by trampling and increase streambank erosion by shearing or sloughing (Platts 1991). These effects tend to increase the streambank angle, which increases stream width, decreases stream depth, and alters or eliminates fish habitat (USEPA 2003a). As discussed above, the transport of eroded soil from the streambank to streams and rivers impacts water quality and aquatic habitats. Removing riparian vegetation also increases the amount of solar radiation reaching the stream and can result in higher water temperatures.

### *Reduced soil infiltration and soil compaction*

Tillage of croplands aerates the upper soil but tends to compact fine textured soils just below the depth of tillage, thus altering infiltration. Use of farm machinery on cropland and adjacent roads causes further compaction, reducing infiltration and increasing surface runoff (Hanson et al. 2003).

Johnson (1992) and Platts (1991) reviewed studies related to livestock grazing and concluded that heavy grazing nearly always decreases infiltration, reduces vegetative biomass, and increases bare soil. Compaction of rangelands generally increases with grazing intensity, although site-specific soil and vegetative conditions are also important factors in determining the effects of soil compaction (Kauffman and Krueger 1984). Reduced soil infiltration and compaction caused by agriculture are two of the factors that accelerate erosion and release of sediments and contaminants in aquatic habitats.

Salts are present in varying amounts in all soils because of the natural weathering process, but agricultural lands that have poor subsurface drainage can lead to high salt concentrations. Likewise, irrigation water, whether from ground or surface water sources has a natural base load of dissolved mineral salts. Irrigation return flows convey the salt to the receiving streams or groundwater reservoirs. If the amount of salt in the return flow is low in comparison to the total stream flow, water quality may not be degraded to the extent that aquatic functions are impaired. However, if the process of water diversion and the return flow of saline drainage water is repeated many times along a stream or river, downstream habitat quality can become progressively degraded (USEPA 2003a). The accumulation of salts, particularly on irrigated croplands, tends to cause soil dispersion, structure breakdown, and decreased infiltration (USEPA 2003a). While salts are generally a greater pollutant for freshwater ecosystems than for estuarine systems, they may adversely affect anadromous fish that depend upon freshwater systems for crucial portions of their life cycles (USEPA 2003a).

### Land-use change (post-agriculture)

When demands for developable land are sufficiently high, the value of land in developed use will exceed its value in agricultural use. In general, conversion of land from agricultural to urban uses is largely irreversible according to the US Department of Agriculture. In the continental United States, census data from urban areas have shown more than a doubling of agricultural land conversion from 25.5 million acres to 55.9 million acres between 1960 and 1990 (USDA 2005). While impacts on aquatic ecosystems from agriculture may be problematic in some areas, conversion of croplands and rangelands to urban and industrial uses may be more harmful in the long-term. Between 1992 and 1997 the state of New York lost approximately 90,000 acres of prime farmland to residential and commercial development, which was 140% faster than in the previous five years (Markham 2006). Refer to the Coastal Development chapter in this report for more information on the impacts of land-use change.

### Release of pesticides, herbicides, and fungicides

The term "pesticide" is a collective description of hundreds of chemicals used to protect crops from damaging organisms with different sources and fates in the aquatic environment and that have varying toxic effects on fish and other aquatic organisms (USEPA 2003a). Pesticides can be divided into four categories according to the target pest: insecticides, herbicides, fungicides, and nematicides (USEPA 2003a). Agricultural activities are a major nonpoint source of pesticide pollution in coastal ecosystems (Hanson et al. 2003). Large quantities of pesticides, perhaps 18-20 pounds of pesticide active ingredient per acre, are applied to vegetable crops in coastal areas to control insect and plant pests (Scott et al. 1999). Soil eroded and transported from croplands and rangelands usually contains a higher percentage of finer and less dense particles, which tend to have a higher affinity for adsorbing pollutants such as insecticides and herbicides (Duda 1985; USEPA 2003a). In addition, agricultural lands are typically characterized by poorly maintained dirt roads, ditches and drains that transport sediments, nutrients, and pesticides directly into surface waters. In many instances, roads, ditches, and drains have replaced headwater streams, and these constructed systems deliver pollutants directly to surface waters (Larimore and Smith 1963). Pesticides are frequently detected in freshwater and estuarine systems that provide fishery habitat.

The most common pesticides include insecticides, herbicides, and fungicides. These are used for pest control on forested lands, agricultural crops, tree farms, and nurseries. Pesticides can enter the aquatic environment as single chemicals or complex mixtures. Direct applications, surface runoff, aerial drift, leaching, agricultural return flows, and groundwater intrusions are all examples of transport processes that deliver pesticides to aquatic ecosystems (Hanson et al. 2003).

Most studies evaluating pesticides in runoff and streams generally find that concentrations can be relatively high near the application site and soon after application but are significantly reduced further downstream and with time (USEPA 2003a). However, some pesticides used in the past, such as dichlorodiphenyl trichloroethane (DDT), are known to persist in the environment for years after application. Chlorinated pesticides, such as DDT, and some of the breakdown products are known to cause malformation and fatality in eggs and larvae, alter respiration, and disrupt central nervous system functions in fish (Gould et al. 1994). In addition, pesticides containing organochlorine compounds accumulate and persist in the fatty tissue and livers of fish and could be a threat to human health for those who consume contaminated fish (Gould et al. 1994).

Pesticides may bioaccumulate in organisms by first being adsorbed by sediments and detritus which are ingested by zooplankton and then eaten by planktivores, which in turn are eaten by fish (ASMFC 1992). For example, the livers of winter flounder from Boston and Salem Harbors, MA, contained the highest concentrations of DDT found on the east coast of the United

States and were ranked first and third, respectively, in the country in terms of total pesticides (Larsen 1992). In the Pocomoke River, MD/DE, a tributary of the Chesapeake Bay, agricultural runoff (primarily from poultry farms) was identified as one of the major sources of contaminants (Karuppiah and Gupta 1996). Blueberry and cranberry agriculture is an important land use in eastern Maine watersheds and involves the use of a number of pesticides, herbicides, and fungicides that may cause immediate mortalities to juvenile Atlantic salmon or can have indirect effects when chemicals enter rivers (USFWS and NMFS 1999). One study investigating the effects of two different classes of pesticides (organochlorines and organophosphates) in South Carolina estuaries found significant affects on populations of the dominant macrofauna species, daggerblade grass shrimp (*Palaemonetes pugio*), and mummichogs (*Fundulus heteroclitus*) (Scott et al. 1999). The study found impacts from pesticide runoff on daggerblade grass shrimp populations may cause community-level disruptions in estuaries; however, the authors concluded that implementation of integrated pest management, best management practices, and retention ponds could significantly reduce the levels of nonpoint source runoff from agriculture (Scott et al. 1999).

### *Endocrine disruptors*

Studies have recently focused on a group of chemicals, called "endocrine disruptors," that when present at extremely low concentrates can interfere with fish endocrine systems. Some of these chemicals act as "environmental hormones" that may mimic the function of the sex hormones androgen and estrogen (Thurberg and Gould 2005). Some of the chemicals shown to be estrogenic include some polychlorinated biphenyl (PCB) congeners, dieldrin, DDT, phthalates and alkylphenols (Thurberg and Gould 2005), which have had or still have applications in agriculture. Several studies have found vitellogenin, a yolk precursor protein, in male fish in the North Sea estuaries (Thurberg and Gould 2005). Metals have also been implicated in disrupting endocrine secretions of marine organisms, potentially disrupting natural biotic processes (Brodeur et al. 1997). However, the long-term effect of endocrine-disrupting substances on aquatic life is not well understood and demands serious attention by the scientific and resource policy communities.

### *Conservation measures and best management practices for croplands, rangelands, livestock, and nursery operations (adapted from Hanson et al. 2003)*

1. Recommend field and landscape buffers to provide cost-effective protection against the cumulative effects of multiple pollutant discharges associated with agricultural activities, including riparian forests, alley cropping, contour buffer strips, crosswind trap strips, field borders, filter strips, grassed waterways with vegetative filters, herbaceous wind barriers, vegetative barriers, and windbreak/shelterbelts.
2. Protect and restore soil quality with natural controls that affect permeability and water holding capacity, nutrient availability, organic matter content, and biological activity of the soil. Some examples of best management practices include cover cropping, crop sequence, sediment basins, contour farming, conservation tillage, crop residue management, grazing management, and the use of low-impact farming equipment.
3. Promote efficient use and appropriate applications of pesticides and irrigated water. Sound agricultural practices include use of integrated pest management, irrigation management, soil testing, and appropriate timing of nutrient applications.
4. Encourage protection and restoration of rangelands with practices such as rotational grazing systems or livestock distribution controls, exclusion of livestock from riparian and aquatic areas,

livestock-specific erosion controls, reestablishment of vegetation, or extensive brush management correction.
5. Avoid locating new confined animal facilities or expansion of existing facilities near riparian habitat, surface waters, and areas with high leaching potential to surface or groundwater. Ensure that adequate nutrient and wastewater collection facilities are in place.
6. Minimize water withdrawals for irrigation and promote water conservation measures, such as water reuse.
7. Site roads for agricultural lands to avoid sensitive areas such as streams, wetlands, and steep slopes.
8. Include best management practices (BMPs) for agricultural road construction plans, including erosion control, avoidance of side casting of road materials into streams, and using only native vegetation in stabilization plantings.
9. Use seasonal restrictions to avoid impacts to habitat during species' critical life history stages (e.g., spawning and egg development periods). Recommended seasonal work windows are generally specific to regional or watershed-level environmental conditions and species requirements.

## Silviculture and Timber Harvest Activities

### *Introduction*

The growth and harvest of forestry products are major land-use types for watersheds along the east coast, particularly in New England, and can have short-term and long-term impacts to riverine habitat (USFWS and NMFS 1999). Forestry is the dominant land-use type in the watersheds of the Dennys, East Machias, Machias, Pleasant, and Narraguagus Rivers in Maine (USFWS and NMFS 1999). Forests that once covered up to 95% of the Chesapeake Bay watershed now cover only 58%, primarily because of land clearing for agriculture and timber (USEPA 2003b). Timber harvest generally removes the dominant vegetation; converts mature and old-growth upland and riparian forests to tree stands or forests of early seral stage; reduces the permeability of soils; increases sedimentation from surface runoff and mass wasting processes; alters hydrologic regimes; and impairs fish passage through inadequate design, construction, and maintenance of stream crossings (Hanson et al. 2003). Silviculture practices can also increase water temperatures in streams and rivers, increase impervious surfaces, and decrease water retention capacity in watersheds (USFWS and NMFS 1999). These watershed changes may result in inadequate river flows; increase stream bank and streambed erosion; sedimentation and siltation of riparian and stream habitat; increase the amount of woody debris; and increase of run-off and associated contaminants (e.g., from herbicides) (Sigman 1985; Hicks et al. 1991; Hanson et al. 2003). Debris (i.e., wood and silt) is released into the water as a result of timber harvest activities and can smother benthic habitat. Poorly placed or designed road construction can cause erosion, producing additional silt and sediment that can impact stream and riparian habitat. Deforestation can alter or impair natural habitat structures and dynamics of the ecosystem.

Four major categories of silviculture activities that can impact fishery habitat are: (1) construction of logging roads; (2) creation of barriers; (3) removal of streamside vegetation; and (4) input of pesticide and herbicide treatments to aquatic habitats.

### *Release of nutrients/eutrophication*

After logging activities, concentrations of plant nutrients in streams and rivers may increase for several years and up to a decade (Hicks et al. 1991). Excess nutrients, combined with increased light regimes caused by the removal of riparian vegetation, can stimulate algal growth; however, the effects of nutrient increases on salmonid populations are not well understood (Hicks et al. 1991). An estimated 41.5 million pounds of nitrogen per year from silviculture activities alone are released into the Chesapeake Bay watershed, contributing to phytoplankton blooms, chronic hypoxia (low dissolved oxygen concentrations), and die-off of SAV (USEPA 2003b).

### *Reduced dissolved oxygen*

Small wood debris and silt resulting from timber harvesting can smother benthic habitat and reduce dissolved oxygen levels in streams (Hicks et al. 1991; Hanson et al. 2003). Fine organic material introduced into streams following logging can result in increased oxygen demand and reduced exchange of surface and intergravel water (Hicks et al. 1991). While low oxygen conditions may not directly kill salmon embryos and alevins in streams after logging, emergent juveniles may have reduced viability (Hicks et al. 1991). Introduction of nutrients into aquatic systems can promote aquatic plant productivity and decay leading to cultural eutrophication (Waldichuk 1993). Anoxic (without oxygen) or hypoxic (low oxygen) conditions have caused widespread ecological problems for the Chesapeake Bay, resulting in a variety ecosystem impacts including the loss of shellfish beds and reductions of fish stocks in the Bay (USEPA 2003b). According to Chesapeake Bay Program modeling, approximately 15% of the nitrogen loads entering the Chesapeake Bay watershed each year are from forestry activities (USEPA 2003b).

### *Altered temperature regimes*

Removing streamside vegetation to construct logging access roads and logging adjacent to streams or rivers increase the amount of solar radiation reaching the water body and can increase water temperatures (Beschta et al. 1987; Hicks et al. 1991). In studies conducted in Alaska, researchers found that maximum temperatures in logged streams without riparian buffers exceeded that of unlogged streams by up to 5ºC, but did not reach lethal temperatures (Hanson et al. 2003). In cold climates, the removal of riparian vegetation can result in lower water temperatures during winter, increasing the formation of ice and damaging and delaying the development of incubating fish eggs and alevins (Hanson et al. 2003). In freshwater habitats of the northeastern United States, the temperature tolerances of cold-water fish such as Atlantic salmon and rainbow smelt may be exceeded leading to local extirpation of the species (USFWS and NMFS 1999). However, increased water temperatures can also increase primary and secondary production, which may lead to greater availability of food for fish (Hicks et al. 1991).

### *Siltation, sedimentation, and turbidity*

Sedimentation in streams resulting from timber harvesting activities can reduce benthic community production, cause mortality of incubating salmon eggs and alevins, reduce the amount of habitat available for juvenile salmon, and lower the productivity of oyster beds (MacKenzie 1983; Hicks et al. 1991; Hanson et al. 2003). Fine sediments deposited in salmon spawning gravel can reduce interstitial water flow, causing reduced dissolved oxygen concentrations, and they can physically trap emerging fry in the gravel (Hicks et al. 1991). Fine sediments on stream bottoms and in suspension can also reduce primary production and invertebrate abundance, reducing the availability of prey for fish (Hicks et al. 1991). Sedimentation in riparian habitat resulting from logging activities can reduce streamside vegetation that impacts bank stabilization, increasing solar radiation reaching the stream. In addition, suspended sediments can alter the behavior and feeding efficiencies of salmonids following timber harvesting (Hicks et al. 1991). Sawdust and pulp from sawmills and lumber companies can also enter streams and rivers and adversely affect benthic habitats of anadromous fish (Moring 2005).

Deforestation and silviculture activities have contributed to excessive amounts of sediments in Chesapeake Bay, which have led to adverse affects on benthic communities like SAV, oysters, and clams (USEPA 2003b). Nearly 1 million tons of sediments are estimated to enter the Chesapeake Bay each year from forestry activities alone, which accounts for approximately 20% of the total sediment loads into the Bay (USEPA 2003b).

### *Bank and soil erosion and altered hydrological regimes*

Timber harvesting may result in inadequate or excessive surface and stream flows, increased stream bank and streambed erosion, and the loss of complex instream habitats. Clear cutting large areas of forests can alter the hydrologic characteristics of watersheds, such as water temperature, and result in greater seasonal and daily variation in stream discharge and flows (Hicks et al. 1991; Hanson et al. 2003).

In addition, logging road construction can destabilize slopes and increase erosion and sedimentation. Mass wasting and surface erosion are the two major types of erosion that can occur from logging road construction. Mass movement of soils, commonly referred to as landslides or debris slides, is associated with timber harvesting and road building on high hazard soils and unstable slopes. The result is increased erosion and sediment deposition in down-slope waterways. Erosion from roadways is most severe when poor construction practices are employed that do not include properly located, designed, and installed culverts or when proper ditching is not utilized (Furniss et al. 1991).

Altered hydrology and flood plain storage patterns around estuaries can effect water residence time, temperature, and salinity and can increase vertical stratification of the water column which inhibits the diffusion of oxygen into deeper water leading to reduced (hypoxic) or depleted (anoxic) dissolved oxygen concentrations (Kennedy et al. 2002).

### *Alteration and loss of vegetation*

By removing vegetation, timber harvesting tends to decrease the absorptive capability of the groundcover vegetation. This, in turn, increases surface runoff during periods of high precipitation. These effects can destabilize slopes, increase erosion, and cause sedimentation and debris input to streams (Hanson et al. 2003). Reductions in the supply of large woody debris to streams can result when old-growth forests are removed, with resulting loss of habitat complexity that is important for successful salmonid spawning and rearing (Hicks et al. 1991; Hanson et al. 2003). Removing riparian vegetation increases the amount of solar radiation reaching the stream and can result in higher water temperatures during summer months. A loss of riparian vegetation can also reduce stream water temperatures during the winter months (Beschta et al. 1987; Hicks et al. 1991).

### *Impaired fish passage*

Poorly placed or ill-designed culverts placed as part of road construction can negatively affect access to riverine habitat by fish. Stream crossings (e.g., bridges and culverts) on forest roads are often inadequately designed, installed, and maintained, and they frequently result in full or partial barriers to both the upstream and downsteam migration of adult and juvenile fish (Hanson et al. 2003). Perched culverts, in which the culvert invert at the downstream end is above the water level of the downstream pool, create waterfalls that can be physical barriers to migrating fish. Undersized culverts can accelerate stream flows to the point that these structures become velocity barriers for migrating fish. Blocked culverts can result in displacement of the stream from the downstream channel to the roadway or roadside ditch (Hanson et al. 2003). Blocked culverts often result from installation of undersized culverts or inadequate maintenance to remove debris. In addition, culverts and bridges deteriorate structurally over time, and failure to replace or remove them at the end of their useful life may cause partial or total blockage of fish passage.

### *Release of pesticides, herbicides, and fungicides*

Riparian vegetation is an important component of rearing habitat for fish, providing shade for maintaining cool water temperatures, food supply, channel stability, and structure (Furniss et al. 1991). Herbicides that are used to suppress terrestrial vegetation can negatively impact these habitat functions (USFWS and NMFS 1999). In addition, insecticides applied to forests to control pests can interfere with the smoltification process of Atlantic salmon, preventing some fish from successfully making the transition from fresh to salt water. Matacil, one pesticide used in the Maine timber industry, is known to contain an endocrine disrupting chemical (USFWS and NMFS 1999). These chemicals act as "environmental hormones" that may mimic the function of the sex hormones androgen and estrogen (Thurberg and Gould 2005). Refer to the Chemical Effects: Water Discharge Facilities chapter for more information on endocrine disruptors. Other possible affects to Atlantic salmon from pesticides may include altered chemical perception of home stream odor and osmoregulatory ability (USFWS and NMFS 1999).

### *Conservation measures and best management practices for silviculture and timber harvest activities*

1. Encourage timber operations to be located as far from aquatic habitats as possible. Buffer zones of 100 ft for first- and second-order streams and greater than 600 feet for fourth- and fifth-order streams are recommended.
2. Ensure that all silviculture and timber operations incorporate conservation plans that include control of nonpoint source pollution, protecting important habitat through landowner agreements, maintaining riparian corridors, and monitoring and controlling pesticide use.
3. Incorporate watershed analysis into timber and silviculture projects. Attention should be given to the cumulative effects of past, present, and future timber sales within a watershed.
4. Logging roads should be sited to avoid sensitive areas such as streams, wetlands, and steep slopes.
5. Include BMPs for timber forest road construction plans, including erosion control, avoidance of side casting of road materials into streams, and using only native vegetation in stabilization plantings.
6. Use seasonal restrictions to avoid impacts to habitat during species' critical life history stages (e.g., spawning and egg development periods). Recommended seasonal work windows are generally specific to regional or watershed-level environmental conditions and species requirements.

## Timber and Paper Mill Processing Activities

### *Introduction*

Timber and paper mill processing activities can affect riverine and estuarine habitats through both chemical and physical means. Timber and lumber processing can release sawdust and wood chips in riverine and estuarine environments where they may impact the water column and benthic habitat of fish and invertebrates. These facilities may also either directly or indirectly release contaminants, such as tannins and lignin products, into aquatic habitats (USFWS and NMFS 1999). Pulp manufacturing converts wood chips or recycled paper products into individual fibers by chemical and/or mechanical means, which are then used to produce various paper products. Paper and pulp mills use and can release a number of chemicals that are toxic to aquatic organisms, including chlorine, dioxins, and acids (Mercer et al. 1997), although a number of these chemicals have been reduced or eliminated from the effluent stream by increased regulations regarding their use.

### *Chemical contaminant releases*

Approximately 80% of all US pulp tonnage comes from kraft or sulfate pulping which uses sodium-based alkaline solutions, such as sodium sulfide and sodium hydroxide (USEPA 2002b). Kraft pulping reportedly involves less release of toxic chemicals, compared to other processes such as sulfite pulping (USEPA 2002b). Paper and pulp mills may also release a number of toxic chemicals used in the process of bleaching pulp for printing and wrapping paper products. The bleaching process may use chlorine, sulfur derivatives, dioxins, furans, resin acids, and other chemicals that are known to be toxic to aquatic organisms (Mercer et al. 1997). These chemicals have been implicated in various abnormalities in fish, including skin and organ tissue lesions, fin necrosis, gill hyperplasia, elevated detoxifying enzymes, impaired liver functions, skeletal deformities, increased incidence of parasites, disruption of the immune system, presence of tumors, and impaired growth and reproduction (Barker et al. 1994; Mercer et al. 1997). Because of concern about the release of dioxins and other contaminants, considerable improvements in the bleaching process have reduced or eliminated the use of elemental chlorine. Approximately 96% of all bleached pulp production uses chlorine-free bleaching technologies (USEPA 2002b).

An endocrine disrupting chemical, 4-nonylphenol, has been used in pulp and paper mill plants in Maine and has been shown to interfere with smoltification processes and the chemical perception of home range, and osmoregulatory ability in Atlantic salmon (USFWS and NMFS 1999). Other studies have implicated pulp and paper effluents in altered egg production, gonad development, sex steroids, secondary sexual characteristics, and vitellogenin concentration in male fish, which is considered to be an indicator of estrogenicity (Kovacs et al. 2005). A study investigating the prevalence of a microsporan parasite found in winter flounder in Newfoundland (Canada) waters observed infestations in the liver, kidney, spleen, heart, and gonads of fish collected downstream from pulp and paper mills, whereas fish collected from pristine sites harbored cysts of the parasite in only the digestive wall (Khan 2004). In addition, flounder with a high prevalence of parasite infections throughout multiple organs were found to have significant impairments to growth, organ mass, reproduction, and survival that were not observed in fish sampled from pristine locations, suggesting a link between those affects and effluent discharged by the pulp and paper mills (Khan 2004).

### *Entrainment and impingement*

Pulp and paper mills require large amounts of water and energy in the manufacturing process. For example, a bleached kraft pulp mill can utilize 4,000-12,000 gallons of water per ton of pulp produced (USEPA 2002b). Diverting water from streams, rivers, and estuaries for pulp and paper mills can entrain and impinge eggs, larvae, and juveniles and may impact local populations of fish and invertebrates. Information is not available on the potential magnitude of entrainment and impingement impacts from wood, pulp, and paper mills. Refer to Physical Effects: Water Intake and Discharge Facilities for more information on entrainment and impingement impacts.

### *Thermal discharge*

Pulp and paper production involves thermal and chemical processing to convert wood fibers to pulp or paper and may result in the release of effluent water with higher than ambient temperatures. There is a potential for cold-water fish such as Atlantic salmon and rainbow smelt to be adversely affected by these facilities. However, information is not available on the potential magnitude of thermal discharge impacts from wood, pulp, and paper mills.

### *Reduced dissolved oxygen*

Pulp and paper mill wastewaters generally contain sulfur compounds with a high biological oxygen demand (BOD), suspended solids, and tannins (USEPA 2002b). The release of these contaminants in mill effluent can reduce dissolved oxygen in the receiving waters. According to the US EPA, however, all kraft pulp mills and nearly all US paper mills have chemical recovery systems in place and primary and secondary wastewater treatment systems installed to remove particulates and BOD (USEPA 2002b).

### *Conversion of benthic substrate*

Sawdust and pulp from sawmills and lumber processing facilities can enter streams and rivers, adversely affecting benthic habitats for anadromous fish (Moring 2005). Pulp and paper mill effluent can contain solid particulates and a high BOD that can alter the benthic habitat of receiving water bodies. The impacts to benthic habitat from past practices of wood, pulp, and paper mills are evident today in some streams and rivers of Maine, including the Penobscot River from Winterport to Bucksport (USFWS and NMFS 1998). Most of the bottom substrate in this stretch of the Penobscot River is covered by bark and sawdust, which substantially reduces the diversity of benthic organisms (USFWS and NMFS 1998). However, chemical recovery systems and wastewater treatment systems should reduce or eliminate most solid wastes from the effluent stream.

### *Alteration of light regimes*

Lumber, pulp, and paper mills releasing effluent containing solids, a high BOD, and tannins can reduce water clarity and alter the light regimes in receiving waters. This can adversely affect primary production and SAV in riverine and estuarine habitat where these facilities are located. Information is not available on the potential magnitude of light regime impacts from wood, pulp, and paper mills.

### *Conservation measures and best management practices for timber and paper mill processing activities*

1. Ensure that lumber, pulp, and paper mills have adequate chemical recovery systems and wastewater treatment systems installed to reduce or eliminate most toxic chemicals and solid wastes from the effluent stream. Ensure that effluent streams do not elevate the ambient water temperatures of the receiving water bodies.
2. Discourage the construction of new lumber, pulp, and paper mills adjacent to riverine and estuarine waters that contain productive fisheries resources. New facilities should be sited so as to avoid the release of effluents in wetlands and open water habitats.
3. Use seasonal restrictions to avoid impacts to habitat during species' critical life history stages (e.g., spawning and egg development periods). Recommended seasonal work windows are generally specific to regional or watershed-level environmental conditions and species requirements.

4. Incorporate watershed analysis into new lumber, pulp, and paper mill facilities, with consideration for the cumulative effects of past, present, and future impacts within the watershed.

# CHAPTER TEN: INTRODUCED/NUISANCE SPECIES AND AQUACULTURE

## Introduced/Nuisance Species

### *Introduction*

Introductions of nonnative invasive species into marine and estuarine waters are a significant threat to living marine resources in the United States (Carlton 2001). Nonnative species can be released intentionally (i.e., fish stocking and pest control programs) or unintentionally during industrial shipping activities (e.g., ballast water releases), aquaculture operations, recreational boating, biotechnology, or from aquarium discharge (Hanson et al. 2003; Niimi 2004). Hundreds of species have been introduced into US waters from overseas and from other regions around North America, including finfish, shellfish, phytoplankton, bacteria, viruses, and pathogens (Drake et al. 2005). The rate of introductions has increased exponentially over the past 200 years, and it does not appear that this rate will level off in the near future (Carlton 2001).

In New England and the mid-Atlantic region, a number of fish, crabs, bryozoans, mollusks, tunicates, and algae species have been introduced since colonial times (Deegan and Buchsbaum 2005). New introductions continue to occur, such as *Convoluta convoluta*, a small carnivorous flatworm from Europe that has invaded the Gulf of Maine (Carlton 2001; Byrnes and Witman 2003); *Didemnum* sp., an invasive species of tunicate that has invaded Georges Bank and many coastal areas in New England (Pederson et al. 2005); the Asian shore crab (*Hemigrapsus sanguineus*) that has invaded Long Island Sound, NY/CT, (Carlton 2001) and other coastal areas; and *Codium fragile* spp. *tomentosoides,* an invasive algal species from Japan that has invaded the Gulf of Maine (Pederson et al. 2005).

Introduced species may thrive best in areas where there has been some level of environmental disturbance (Vitousek et al. 1997; USFWS and NMFS 1999; Minchinton and Bertness 2003). For example, in riverine systems alteration in temperature and flow regimes can provide a niche for nonnative species to invade and dominate over native species such as salmon (USFWS and NMFS 1999). Invasive species introductions can result in negative impacts to the environment and to society, with millions of dollars being expended for research, control, and management efforts (Carlton 2001).

The impacts associated with introduced/nuisance species can involve habitat, species, and genetic-level effects. Introduced/nuisance species can impact the environment in a variety of ways, including: (1) habitat alterations; (2) trophic alterations; (3) gene pool alterations; (4) alterations to communities and competition with native species; (5) introduced diseases; (6) changes in species diversity; (7) alteration in the health of native species; and (8) impacts to water quality. The following is a review of the potential environmental impacts associated with the introduction of nonnative aquatic invasive/nuisance species into marine, estuarine, and freshwater ecosystems.

### *Habitat alterations*

Introduced species can have severe impacts on the quality of habitat (Deegan and Buchsbaum 2005). Nonnative aquatic plant species can infest water bodies, impair water quality, cause anoxic conditions when they die and decompose, and alter predator-prey relationships. Fish may be introduced into an area to graze and biologically control aquatic plant invasions. However, introduced fish may also destroy habitat, which can eliminate nursery areas for native juvenile fishes, accelerate eutrophication, and cause bank erosion (Kohler and Courtenay 1986).

Habitat has been altered by the introduction of invasive species in New England. For example, the green crab (*Carcinus maenus*) an exotic species from Europe, grazes on submerged aquatic vegeation and can interfere with eelgrass restoration efforts (Deegan and Buchsbaum 2005). *Didemnum* sp. is an invasive tunicate that has colonized the northern edge of Georges Bank, as well as many coastal areas in New England. This filter-feeding organism forms dense mats that encrust the seafloor, which can prevent the settlement of benthic organisms, reduce food availability for juvenile scallops and groundfish, and smother organisms attached to the substrate (e.g., Atlantic sea scallops [*Placopectin magellanicus*] in spat and juvenile stages) (Pederson et al. 2005; Valentine et al. 2007) and could have impacts to productive fishing grounds in New England and elsewhere. There is no evidence at this time that the spread of the tunicate on Georges Bank will be held in check by natural processes other than smothering by moving sediments; however, its offshore distribution may be limited by temperatures too low for reproduction (Valentine et al. 2007).

An invasive species of algae from Japan, *Codium fragiles* spp. *tomentosoides*, also referred to as deadman's fingers, has invaded subtidal and intertidal marine habitats in the Gulf of Maine and mid-Atlantic. Deadman's fingers can outcompete native kelp and eelgrass, thus destroying habitat for finfish and shellfish species (Pederson et al. 2005). The common reed (*Phragmites australis*) a nonnative marsh grass, has invaded coastal estuaries and can exclude native brackish and salt marsh plant species such as smooth cordgrass (*Spartina alterniflora*) from their historic habitat (Burdick et al. 2001; Minchinton and Bertness 2003; Deegan and Buchsbaum 2005). *Phragmites* invasions can increase the sedimentation rate in marshes and reduce intertidal habitat available for fish species in New England (Deegan and Buchsbaum 2005).

### *Trophic alterations and competition with native species*

Introduced species can alter the trophic structure of an ecosystem via increased competition for food and space between native and nonnative species (Kohler and Courtenay 1986; Caraco et al. 1997; Strayer et al. 2004; Deegan and Buchsbaum 2005) as well as through predation by introduced species on native species (Kohler and Courtenay 1986). Competition may result in the displacement of native species from their habitat or a decline in recruitment, which are factors that can collectively contribute to a decrease in population size (Kohler and Courtenay 1986). For example, introductions of the invasive zebra mussel (*Dreissena polymorpha*) in the Hudson River, NY/NJ, estuary coincided with a decline in the abundance, decreased growth rate, and a shift in the population distribution of commercially and recreationally important species (Strayer et al. 2004). Zebra mussels have altered trophic structure in the Hudson River estuary by withdrawing large quantities of phytoplankton and zooplankton from the water column, thus competing with planktivorous fish. Phytoplankton is the basis of the food web, and altering the trophic levels at the bottom of the food web could have a detrimental, cascading effect on the aquatic ecosystem. Increased competition for food between the zebra mussel and open-water commercial and recreational species such as the American shad (*Alosa sapidissima*) and black sea bass (*Centropristis striata*) has been associated with large, pervasive alterations in young-of-the-year fish, which can result in interspecies competition and alterations in trophic structure (Strayer et al. 2004; Deegan and Buchsbaum 2005).

Predation on native species by nonnative species may increase the mortality of a species and could also alter the trophic structure (Kohler and Courtenay 1986). Whether the predation is on the eggs, juveniles, or adults, a decline in native forage species can affect the entire food web (Kohler and Courtenay 1986). For example, the Asian shore crab invaded Long Island Sound and has an aggressive predatory behavior and voracious appetite for crustaceans, mussels, young clams, barnacles, periwinkles, polychaetes, macroalgae, and salt marsh grasses. The removal of the forage base by this invasive crab could have a ripple effect throughout the food web that could restructure communities along the Atlantic coast (Tyrrell and Harris 2000; Brousseau and Baglivo 2005).

### *Alterations to communities*

Introductions of nonnative species may result in alterations to communities and an increase in competition for food and habitat (Deegan and Buchsbaum 2005). For example, the green crab is an exotic species from Europe which preys on native soft-shelled clams and newly settled winter flounder (*Pseudopleuronectes americanus*) (Deegan and Buchsbaum 2005).

Nonnative marsh grass introductions can alter habitat conditions, resulting in changes in the fauna of salt marsh habitat. Alterations to communities have been noted in areas in which native marsh cordgrass habitat has been invaded by the invasive, exotic *Phragmites* (Posey et al. 2003). *Phragmites* has been implicated in alteration of the quality of intertidal habitats, including: lower abundance of nekton in *Phragmites* habitat; reduced utilization of this habitat by other species during certain life stages (Weinstein and Balletto 1999; Able and Hagan 2000); decreased density of gastropods, oligochaetes, and midges (Posey et al. 2003); decreased bird abundance and species richness (Benoit and Askins 1999); and avoidance of *Phragmites* by juvenile fishes (Weis and Weis 2000).

### *Gene pool alterations*

Native species may hybridize with introduced species that have a different genetic makeup (Kohler and Courtenay 1986), thus weakening the genetic integrity of wild populations and decreasing the fitness of wild species via breakup of gene combinations (Goldburg et al. 2001). Aquaculture operations have the potential to be a significant source of nonnative introductions into North American waters (Goldburg and Triplett 1997; USCOP 2004). Escaped aquaculture species can alter the genetic characteristics of wild populations when native species interbreed with escaped nonnative or native aquaculture species (USFWS and NMFS 1999).

In the Gulf of Maine, the wild Atlantic salmon (*Salmo salar*) population currently exhibits poor marine survival and low spawning stock and is in danger of becoming extinct, which makes the species particularly vulnerable to genetic modification via interbreeding with escaped aquaculture species. Any genetic modification combined with other threats such as reduced water levels, parasites and diseases, commercial and recreational fisheries, loss of habitat, poor water quality, and sedimentation may threaten or potentially extirpate the wild salmon stock in the Gulf of Maine (USFWS and NMFS 1999). Refer to the Aquaculture section of this chapter for a more detailed discussion on impacts from aquaculture operations.

### *Introduced diseases*

Introduced aquatic species are often vectors for disease transmittal that represent a significant threat to the integrity and health of native aquatic communities (Kohler and Courtenay 1986). Bacteria, viruses, and parasites may be introduced advertently or inadvertently and can reduce habitat quality (Hanson et al. 2003). The introduction of pathogens can have lethal or sublethal effects on aquatic organisms and has the potential to impair the health and fitness level of wild fish populations. Sources of introduced pathogens include industrial shipping, recreational boating, dredging activities, sediment disposal, municipal and agricultural runoff, wildlife feces, septic systems, biotechnology labs, aquariums, and transfer of oyster spat and other species to new areas for aquaculture or restoration purposes (ASMFC 1992; Boesch et al. 1997).

Parasite and disease introductions into wild fish and shellfish populations can be associated with aquaculture operations. These diseases have the potential to lower the fitness level of native species or contribute to the decline of native populations (USFWS and NMFS 1999). Examples include the MSX (multinucleated sphere unknown) oyster disease introduced through the Pacific oyster (*Crassostrea gigas*) which contributed to the decline of native oyster (*Crassostrea virginica*) populations in Delaware Bay, DE/NJ, and Chesapeake Bay, MD/VA, (Burreson et al. 2000; Rickards and Ticco 2002) and the Infectious Salmon Anemia (ISA) that has spread from salmon farms in New Brunswick, Canada, to salmon farms in Maine (USFWS and NMFS 1999). Refer to the Aquaculture section of this chapter for more information regarding diseases introduced through aquaculture operations.

### *Changes in species diversity*

Introduced species can rapidly dominate a new area and can cause changes within species communities to such an extent that native species are forced out of the invaded area or undergo a decline in abundance, leading to changes in species diversity (Omori et al. 1994). For example, changes in species distribution have been seen in the Hudson River, where the invasion of zebra mussels caused localized changes in phytoplankton levels and trophic structure that favored littoral zone species over open-water species. The zebra mussel invasion resulted in a decline in abundance of open-water fishes (e.g., American shad) and an increase in abundance for littoral zone species (e.g., sunfishes) (Strayer et al. 2004). Shifts in the distribution and abundance of species caused by introduced species can effect the diversity of species in an area.

Alterations in species diversity have been noted in areas in which native *Spartina alterniflora* habitat has been invaded by the exotic haplotype, *Phragmites australis* (Posey et al. 2003). *Phragmites* can rapidly colonize a marsh area, thus changing the species of marsh grass present at that site. In addition, *Phragmites* invasions have been shown to change species use patterns and abundance at invaded sites, potentially causing a cascading of effects to the species richness and diversity of a community.

Benthic species diversity can be altered by the introduction of shellfish for aquaculture purposes (Kaiser et al. 1998) and for habitat restoration projects. Cultivation of shellfish such as hard clams often requires the placement of gravel or crushed shell on the substrate. Changes in benthic structure can result in a shift in the community at that site (e.g., from a polychaete to a bivalve and nemertean dominated benthic community) which may have the effect of reduced diversity (Simenstad and Fresh 1995; Kaiser et al. 1998). However, community diversity may be enhanced by the introduction of aquaculture species and/or the modification of the substrate (Simenstad and Fresh 1995). In addition, changes in species diversity may occur as a result of oyster habitat restoration. Oyster reefs provide habitat for a variety of resident and transient species (Coen et al. 1999), so restoration activities that introduce oysters into an area may result in localized changes in species diversity, as reef-building organisms and fish are attracted to the restoration site. Refer to the section on Aquaculture of this chapter for more information regarding altered species diversity caused by aquaculture activities.

### *Alterations in the health of native species*

The health of native species can be impaired by the introduction of new species into an area. A number of factors may contribute to reduced health of native populations, including: (1) competition for food may result in a decrease in the growth rate and local abundance (Strayer et al. 2004) or the decline in the entire population (USFWS and NMFS 1999) of native species; (2) aggressive and fast growing nonnative predators can reduce the populations of native species (Pederson et al. 2005); (3) diseases represent a significant threat to the integrity and health of native aquatic communities and can decrease the sustainability of the native population (Kohler and

Courtenay 1986; USFWS and NMFS 1999; Rickards and Ticco 2002; Hanson et al. 2003); and (4) the genetic integrity of native species may be compromised through hybridization with introduced species (Kohler and Courtenay 1986), which can also decrease the fitness of wild species via breakup of gene combinations (Goldburg et al. 2001). The factors listed above, in combination with potential impact on the habitats of native species, can collectively result in long-term impacts to the health of native species (Burdick et al. 2001; Minchinton and Bertness 2003; Deegan and Buchsbaum 2005; Pederson et al. 2005).

### *Impacts to water quality*

Invasive species can affect water quality in marine, estuarine, and riverine environments because they have the potential to outcompete native species and dominate habitats. For example, nonnative aquatic plant species, which may not have natural predators in their new environments, can proliferate within water bodies, impair water quality, and cause anoxic conditions when they die and decompose. Fish species such as grass carp (*Ctenopharyngodon idella*) and tilapia (Cichlidae), introduced to control noxious weeds, can accelerate eutrophication through fecal decomposition of nutrients previously stored in the plants (Kohler and Courtenay 1986). In addition, fish introduced to control invasive plant species can increase turbidity in the water column from the grazing behavior itself (Kohler and Courtenay 1986).

Introduced nonnative algal species from anthropogenic sources such as ballast water and shellfish transfer (e.g., seeding) combined with nutrient overloading may increase the intensity and frequency of algal blooms. An overabundance of algae can degrade water quality when they die and decompose, which depletes oxygen levels in an ecosystem. Oxygen depletion can result in ecological "dead zones," reduced light transmittance in the water column, seagrass and coral habitat degradation, and large-scale fish kills (Deegan and Buchsbaum 2005).

### *Conservation measures and best management practices for impacts on aquatic habitats from introduced/nuisance species*

1. Do not introduce exotic species for aquaculture purposes unless a thorough scientific evaluation and risk assessment is performed. Aquaculturist should be encouraged to only culture native species in open-water operations.
2. Prevent or discourage boaters, anglers, aquaculturists, traders, and other potential handlers of introduced species from accidental or purposeful introduction of species into ecosystems where these species are not native. In addition, measures should be taken to prevent the movement or transfer of exotic species into other waters.
3. Encourage vessels to perform a ballast water exchange in marine waters (in accordance with the US Coast Guard's voluntary regulations) to minimize the possibility of introducing exotic species into estuarine habitats. Ballast water taken on in marine waters will contain fewer organisms, and these organisms will be less likely to become invasive in estuarine conditions than are species transported from other estuaries.
4. Discourage vessels that have not performed a ballast water exchange from discharging their ballast water into estuarine receiving waters.
5. Require vessels brought from other areas over land via trailering to clean any surfaces that may harbor nonnative plant or animal species (e.g., propellers, hulls, anchors, fenders). Bilges should be emptied and cleaned thoroughly with hot water or a mild bleach solution. These activities should be performed in an upland area to prevent introduction of nonnative species to aquatic environments during the cleaning process.

6. Encourage natural resource managers to provide outreach materials on the potential impacts resulting from releases of nonnative species into the natural environment.
7. Limit importation of ornamental fishes to licensed dealers.
8. Use only local, native fish for live seafood or bait.
9. Encourage natural resource managers to identify areas where invasive species have become established at an early time in the infestation and pursue efforts to remove them, either manually or by other methods.
10. Encourage natural resource managers to identify methods that eradicate or reduce the spread of invasive species (e.g., reducing *Phragmites* in coastal marshes by mitigating the effects of tidal restrictions).
11. Treat effluent from public aquaria displays, laboratories, and educational institutes that are using exotic species prior to discharge for the purpose of preventing the introduction of viable animals, plants, reproductive material, pathogens, or parasites into the environment.

# Aquaculture

## *Introduction*

Aquaculture is defined as the controlled cultivation and harvest of aquatic organisms, including finfish, shellfish, and aquatic plants (Goldburg et al. 2001, 2003). Aquaculture operations are conducted at both land and water facilities. Land-based aquaculture systems include ponds, tanks, raceways, and water flow-through and recirculating systems. Water-based aquaculture systems include netpens, cages, ocean ranching, longline culture, and bottom culture (Goldburg and Triplett 1997).

Aquaculture can provide a number of socio-economic benefits, including food provision, improved nutrition and health, generation of income and employment, diversification of primary products, and increased trade earnings through the export of high-value products (Barg 1992). Aquaculture can also provide environmental benefits by supporting stocking and release of hatchery-reared organisms, countering nutrient and organic enrichment in eutrophic waters from the culture of some mollusk and seaweed species, and because aquaculture operations relies on good water quality, the prevention and control of aquatic pollution (Barg 1992).

However, freshwater, estuarine, and marine aquaculture operations have the potential to adversely impact the habitat of native fish and shellfish species. The impact of aquaculture facilities varies according to the species cultured, the type and size of the operation, and the environmental characteristics of the site. Intensive cage and floating netpen systems typically have a greater impact because aquaculture effluent is released directly into the environment. Pond and tank systems are less harmful to the environment because waste products are released in pulses during cleaning and harvesting activities rather than continuously into the environment (Goldburg et al. 2001). The relative impact of finfish and shellfish aquaculture differs depending on the foraging behavior of the species. Finfish require the addition of a large amount of feed into the ecosystem, which can result in environmental impacts impacts from the introduction of the feed, but also from the depletion of species harvested to provide the feed. Bivalves are filter feeders and typically do not require food additives; however, fecal deposition can result in benthic and pelagic habitat impacts, changes in trophic structure (Kaspar et al. 1985; Grant et al. 1995), and nutrient and phytoplankton depletion (Dankers and Zuidema 1995).

Similar to the introduced/nuisance species section of this chapter, aquaculture activities can effect fisheries at both a habitat and species-level. Typical environmental impacts resulting from aquaculture production include: (1) impacts to the water quality from the discharge of organic wastes and contaminants; (2) seafloor impacts; (3) introductions of exotic invasive species; (4) food web impacts; (5) gene pool alterations; (6) changes in species diversity; (7) sediment deposition; (8) introduction of diseases; (9) habitat replacement or exclusion; and (10) habitat conversion. The following is a review of the known and potential environmental impacts associated with the cultivation and harvest of aquatic organisms in land- and water-based aquaculture facilities.

### *Discharge of organic wastes*

Aquaculture operations can degrade the quality of the water column and the benthic environment via the discharge of organic waste and other contaminants (Goldburg et al. 2001; USCOP 2004). Organic waste includes uneaten fish food, urine, feces, mucus, and byproducts of respiration, which can have an adverse effect on both benthic and pelagic organisms when released into marine, estuarine, and riverine environments.

Uneaten fish food can contribute a significant amount of nutrients to the ecosystem at aquaculture sites (Kelly 1992; Goldburg and Triplett 1997). Farmed fish are typically fed "forage fish" of low economic value, such as anchovies (Engraulidae) and menhaden (*Brevoortia* sp.), which are either fed directly to aquaculture species or processed into dry feed pellets. However, these "forage fish," while having low economic value, may be highly important to other species and the aquatic ecosystem. A large percentage of nutrients contained in farmed fish food are lost to the environment through organic waste. As much as 80% of total nitrogen and 70% of total phosphorus fed to farmed fish may be released into the water column through fish wastes (Goldburg et al. 2001).

In New England, the majority of aquaculture operations are located in Maine, with Cobscook Bay being the primary site of finfish aquaculture operations. Recent research in Cobscook Bay and in neighboring waters of New Brunswick, Canada, has shown the primary sources of nutrients in the area are finfish aquaculture operations and the open ocean (Goldburg et al. 2001). Research conducted at an aquaculture facility with 200,000 salmon has revealed that the amount of nitrogen, phosphorus, and feces discharged from the facility are equivalent to that released from untreated sewage produced by 20,000, 25,000, and 65,000 people, respectively (Goldburg et al. 2001).

The release of high concentrations of nutrients can negatively affect an aquatic system through eutrophication. Eutrophication of an aquatic system can occur when nutrients, such as nitrogen and phosphorus, are released in high concentrations and over long periods of time. Eutrophication can stimulate the growth of algae and other primary producers and, in some cases, may develop into "algal blooms" (Hopkins et al. 1995; Goldburg et al. 2001; Deegan and Buchsbaum 2005). Although the effects of eutrophication are not necessarily always adverse, they are often extremely undesirable and include: (1) increased incidence, extent, and persistence of noxious or toxic species of phytoplankton; (2) increased frequency, severity, spatial extent, and persistence of low oxygen conditions; (3) alteration in the dominant phytoplankton species and the nutritional-biochemical "quality" of the phytoplankton community; and (4) increased turbidity of the water column because of the presence of algae blooms (O'Reilly 1994).

Oxygen can be depleted in the water column during bacterial degradation of algal tissue or when algal respiration exceeds oxygen production and can result in hypoxic or anoxic "dead zones," reduced water clarity, seagrass habitat degradation, and large-scale fish kills (Deegan and Buchsbaum 2005). Algal blooms may contain species of phytoplankton such as dinoflagellates that can produce toxins, cause toxic blooms (e.g., red tides), kill large numbers of fish, contaminate shellfish beds, and cause health problems in humans. Coastal and estuarine ecosystems in the United States are already moderately to severely eutrophic (Goldburg et al. 2001; Goldburg and

Triplett 1997) and are expected to worsen in 70% of all coastal areas over the next two decades (USEPA 2001). Consequently, the frequency and severity of toxic algal blooms could increase in the future. Refer to the Coastal Development and Chemical Effects: Water Discharge Facilities chapters for more information on eutrophication and harmful algal blooms.

### *Discharge of contaminants*

In addition to organic waste, chemicals and other contaminants that are discharged as part of the aquaculture process can affect benthic and pelagic organisms (Hopkins et al. 1995; Goldburg and Triplett 1997). Chemicals are typically released directly into the water, including antibiotics that fight disease; pesticides that control parasites, algae, and weeds; hormones that initiate spawning; vitamins and minerals to promote fish growth; and anesthetics to ease handling of fish during transport. These chemical agents are readily dispersed into marine, estuarine, and freshwater systems and can be harmful to natural communities. Few chemicals have been approved for disease treatment in US aquaculture operations, although veterinarians can prescribe human and animal drugs use in food fish (Goldburg et al. 2001).

Antibiotics are given to fish and shrimp via injections, baths, and oral treatments (Hopkins et al. 1995; Goldburg and Triplett 1997). The most common method of oral administration is the incorporation of drugs into feed pellets, which results in a greater dispersion of antibiotics in the marine environment. Antibiotics, including those toxic to humans, typically bind to sediment particles, may remain in the environment for an extended period of time, can accumulate in farmed and wild fish and shellfish populations, and can harm humans when ingested.

Herbicides are chemicals used to control aquatic weeds in freshwater systems, and algicides are herbicides specifically formulated to kill algae; dissolved oxygen levels in ponds can be reduced when the algae die and decompose. A common ingredient in algicides is copper, which is toxic to aquatic organisms. Applications of herbicides or algicides must be carefully considered for their toxicity to aquaculture organisms and to humans, as well as their tendency to bioaccumulate in fish and shellfish tissues (Goldburg and Triplett 1997). While these chemicals may not be applied within riverine or estuarine systems, they may find their way there through stormwater runoff. Pesticides must also be carefully monitored for their effects on aquatic organisms and habitat. For example, antifouling compounds such as copper and organic tin compounds were historically used in the aquaculture industry to prevent fouling organisms from attaching to aquaculture structures. These chemicals accumulate in farmed and wild organisms, especially in shellfish species, and the use of organic tin compounds is now banned for use in both Washington and Maine. Aquaculturalists have used the insecticide, Sevin, for 35 years in Willapa Bay, WA, to control burrowing shrimp that destabilize sediment. Sevin kills other organisms such as the Dungeness crab (*Cancer magister*), and it should be used in moderation to minimize the impacts of the aquaculture industry on other important commercial fisheries (Goldburg and Triplett 1997). For additional information on the release of pesticides, refer to the Agriculture and Silviculture and Coastal Development chapters of this report.

### *Seafloor impacts*

Aquaculture operations not only can cause environmental impacts through the discharge of contaminants and organic wastes, but these operations can also affect the seafloor as a result of the deposition of waste products, the placement of aquaculture structures on the seafloor, and the harvesting of aquaculture species.

Aquaculture operations can have a wide range of biological, chemical, and physical impacts on seafloor habitat stemming from organic material deposition, shading effects, damage to habitat from aquaculture structures and operations, and harvesting with rakes and dredges (USFWS and NMFS 1999; Goldburg et al. 2001). Organic material deposition beneath netpens and cages can smother organisms, change the chemical and biological structure of sediment, alter species biomass and diversity, and reduce oxygen levels. The physical and chemical conditions present at the aquaculture site will influence the degree to which organic waste affects the benthic community. At aquaculture sites with slower currents and softer sediments, benthic community impacts will generally be localized; whereas sites with stronger currents and coarser sediments will generally have widely distributed but less intense benthic community effects downstream of the site.

At both land-based and water-based aquaculture facilities, accumulations of large amounts of carbon and nutrient-rich sediment may produce anaerobic conditions in sediments and cause the release of hydrogen sulfide and methane, two gases toxic to fish (Goldburg and Triplett 1997). In Maine, seafloor impacts resulting from sediment deposition at salmon farms include the growth of the bacterial mold *Beggiatoa* sp., which degrades water quality and subsequently lowers species diversity and biomass beneath the pens (Goldburg and Triplett 1997).

Suspended shellfish culture techniques may cause changes in benthic community structure similar to those conditions found under netpens. Filter-feeding shellfish "package" phytoplankton and other food particles into feces and pseudofeces, which are deposited on the seafloor and may cause local changes in benthic community structure (Grant et al. 1995; Goldburg and Triplett 1997). In Kenepuru Sound, New Zealand, a mussel aquaculture site consistently showed a higher organic nitrogen pool than at the reference site, indicating that organic nitrogen was accumulating in the sediments below the mussel farm (Kaspar et al. 1985). The benthic community at the mussel farm was composed of species adaptable to low-oxygen levels that live in fine-textured, organically rich sediments, while the reference site consisted of species that typically reside in highly oxygenated water (Kaspar et al. 1985).

Aquaculture structures can have direct impacts on seafloor habitat, including shading of seafloor habitat by netpens and cages (NEFMC 1998; USFWS and NMFS 1999). Shading can impede the growth of SAV that provides shelter and nursery habitat to fish and their prey species (Barnhardt et al. 1992; Griffin 1997; Deegan and Buchsbaum 2005). Seagrasses and other sensitive benthic habitats may also be impacted by the dumping of shells onto the seafloor for use in shellfish aquaculture operations (Simenstad and Fresh 1995). Shell substratum helps to stabilize the benthos and improve growth and survival of the cultured shellfish species. The placement of this material on the bottom not only causes a loss in seagrass and other habitat, but substrate modification also induces a localized change in benthic community composition (Simenstad and Fresh 1995).

Harvesting practices also have the potential to adversely affect seafloor habitat. Perhaps the most detrimental is the mechanical harvesting of shellfish (e.g., the use of dredges). Polychaete worms and crustaceans may be removed or buried during dredging activities (Newell et al. 1998). Mechanical harvesting of shellfish may also adversely affect benthic habitat through direct removal of seagrass and other reef-building organisms (Goldburg and Triplett 1997).

### *Introductions of exotic invasive species*

Aquaculture operations have the potential to be a significant source of nonnative introductions into North American waters (Goldburg and Triplett 1997; USCOP 2004). The cultivation of nonnative species becomes problematic when fish escape or are intentionally released into the marine environment. As discussed in the above section on introduced/nuisance species, introduced species can reduce biodiversity, alter species composition, compete with native species for food and habitat, prey on native species, inhibit reproduction, modify or destroy habitat, and introduce new parasites or diseases into an ecosystem (Goldburg and Triplett 1997; USFWS and

NMFS 1999). Impacts from introduced aquaculture species may result in the displacement or extinction of native species, which is believed to be a contributing factor in the decline of seven endangered or threatened fish species populations listed under the Endangered Species Act (Goldburg and Triplett 1997).

In Maine, escaped aquaculture salmon can disrupt redds (i.e., spawning nests) of wild salmon, transfer disease or parasites, compete for food and habitat, and interbreed with wild salmon (USFWS and NMFS 1999). Escaped aquaculture salmon represent a significant threat to wild salmon in Maine because even at low levels of escapement, aquaculture salmon can represent a large proportion of the salmon returns in some rivers. Escaped Atlantic salmon have been documented in the St. Croix, Penobscot, East Machias, Dennys, and Narraguagus rivers in Maine. Escapees represented 89% and 100% of the documented runs for the Dennys River in 1994 and 1997, respectively, and 22% of the documented run for the Narraguagus River in 1995 (USFWS and NMFS 1999). In 2000, only 22 wild Atlantic salmon in Maine were documented as returning to spawn in their native rivers; however, total adult returning spawners may have numbered approximately 150 fish (Goldburg et al. 2001).

Cultivating a reproductively viable European stock of Atlantic salmon in Maine waters poses a risk to native populations because of escapement and the subsequent interbreeding of genetically divergent populations (USFWS and NMFS 1999). The wild Atlantic salmon population in the Gulf of Maine currently exhibits poor marine survival and low spawning stock size, is particularly vulnerable to genetic modification, and is in danger of becoming extinct. Dilution of the gene pool, when combined with environmental threats such as reduced water levels, parasites and diseases, commercial and recreational fisheries, loss of habitat, poor water quality, and sedimentation could extirpate the wild salmon stock in the Gulf of Maine (USFWS and NMFS 1999). For additional discussions on this topic, refer to the subsection in this chapter on Gene Pool Alterations.

### *Food web impacts*

Aquaculture operations have the potential to impact food webs via localized nutrient loading from organic waste and by large-scale removals of oceanic fish for dry-pellet fish feed (Goldburg and Triplett 1997). As reviewed in previous sections of this chapter, nutrients in discharged organic waste may affect local populations by changing community structure and biodiversity. These localized changes may have broader implications to higher trophic level organisms. For example, biosedimentation at a mussel aquaculture site had a strong effect on benthic community structure both below and adjacent to mussels grown on rafts (Kaspar et al. 1985). Benthic species located beneath and adjacent to mussel rafts included sponges, tunicates, and calcareous polychaete worms, while benthic species at the reference site included bivalve mollusks, brittle stars, crustaceans, and polychaete worms. The shift in benthic community structure at the shellfish aquaculture site may have had implications in higher trophic levels in the ecosystem.

Large-scale removals of anchovy, herring, sardine, jack mackerel, and other pelagic fishes for the production of fish feed has an impact on the food web. Approximately 27% (31 million metric tons) of the world's fish harvest is now used to produce fish feeds, and about 15% of this is used in aquaculture production (Goldburg and Triplett 1997). Feeding fish to other fish on a commercial scale is highly energy-inefficient and may have environmental implications and impacts on other species. Higher trophic levels depend on small pelagic fishes for growth and survival, so the net removal of protein can have significant effects on sea birds, mammals, and commercially important fish species (Goldburg and Triplett 1997).

## *Gene pool alterations*

Escaped aquaculture species can alter the genetic characteristics of wild populations when native species interbreed with escaped nonnative or native aquaculture species or escaped genetically engineered aquaculture species (USFWS and NMFS 1999; Goldburg et al. 2001; USCOP 2004). Interbreeding of the wild population with escaped nonnative species is problematic, as discussed in the Introduced/Nuisance Species section of this chapter. Interbreeding of the wild population with escaped, native species may also be problematic because of the genetic differences between the escaped native and the wild native populations. Aquaculture operations often breed farmed fish for particular traits, such as smaller fins, aggressive feeding behavior, and larger bodies. Therefore, the genetic makeup of escaped native and wild native fish may be different, and interbreeding may decrease the fitness of wild populations through the breakup of gene combinations and the loss of genetic diversity (Goldburg et al. 2001).

Atlantic salmon aquaculture in New England has been established from Cape Cod, MA, north to Canada, although most of this activity is clustered at the Maine-New Brunswick border. In 1994, thousands of Atlantic salmon escaped from an aquaculture facility during a storm event; many of these fish spread into coastal rivers in eastern Maine (Moring 2005). In 2000, a similar storm event in Maine resulted in the escapement of 100,000 salmon from a single farm, which is more than 1,000 times the documented number of native adult Atlantic salmon. Canada is experiencing similar problems with aquaculture escapees and the interbreeding of wild and farmed salmon populations. In 1998, 82% of the young salmon leaving the Magaguadavic River in New Brunswick originated from aquaculture farms (Goldburg et al. 2001). Escapees can and do breed with wild populations of Atlantic salmon, which is a concern because interbreeding can alter the genetic makeup of native stocks (Moring 2005).

Escaped genetically engineered aquaculture species may exacerbate the problem of altering the gene pool of native fish stocks. Genetically engineered (i.e., transgenic) species are being developed by inserting genes from other species into the DNA of fish for the purpose of altering performance, improving flesh quality, and amplifying traits such as faster growth, resistance to diseases, and tolerance to freezing temperatures (Goldburg and Triplett 1997; Goldburg et al. 2001). For example, genetically engineered Atlantic salmon have an added hormone from chinook salmon that promotes faster growth, which may reduce costs for growers (Goldburg et al. 2001, 2003). Although no transgenic fish products are commercially available in the United States, at least one company has applied for permission through the Food and Drug Administration to market a genetically-engineered Atlantic salmon for human consumption (Goldburg et al. 2001, 2003). Transgenic aquaculture escapees could impair wild Atlantic salmon stocks via competition, predation, and expansion into new regions. Interbreeding could weaken the genetic integrity of wild salmon populations and have long-term, irreversible ecological effects (Goldburg et al. 2001).

## *Impacts to the water column and water quality*

Aquaculture may impact the water column via organic and contaminant discharge from land- and water-based aquaculture sites (NEFMC 1998). As discussed in other sections of this chapter, aquaculture discharges include nutrients, toxins, particulate matter, metabolic wastes, hormones, pigments, minerals, vitamins, antibiotics, herbicides, and pesticides. Water quality in the vicinity of finfish aquaculture operations may be impaired by the discharge of these compounds. The water column may become turbid as a result of this discharge, which can degrade overall habitat conditions for fish and shellfish in the area. Discharge may contribute to nutrient loading, which may lead to eutrophic conditions in the water column. Eutrophication often results in oxygen depletion, finfish and shellfish kills, habitat degradation, and harmful algal blooms that may impact human health.

Shellfish aquaculture operations have the potential to improve water quality by filtration of nutrients and suspended particles from the water column (Newell 1988). However, bivalves may contribute to the turbidity of the pelagic environment via their waste products (Kaspar et al. 1985; Grant et al. 1995). These waste products are expelled as feces and pseudofeces, which can be suspended into the water column, thus contributing to nutrient loads near aquaculture sites. Nutrient overenrichment often results in oxygen depletion, toxic gas generation, and harmful algal blooms, thus impairing the water quality near shellfish aquaculture sites. Therefore, both finfish and shellfish aquaculture operations have the potential to adversely affect water quality beneath aquaculture structures and in the surrounding environment. For additional information on discharge of nutrients and its subsequent effects on the water column via eutrophication and algal blooms, see the subsections on the Discharge of Organic Wastes and Discharge of Contaminants in this chapter, as well as the chapters on Agriculture and Silviculture, Coastal Development, and Alteration of Freshwater Systems of this report.

### *Changes in species diversity*

Species diversity and abundance may change in the vicinity of aquaculture farms as a result of effluent discharges or habitat modifications that alter environmental conditions. Changes in species diversity may occur through increased organic waste in pelagic and benthic environments, modification to bottom habitat, and the attraction of predators to the farmed species. Accumulated organic waste beneath aquaculture structures may change benthic community structure. In Maine, salmon netpen aquaculture can alter the benthos by shifting microbial and macrofaunal species to those adapted to enriched organic sediments. At one netpen site, epibenthic organisms were more numerous near the pen than at reference sites, suggesting that benthic community structure can be altered by salmon aquaculture in coastal Maine waters (Findlay et al. 1995).

Cultivated mussels can alter species diversity via biodeposition. Benthic habitat can shift from communities of bivalve mollusks, brittle stars, crustaceans, and polychaete worms to communities of sponges, tunicates, and calcareous polychaete worms beneath mussel aquaculture sites. The difference between the two sites represents a change in species diversity from those that typically reside in highly oxygenated water to those species adaptable to low-oxygen levels that can live in areas with fine-textured, organically rich sediments (Kaspar et al. 1985).

Benthic habitat modification at shellfish aquaculture sites can alter species diversity (Kaiser et al. 1998). Cultivation of shellfish such as hard clams requires the placement of gravel or crushed shell on the substrate. Seed clams are placed on the substrate in bags or directly on substrate covered with protective plastic netting. Benthic structure at shellfish aquaculture sites can therefore shift from polychaete-dominated communities to bivalve and nemertean-dominated communities, which could have repercussions for other trophic levels (Simenstad and Fresh 1995; Kaiser et al. 1998). However, community diversity may be enhanced by the introduction of aquaculture species and the modification of the substrate. For example, the placement of gravel in the intertidal area, the placement of substrates suitable for macroalgal attachment, or predator exclusion nets in some habitats may enhance epibenthos diversity and standing stock (Simenstad and Fresh 1995).

Open water netpens may alter species diversity by attracting wild fish or other predators to the aquaculture site (Vita et al. 2004). Wild benthic and pelagic species are attracted to uneaten pellet feed and other discharged effluent, which can result in impacts to the food web (Vita et al. 2004). Predators such as seals, sea lions, and river otters may also be attracted to aquaculture pens to feed on farmed species, which can alter communities in the vicinity of aquaculture sites (Goldburg et al. 2001).

### *Sediment deposition*

The effects of sediment deposition include eutrophication of the water column; toxic algal blooms; hypoxic or anoxic zones caused by microbial degradation; and the spread of contaminants such as antibiotics, herbicides, pesticides, hormones, pigments, minerals, and vitamins. The impacts of sediment deposition from discharged organic waste and contaminants on the water column and on the seafloor have been discussed in the Discharge of Organic Wastes, Discharge of Contaminants, Seaflood Impacts, Food Web Impacts, Changes in Species Diversity, and Habitat Exclusion and Replacement/Conversion subsections of this chapter.

### *Introduction of diseases*

Parasite and disease introductions into wild fish and shellfish populations are often associated with aquaculture operations and have the potential to lower the fitness level of native species or contribute to the decline of native populations. For example, in the 1940s and 1950s, scientists inadvertently introduced a new disease into eastern US waters when they attempted to restore declining populations of the eastern oyster (*Crassostrea virginica*) via the introduction of the Pacific oyster (*Crassostrea gigas*) (Burreson et al. 2000; Rickards and Ticco 2002). *Haplosporidium nelsoni* is a protistan parasite that causes MSX oyster disease and was present amongst the Pacific oysters introduced in east coast waters. MSX spread from Delaware Bay to the Chesapeake Bay and contributed to the decline in the native oyster population. MSX and another pathogenic disease, Dermo (*Perkinsus marinus*), have collectively decimated the native oyster population remaining along the much of the eastern US coast (Rickards and Ticco 2002).

In eastern Maine and New Brunswick, an outbreak of two diseases in both wild and cultured stocks of Atlantic salmon suggests that cultured stocks are acting as reservoirs of diseases and are now passing them on to wild stocks (Moring 2005). In addition to diseases, sea lice are a flesh-eating parasite that has been passed from farmed salmon to wild salmon when wild salmon migrate through coastal waters. Sea lice also can serve as a host for Infectious Salmon Anemia (ISA), which is a virus that has spread from salmon farms in New Brunswick to salmon farms in Maine (USFWS and NMFS 1999). The ISA virus causes fatalities in salmon at aquaculture facilities, and this virus has been detected in both escaped farmed salmon and wild salmon populations. ISA first appeared in New Brunswick in 1996, was detected in the United States in 2001, and represents a significant threat to wild salmon populations (Goldburg et al. 2001).

### *Habitat exclusion and replacement/conversion*

Aquaculture operations require the use of space, which results in the conversion of natural aquatic habitat that could have been used by native organisms for spawning, feeding, and growth. Approximately 321,000 acres of fresh water habitat and 64,000 acres of salt-water habitat have been converted for use in aquaculture operations in the United States (Goldburg et al. 2001). Aquaculture facilities may exclude aquatic organisms from their native habitat through the placement of physical barriers to entry or through changes in environmental conditions at aquaculture sites. Nets, cages, concrete, and other barriers exclude aquatic organisms from entering the space in which the aquaculture structures are placed. By effectively acting as physical barriers for wild populations, these formerly usable areas are no longer available as habitat for fish and shellfish species to carry out their life cycles. Aquaculture facilities may physically exclude wild stocks of fish, such as Atlantic salmon, from reaching critical spawning habitat upstream of the facilities (Goldburg et al. 2001).

Changes in environmental conditions at the aquaculture site may also exclude aquatic organisms from their native habitat. Discharge of organic waste and contaminants beneath aquaculture netpens and cages may render pelagic and benthic habitat unusable through nutrient loading and the subsequent effects of eutrophication. Low dissolved oxygen caused by eutrophication may force native species out of their habitat, while harmful algal blooms can cause widespread fish kills or exclude fish from areas affected by the outbreak (Goldburg and Triplett 1997). In the case of large shellfish aquaculture operations, filtering bivalves can also decrease the amount and type of nutrients and phytoplankton available to other species. This reduction in nutrients and phytoplankton can stimulate competition between populations of cultured and native species (Dankers and Zuidema 1995). Nutrient and phytoplankton removal could have a cascade effect on the trophic structure of the ecosystem (NEFMC 1998), which may eventually cause mobile species to relocate to other areas. Nonetheless, bivalves grown in open-water mariculture facilities can provide similarily beneficial filtering functions as native bivalves by contributing to the control nutrients, suspended sediments, and water column phytoplankton dynamics.

Aquaculture can result in the replacement or conversion of the natural benthic and pelagic community in the area surrounding the facility. For example, shellfish aquaculture can eliminate seagrass beds when shell material is dumped on the seafloor (Simenstad and Fresh 1995). Seagrass beds in the vicinity of shellfish culture operations may be eliminated during harvesting, which may temporarily reduce levels of biodiversity by reducing habitat for other marine species. Habitat conversion also takes place at netpen sites in which sediment deposition causes underlying habitat to become eutrophic. Sensitive benthic habitats beneath the netpens, such as seagrasses, may be eliminated or degraded by poor water quality conditions, thus converting viable habitat to unusable or less productive seafloor area (Goldburg and Triplett 1997).

Although the effects of replacement and exclusion of habitat by aquaculture facilities are often negative, there may be some positive effects of the structures. For example, cages, anchoring systems, and other devices can increase the structural complexity to the benthic and pelagic environment, which can provide shelter and foraging habitat for some native species. Open-water shellfish mariculture operations can provide some of the same habitat benefits as natural shellfish beds, such as refugia from predation and feeding habitat for juvenile and adult mobile species. Under some conditions, seafloor productivity may increase near aquaculture sites.

### *Conservation measures and best management practices for aquaculture*

1. Assess the aquatic resources in the area when siting new aquaculture facilities, including benthic communities, the proximity to wild stocks, migratory corridors, competing resource uses (e.g., commercial fishing, recreational uses, other aquaculture facilities), hydrographic conditions, and upstream habitat uses.
2. Avoid siting of aquaculture operations in or near sensitive benthic communities, such as submerged aquatic vegetation.
3. Avoid enclosing or impounding tidally influenced wetlands for mariculture purposes.
4. Ensure that aquaculture operations adequately address disease issues to minimize risks to wild stocks.
5. Employ methods to minimize escape from culture facilities to minimize potential genetic impacts and to prevent disruption of natural aquatic communities.
6. Design aquaculture facilities to meet applicable environmental standards for wastewater treatment and sludge control.

7. Locate aquaculture facilities to minimize discharge effects on habitat and locate water intakes to minimize entrainment of native fauna.
8. Evaluate and control the use of antibiotics, pesticides, and herbicides in aquaculture operations. Avoid direct application of carbaryl or other pesticides in water.
9. Consider biological controls to reduce pest populations, such as small, native species that feed on sea lice and fouling organisms.
10. Reduce the metabolic stress of aquaculture species in order to eliminate or reduce the need for using chemicals. Measures to reduce stress include improving water quality, lowering stock densities, and minimizing handling of fish.
11. Use aquaculture gear designed to minimize entanglement of native species attracted to the aquaculture operation (e.g., predators, such as marine mammals and birds).
12. Exclude exotic species from aquaculture operations until a thorough scientific evaluation and risk assessment is performed.
13. Locate aquaculture facilities rearing nonnative species upland and use closed-water circulation systems.
14. Treat effluent from public aquarium displays, laboratories, and educational institutes that are using exotic species prior to discharge for the purpose of preventing the introduction of viable animals, plants, reproductive material, pathogens, or parasites into the environment.
15. Consider growing several cultured species together, such as finfish, shellfish, algae, and hydroponic vegetables to reduce nutrient and sediment loads on the ecosystem.
16. Develop a monitoring program at the site to evaluate habitat and water quality impacts and the need for corrective measures through adaptive management.

# CHAPTER ELEVEN: GLOBAL EFFECTS AND OTHER IMPACTS

## Climate Change

### *Introduction*

The earth's climate has changed throughout geological history because of a number of natural factors that affect the radiation balance of the planet, such as changes in earth's orbit, the output of the sun, and volcanic activity (IPCC 2007a). These natural changes in the earth's climate have resulted in past ice ages and periods of warming that take place over several thousand years. An example of changes to earth's climate over recent geological timeframes caused by natural factors has been observed in slowly rising global temperatures and sea levels since the end of the Pleistocene epoch (about 10,000 years before present). However, the rate of warming observed over the past 50 years is unprecedented in at least the previous 1,300 years (IPCC 2007a). The Intergovernmental Panel on Climate Change (IPCC) concludes that recent human-induced increases in atmospheric concentrations of greenhouse gases are expected to cause much more rapid changes in the earth's climate than have previously been experienced (IPCC 2007a). The buildup of greenhouse gases (primarily carbon dioxide) is a result of burning fossil fuels and forests and from certain agricultural activities. Other greenhouse gases released by human activities include nitrous oxide, methane, and chlorofluorocarbons. The global atmospheric concentration of carbon dioxide has increased from about 280 ppm during preindustrial times to 379 ppm in 2005, which far exceeds the natural range over the last 650,000 years (180-300 ppm) as determined from ice cores (IPCC 2007a).

In the Fourth Assessment Report of the IPCC, the Contribution of Working Group I issued the following conclusions (IPCC 2007a):

> Warming of the climate system is unequivocal, as is now evident from observations of increases in global average air and ocean temperatures, widespread melting of snow and ice, and rising global average sea level. Most of the observed increase in globally averaged temperatures since the mid-20th century is *very likely* due to the observed increase in anthropogenic greenhouse gas concentrations.

In order to consider various possible futures for climate change effects, the IPCC developed a series of models, or scenarios, based upon different levels of greenhouse gas emissions. The higher-emissions scenario represented fossil fuel-intensive economic growth and global human population that peaks around 2050 and then declines. This model assumes atmospheric carbon dioxide concentrations to reach about 940 ppm by 2100, or about three times preindustrial levels (Frumhoff et al. 2007). The lower-emissions scenario also represents a global human population that peaks around 2050 but assumes a much faster shift to less fossil fuel-intensive industries and more resource-efficient technologies. This model assumes carbon dioxide concentrations to peak around 2050 and then to decline to about 550 ppm by 2100, which is about double preindustrial levels (Frumhoff et al. 2007).

Based on current global climate models for greenhouse gas emission scenarios, some of the 2007 IPCC report conclusions were:

1. By 2100 average global surface air temperatures will increase by 1.8°C (lower-emissions scenario) to 4.0°C (higher-emissions scenario) above 2000 levels. The most drastic warming will occur in northern latitudes in the winter.
2. Sea level rose 12-22 cm in the 20th century and may rise another 18-38 cm (lower-emissions scenario) and as high as 26-59 cm (higher-emissions scenario) by 2099. However, these projections were based upon contributions from increased ice flow from Greenland and Antarctica at rates observed for the 1993-2003 period. If this contribution were to grow linearly with global average temperature change, the upper ranges for sea level rise would increase by an additional 10-20 cm.
3. Global precipitation is likely to increase, with more precipitation and more intense storms in the mid to high latitudes in the northern hemisphere.
4. Increasing atmospheric carbon dioxide concentrations may acidify the oceans, reducing pH levels by 0.14 and 0.35 units by 2100, adding to the present decrease of 0.1 units since preindustrial times.

The average annual atmospheric temperature across the northeastern United States has risen by approximately 0.8ºC since 1900, although this warming trend has increased to approximately 0.3ºC per decade since 1970 (Frumhoff et al. 2007). Most climate models indicate the region will experience continued increased warming over the next century (Frumhoff et al. 2007; IPCC 2007a). Climate change models predict increased warming under the lower-emissions scenario to be 2.2-4.2°C and 3.8-7.2°C under the higher-emissions scenario by 2100 in New England and eastern Canada (Frumhoff et al. 2007). Over the next several decades, the greatest temperature changes are expected to be in the wintertime and early spring with warm periods expected to increase in frequency and duration (Nedeau 2004). For example, the average winter temperature in over the next few decades are expected to increase 1.4-2.2°C under both emission scenarios, while average summer temperature increases are expected to be 0.8-1.9°C (Frumhoff et al. 2007). However, by the end of the century, the average winter temperature is expected to increase 4.4-6.7°C under the higher-emissions scenario, while summer temperature is expected to increase 3.3-7.8°C (Frumhoff et al. 2007). Long-term increases in average temperatures, the frequency and intensity of extreme temperature and climatic events, and the timing of seasonal temperature changes can have adverse effects on ecosystem function and health. Combined with extreme precipation and drought and rising sea levels, these effects have the potential to result in considerable adverse changes to the northeast region's ecosystems.

Primary impacts of global climate change that may threaten riverine, estuarine, and marine fishery resources include:

1. Increasing rates of sea-level rise and intensity and frequency of coastal storms and hurricanes will increase threats to shorelines, wetlands, and coastal ecosystems;
2. Marine and estuarine productivity will change in response to reductions in ocean pH and alterations in the timing and amount of freshwater, nutrients, and sediment delivery;
3. High water temperatures and changes in freshwater delivery will alter estuarine stratification, residence time, and eutrophication and;
4. Increased ocean temperatures are expected to cause poleward shifts in the ranges of many marine organisms, including commercial species, and these shifts may have secondary effects on their predators and prey.

These affects may be intensified by other ecosystem stresses (pollution, harvesting, habitat destruction, invasive species), leading to more significant environmental consequences. It should be noted that while the general consensus among climate scientists today indicates a current and future warming of the earth's climate caused by emissions of greenhouse gases from anthropogenic sources, the anticipated effects at regional and local levels are less understood. Consequently, there are degrees of uncertainty regarding the specific effects to marine organisms and communities and their habitats from climate change. For example, although most climate models predict an increase in extreme rainfall events in the northeast region of the United States, the regional projections for average annual precipitation and runoff vary considerably (Scavia et al. 2002).

This section attempts to address some of the possible effects of global climate change to fishery resources in the northeast region of the United States. The effects discussed in this report reflect the general topics identified by participants of the Technical Workshop on Impacts to Coastal Fishery Habitat from Nonfishing Activities. However, other possible effects and consequences of climate change have been suggested, some of which may be inconsistent with those described in this report. A complete and thorough discussion of this rapidly-developing area of science is beyond the scope of this report. For a more thorough assessment of impacts caused by climate change, we recommend the reader refer to the publications cited in this chapter, as well as new research that will emerge subsequent to this report.

### *Alteration of hydrological regimes*

The hydrologic cycle controls the strength, timing, and volume of freshwater input, as well as the chemical and sediment load to estuaries and coastal waters (Scavia et al. 2002). Precipitation across the continental United States has increased by about 10% in the past 100 years or so, primarily reflected in the heavy and extreme daily precipitation events (Karl and Knight 1998; USGS 2005). This trend is also evident in the northeastern US region, which has experienced an increase in annual average precipitation by about 5-10% since 1900 (Frumhoff et al. 2007). In addition, increased early spring streamflows have occurred over the past century in New England, possibly a result of earlier melting of winter snowpack caused by increased air temperatures and/or greater rainfall (Hodgkins and Dudley 2005).

The IPCC Working Group II Report on Climate Change Impacts, Adaptation, and Vulnerability (IPCC 2007b) concluded that by mid-century average annual river runoff and water availability are projected to increase by 10-40% at high latitudes and in some wet tropical areas and decrease by 10-30% over some dry regions at mid-latitudes and in the dry tropics. For the northeastern United States, climate change models indicate an increase in precipitation over the next 100 years (Frumhoff et al. 2007; IPCC 2007b). By the end of the century, the average annual precipitation is expected to increase by about 10%; however, the average winter precipitation is expected to increase 20-30%, and a much greater proportion of the precipitation would be expected to fall as rain rather than snow (Frumhoff et al. 2007; IPCC 2007b). Climate models also predict more frequent, heavy-precipitation events, which are expected to increase the probability of high-flow events in Maine, New Hampshire, and Vermont streams and rivers by about 80% during late winter and spring (Frumhoff et al. 2007). These changes in the intensity and frequency of high-flow events have the potential to increase the export of nutrients, contaminants, and sediments to our estuaries. Climate-related changes in the northeast region may alter the timing and amount of water availability. For example, increased temperatures during summer months can increase evapotranspiration rates. Combined with reduced summer rainfall, these changes can cause reductions in soil moisture and streamflows that may lead to seasonal drought (Frumhoff et al. 2007).

Accelerated sea-level rise resulting from climate change threatens coastal wetlands through inundation, erosion, and saltwater intrusion (Kennedy et al. 2002; Scavia et al. 2002). The quantity of freshwater discharges affects salt marshes because river flow and runoff deliver sediments that are critical for marshes to maintain or increase its elevation. An increase in freshwater discharge could increase supply of sediment and allow coastal wetlands to cope with sea-level rise (Scavia et al. 2002). However, some coastal areas may experience a decrease in precipitation and freshwater runoff, causing salt marsh wetlands to become sediment-starved and ultimately lost as sea levels rise and marshes are drowned (Kennedy et al. 2002). Greater periods of drought leading to a decrease in freshwater discharge might also cause salinity stress in salt marshes. Rising sea levels will also allow storm surges to move further inland and expose freshwater wetlands to high salinity waters.

Estuaries may be affected by changes in precipation and freshwater discharge from rivers and runoff from land. Precipitation patterns and changes in freshwater inflow can influence water residence time, salinity, nutrient delivery, dilution, vertical stratification, and phytoplankton growth and abundance (Scavia et al. 2002). Patterns of more frequent heavy-precipitation events during winter and spring months and increased temperature and reduced rainfall during summer months may exacerbate existing nutrient over-enrichment and eutrophication conditions that already stress estuarine systems (Scavia et al. 2002; Frumhoff et al. 2007).

A decline in the atmospheric pressure at the sea surface in the central Arctic during the late 1980s led to increased delivery of warmer, higher-salinity Atlantic water into the Arctic Ocean, mainly via the Barents Sea (Greene and Pershing 2007). In addition, there has been an increase in continental melting of permafrost, snow, and ice which, combined with increased precipitation, has resulted in greater river discharge into the Arctic Ocean over the past three decades. This is believed to have led to accelerated sea ice melting and reductions in Arctic sea ice. Although the relative importance of human versus natural climate forces in driving the observed changes in atmospheric and ocean circulation patterns continues to be debated, it has led to an enhanced outflow of low-salinity waters from the Arctic and general freshening of shelf waters from the Labrador Sea to the Mid-Atlantic Bight beginning in the early 1990s (Greene and Pershing 2007). Increased freshwater input in the upper layers of the ocean results in increased stratification, which suppresses upwelling of nutrients into the upper regions of the ocean and generally reduces the productivity of phytoplankton (Kennedy et al. 2002). Conversely, increased freshwater flux and stratification could also lead to enhanced biological productivity in some systems by enabling organisms to remain longer in the photic zone (Scavia et al. 2002). Greene and Pershing (2007) reported enhanced ocean stratification caused by increased freshwater outflow from the Arctic during the 1990s. They attributed increased phytoplankton and zooplankton production and abundance during the autumn, a period when primary production would otherwise be expected to decline, with enhanced freshening of the Northwest Atlantic shelf (Greene and Pershing 2007). Although some climate models predict a net decrease in global phytoplankton productivity under doubled atmospheric carbon dioxide conditions caused by increased thermal stratification and reduced nutrient upwelling, simple extrapolation to particular northeast marine waters is difficult (Kennedy et al. 2002). The climatic variability associated with natural, large-scale phenomena such as the El Nino-Southern Oscillation and the North Atlantic Oscillation/Northen Hemisphere Annular Mode effects water column mixing and stratification on regional and global scales and has implications on the productivity of the oceans. These natural phenomena may act in tandem with, or in opposition to, anthropogenic climate change (Kennedy et al. 2002).

A number of computer climate models indicate a slowing of the “overturning” process of ocean waters, known as the thermohaline circulation (THC). This phenomenon appears to be driven by a reduction in the amount of cold and salty, and hence, more dense water sinking into the depths of the ocean. In fact, surface waters of the North Atlantic Ocean have been warming in recent decades and parts of the North Atlantic Ocean are also becoming less salty (Nedeau 2004).

In the North Atlantic, a weakening of the THC is related to wintertime warming and increased freshwater flow into the Arctic Ocean and the North Atlantic Ocean (Nedeau 2004). An increased weakening of the THC could lead to a complete shut down or southward shift of the warm Gulf Stream, as was experienced during the last glacial period (Nedeau 2004). However, the response of the THC to global climate change remains uncertain, and predictions are dependent upon future greenhouse gas emissions and temperature increases (Kennedy et al. 2002). On a regional level, changes in ocean current circulation patterns may alter temperature regimes, vertical mixing, salinity, dissolved oxygen, nutrient cycles, and larval dispersal of marine organisms in the northeast coastal region, ultimately leading to a net reduction in oceanic productivity (Nedeau 2004).

### *Alteration of temperature regimes*

Sea surface temperatures of the northeastern US coast have increased more than 0.6°C in the past 100 years, and are projected to increase by another 3.8-4.4°C under the high-emissions scenario and by 2.2-2.8°C under the lower-emissions scenario over the next 100 years (Frumhoff et al. 2007). The IPCC Working Group II Report (IPCC 2007b) concluded there is "high confidence" that observed changes in marine and freshwater biological systems are associated with rising water temperatures, including: (1) shifts in ranges and changes in algal, plankton, and fish abundance in high-latitude oceans; (2) increased algal and zooplankton abundance in high-latitude and high-altitude lakes; and (3) range changes and earlier migrations of fish in rivers.

Temperature affects nearly every aspect of marine environments, from cellular processes to ecosystem function. The distribution, abundance, metabolism, survival, growth, reproduction, productivity, and diversity of marine organisms will all be affected by temperature changes (Kennedy et al. 2002; Nedeau 2004). Most marine organisms are able tolerate a specific temperature range and will become physiologically stressed or die after exposure to temperatures above or below the normal range. At sublethal levels, temperature extremes can effect the growth and metabolism of organisms, as well as behavior and distribution patterns. Reproduction timing and the rates of egg and larval development are dependent upon water temperatures. The reproductive success of some cold water fish species may be reduced if water temperatures rise above the optimum for larval growth (Mountain 2002). For example, cold-adapted species, such as winter flounder (*Pseudopleuronectes americanus*), Atlantic cod (*Gadus morhua*), Atlantic salmon (*Salmo salar*), and ocean quahog (*Artica islandica*) may not be able to compete with warm-adapted species if coastal water temperatures increase, particularly for those populations that may be living near the southern distribution limit (Kennedy et al. 2002).

The predicted increase in water temperatures resulting from climate change, combined with other factors such as increased precipitation and runoff, may alter seasonal stratification in the northeast coastal waters. Stratification could affect primary and secondary productivity by altering the composition of phytoplankton and zooplankton, thus affecting the growth and survival of fish larvae (Mountain 2002). In the northeast Atlantic, studies have found shifts in the timing and abundance of plankton populations with increasing ocean temperatures (Edwards and Richardson 2004; Richardson and Schoeman 2004). Edwards and Richardson (2004) found long term trends in the timing of seasonal peaks in plankton populations with increasing sea surface temperatures. However, the magnitude of the shifts in seasonal peaks were not equal among all trophic groups, suggesting alterations in the synchrony of timing between primary, secondary, and tertiary production. Richardson and Schoeman (2004) reported effects of increasing sea surface temperatures on phytoplankton abundances in the North Sea. Phytoplankton production tended to increase as cooler ocean areas warmed, probably because higher water temperatures boost phytoplankton metabolic rates. However, in warmer ocean areas phytoplankton became less abundant as sea surface temperatures increased further, possibly because warm water blocks nutrient-rich deep water from rising to the upper strata where phytoplankton exist (Richardson and Schoeman 2004). These effects have been implicated as a factor in the decline in North Sea cod stocks (Edwards and Richardson 2004; Richardson and Schoeman 2004). Impacts to the base of the food chain would not only affect fisheries but will impact entire ecosystems.

Mountain (2002) predicted a northward shift in the distributional patterns of many species of fish because of increasing water temperatures in the Mid-Atlantic region as a result of climate change. Nearly thirty years of standardized catch data on the northeast continental shelf revealed significant surface and bottom water temperature anomalies that resulted in changes to the distribution of 26 out of 30 fish species examined (Mountain and Murawski 1992). Increased water temperatures were correlated with fish moving northward or shallower to cooler water (Mountain and Murawski 1992). Perry et al. (2005) investigated the distributional patterns of demersal fish species in the North Sea and found two-thirds of all species examined shifted in latitude or depth or both in response to increasing water temperatures. This study reported that most of the species with shifting distributions had moved north or to greater depths in areas of cooler waters. Temperature induced shifts in the distribution of fish have implications for stock recruitment success and abundance. Based on the projected sea surface temperature increases under the higher-emission scenarios, Frumhoff et al. (2007) predicted bottom temperatures by the year 2100 on Georges Bank would approach the 30ºC threshold of thermally-suitable habitat and practical limit of Atlantic cod distribution. The 26ºC threshold for the growth and survival of young cod would be exceeded by the end of the century under both emission scenarios on Georges Bank (Frumhoff et al. 2007).

The frequency of diseases and pathogens may increase with warming ocean temperatures caused by climate change. For example, Dermo, a disease that affects commercially valuable oysters, exhibits higher infection rates with increased temperature and salinity. Warm, dry periods (e.g., summer drought) may make oysters more susceptible to this disease. Extremely warm waters in New England and the mid-Atlantic regions are suspected as playing a role causing disease and mortality events in American lobsters (*Homarus americanus*), including lobster-shell disease, parasitic paramoebiasis, and calcinosis (Frumhoff et al. 2007). The eelgrass wasting disease pathogen (*Labyrinthula zosterae*) has reduced eelgrass beds throughout the east coast in the past and may become more problematic because of its preference for higher salinity waters and warmer water (both of which are expected in some estuaries because of sea-level rise) (Nedeau 2004).

### *Changes in dissolved oxygen concentrations*

Dissolved oxygen concentrations are influenced by the temperature of the water. Because warmer water holds less oxygen than does colder water, increased water temperatures will reduce the dissolved oxygen in bodies of water that are not well mixed. This may exacerbate nutrient-enrichment and eutrophication conditions that already exist in many estuaries and marine waters in the northeastern United States. Increased precipitation and freshwater runoff into estuaries would effect water residence time, temperature and salinity, and increase vertical stratification of the water column, which inhibits the diffusion of oxygen into deeper water leading to reduced (hypoxic) or depleted (anoxic) dissolved oxygen concentrations in estuaries with excess nutrients (Kennedy et al. 2002; Scavia et al. 2002; Nedeau 2004). Increased vertical stratification of the water column occurs with increasing freshwater inflow and decreasing salinities, resulting from greater precipitation and storm water input. In addition, increased water temperatures in the upper strata of the water column also increase water column stratification.

Some species may be adversely affected by increasing surface water temperatures caused by climate change as they seek cooler and deeper waters. Deeper areas may be susceptible to hypoxic conditions near the bottom in stratified, poorly mixed estuarine and marine environments and would be unfavorable to many species. The habitats of aquatic species may be "squeezed" by warming surface waters and hypoxic bottom waters, resulting in greater physiologic stress and metabolic costs or death if the stress does not abate (Kennedy et al. 2002). However, an increase in coastal storm frequency and intensity, as predicted with some climate models, may contribute to some increase in vertical mixing of shallow habitats and reduce the effects of stratification.

Some phytoplankton populations may respond positively to increases in water temperatures and available carbon dioxide, which most climate models project are likely as a result of global warming (IPCC 2007a). Increased precipitation and runoff can increase the nutrient loads entering estuaries and marine waters that further exacerbate the proliferation of algae in nearshore waters. As algae die and begin to sink to the bottom, the decomposition of this increased organic material will consume more oxygen in the water, increasing the occurrence of hypoxic and anoxic conditions in coastal waters (Nedeau 2004).

### *Nutrient loading and eutrophication*

Nitrate driven eutrophication is one of the greatest threats to the integrity of many estuaries in the northeast region (NRC 2000; Cloern 2001; Howarth et al. 2002). Increases in the amount of precipitation are very likely in northern latitudes (IPCC 2007a), and excess nutrients exported from watersheds and delivered to estuarine and marine waters may increase if freshwater flow from rivers and stormwater discharges are greater. Higher nutrient loads may increase the incidence of eutrophication and harmful algal blooms, which can cause hypoxia or anoxia in nearshore coastal waters. These effects on water quality can also negatively impact benthic communities and submerged aquatic vegetation (SAV). The environmental effects of excess nutrients or sediments are the most common and significant causes of SAV decline worldwide (Orth et al. 2006).

### *Release of contaminants*

Increased precipitation and freshwater runoff may increase because of climate change and may lead to increased contaminant loading in coastal waters. Contaminants, such as hydrocarbons, metals, organic and inorganic chemicals, sewage, and wastewater materials, can be flushed from the watershed and exported to coastal waters, especially if the frequency and intensity of storms and floods are affected (Kennedy et al. 2002). These contaminants may be stored in coastal sediments or taken up directly by biota (e.g., bacteria, plankton, shellfish, or fish) and could ultimately affect fisheries and human health. Sea-level rise would inundate lowland sites near the coast, many of which contain hazardous substances that could leach contaminants into nearshore habitats (Bigford 1991).

### *Loss of wetlands and other fishery habitat*

Global warming is expected to accelerate the rate of sea-level rise by expanding ocean water and melting alpine glaciers over the next century (Schneider 1998; IPCC 2007a). Average global sea levels rose 12-22 cm between 1900 and 2000 and are expected to rise another 18-38 cm (lower-emissions scenario) and as high as 26-59 cm (higher-emissions scenario) by 2100 (IPCC 2007a). In the US Atlantic coast, relative sea levels over the last century have risen approximately 18 cm in Maine and as much as 44 cm in Virginia (Zervas 2001). Sea-level rise may affect diurnal tide ranges, causing coastal erosion, increasing salinity in estuaries, and changing the water content of shoreline soils. Accelerated sea-level rise threatens coastal habitats with inundation, erosion, and saltwater intrusion (Scavia et al. 2002; Frumhoff et al. 2007). Sea-level rise may indundate salt marshes and coastal wetlands, at which point shorelines will either need to build upward (accrete) to keep pace with rising sea levels or migrate inland to keep pace with drowning/erosion on the seaward edge. In cases where the upland edge is blocked by steep topography (e.g., bluffs) or human development (e.g., shoreline protection structures) coastal wetlands including salt marsh will be lost (Scavia et al. 2002; Frumhoff et al. 2007; IPCC 2007b). Conservative estimates of losses to saline and freshwater wetlands from sea-level rise range from 47-82% of the nation's coastal wetlands, or approximately 2.3-5.7 million acres (Bigford 1991). Shoreline protection structures can also prevent the shoreward migration of SAV necessitated by sea-level rise (Orth et al. 2006).

Worldwide distribution, productivity, and function of SAV may be effected by climate change. Perhaps most critical to SAV are impacts from increases in seawater temperature resulting from the greenhouse gas effect; secondary impacts of changing water depths and tidal range caused by sea-level rise, altered current circulation patterns and current velocities; changes in salinity regimes; and potential impacts on plant photosynthesis and productivity resulting from increased ultraviolet-B radiation and carbon dioxide concentrations (Short and Neckles 1999).

The distribution and productivity of coastal wetlands may be effected by rising sea levels, altered precipitation patterns, changes in the timing and delivery of freshwater and sediment, and increases in atmospheric carbon dioxide and temperature (Scavia et al. 2002). Increased atmospheric carbon dioxide could increase plant production for some coastal wetland species, assuming other factors such as nutrients and precipitation are not limiting. However, rising sea levels may inhibit the growth of some brackish and freshwater marshes and swamps.

### *Shoreline erosion*

Millions of cubic yards of sand are placed on northeast coastal beaches each year by state and federal governments to combat shoreline erosion. In addition, a variety of hard structures such as seawalls, revetments, groins, and jetties have been installed to protect eroding shorelines. Yet some areas of the northeast, such as Cape Cod, MA, Long Island, NY/CT, and coastal New Jersey, continue to experience a net loss of shoreline and have been identified by the US Geological Survey as being particularly at risk from sea-level rise (Frumhoff et al. 2007). It is uncertain how these engineering measures might affect the ability of natural processes to respond to future sea-level rise (Gutierrez et al. 2007). There exists a high degree of uncertainty in predicting long-term shoreline changes because of the uncertainty of the rate of future sea-level rise and the complex interactions of regional sediment budgets, coastal geomorphology, and anthropogenic influences, such as beach nourishment and seawall construction. However, Gutierrez et al. (2007) reported an increased likelihood for erosion and shoreline retreat for all types of mid-Atlantic coastal shorelines, including an increased likelihood for overwash and inlet breaching and the possibility of segmentation or disintegration of some barrier islands.

An increase in freshwater discharge, storm frequency and intensity, and sea-level rise can lead to increased erosion rates along coastal shorelines (Scavia et al. 2002). The loss of riparian and salt marsh vegetation because of climate change effects could serve as a feedback loop that reduces the ability of wetlands to withstand further increases in sea level and storm effects, which may exacerbate the effects of coastal erosion.

### *Alteration of salinity regimes*

Vertical mixing in coastal waters is influenced by several factors, including water temperatures and freshwater input, so warmer temperatures may affect the thermal stratification of estuaries (Nedeau 2004). Climate models project increased average temperatures and precipitation, particularly during the winter, in the northeastern US region (Frumhoff et al. 2007). Hotter and drier summers and warmer, wetter winters will alter the timing and volume of freshwater runoff and river flows. If freshwater flow from rivers is reduced or increased, salinities in rivers and estuaries will be altered which will have profound affects on the distribution and life history requirements of coastal fisheries. For example, increased freshwater input into estuaries would lower salinities in salt marsh habitat which could enhance conditions for invasive exotic plants that prefer low-salinity conditions, such as *Phragmites* or purple loosestrife (*Lythrum salicaria*). Increased freshwater runoff will increase vertical stratification of estuaries and coastal waters, which could have indirect effects on estuarine and coastal ecosystems (Kennedy et al. 2002). For example, upwelling of deep, nutrient-rich seawater could be reduced, leading to reductions in primary productivity in coastal waters. Rising sea levels could cause estuarine wetlands to be inundated with higher salinity seawater, altering the ecological balance of highly productive fishery habitat.

### *Alteration of weather patterns*

Numerous long-term changes in climate have already been observed at continental, regional, and ocean basin scales, including changes in Arctic temperatures, ice, ocean salinity, wind patterns; and increased occurrences of extreme weather events including droughts, heavy precipitation, heat waves, and intensity of tropical cyclones (IPCC 2007a).

There is observational evidence for an increase in intense tropical cyclone activity in the North Atlantic since the 1970s, correlated with increased tropical sea-surface temperatures (IPCC 2007a). Increases in the amount of precipitation are very likely in high latitudes, and extra-tropical storms are projected to move poleward (Frumhoff et al. 2007; IPCC 2007a). Although there continues to be debate over the link between global warming and increased hurricane frequency, observed ocean warming is a key condition for the formation and strengthening of hurricanes (Frumhoff et al. 2007). The integrity of shorelines and wetlands would be threatened by increased intensity and frequency of coastal storms and hurricanes resulting from climate change. The loss of coastal wetland vegetation and increased erosion of shorelines and riparian habitats caused by storms would have an adverse effect on the integrity of aquatic habitats. Reductions in dissolved oxygen concentrations and salinity are phenomena associated with coastal storms and hurricanes, and most aquatic systems require weeks or months to recover following severe storms (Van Dolah and Anderson 1991). Increased frequency and intensity of storms could lead to chronic disturbances and have adverse consequences on the health and ecology of coastal rivers and estuaries.

### *Changes in water alkalinity*

Increasing atmospheric carbon dioxide concentrations can alter seawater carbonate chemistry by lowering seawater pH, carbonate ion concentration, and carbonate saturation state and by increasing dissolved carbon dioxide concentration (Riebesell 2004). According to the IPCC Working Group I Fouth Asssessment, increasing atmospheric carbon dioxide concentrations may acidify the oceans, reducing pH levels by 0.14 and 0.35 units by 2100 (IPCC 2007a). The uptake of anthropogenic carbon since 1750 has led to an average decrease in pH of 0.1 units; however, the effects of observed ocean acidification on marine ecosystems are unclear at this time (IPCC 2007b).

Increased acidity in oceans is expected to effect calcium carbonate availability in seawater, which would lower the calcification rates in marine organisms (e.g., mollusks and crustaceans, some plankton, hard corals) (IPCC 2007b). Alteration of water alkalinity could have severe impacts on primary and secondary production, which have implications at the ecosystem level (Orr et al. 2005). Increasing atmospheric carbon dioxide concentrations and altered seawater carbonate chemistry could have a range of effects, including physiological changes to marine plankton on the organismal level, changes in ecosystem structure and regulation, and large scale shifts in biogeochemical cycling (Riebesell 2004). For example, increased carbon dioxide concentrations are predicted to decrease the carbonate saturation state and cause a reduction in biogenic calcification of corals and some plankton, including coccolithophorids and foraminifera; however, increasing carbon dioxide concentrations could increase the rates of photosynthetic carbon fixation of some calcifying phytoplankton (Riebesell 2004).

### *Changes in community and ecosystem structure*

The geographic distributions of species may expand, contract, or otherwise adjust to changing oceanic temperatures, creating new combinations of species that could interact in unpredictable ways. Fish communities are likely to change. For example, warming oceans may cause the southern range of northern species, such as Atlantic cod, American plaice (*Hippoglossoides platessoides*), haddock (*Melanogrammus aeglefinus*), and Atlantic halibut (*Hippoglossus hippoglossus*), to shift north as will the northern range limit of southern species, such as butterfish (*Peprilus triacanthus*) and menhaden (*Brevoortia tyrannus*) (Nedeau 2004; Frumhoff et al. 2007). Mountain and Murawski (1992) reported changes in the distribution of selected fish stocks in the northeast continental shelf that were attributed to changes in surface and bottom water temperatures. Distributional changes attributed to increased water temperatures were observed in 26 out of the 30 species examined and resulted in fish moving northward or shallower towards cooler water (Mountain and Murawski 1992). Temperature induced shifts in the distribution of fish have implications for stock recruitment success and abundance. Short-lived fish species may show the most rapid demographic responses to temperature changes, resulting in stronger distributional responses to warming (Perry et al. 2005). Range shifts could create new competitive interactions between species that had not evolved in sympatry, causing further losses of competitively inferior or poorly adapted species.

Because of changes in the atmospheric and oceanic circulation patterns in the Arctic Ocean, the Northwest Atlantic shelf waters became fresher during the 1990s relative to the 1980s (Greene and Pershing 2007). This freshening was believed to have enhanced stratification of shelf waters and led to greater phytoplankton and zooplankton production and abundance during the autumn, a period when primary production would otherwise be expected to decline (Greene and Pershing 2007). Although it is uncertain as to whether the increased abundances of plankton during the 1990s were solely attributed to enhanced stratification caused by greater inflow of freshwater (bottom-up control), overfishing of large predators, such as Atlantic cod (top-down control) or some combined effect, it is clear that changes in climate and oceanic circulation patterns can have profound effects on ecosystem functions and productivity (Greene and Pershing 2007). Mountain (2002) proposed several possible effects to fish stocks in the mid-Atlantic region in response to increased water temperatures, increased seasonal stratification of the water column, and changes in regional ocean circulation patterns. Direct effects included northward shift in stock distributions and reduced reproductive success for some cold water species because of increased water temperatures; indirect effects included changes in phytoplankton productivity and species composition that can impact the lower trophic levels affecting recruitment success of fish stocks (Mountain 2002).

Migratory and anadromous fish such as salmon and shad may be affected by climate change because they depend on the timing of seasonal temperature-related events as cues for migration. Ideal river and ocean temperatures may be out of synch as climate changes, making the saltwater-to-freshwater transition difficult for spawning adults or the freshwater-to-saltwater transition difficult for ocean-bound juveniles. Migration routes, timing of migration, and ocean growth and survival of fish may also be affected by altered sea-surface temperatures (Nedeau 2004).

Invasive species may flourish in a changing climate when shifting environmental conditions give certain species a foothold in a community and a competitive advantage over native species. Species inhabiting northern latitude islands may be particularly vulnerable as nonnative organisms adapted to warmer climates take advantage of changing climatic conditions (Scavia et al. 2002; IPCC 2007b).

Increases in the severity and frequency of coastal storms may result in cumulative losses of coastal marshes by eroding the seaward edge, causing flooding further inland, changing salinity regimes and marsh hydrology, and causing vegetation patterns to change. Healthy salt marshes can buffer upland areas (including human structures) from storm damage, and this ecosystem function will be impaired if marshes are destroyed or degraded. Increased sea-surface temperatures, sea-level rise, and intensity of storms and associated surge and swells, combined with more localized effects such as nutrients and increased loading of sediments, have had demonstrable impacts on SAV beds worldwide (Orth et al. 2006). The loss or degradation of freshwater, brackish, and salt marsh wetlands, SAV and shellfish beds, and other coastal habitats will affect critical habitat for many species of wildlife, which may ultimately affect biodiversity, coastal ecosystem productivity, fisheries, and water quality.

### *Changes in ocean/coastal uses*

Commercial fisheries could be impacted by the cumulative effects of climate change, including rising sea levels and water temperatures and habitat degradation in estuaries, rivers, and coastal wetlands. Approximately 32% of species important to fisheries in New England are dependent upon estuaries during some portion of their life histories (Nedeau 2004). Climate change could also affect human health and the use of ocean resources if the frequency and intensity of harmful algal blooms, fish and shellfish diseases, coastal storms, and impacts to coastal wetlands increase. These effects, combined with sea-level rise, may result in a loss or inability to utilize coastal resources. Climate-induced changes to marine ecosystems will require consideration of longer time-scale effects in fisheries and coastal management strategies.

The IPCC Working Group II Report (IPCC 2007b) concluded there is “high confidence” that climate change will cause regional changes in the distribution and production of particular fish species, with adverse effects projected for aquaculture and fisheries. Conservative predictions of impacts to fisheries resources from sea-level rise and habitat loss from climate change would likely dwarf those impacts now attributed to direct human activities, like water quality degradation, coastal development, and dredging (Bigford 1991). It is possible that nonclimate stresses will increase the vulnerability to climate change impacts by reducing resilience and adaptive capacity (IPCC 2007b). However, it is likely that sustainable development, along with implementing strategies of climate change mitigation and adaptation, technological development (to enhance adaptation and mitigation), and research (on climate science, impacts, adaptation, and mitigation) can minimize some of the risks associated with climate change (IPCC 2007b).

The development of strategic mitigation and adaptation measures to address global climate change are beyond the scope of this report. However, conservation measures and best management practices that are consistent with sound coastal management and sustainable development may help mitigate some of the effects of global warming.

### *Conservation measures and best management practices for climate change impacts to aquatic habitat*

1. Promote soft shore protection techniques, such as salt marsh restoration and creation and beach dune restoration, as alternatives to hard-armoring approaches.
2. Consider vertical structures such as concrete bulkheads for shoreline stabilization only as a last resort.
3. Establish setback lines for coastal development and rolling easements based on sea-level rise and subsidence projections that include local land movement.
4. Avoid development projects that involve wetland filling and increase impervious surfaces.
5. Improve land use practices, such as more efficient nutrient management and more extensive restoration and protection of riparian zones and wetlands.
6. Encourage the development and use of renewable, nongreenhouse gas emitting energy technologies, whenever practicable and feasible.
7. Encourage local, regional, and federal agencies to consider implications of climate change in their decision-support analysis and documents (e.g., National Environmental Policy Act) regarding permit decisions and funding programs.
8. Encourage the use of energy efficient technologies to be integrated into commercial and residential construction, including renewable energy and energy efficient heating and cooling systems and insulation.
9. Encourage the use of fuel-efficient vehicles and mass transportation systems.
10. Encourage communities and states to develop and implement strategies for sustainable development and greenhouse gas reduction initiatives, such as through the International Council for Local Environmental Initiatives (ICLEI).

## Ocean Noise

### *Introduction*

Sound is the result of energy created by a mechanical action dispersed from a source at a particular velocity and causes two types of actions: an oscillation of pressure in the surrounding environment and an oscillation of particles in the medium (Stocker 2002). Because water is 3500 times denser than air, sound travels five times faster in water (Stocker 2002). The openness of the ocean and relative density of the ocean medium allow for the transmission of sound energy over long distances. Factors that affect density include temperature, salinity, and pressure. These factors are relatively predictable in the open ocean but highly variable in coastal and estuarine waters. As a result of these factors along with water depth and variable nearshore bathymetry, sound attenuates more rapidly with distance in shallow compared to deep water (Rogers and Cox 1988).

Noise in the ocean environment can be categorized as natural and anthropogenic sources. Naturally generated sounds come from wind, waves, ice, seismic activity, tides and currents, and thunder, among other sources. Many sea animals use sound in a variety of ways; some use sound passively and others actively. Passive use of sound occurs when the animal does not create the sound that it senses but responds to environmental and ambient sounds. These uses include detection of predators, location and detection of prey, proximity perception of cospecies in schools or colonies, navigation, and perception of changing environmental conditions such as seismic movement, tides, and currents. Animals also create sounds to interact with their environment or other animals in it. Such active uses include sonic communication with cospecies for feeding and spawning (e.g., oyster toadfish [*Opsanus tau*]), territorial and social interactions, echolocation (e.g., marine mammals), stunning and apprehending prey, long distance navigation and mapping (e.g., sharks and marine mammals), and the use of sound as a defense against predators (e.g., croakers) (Stocker 2002).

The degree to which an individual fish exposed to noise will be affected is dependent upon a number of variables, including: (1) species of fish; (2) fish size; (3) presence of a swimbladder; (4) physical condition of the fish; (5) peak sound pressure and frequency; (6) shape of the sound wave (rise time); (7) depth of the water; (8) depth of the fish in the water column; (9) amount of air in the water; (10) size and number of waves on the water surface; (11) bottom substrate composition and texture; (12) tidal currents; and (13) presence of predators (Hanson et al. 2003).

Anthropogenic sources of noise include commercial shipping, seismic exploration, sonar, acoustic deterrent devices, and industrial activities and construction. The ambient noises in an average shipping channel are a combination of propeller, engine, hull, and navigation noises. In coastal areas the sounds of cargo and tanker traffic are multiplied by complex reflected paths – scattering and reverberating because of littoral geography. These cargo vessels are also accompanied by all other manner of vessels and watercraft: commercial and private fishing boats, pleasure craft, personal watercraft (e.g., jet skis) as well as coastal industrial vessels, public transport ferries, and shipping safety and security services such as tugs boats, pilot boats, US Coast Guard and coastal agency support craft, and of course all varieties of US Navy ships – from submarines to aircraft carriers. In large part, anthropogenic activities creating ocean noise are concentrated in coastal and nearshore areas. The most pervasive anthropogenic ocean noise is caused by transoceanic shipping traffic (Stocker 2002). The average shipping channel noise levels are 70-90 dB, which is as much as 45 dB over the natural ocean ambient noise in surface regions (Stocker 2002). Ships generate noise primarily by propeller action, propulsion machinery, and hydraulic flow over the hull (Hildebrand 2004). Considering all of these noises together, noise generated from a large container vessel can exceed 190 dB at the source (Jasny et al. 1999). Refer to the Marine Transportation chapter for additional information on ocean noises generated from vessels.

The loudest noises may be the sounds of marine extraction industries such as oil drilling and mineral mining (Stocker 2002). The most prevalent sources of these sounds are from "air guns" used to create and read seismic disturbances. Air guns are used in seismic exploration to create a sound pressure wave that aids in reflection profiling of underlying substrates for oil and gas. These devices generate and direct huge impact noises into the ocean substrate. Offshore oil and gas exploration generally occurs along the continental margins; however, a recent study indicated that air gun activity in these areas propagates into the deep ocean and is a significant component of low frequency noise (Hildebrand 2004). Peak source levels of air guns typically are 250-255 dB. Following the exploration stage, drilling, coring, and dredging are performed during extraction which also generates loud noises. Acoustic telemetry is also associated with positioning, locating, equipment steering, and remotely operated vessel control to support extraction operations (Stocker 2002).

Sonar systems are used for a wide variety of civilian and military operations. Active sonar systems send acoustic energy into the water column and receive reflected and scattered energy. Sonar systems can be classified into low (<1 kHz), mid (1-20 kHz), and high frequency (>20 kHz). Most vessels have sonar systems for navigation, depth sounding, and "fish finding." Some commercial fishing boats also deploy various acoustic aversion devices to keep dolphins, seals, and turtles from running afoul of the nets (Stocker 2002).

Because the ocean transfers sound over long distances so effectively, various technologies have been designed to make use of this feature (e.g., long distance communication, mapping, and surveillance). Since the early 1990s, it has been known that extremely loud sounds could be transmitted in the deep-ocean isotherm and could be coherently received throughout the seas. Early research in the use of deep-ocean noise was conducted to map and monitor deep-ocean water temperature regimes. Since the speed of sound in water is dependent on temperature, this characteristic was used to measure the temperature of the deep water throughout the sea. This technology has been used to study long-term trends in deep-ocean water temperature that could give a reliable confirmation of global warming. This program, Acoustic Thermometry of Ocean Climates (ATOC), uses receivers stationed throughout the Pacific Basin from the Aleutian Islands to Australia. ATOC is a long wavelength, low frequency sound in the 1-500 Hz band and is the first pervasive deep-water sound channel transmission, filling an acoustical niche previously only occupied by deep sounding whales and other deep water creatures (Stocker 2002). Concurrent with the development of ATOC, the US Navy and other North American Treaty Organization (NATO) navies have developed other low frequency communications and surveillance systems. Most notable of these is low frequency active sonar (LFAS) on a mobile platform, or towed array (Stocker 2002). Recently, the use of LFAS for military purposes has received considerable attention and controversy because of the concerns that this technology has resulted in injury and death to marine mammals, particularly threatened and endangered whales. Fernandez et al. (2005) found the occurrence of mass stranding events of beaked whales in the Canary Islands to have a temporal and spatial coincidence with military exercises using mid-frequency sonar. Beaked whales that died after stranding were found to have injuries to tissues consistent with acute decompression-like illness in humans and laboratory animals. Additional monitoring and research will need to be conducted to determine the degree of threat sonar has on marine organisms, particularly marine mammals. The effects of LFAS on bony fish and elasmobranches are unknown at this time.

Industrial and construction activities concentrated in nearshore areas contribute to ocean noise. Primary activities include pile driving, dredging, and resource extraction and production activities. Pile driving activities, which typically occur at frequencies below 1000 Hz, have led to mortality in fish (Hastings and Popper 2005). Intensity levels of pile driving have been measured up to 193 dB in certain studies (Hastings and Popper 2005). Refer to the chapter on Coastal Development for additional information on the affects of pile driving.

Underwater blasting with explosives is used for a number of development activities in coastal waters. Blasting is typically used for dredging new navigation channels in areas containing large boulders and ledges; decommissioning and removing bridge structures and dams; and construction of new in-water structures such as gas and oil pipelines, bridges, and dams. The potential for injury and mortality to fish from underwater explosives has been well-documented (Hubbs and Rechnitzer 1952; Teleki and Chamberlain 1978; Linton et al. 1985; and Keevin et al. 1999). Generally, aquatic organisms that possess air cavities (e.g., lungs, swim bladders) are more susceptible to underwater blasts than are those without. In addition, smaller fish are more likely to be impacted by the shock wave of underwater blasts than are larger fish, and the eggs and embryos tend to be particularly sensitive (Wright 1982). However, fish larvae tend to be less sensitive to blasts than are eggs or post-larval fish, probably because the larval stages do not yet possess air bladders (Wright 1982). Impacts to fishery habitat from underwater explosives may include sedimentation and turbidity in the water column and benthos and the release of contaminants (e.g., ammonia) in the water column with the use of certain types of explosives.

Noise generated from anthropogenic sources covers the full frequency of bandwidth used by marine animals (0.001-200 kHz), and most audiograms of fishes indicate a higher sensitivity to sound within the 0.100-2 kHz range (Stocker 2002). Evidence indicates that fish as a group have very complex and diverse relationships with sound and how they perceive it. It should be noted that relatively little direct research has been conducted on the impacts of noise to marine fish. However, some studies and formal observations have been conducted that elucidate general categories of impacts to fish species. Noise impacts to fish can generally be divided into four categories: (1) physiological; (2) acoustic; (3) behavioral; and (4) cumulative.

### *Physiological impacts to fish*

Increased pressure from high noise levels may have impacts on other nonauditory biological structures such as swim bladders, the brain, eyes, and vascular systems (Hastings and Popper 2005). Any organ that reflects a pressure differential between internal and external conditions may be susceptible to pressure-related impacts. Some of the resulting affects on fish include a rupturing of organs and mortality (Hastings and Popper 2005). Sounds within autonomic response ranges of various organisms may trigger physiological responses that are not environmentally adapted in healthful ways (Stocker 2002).

The lethality of underwater blasts on fish is dependent upon the detonation velocity of the explosion; however, a number of other variables may play an important role, including the size, shape, species, and orientation of the organism to the shock wave, and the amount, type of explosive, detonation depth, water depth, and bottom type (Linton et al. 1985). Fish with swimbladders are the most susceptible to underwater blasts, owing to the effects of rapid changes in hydrostatic pressures on this gas-filled organ. The kidney, liver, spleen, and sinus venosus are other organs that are typically injured after underwater blasts (Linton et al. 1985).

### *Acoustic impacts to fish*

Acoustic impacts include damage to auditory tissue that can lead to hearing loss or threshold shifts in hearing (Jasny et al. 1999; Heathershaw et al. 2001; Hastings and Popper 2005). Temporary threshold shifts and permanent threshold shifts may result from exposure to low levels of sound for a relatively long period of time or exposure to high levels of sound for shorter periods. Threshold shifts can impact a fish's ability to carry out its life functions.

### *Behavioral impacts to fish*

While tissue damage would be a significant factor in compromising the health of fish, other effects of anthropogenic noise are more pervasive and potentially more damaging. For example, masking biologically significant sounds by anthropogenic interference could compromise acoustical interactions from feeding to breeding, to community bonding, to schooling synchronization, and all of the more subtle communications between these behaviors. Anthropogenic sounds that falsely trigger these responses may have animals expend energy without benefits (Stocker 2002). With respect to behavioral impacts on fish, studies in this area have been limited. Clupeid fish, including Atlantic herring (*Clupea harengus*) are extremely sensitive to noise, and schools have been shown to disperse when approached by fishing gear, such as trawls and seines (NOAA Fisheries 2005). Several studies indicate that catch rates of fish have decreased in areas exposed to seismic air gun blasts (Engås et al. 1996; Hastings and Popper 2005). These results imply that fish relocate to areas beyond the impact zone. One study indicated that catch rates increased 30-50 km away from the noise source (Hastings and Popper 2005). Several studies have indicated that increased background noise and sudden increases in sound pressure can lead to elevated levels of stress in many fish species (Hastings and Popper 2005). Elevated stress levels can increase a fish's vulnerability to predation and other environmental impacts. New studies are addressing the masking effects by background noise on the ability of fish to understand their surroundings. Because fish apparently rely so heavily on auditory cues to develop an "auditory scene," an increase in ambient background noise can potentially reduce a fish's ability to receive those cues and respond appropriately (Jasny et al. 1999; Scholik and Yan 2002; Hastings and Popper 2005). Furthermore, the auditory threshold shifts of fish exposed to noise may not recover even after termination of the noise exposure (Scholik and Yan 2002).

### Cumulative impacts to fish

Few research efforts have focused on the cumulative effects of anthropogenic ocean noise on fish. Subtle and long-term effects on behavior or physiology could result from persistent exposure to certain noise levels leading to an impact on the survival of fish populations (Jasny et al. 1999; Hastings and Popper 2005).

### Conservation measures and best management practices for ocean noise

1. Develop mitigation strategies for noise impacts to consider the frequency, intensity, and duration of exposure and evaluate possible reductions of each of these three factors. Mitigation strategies for ocean noise are challenged by the fact that a sound source may move in addition to the movement of affected fish in and out of the insonified region.
2. Assess the "acoustic footprint" of a given sound source and develop standoff ranges for various impact levels. Standoff ranges can be calculated by using damage risk criteria for species exposure, source levels, sound propagation conditions, and acoustic attenuation models. Development of standoff ranges implies that sound sources be relocated or reduced since the sound receptors (fish) are more difficult to control. Because the potential number of species affected and their location is most likely unknown, development of a generic approach for mitigation by using the species with the most sensitive hearing would produce a precautionary approach to reducing impacts on all animals (Heathershaw et al. 2001).
3. Recommend an assessment and designation of "acoustic hotspots" that are particularly susceptible to acoustic impacts and reducing sound sources around them. These hotspots may include seasonal areas for particularly susceptible life history activities like spawning or breeding (Jasny et al. 1999).
4. Recognize that reducing noise intensity at the source primarily relies on technological solutions. These options include the use of "quiet" technology in marine engines and using bubble curtains for activities such as pile driving.
5. Encourage the use of sound dampening technologies for vessels and port/marine infrastructure to reduce ocean noise impacts to aquatic organisms.
6. Manage the duration of sound when the source level of a sound cannot be reduced in order to reduce impacts. Underwater sounds should be avoided during sensitive times of year (e.g., upstream and downstream river migrations, spawning, and egg and larvae development).
7. Avoid using underwater explosives in areas supporting productive fishery habitats. The use of less destructive methods should be encouraged, whenever possible. In some cases, the use of mechanical devices (e.g., ram hoe, clamshell dredge) may reduce impacts associated with rock and ledge removal.
8. Investigate options to mitigate the impacts associated with underwater explosives. Avoiding use during sensitive periods (e.g., upstream and downstream river migrations, spawning, and egg and larvae development) may be one of the most effective means of minimizing impacts to fishery resources. Other methods may include the use of bubble curtains; stemming (back-filling charge holes with gravel); delayed charges (explosive charges broken down into a series of smaller charges); and the use of repelling charges (small explosive charges used to frighten and drive fish away from the blasting zone) (Keevin 1998).

# Atmospheric Deposition

## *Introduction*

Pollutants travel through the atmosphere for distances of up to thousands of miles, often times to be deposited into rivers, estuaries, and nearshore and offshore marine environments. Substances such as sulfur dioxide, nitrogen oxide, carbon monoxide, lead, volatile organic compounds, particulate matter, and other pollutants are returned to the earth through either wet or dry atmospheric deposition. Wet deposition removes gases and particles in the atmosphere and deposits them to the earth's surface by means of rain, sleet, snow, and fog. Dry deposition is the process through which particles and gases are deposited in the absence of precipitation. Deposition of nutrients (i.e., nitrogen and phosphorous) and contaminants (e.g., polychlorinated biphenyl [PCB] and mercury) into the aquatic system are of particular concern because of the resulting impacts to fisheries and health-risks to humans.

Atmospheric inputs of nutrients and contaminants differ from riverine inputs in the following ways: (1) riverine inputs are delivered to the coastal seas at their margins, whereas atmospheric inputs can be delivered directly to the surface of the central areas of coastal seas and hence exert an impact in regions less directly affected by riverine inputs; (2) atmospheric delivery occurs at all times, whereas riverine inputs are dominated by seasonal high-flows and coastal phytoplankton activity; (3) atmospheric inputs are capable of episodic, high deposition events associated with natural or manmade phenomena (e.g., volcanic eruptions, forest fires); and (4) atmospheric inputs of nitrogen are chemically different from river inputs in that rivers are dominated by nitrous oxides, phosphorus, and silica, while atmospheric inputs include reduced and oxidized nitrogen, but no significant phosphorus or silica (Jickells 1998). While there is little information on the direct effects of atmospheric deposition on marine ecosystems, management strategies must attempt to address these variations in inputs from terrestrial and atmospheric pathways.

## *Nutrient loading and eutrophication*

Nutrient pollution is currently the largest pollution problem in the coastal rivers and bays of the United States (NRC 2000). Nitrogen inputs to estuaries on the Atlantic and Gulf Coasts of the United States are now 2-20 times greater than during preindustrialized times (Castro et al. 2003). Sources of nitrogen include emissions from automobiles, as well as urban, industrial, and agricultural sources. Atmospheric deposition is one means of nitrogen input into aquatic systems, with atmospheric inputs delivering 20 to greater than 50% of the total input of nitrogen oxide to coastal waters (Paerl 1995). One of the most rapidly increasing means of nutrient loading to both freshwater systems and the coastal zone is via atmospheric pathways (Anderson et al. 2002).

Precipitation readily removes most reactive nitrogen compounds, such as ammonia and nitrogen oxides, from the atmosphere. These compounds are subsequently available as nutrients to aquatic and terrestrial ecosystems. Because nitrogen is commonly a growth-limiting nutrient in streams, lakes, and coastal waters, increased concentrations can lead to eutrophication, a process involving excess algae production, followed by depletion of oxygen in bottom waters. Hypoxic and anoxic conditions are created as algae die off and decompose. Harmful algal blooms associated with unnatural nutrient levels have been known to stimulate fish disease and kills. In addition, phytoplankton production increases the turbidity of waters and may result in a reduced photic zone and subsequent loss of submerged aquatic vegetation. Anoxic conditions, increased turbidity, and fish mortality may result from increased nitrogen inputs into the aquatic system, potentially altering long-term community dynamics (NRC 2000; Castro et al. 2003). Refer to the chapters on

Agriculture and Silviculture, Coastal Development, Alteration of Freshwater Systems, and Chemical Effects: Water Discharge Facilities for further discussion on impacts to fisheries from eutrophication.

The atmospheric component of nitrogen flux into estuaries has often been underestimated, particularly with respect to deposition on the terrestrial landscape with subsequent export downstream to estuaries and coastal waters (Howarth et al. 2002). The deposition of nitrogen on land via atmospheric pathways impacts aquatic systems when terrestrial ecosystems become nitrogen saturated. Nitrogen saturation means that the inputs of nitrogen into the soil exceed the uptake ability by plants and soil microorganisms. Under conditions of nitrogen saturation, excess nitrogen leaches into soil water and subsequently into ground and surface waters. This leaching of excess nitrogen from the soils degrades water quality. Such conditions have been known to occur in some forested watersheds in the northeastern United States, and streams that drain these watersheds have shown increased levels of nitrogen from runoff (Williams et al. 1996).

In one study, quantifying nitrogen inputs for 34 estuaries on the Atlantic and Gulf Coasts of the United States, atmospheric deposition was the dominant nitrogen source for three estuaries, and six estuaries had atmospheric contributions greater than 30% of the total nitrogen inputs (Castro et al. 2003). In the northeastern United States, atmospheric deposition of oxidized nitrogen from fossil-fuel combustion may be the major source of nonpoint input. Evidence suggests a significant movement of nitrogen in the atmosphere from the eastern United States to coastal and offshore waters of the North Atlantic Ocean where it is deposited (Holland et al. 1999). Nitrogen fluxes in many rivers in the northeastern United States have increased 2- to 3-fold or more since 1960, with much of this increase occurring between 1965 and 1988. Most of this increase in nitrogen was attributed to increased atmospheric deposition originating from fossil-fuel combustion onto the landscape (Jaworski et al. 1997).

### *Mercury loading/bioaccumulation*

Mercury is a hazardous environmental contaminant. Mercury bioaccumulates in the environment, which means it can collect in the tissues of a plant or animal over its lifetime and biomagnify (i.e., increases in concentration within organisms between successive trophic levels) within the food chain. Fish near the top of the food chain often contain high levels of mercury, prompting the United States and Canada to issue health advisories against consumption of certain fish species. The US Food and Drug Administration reports certain species, including sharks, swordfish (*Xiphias gladius*), king mackerel (*Scombermorus cavalla*), and tilefish (*Lopholatilus chamaeleonticeps*), to have typically high concentrations of mercury (USFDA 2004).

One of the most important anthropogenic sources of mercury pollution in aquatic systems is atmospheric deposition (Wang et al. 2004). The amount of mercury emitted into the atmosphere through natural and reemitted sources was estimated to be between 1500-2500 metric tons/year in the late 20$^{th}$ century (Nriagu 1990). Industrial activities have increased atmospheric mercury levels, with modern deposition flux estimated to be 3-24 times higher than preindustrial flux (Bindler 2003). More than half of the total global mercury emissions are from incineration of solid waste, municipal and medical wastes, and combustion of coal and oil (Pirrone et al. 1996).

Studies strongly support the theory that atmospheric deposition is an important (sometimes even the predominant) source of mercury contamination in aquatic systems (Wang et al. 2004). Mercury exists in the atmosphere predominately in the gaseous form, although particulate and aqueous forms also exist (Schroeder et al. 1991). Gaseous mercury is highly volatile, remaining in the atmosphere for more than one year, making long-range atmospheric transport a major environmental concern (Wang et al. 2004).

Concentrations of mercury in the atmosphere and flux of mercury deposition vary with the seasons, and studies suggest that atmospheric mercury deposition is greatest in summer and least in winter (Mason et al. 2000). Different, site-specific factors may influence the transport and transformation of mercury in the atmosphere. Wind influences the direction and distance of deposition from the source, while high moisture content may increase the oxidation of mercury, resulting in the rapid settlement of mercury into terrestrial or aquatic systems. Mercury that is deposited on land can be absorbed by plants through their foliage and ultimately be passed into watersheds by litterfall (Wang et al. 2004).

Mercury and other metal contaminants are found in the water column and persist in sediments (Buchholtz ten Brink et al. 1996). Mercury is toxic in any form according to some scientists, but when absorbed by certain bacteria such as those in marine sediments, it is converted to its most toxic form, methyl mercury. Methyl mercury can cause nerve and developmental damage in humans and animals. Mercury inhibits reproduction and development of aquatic organisms, with the early life-history stages of fish being the most susceptible to the toxic impacts associated with metals (Gould et al. 1994). Metals have also been implicated in disrupting endocrine secretions of aquatic organisms, potentially disrupting natural biotic properties (Brodeur et al. 1997). Direct mortality of fish and invertebrates by lethal concentrations of metals may occur in some instances. Refer to the Coastal Development and Chemical Effects: Water Discharge Facilities chapters for more information on impacts from mercury contamination.

### *PCB and other contaminants*

PCB congeners are a group of organic chemicals which can be odorless or mildly aromatic and exist in solid or oily-liquid form. They were formerly used in the United States as hydraulic fluids, plasticizers, adhesives, fire retardants, way extenders, dedusting agents, pesticide extenders, inks, lubricants, cutting oils, manufacturing of heat transfer systems, and carbonless reproducing paper. Most uses of PCB were banned by the US Environmental Protection Agency in 1979; however this persistent contaminant continues to enter the atmosphere mainly by cycling from soil to air to soil again. PCB is also currently released from landfills, incineration of municipal refuse and sewage sludge, and improper (or illegal) disposal of PCB-contaminated materials, such as waste transformer fluid, to open areas (USEPA 2005a).

PCB compounds are a mixture of different congeners of chlorobiphenyl. In general, the persistence of PCB increases with an increase in the degree of chlorination. Mono-, di- and trichlorinated biphenyls biodegrade relatively rapidly, tetrachlorinated biphenyls biodegrade slowly, and higher chlorinated biphenyls are resistant to biodegradation. If released to the atmosphere, PCB will primarily exist in the vapor-phase and have a tendency to become associated with the particulate-phase as the degree of chlorination of the PCB increases. Physical removal of PCB from the atmosphere is accomplished by wet and dry deposition (USEPA 2005b).

Although restrictions were first placed on the use of PCBs in the United States during the 1970s, lipid-rich finfish and shellfish tissues have continued to accumulate PCBs, dichlorodiphenyl trichloroethane (DDT), and chlordane from the environment (Kennish 1998). PCB congeners are strongly lipophilic and accumulate in fatty tissues including egg masses, affecting the development of fish as well as posing a threat to human health through the consumption of contaminated seafood. Refer to the chapters on Coastal Development and Chemical Effects: Water Discharge Facilities for more additional information on PCB contamination.

### *Alteration of ocean alkalinity*

The influx of acid to the aquatic environment occurs through the atmospheric precipitation of two predominant acids, sulfuric acid and nitric acid, making up acid rain (i.e., pH less than 5.0). Sulfur dioxide is produced naturally by volcanoes and decomposition of plants, while the main anthropogenic source is combustion, especially from coal-burning power plants. In eastern North America, acid rain is ubiquitous because of the presence of coal-burning power plants (Baird 1995). Other sources of sulfuric acid in the atmosphere include oil refinement, cleaning of natural gas, and nonferrous smelting. Affects on biological life depend strongly on soil composition. Granite and quartz have little capacity to neutralize acid, while limestone or chalk can efficiently neutralize acids. Under acidic conditions, aluminum is leached from rocks. Both acidity and high concentrations of dissolved aluminum are responsible for decreases in fish populations observed in many acidified water systems (Baird 1995).

The freshwater environment does not have the buffering capacity of marine ecosystems, so acidification has serious implications on riverine habitat. Low pH (below 5.0) has been implicated with osmoregulation problems (Staurnes et al. 1996), pathological changes in eggs (Peterson et al. 1980; Haines 1981), and reproduction failure in Atlantic salmon (Watt et al. 1983). Cumulative, long-term deposition of acid into the aquatic environment can hinder the survival and sustainability of fisheries by disrupting and degrading important fish and shellfish habitat. Refer to the Coastal Development and Chemical Effects: Water Discharge Facilities chapters for additional information on the affects of acidification of aquatic habitats.

### *Conservation measures and best management practices for atmospheric deposition*

1. Install scrubbers for flue-gas desulfurization in electricity generating powerplants, oil refineries, nonferrous smelters, and other point sources of sulfur dioxide emissions.
2. Use integrated, gas-scrubbing systems on municipal waste combustion units.
3. Reduce sulfur dioxide emissions by substituting natural gas or low-sulfur coal for high-sulfur coal at power plants.
4. Encourage renewable energy generation using wind, solar, and geothermal technologies.
5. Encourage the use of fuel-efficient vehicles and mass transportation systems.
6. Encourage the separation of batteries from the waste stream to reduce the release of mercury vapors through waste incineration.
7. Lower volatization and/or erosion and resuspension of persistent compounds through remediation at waste sites.

## Military/Security Activities

The operations of the US military span the globe and are carried out in coastal, estuarine, and marine habitats. Military operations have the potential to adversely impact fish habitat through training activities conducted on land bases as well as in coastal rivers and the open ocean. Military operations also impact fish habitat and larger ecological communities during wars (Literathy 1993).

Because many military bases and training activities are located in coastal areas and oftentimes directly on shorelines, they can cause impacts similar to those mentioned in other parts of this document (e.g., coastal development, dredging, sewage discharge, road construction, shoreline protection, over-water structures, pile driving, port and marina operations, and vessel operations). In addition to these conventional activities, the military often stockpiles and disposes of toxic chemicals on base grounds. Toxic dumping on base grounds has led to the contamination of groundwater at Otis Air National Guard Base on Cape Cod, MA, (NRDC 2003) and in Vieques, Puerto Rico.

The United States Navy also uses sonar systems that create large amounts of noise in ocean waters. The Surveillance Towed Array Sensor System (SURTASS) low frequency active sonar produces extremely loud low frequency sound that can be heard at 140 dB from 300 miles away from the source (NRDC 2004). Sixty percent of the US Navy's 294 ships are equipped with mid-frequency sonar devices that can produce noise above 215 dB (NRDC 2002). The intensity of these noises in the water column can cause a variety of impacts to fish, marine mammals, and other marine life such as behavior alterations, temporary and permanent impairments to hearing, and mortality. Other sources of underwater noise from military activities may include explosive devices and ordnances during training exercises and during wartime. Refer to the Ocean Noise section in this chapter for more information on impacts associated with sonar, as well as the Marine Transportation and Coastal Development chapters for information related to blasting impacts.

## Natural Disasters and Events

### *Introduction*

Natural events and natural disasters of greatest concern for the northeastern United States include hurricanes, floods, and drought. These events may impact water quality, alter or destroy habitat, alter hydrological regimes, and result in changes to biological communities. Natural disasters have the potential to impact fishery resources, such as displacing plankton and fish from preferred habitat and altering freshwater inputs and sediment patterns. While these effects may not themselves pose a threat to coastal ecosystems, they may have additive and synergistic effects when combined with anthropogenic influences such as the release of agricultural and industrial pollutants in storm water.

### *Water quality impacts*

Water quality degradation by hurricanes can be exacerbated by human activities. Hurricanes and posthurricane flooding have been known to result in large freshwater inputs and high concentrations of nutrients into river and estuarine waters, causing reductions in water quality and massive fish kills (Mallin et al. 1999). For example, when Hurricane Fran struck North Carolina in the Cape Fear River area in 1996, the following impacts were reported as a result of the hurricane: (1) power failures caused the diversion of millions of liters of raw and partially treated human waste into rivers when sewage treatment plants and pump stations were unable to operate; (2) dissolved oxygen concentrations decreased in parts of the Cape Fear River for more than three weeks following the hurricane; (3) ammonium and total phosphorous concentrations were the highest recorded in 27 years of monitoring in Northeast Cape Fear River following the hurricane and; (4) sediment-laden waters flowing into Cape Fear River increased turbidity levels (Mallin et al. 1999).

Generally, high rates of flushing and reduced water residence times will inhibit the formation of algal blooms in bays and estuaries. However, the input of large amounts of human and animal waste can greatly increase the biological oxygen demand and lead to hypoxic conditions in aquatic systems. In addition to the diversion of untreated waste from sewage treatment plants during Hurricane Fran, several swine waste lagoons were breached, overtopped, or inundated, discharging large quantities of concentrated organic waste into the aquatic environment (Mallin et al. 1999). Other sources of nutrient releases during storms and subsequent flooding events include septic systems on private residences built on river and coastal floodplains.

Natural disasters, such as hurricanes, may also put vessels (e.g., oil tankers) and coastal industrial facilities (e.g., liquefied natural gas [LNG] facilities, nuclear power plants) at risk of damage and contaminant spills. Tanker ship groundings generally occur during severe storms, when moorings are more susceptible to being broken and the control of a vessel may be lost or compromised. The release of toxic chemicals from damaged tanks, pipelines, and vessels threaten aquatic organisms and habitats.

### *Changes to community composition*

Major storm events may impact benthic communities through a variety of mechanisms, including increased sedimentation, introduction of contaminants, reduction in dissolved oxygen, short-term changes in salinity, and disturbance from increased flow. Monitoring of environmental impacts following Hurricane Fran in 1996 indicated that significant declines in benthic organism abundance were observed up to three months after the storm. However, significant declines in benthic abundance generally did not occur in areas where levels of dissolved oxygen recovered quickly after the storm (Mallin et al. 1999). Poorly flushed bays and inland river floodplains are areas that typically exhibit greater magnitude and duration of storm-related impacts.

### *Loss/alteration of habitat*

The rate of accretion and erosion of coastal areas is influenced by wave energy impacting the shoreline, and natural events such as hurricanes will accelerate this process. Erosion may occur as a function of hydraulic scour produced by hurricane overwash and offshore-directed wave energy. Accretion of materials resulting from overwash deposition may result in subsequent flood tidal delta development. Extreme climatic events, such as hurricanes and tsunamis, can have large-scale impacts on submerged aquatic vegetation communities (Orth et al. 2006). Loss or alteration of coastal habitat as a result of storms may be exacerbated by the effects of shoreline development and erosion control measures. For example, the creation of hardened shoreline structures (e.g., seawalls, jetties) and storm-water control systems can focus storm energy and redirect storm water to wetlands, resulting in increased erosion and habitat loss in productive fishery habitat.

### *Alteration of hydrological regimes*

Hurricane and flood events result in large volumes of water delivered to the watershed in a relatively short period of time. These events can alter the hydrology of wetlands, streams, and rivers by increasing erosion and overwhelming flood control structures. Freshwater flows into rivers draining into Charleston Harbor in South Carolina increased as much as four times the historical average after Hurricane Hugo in 1989 (Van Dolah and Anderson 1991). Reduced dissolved oxygen concentrations were observed in all portions of the Charleston Harbor estuary following Hurricane Hugo, with hypoxic conditions in some of the rivers in the watershed. The decomposition of vegetation and the failure of septic and sewer systems overflowing into the watershed as a result of this hurricane was identified as the primary cause of the high organic loads (Van Dolah and Anderson 1991). At the other extreme, drought will result in reduced run-off and low flows in streams and rivers that drain into estuaries and bays. Low freshwater input resulted in dramatic reductions in phytoplankton and zooplankton in San Francisco Bay, CA, reducing pelagic food for fish populations (Bennett et al. 1995). Larval starvation may limit recruitment. During low-flow years, toxins from agricultural and urban runoff are less diluted which can also harm fish.

### *Conservation measures and best management practices for natural disasters and events*

1. Require backup generating systems for publicly owned waste treatment facilities.
2. Prohibit development of high-risk facilities, such as animal waste lagoons, storage of hazardous chemicals within the 100-year floodplain.
3. Ensure that all industrial and municipal facilities involving potentially hazardous chemicals and materials have appropriate emergency spill response plans, including emergency notification systems and spill cleanup procedures, training, and equipment.
4. Encourage the protection and restoration of coastal wetlands and barrier islands, which buffer the affects of storm events by dissipating wave energy and retaining floodwaters.
5. Discourage new construction and development in or near coastal and riparian wetlands.
6. Discourage the use of "hard" shoreline stabilization, such as seawalls and bulkheads.
7. Limit emergency authorizations (e.g., federal Clean Water Act permits) for reconstruction projects to replacing structures that were in-place and functional at the time of the natural disaster/event and do not include the expansion of structures and facilities.

## Electromagnetic Fields

Anthropogenic activities are responsible for the majority of the overall electromagnetic fields (EMF) emitted into the environment, with natural sources making up the remainder. Levels of EMF from anthropogenic sources have increased steadily over the past 50-100 years (WHO 2005). Anthropogenic sources of EMF include undersea power cables, high voltage power lines, radar, FM radio and TV transmitters, cell phones, high frequency transmitters for atmospheric research, and solar power satellites. The EMF created by undersea power cables may have some adverse affect on marine organisms. Undersea power cables transfer electric power across water, usually conducting very large direct currents (DC) of up to a thousand amperes or more. It has been inferred that undersea cables can interfere with the prey sensing or navigational abilities of animals in the immediate vicinity of the sea cables (See also the Cables and Pipelines section of the Energy-related Activities chapter). Few published, peer reviewed scientific articles on the environmental effects of electromagnetic fields on aquatic organisms exist. However, the World Health Organization cosponsored an international seminar in October 1999 entitled "Effect of Electromagnetic Fields on the Living Environment" to focus attention on this subject. A review of the information presented at the seminar was prepared by Foster and Repacholi (2000).

Electromagnetic fields are the product of both natural and artificial sources. Natural sources of EMF include radiation from the sun, the earth's magnetic fields, the atmosphere (e.g., lightning discharges), and geological processes (WHO 2005). Marine animals are also exposed to natural electric fields caused by sea currents moving through the geomagnetic field. Examples of anthropogenic sources of EMF include undersea power cables and US Navy submarine communication systems (Foster and Repacholi 2000). Mild electroreception by teleost (bony) fishes occurs through external pit organs that interpret minute electrical currents in the water (Moyle and Cech 1988). However, elasmobranches (i.e., sharks, skates, and rays) are unique in that they possess well-developed electroreceptive organs, called Ampullae of Lorenzini, that enable them to detect weak electric fields in the surrounding seawater as low as 0.01 μV/m (Kalmijn 1971). Elasmobranchs are able to receive information about the positions of their prey, the drift of ocean currents, and their magnetic compass headings from electric fields in their surrounding environment.

Most aquatic organisms emanate low-frequency electric fields that can be detected by fish, such as skates and rays, through a process known as "passive electrolocation" or "passive electroreception." Passive electroreception allows animals to sense electric fields generated in the environment, thereby allowing predators to detect prey by the electric fields that individual fauna emanate. Elasmobranchs have demonstrated during controlled experiments the ability to detect artificially created electric fields (1-5 μA) that are similar to those produced by prey (Kalmijn 1971). The other form of electroreception is "active electroreception" and occurs when an animal detects changes in their own electric field caused by the electric field produced by prey in the vicinity. This ability to detect disturbances to an individual's own electric field is rare, occurring only in a few families of weakly electric fish, none of which are found in the Northwest Atlantic Ocean.

There is evidence that elasmobranches also use their ability to detect electric fields for the purpose of navigation. For example, blue sharks (*Prionace glauca*) have been observed migrating in the North Atlantic Ocean maintaining straight courses for hundreds of kilometers over many days (Paulin 1995). The two modes of detection used for navigation are: (1) passive detection (when an animal estimates its drift from the electrical fields produced by interactions of tidal and wind-driven currents and the vertical component of the earth's magnetic field); or (2) active detection (when the animal derives its magnetic compass heading from the electrical field it generates by its interaction with the horizontal component of the earth's magnetic field) (Gill and Taylor 2001).

### *Changes in migration of marine organisms*

Anthropogenic sources of EMFs may affect social behavior, communications, navigation, and orientation of those animals that rely on the earth's magnetic field. Certain fish rely on the natural (geomagnetic) static magnetic field as one of a number of parameters believed to be used as orientation and navigational cues. For example, stingrays have demonstrated their ability during training experiments to orient relative to uniform electric fields similar to those produced by ocean currents (Kalmijn 1982). In addition, the small-spotted catshark (*Scyliorhinus canicula*) and the thornback skate (*Raja clavata*) have shown a remarkable sensitivity to electric fields (Kalmijn 1982). However, studies demonstrating an impact on the ability of marine organisms to migrate because of anthropogenic sources of EMFs have not been found. Foster and Repacholi (2000) noted the sensitivity of sharks to low frequency electric fields and a potential mechanism for adverse effects from DC fields but made no mention of adverse effects from EMFs.

### *Changes to feeding behavior*

Electric or magnetic fields near sea cables may affect prey sensing of electrically or magnetically sensitive species. Submarine cables may attract species when the field intensity approximates that of their natural prey. Smooth dogfish (*Mustelus canis*) and the blue shark have been observed to execute apparent feeding responses to dipole electric fields designed to mimic prey (Kalmijn 1982). Less is known about how elasmobranches respond in the presence of stronger EMFs that exist closer to the cable. Depending on the presence and strength of electric fields, the feeding behavior of elasmobranches could be altered by submarine cables.

The possible affects of exposure to EMF depend on a coupling between the external field and the body of the animal and the biological response mechanisms. The size of the animal, frequency of the field, and whether the pathway of exposure is via air or water will determine effects to the animal. It has been suggested that monopolar power links are more likely to affect aquatic animals than bipolar links do because they produce perceptible levels of fields over larger distances from the cables (Kalmijn 2000). Sea cables are isolated from the surrounding water by layers of insulation and metal sheathing, yet electric fields that can exceed natural ambient levels remain detectable (Foster and Repacholi 2000). The flow of seawater past the cables can create electric fields by magnetic induction. The resulting field strength in the seawater can exceed naturally occurring levels and depends on the flow velocity, whether or not the observer is moving with respect to the water, and on the electrical conductivity of nearby surfaces (Foster and Repacholi 2000).

Further directed research should be conducted to examine the effect of EMFs from underwater transmission lines on marine organisms. Increased understanding is needed about the effects of cable burial within different substrata and the range of frequencies and sensitivities of electric fields that marine species are capable of detecting.

### *Conservation recommendations and best management practices for electromagnetic fields*

1. Map proposed submarine cable routes with marine resource utilization in a geographic information system database to provide information on potential interference with elasmobranch fishes and other organisms. Particular attention should be paid to known nursery and pupping grounds of coastal shark species.
2. Bury submarine cables below the seafloor to potentially reduce possible interference with the electroreception of fishes. However, the benefits of cable burial to minimize potential impacts to elasmobranchs should be weighed with the adverse effects associated with trenching on the seafloor.
3. Place new submarine electric transmission lines within existing transmission corridors to minimize the cumulative effect of transmission lines across the ocean bottom to the extent practicable.

# CHAPTER TWELVE: COMPENSATORY MITIGATION

## Introduction

The purpose of this chapter is to describe the need for and use of compensatory mitigation within the context of regulatory review of proposed coastal development activities. This topic has purposefully been included in a separate chapter of this report to reflect NOAA National Marine Fisheries Services' view that compensatory mitigation is a process that is distinct and separate from impact avoidance and minimization. Only a cursory discussion of compensatory mitigation has been attempted in this report because of the complexity and depth that would be required to cover this topic. We have provided a list of websites and publications that the reader may want to refer to for more detailed discussion of compensatory mitigation.

Compensatory mitigation is a means of offsetting unavoidable impacts to natural resources. It cannot be stressed strongly enough that compensatory mitigation should not be considered until a thorough and exhaustive assessment of project alternatives that may be less environmentally damaging and options for avoiding and minimizing impacts has been completed, and all remaining impacts are "unavoidable." The term "unavoidable impacts" is used ubiquitously in environmental impact assessments developed to meet various requirements of the National Environmental Policy Act (NEPA), Clean Water Act (CWA), Magnuson-Stevens Fishery Conservation and Management Act (MSA), Fish and Wildlife Coordination Act, and other laws and regulations.

The MSA identified the continuing loss of marine, estuarine, and other aquatic habitats to be one of the greatest long-term threats to the viability of commercial and recreational fisheries. The consultation requirements of §305(b)(4)(A) of the MSA require that NOAA National Marine Fisheries Service provide recommendations, which may include measures to avoid, minimize, mitigate, or otherwise offset adverse effects on essential fish habitat (EFH), to federal or state agencies for activities that would adversely effect EFH.

According to NEPA regulations, environmental assessments and environmental impact statements must include a discussion of the means to mitigate adverse environmental impacts. However, according to NEPA guidance, the term "mitigation" includes avoidance and minimization in addition to compensatory mitigation, and NEPA does not strictly require agencies to first avoid and minimize before utilizing compensatory mitigation to offset adverse effects. NEPA regulations do, however, require agencies to assess and discuss the environmental effects of all reasonable alternatives, including the means to mitigate any adverse effects.

The Federal CWA 404(b)(1) guidelines prohibit the discharge of dredge or fill material in waters of the United States if there is a practicable alternative. The 404(b)(1) guidelines also require that all waters of the United States will be accorded the full measure of protection under the CWA, including the requirements for appropriate and practicable mitigation. "Appropriate" is based on the values and functions of the aquatic resource that will be impacted, and "practicable" is defined as that which is available and capable of being done after taking into consideration the cost, existing technology, and logistics in light of overall project purposes. The Memorandum of Agreement (MOA) between the US Environmental Protection Agency and the Department of the Army Concerning the Determination of Mitigation under the Clean Water Act Section 404(b)(1) Guidelines states, "Appropriate and practicable compensatory mitigation is required for unavoidable adverse impacts which remain after all appropriate and practicable minimization has been required." This MOA established a three-part sequential process to help guide mitigation decisions, which includes: (1) avoidance – adverse impacts are to be avoided and no discharge shall be permitted if there is a practicable alternative with less adverse impact; (2) minimization – if impacts cannot be avoided, appropriate and practicable steps to minimize adverse impacts must be taken; and (3) compensation – appropriate and practicable compensatory mitigation is required for unavoidable adverse impacts which remain (USDOA and USEPA 1989).

The need for exhausting all practicable alternatives to avoid and minimize adverse impacts prior to consideration of compensatory mitigation is necessary because of the inherent risks associated with compensatory mitigation. Establishing (creating), reestablishing (restoring), and rehabilitating (enhancing) degraded wetlands and/or aquatic habitats have inherent risks. Replicating or restoring the physical and chemical characteristics of fishery habitat, including soil/sediment hydrology and chemistry, hydrologic connections, and water quality are complex undertakings and can require years to achieve desired results. Replicating and restoring the full ecological functions and values of fishery habitat may not occur without additional effort and cost, and there are no assurances of success. In addition, evaluating mitigation performance and success can require considerable pre- and postconstruction monitoring and assessment, which can be time consuming and costly. For these and other reasons, compensatory mitigation should be viewed as a "last resort" option to achieve effective mitigation, with avoidance and minimization of impacts being the initial focus during the impact assessment process.

Once all practicable alternatives have been considered satisfactorily and a least damaging practicable alternative has been selected that effectively avoids and minimizes adverse effects to the maximum extent practicable, measures to offset unavoidable impacts should be assessed and utilized. Compensatory mitigation can be accomplished on-site or off-site (i.e., in relation to the area being impacted) and can either be in-kind or out-of-kind (i.e., compensation with the same or different ecological functions and values). Generally, in order to achieve the functional replacement of the same or similar ecological resources, in-kind should be considered over out-of-kind compensatory mitigation. However, compensatory mitigation decisions are often made in the context of landscape and watershed implications, as well as logistical and technological limitations. Out-of-kind mitigation, should it be considered, should provide services of equal or greater ecological value and should only be employed if in-kind mitigation is deemed impracticable, unfeasible, or less desirable in the watershed context. However, replacing lost or degraded tidal wetlands or other intertidal/subtidal habitats with nontidal (e.g., freshwater) wetlands should not occur.

Compensatory mitigation can be broadly categorized as restoration, creation, enhancement, and preservation (USACE 2002). Restoration includes reestablishment of a wetland or other aquatic resource with the goal of returning natural or historic functions and characteristics to a former or degraded habitat. Restoration may result in a net gain in ecological function and area. Creation or establishment consists of the development of a wetland or other aquatic resource through manipulation of the physical, chemical, or biological characteristics where a wetland did not previously exist. Creation results in a net gain in ecological function and area. Enhancement or rehabilitation includes activities within existing wetlands that heighten, intensify, or improve one or more ecological functions. Enhancement may result in improved ecological function(s), but does not result in a gain in area. Preservation is designed to protect important wetland or other aquatic resources into perpetuity through implementation of appropriate legal and physical mechanisms (i.e., conservation easements, title transfers). Preservation may include protection of upland areas adjacent to wetlands or other aquatic resources. Preservation does not result in a net gain of wetland acres or other aquatic habitats and should only be used in exceptional circumstances. Preservation is best applied in conjunction with restoration and/or enhancement of ecological functions and values and rarely as the sole means of compensation.

Compensatory mitigation can be provided in the form of project-specific mitigation, mitigation banking, or in-lieu fee mitigation (USEPA 2003). Project-specific mitigation is generally undertaken by a permittee or agency in order to compensate for resource impacts resulting from a specific action or permit. The permittee or agency performs the mitigation and is ultimately responsible for implementation and success of the mitigation. Mitigation banking is a wetland area that has been restored, created, or enhanced, which is then set aside ("banked") to compensate for future impacts to wetlands or other aquatic resources. The value of a bank is determined by quantifying the resource functions restored or created in terms of "credits," which can be acquired, upon the approval of regulatory agencies, to meet a project's requirements for compensatory mitigation. The bank sponsor is ultimately responsible for the success of the project. In-lieu fee mitigation involves a program where funds are paid to a natural resource management entity by a permittee or agency to meet their requirements of compensatory mitigation. The fees are used to fund the implementation of either specific or general wetland or other aquatic resource conservation projects. The management entity may be a third party (e.g., nongovernmental organizations, land trusts) or a public agency that specializes in resource conservation, restoration, and enhancement programs.

Below are some general topics and recommendations regarding the assessment and implementation of compensatory mitigation for actions that may adversely affect fishery resources. It may be necessary to include some of these measures as permit conditions or in decision documents in order to ensure that compensatory mitigation is completed satisfactorily and within the agreed upon timeframes.

### *Baseline information*

The primary purpose of providing effective compensatory mitigation should be to restore or replace the ecological functions and values of resources. In order to assess the effectiveness of compensatory mitigation, the baseline or existing functions and values of the project impact site must be known, as well as the target functions and values for the completed compensatory mitigation site. This can only be accomplished through site-specific monitoring and resource assessments. There are a number of assessment methodologies available to accomplish this, and it is important to determine the method(s) that should be used in advance because it will be necessary for the performance evaluation of the completed mitigation site.

Generally, compensatory mitigation should be provided for direct and indirect impacts, as well as short-term, long-term, and cumulative impacts to fishery resources. Indirect, long-term, and cumulative impacts of a development project may be more difficult to identify and quantify than short-term impacts, but they are no less important. In some cases, the adverse effects on aquatic resources from indirect, long-term, and cumulative impacts may be greater than the direct, short-term construction-related impacts. For example, the direct construction-related impacts of deepening a navigation channel for the purpose of expanding a commercial marina may only involve the removal of bottom sediments in the existing channel. Even so, the dredging project may also result in other short-term impacts to benthic resources from sedimentation and turbidity and anchor damage from vessels. Expansion of a marina operation may result in long-term and cumulative impacts to seagrass and riparian vegetation from vessel wakes and prop scour and in chronic turbidity and sedimentation from larger and more frequent vessel activity. Long-term and cumulative impacts from a development project may also determine whether compensatory mitigation is more appropriately located on-site or off-site.

### *Compensatory mitigation plan*

A clear and concise description of the specific habitats and the functions and values that are intended to be restored should be provided in the mitigation plan. Wetlands and other aquatic habitats provide numerous functions and values within an ecosystem, so it is important to identify the specific functions and values that the compensatory mitigation is intended to restore or replace. Performance criteria should be established (e.g., 80% vegetation cover by target species by the end of the second growing season), and specific monitoring and analytical methods to assess the success of the mitigation should be stipulated in advance.

Adaptive management should be incorporated into mitigation plans, when appropriate. While clear and concise performance criteria are important in all compensatory mitigation plans, monitoring data and predetermined ecological indicators should be used to guide the progress of the mitigation and ensure mitigation objectives are met. Effective compensatory mitigation plans should recognize the importance of adaptive management and allow for corrective action when performance measures are not being met.

A compensatory mitigation plan should include requirements for monitoring and performance reporting, including the content and frequency of reports and who should receive the reports. Generally, the reports should be provided concurrently with the completion of performance monitoring to allow for corrective actions to be taken should success criteria not be met. Other features of a mitigation plan may include measures to ensure mitigation site protection, financial assurances, and a description of long-term maintenance requirements, if necessary, and the party or parties responsible for completing the mitigation requirements.

### *Contingency plans*

Contingency plans for the mitigation plan may be necessary to ensure that adequate compensation is provided, particularly for mitigation that is considered a high-risk endeavor, such as restoration of eelgrass beds. The contingency plan may be necessary to extend the completion of the mitigation plan, and it may require supplemental effort (e.g., planting) or call for alternative mitigations (e.g., out-of-kind). If it is determined that mitigation contingencies are necessary, they should be specified in the permit or decision documents.

### *Mitigation timing*

To minimize the time lag between the loss of wetlands or other aquatic resources and the completion of the compensatory mitigation project, implementation of mitigation construction should begin as soon as possible. For example, if mitigation construction must begin during a specific time of year or the ecological functions and values at the mitigation site require multiple years before being realized, it may be desirable for the compensatory mitigation project to begin before the resource impacts occur.

### *Interim losses*

In situations where there will be delays in implementation of compensatory mitigation or a compensatory mitigation project requires several years to complete, interim or temporal losses of ecological functions and values may be substantial. In these cases, compensation of the interim losses of ecological functions and values should be included in the compensatory mitigation plan. There are a number of ways in which compensation of interim losses can be assessed, such as increasing the ratio of acreage lost to acreage replaced. However, “loss of services” analyses, such as the Habitat Equivalency Analysis (HEA), have been used successfully in a number of restoration projects (NOAA 2006). The HEA assumes there is a one-to-one tradeoff between the resource services at the compensatory restoration site and the resource impact site. In other words, it assumes that the resources can be compensated for past losses through habitat replacement projects providing the replacement resources are the same type as the lost or damaged resources (i.e., in-kind mitigation).

For more information and a more detailed discussion about compensatory mitigation, the reader may refer to the following resources.

# CONCLUSIONS AND RECOMMENDATIONS

The purpose of this chapter is to synthesize the information discussed in the previous chapters of this report and to identify topics for future research and focus. In addition, the participants of the technical workshop on nonfishing impacts identified activities that are known or suspected to have adverse impacts on fisheries habitat, and we have attempted to draw some conclusions (based upon the effects scores) concerning those activities and effects that deserve further scrutiny and discussion. While many of these activities clearly have known direct, adverse impacts on the quantity and quality of fisheries habitat, their effects at the population and ecosystem level are not well known or understood. For example, there are a number of ports and harbors in the northeast region that have been identified as the most contaminated sites in US coastal waters for polycyclic aromatic hydrocarbons, chlorinated hydrocarbons, and trace metals (USEPA 2004; Buchsbaum 2005). Although many of the effects of these pollutants at the cellular, physiological, and whole organism level are known, information on the effects at the population and ecosystem level is less understood.

There were some noteworthy results from the technical workshop, particularly regarding the geographic areas that scored high for some of the activity types and effects. As one might expect, the workshop participants considered impacts on fisheries habitats to be generally focused in nearshore coastal areas. These results are not particularly surprising considering the proximity of riverine and nearshore habitats to industrial facilities, shipping, and other coastal development. Rivers, estuaries, and coastal embayments are essential for fisheries because they serve as nurseries for the juvenile stages of species harvested offshore or as habitats for the prey of commercially important species (Deegan and Buchsbaum 2005). Estuarine and wetland dependent fish and shellfish species account for about 75% of the total annual seafood harvest of the United States (Dahl 2006). In the workshop session on alteration of freshwater systems, several effects scored high in the estuarine/nearshore ecosystem in addition to the riverine ecosystem. For example, impaired fish passage and altered temperature regimes scored high for the riverine and estuarine/nearshore ecosystems in the dam construction/operation and water withdrawal activity types, suggesting that the participants viewed these activities to have broad ecosystem impacts.

Most effects in both the chemical and physical effects workshop sessions scored high in the riverine and estuarine/nearshore ecosystems. In addition, a few of these effects also scored high in the marine/offshore ecosystem. For the chemical effects session, the release of nutrients/eutrophication, release of contaminants, development of harmful algal blooms, contaminant bioaccumulation/biomagnification, and all effects under the combined sewer overflows impact type scored high in all ecosystem types. The concern of the workshop participants regarding these impacts seems to reflect recently published assessments on threats to coastal habitats (USEPA 2004; Deegan and Buchsbaum 2005; Lotze et al. 2006). For example, the 2004 National Coastal Condition Report (USEPA 2004) assessed the condition of estuaries in the northeast to be poor, with 27% of estuarine area as impaired for aquatic life, 31% impaired for human use, and an additional 49% as threatened for aquatic life use. One of the primary factors contributing to poor estuarine conditions in the northeast region is poor water quality, which is typically caused by high total nitrogen loading, low dissolved oxygen concentrations, and poor water clarity. In the northeast region, the contributing factors associated with nutrient enrichment are principally high human population density and, in the mid-Atlantic states, agriculture (USEPA 2004). In addition, harmful algal blooms (HABs) have been associated with eutrophication of coastal waters, which can deplete oxygen in the water, result in hypoxia or anoxia, and lead to large-scale fish kills (Deegan and Buchsbaum 2005). HABs may also contain species of algae that produce toxins, such as red tides, that can kill or otherwise negatively affect large numbers of fish and shellfish, contaminate shellfish beds, and cause health problems in humans. The extent and severity of coastal eutrophication and HABs will likely continue and may worsen as coastal human population density increases. Considerable attention should be focused on the effects of eutrophication on habitat and water quality, the populations of fish and shellfish, and the role of natural versus anthropogenic sources of nutrients in the occurrence of HABs.

For the workshop session on physical effects, entrainment and impingement effects scored high in all ecosystem types. Entrainment and impingement of eggs, larvae, and juvenile fish and shellfish are increasingly being identified as potential threats to fishery populations from a wide variety of activities, including industrial and municipal water intake facilities, electric power generating facilities, shipping, and liquefied natural gas facilities (Hanson et al. 1977; Travnichek et al. 1993; Richkus and McLean 2000; Deegan and Buchsbaum 2005). Future research is needed to assess the long-term and cumulative effects that entrainment and impingement from these activities have on fish stocks, their prey, and higher trophic levels of the marine ecosystem.

The participants of the workshop session on global effects and other impacts scored most effects in the estuarine/nearshore ecosystem as high. However, several effects of climate change scored high for all ecosystems, including alteration of temperature and hydrological regimes, alteration of weather patterns, and changes in community structure. The effects of climate change related to commercial and recreational fisheries have not as of yet been the focus of extensive research. However, greater emphasis on this topic will likely be necessary as the effects of global warming become more pronounced (Bigford 1991; Frumhoff et al. 2007).

A number of activities and effects were identified during the workshop and in the preparation of this report that may pose substantial threats to fisheries habitat, but the extent of the problems they represent and their implications to aquatic ecosystems are not well understood. Some of these activities and effects have only recently been recognized as potential threats, such as the effects of endocrine disrupting chemicals on aquatic organisms and the threats to fisheries from global warming and will require additional research to have a clearer understanding of the mechanism and scope of these problems. However, other effects such as sedimentation on benthic habitats and biota have been the focus of considerable research and attention, but questions remain as to the lethal and sublethal thresholds of sedimentation effects on individual species and its effects on populations. For example, although sedimentation caused by navigation channel dredging is known to adversely affect the demersal eggs of winter flounder (*Pseudopleuronectes americanus*) (Berry et al. 2004; Klein-MacPhee et al. 2004; Wilber et al. 2005) a better understanding of how the intensity and duration of egg burial effects mortality is needed (i.e., lower lethal thresholds). In addition, how do grain size, the type and amount of contamination, and background suspended sediment concentrations affect egg and larvae survival rates, and what are the implications at the population level?

A number of energy-related activities were assessed for adverse effects on fisheries habitat in the technical workshop and in the corresponding report chapter, including offshore liquefied natural gas platforms, wind turbines, and wave and tidal energy facilities. Although various impacts were discussed, there have not been any facilities of this type constructed in the northeast region of the United States at the time of this report. Although we believe the resource assessments for these types of facilities have been based upon the best available information, further monitoring and assessments will be necessary once they are constructed.

The workshop participants identified a number of chemical effects in several sessions that may have a high degree of impact on fisheries, such as endocrine disrupting chemicals and pharmaceuticals in treated wastewater. Pharmaceuticals and personal care products (PPCP) can persist in treated wastewater and have been found in natural surface waters at concentrations of parts per thousand to parts per billion (Daughton and Ternes 1999). Although the range of concentrations of PPCPs may not pose an acute risk, because aquatic organisms may be exposed continually and for multi-generations, the effects on coastal aquatic communities are a major concern (USEPA 2007). Some of these PPCPs include steroid compounds, which may also be endocrine disruptors. Endocrine disruptors can mimic the functions of sex hormones, androgen and estrogen, and can interfere with reproductive functions and potentially result in population-level impacts. Some chemicals shown to be estrogenic include polychlorinated biphenyl (PCB) congeners, pesticides (e.g., dieldrin, dichlorodiphenyl trichloroethane [DDT]), and compounds used in some industrial manufacturing (e.g., phthalates, alkylphenols) (Thurberg and Gould 2005). In addition, some metal compounds have also been implicated in disrupting endocrine secretions of marine organisms (Brodeur et al. 1997). Additional investigation into the effects of PPCPs and endocrine disruptors on aquatic organisms and their potential impacts at the population and ecosystem level is needed.

In addition, the workshop participants identified a number of adverse effects on aquatic ecosystems from introduced/nuisance species, particularly in the estuarine/nearshore ecosystem. Introduction of nonnative invasive species into marine and estuarine waters poses a significant threat to living marine resources in the United States (Carlton 2001). Nonnative species introductions occur through a wide range of activities, including hull fouling and ballast water releases from ships, aquaculture operations, fish stocking and pest control programs, and aquarium discharges (Hanson et al. 2003; Niimi 2004). The rate of introductions has increased exponentially over the past 200 years, and it does not appear that this rate will level off in the near future (Carlton 2001). Increased research focused towards reducing the rate of nonnative species introductions is needed, in addition to a better understanding of the effects of nonnative species on fisheries in the United States.

Overfishing, including fishing effects on habitat, is likely the greatest factor in the decline of groundfish species in New England (Buchsbaum 2005) and is responsible for the majority of fish and shellfish species depletions and extinctions worldwide (Lotze et al. 2006). However, habitat loss and degradation through nonfishing activities (including pollution, eutrophication, and sedimentation) closely follow exploitation as a causative agent in fishery declines and may be equally or more important for some species such as Atlantic salmon (*Salmo salar*) (Buchsbaum 2005; Lotze et al. 2006). Cumulative effects likely play a role in a large majority of historic changes in fish stocks. Worldwide, nearly half of all marine and estuarine species depletions and extinctions involve multiple human impacts, most notably exploitation and habitat loss (Lotze et al. 2006). It is imperative that management measures intended to reduce exploitation, increase habitat protection, and improve water quality be applied holistically and that the cumulative effects of multiple human interactions be considered in both management and conservation strategies (Lotze et al. 2006). The challenges of quantifying the cumulative effects of nonfishing impacts are vast and complex. Nonetheless, the importance of nonfishing impacts on the coastal ecosystem will likely become greater in the future, and we believe fishery managers would be well served by beginning to collaborate with coastal resource managers and integrate signals from nonfishing effects and stresses on the ecosystem with traditional stock assessment models.

Re: Endangered Species Act Section 7 Formal Consultation and Magnuson-Stevens Fishery Conservation and Management Act Essential Fish Habitat Consultation for the Coos Bay Airport Expansion in North Bend (HUC: 171003040303), Coos County, Oregon

Dear Ms. Morgan:

The enclosed document contains a biological opinion (Opinion) prepared by the National Marine Fisheries Service (NMFS) pursuant to section 7(a)(2) of the Endangered Species Act (ESA) on the effects of the Federal Aviation Administration's (FAA) proposal to fund the Coos Bay Airport Expansion in North Bend (HUC: 171003040303), in Coos County, Oregon. In this Opinion, NMFS concludes that the proposed action is not likely to jeopardize the continued existence of Oregon Coast (OC) coho salmon (*Oncorhynchus kisutch*), or result in the destruction or adverse modification of designated critical habitat for OC coho salmon. This Opinion also concludes the proposed action is not likely to jeopardize the continued existence of the southern distinct population segment of North American green sturgeon (*Acipenser medirostris*).

As required by section 7 of the ESA, NMFS is providing an incidental take statement (ITS) for OC coho salmon with the Opinion. The ITS describes reasonable and prudent measures NMFS considers necessary or appropriate to minimize the impact of incidental take associated with this action. The ITS sets forth nondiscretionary terms and conditions, including reporting requirements, that the FAA and their applicant must comply with to carry out the reasonable and prudent measures. Incidental take from actions that meet these terms and conditions will be exempt from the ESA's prohibition against the take of ESA-listed species.

This document also includes the results of our analysis of the action's likely effects on essential fish habitat (EFH) pursuant to section 305(b) of the Magnuson-Stevens Fishery Conservation and Management Act (MSA), and includes two conservation recommendations to avoid, minimize or otherwise offset potential adverse effects on EFH. These conservation recommendations are a subset of the terms and conditions found in the ITS. Section 305(b)(4)(B) of the MSA requires Federal agencies to provide a detailed written response to NMFS within 30 days after receiving these recommendations.

If the response is inconsistent with the EFH conservation recommendations, the FAA must explain why the recommendations will not be followed, including the scientific justification for any disagreements over the effects of the action and the recommendations.

In response to increased oversight of overall EFH program effectiveness by the Office of Management and Budget, NMFS established a quarterly reporting requirement to determine how many conservation recommendations are provided as part of each EFH consultation and how many are adopted by the action agency. Therefore, in your statutory reply to the EFH portion of this consultation, please clearly identify the number of conservation recommendations accepted.

If you have questions regarding this consultation, please contact Ken Phippen, Branch Chief of the Southwest Oregon Habitat Branch of the Oregon State Habitat Office, at 541.957.3385.

Sincerely,

Michael Tehan

## TABLE OF CONTENTS

# INTRODUCTION

This document contains a biological opinion (Opinion) and incidental take statement (ITS) prepared in accordance with section 7(b) of the Endangered Species Act (ESA) of 1973, as amended (16 U.S.C. 1531, *et seq.*), and implementing regulations at 50 C.F.R. 402. The National Marine Fisheries Service (NMFS) also completed an essential fish habitat (EFH) consultation, prepared in accordance with section 305(b)(2) of the Magnuson-Stevens Fishery Conservation and Management Act (MSA) (16 U.S.C. 1801, *et seq.*) and implementing regulations at 50 CFR 600.

The docket for this consultation is on file at the Southwest Oregon Habitat Branch in Roseburg, Oregon.

## Background and Consultation History

On December 1, 2006, NMFS received a letter and biological assessment (BA) from the Seattle Airports District Office of the Federal Aviation Administration (FAA), requesting consultation on the effects of funding a construction project at the Southwest Oregon Regional Airport in North Bend, Oregon. The request for consultation was made pursuant to section 305(b)(2) of the MSA. The funding would allow the Southwest Oregon Regional Airport to improve airport safety and meet FAA design requirements by expanding an existing taxiway and adding a new air traffic control tower. The proposed changes will require that a 1,000-foot long by 65-foot wide section of Coos Bay be filled to accommodate the expansion.

The Southwest Oregon Regional Airport (formerly known as the North Bend Municipal Airport) began in 1936 as a local Work Project Administration (WPA) project. The airfield became an Auxiliary Air Facility in 1942. In 1947, the airfield was deeded to the City of North Bend. The most recent airport expansion occurred in 1988, and extended Runway 4-22. The airport is currently owned and operated by the Coos County Airport District (CCAD). It is the only commercial airport on the Oregon Coast.

A field trip was held on November 1, 2006, to visit the construction site and nearby mitigation site. Representatives from W&H Pacific (consultant), the U.S. Army Corps of Engineers, the Ocean and Coastal Program of the Oregon Land Conservation and Development Commission, Oregon Department of Fish and Wildlife (ODFW), and the Southwest Oregon Regional Airport attended the field trip.

On July 16, 2007, the Southwest Oregon Habitat Branch of the NMFS received the final Environmental Assessment (EA) for the project. This final assessment provided key information that outlined the proposed activities at the Mangan mitigation site on Haynes Inlet.

On October 5, 2007, NMFS issued an EFH consultation (refer to NMFS No.: 2006/06108) completing MSA consultation to the Federal Aviation Administration (FAA) for their proposed funding of the Coos Bay Airport Expansion and provided two conservation recommendations to avoid, minimize or otherwise offset potential adverse effects to EFH. Some upland work has occurred to prepare the site, but project area work previously permitted and with the potential to impact EFH has not been completed. Deployment of temporary coffer-dams was attempted before the lapse of the in-water work period, but was discontinued due to delays encountered while deploying the coffer dam, as described below. Wetland and estuarine habitat mitigation construction has taken place at the Mangan mitigation site, but elements including the breech of the dike and installation of work area isolation structures associated with this activity, have not taken place.

The relocation of taxiway C at the Southwest Oregon Regional Airport requires the placement of fill material into the Coos Bay estuary. The erosion control plan called for the installation of a temporary cofferdam with a minimum 10 feet of clearance between the toe of slope and the back of the cofferdam. Removal of existing riprap along the old embankment, compaction of the proposed fill area, and filling/completion of the proposed taxiway and new embankment were to be completed only after this structure had been installed.

Due to the nature of substrate in the project area and the isolation structure, a standard cofferdam was deemed to be inappropriate for the project area by cofferdam suppliers and the contractor. In response, the contractor selected a water-filled temporary dam for work area isolation. Such a structure typically produces fewer impacts, requires less installation time, and does not require stable foundation substrate-as was the case with other cofferdams.

The water-filled dam was received at the project site in early January, 2008. Deployment of the dam began soon after its arrival at the site. Delays and problems with the deployment of the water dam began almost immediately. Tidal timing, rupture of internal bladders, and long delays in receiving replacement parts and technical staff from the suppliers added to multiple delays. Finally, after additional deployment attempts and structure failures, the water filled dams were abandoned as viable options for work area isolation. At this time, the in-water work period at the project site had lapsed and plan changes were deemed necessary.

Multiple conference calls were conducted between personnel from W&H Pacific, ODFW, and NMFS personnel to discuss the project status and consultation strategy. On May 27, 2008, the FAA transmitted a letter to the NMFS requesting reinitiation of the MSA consultation due to changes in the proposed work. The FAA also requested initiation of formal consultation under the ESA for the newly-listed Oregon Coast (OC) coho salmon (*Oncorhynchus kisutch*) and its designated critical habitat, and for the newly-listed Southern distinct population segment (DPS) of the North American green sturgeon (*Acipenser medirostris*). Southern DPS green sturgeon individuals were recently determined to inhabit Coos Bay, therefore the FAA chose to initiate ESA consultation on this ESA-listed species.

The FAA concluded that funding the proposed action may adversely affect OC coho salmon, critical habitat for OC coho salmon, southern DPS green sturgeon and EFH designated for Pacific salmon and groundfish.

**Description of the Proposed Action**

The proposed action is to fund the remaining elements of an expansion of a runway and taxiway at the Southwest Oregon Regional Airport in North Bend, Coos County, Oregon. The expansion will improve airport safety but will not increase the operational capacity of the airport, nor will it allow larger aircraft to use the airport.

The following descriptions summarize the proposed project changes that remain to be completed at the Airport and the Mangan mitigation site that are pertinent to review and consultation by NMFS. The summary includes the proposed changes to timing and staging.

**Taxiway C Relocation – Southwest Oregon Regional Airport.** In response to a need for plan changes, an alternative isolation method for the site has been devised. This method involves the construction of a coarse gravel pier extending eastward to westward from the existing embankment near the current stormwater discharge and then north to the existing taxiway C embankment as depicted in the Embankment Plan – Sheet C-15A. The pier will match the toe of slope of the final grade proposed for the fill area in the original plan. The pier will be constructed in the following order:

1. Work will commence from east to west, and then north.
2. Geotextile fabric will be placed on the bay bottom.
3. Aggregate will be placed on the geotextile fabric to a height of 6.62 feet, the elevation of highest measured tide.
4. Geotextile fabric will be wrapped around the aggregate and secured.
5. The closure of the pier will be completed at low tide to avoid fish entrapment within the structure.

Dewatering of the fill area will pump water into the existing stormwater containment pond for sediment control. Fill activities will be conducted during low and low slack tides to reduce the generation of local turbidity. The pier construction process and general work conditions during filling will be monitored for sediment and fish entrapment. In the event of fish salvage behind the pier structure, beach seines and dip nets will be utilized to remove fish to bay waters. Fish salvage is expected to be conducted by a W&H Pacific biologist.

Following completion of compaction and filling in the internal fill area, the pier will be capped with additional fill materials to the proposed final elevation of the new taxiway alignment and previously specified riprap will be installed on the bay-side face of the pier. See Sheet C-22A for a detail of the sequence of fill and pier (embankment) construction.

Construction of the pier work containment structure constitutes in-water work, but does not constitute a difference in fill volumes or the final development footprint. The estimated time for construction of the pier is expected to be no more than 2 weeks. Following recommendations and considering environmental conditions, construction of the structure will not commence until after June 30, 2008. This timing is out of the in-water work period for the watershed, but is during the driest time of the year for the region and is out of the expected peak outmigration time for OC coho salmon smolts.

**Mangan Mitigation Site – Taxiway C Wetland Impacts Mitigation Site.** The creation of the Mangan mitigation site involves the restoration of mud flats and salt marsh from diked agricultural lands. The primary element of the mitigation site is the removal of an existing levee to introduce tidal action to the site. As specified in the original demolition plan, the levee removal work was to be isolated by a temporary coffer dam as designed for the taxiway. Following failure of the water-dam at the Airport site, the device was rejected for work area isolation at the Mangan site as well.

In lieu of utilizing the water-dam, the levee removal work will be isolated from the Haynes Inlet by the deployment of two 5-foot tall silt fences spaced 5 feet apart. These silt fences would be installed as close to the toe of the existing levee as practical. See Existing Conditions Demolition Plan Sheets WL-02 and WL-03 for details. All excavation at elevations within tidal influence will be conducted when tidal waters are not in the project area.

Upon complete removal of the existing levee, both silt fences will be removed from the project area. The site will be monitored for fish stranding and turbidity while the silt fences are deployed. In the event that fish are stranded behind the silt fences and in the work area, W&H Pacific biologists will coordinate salvage efforts with ODFW. Stranded fish will be removed from the work area with beach seines and dip nets and returned to Haynes Inlet.

Demolition of the levee (in-water work) is expected to take no more than 5 days – with excavated materials being used to add to the new levee elevation. All other work besides installation of salt marsh plantings is completed to date and does not require in-water work. The proposed in-water work at the site is expected to be conducted after June 30, 2008, for the same reasons specified for the pier construction at the airport. The site will be monitored for sedimentation and fish entrapment while the sediment barriers are deployed.

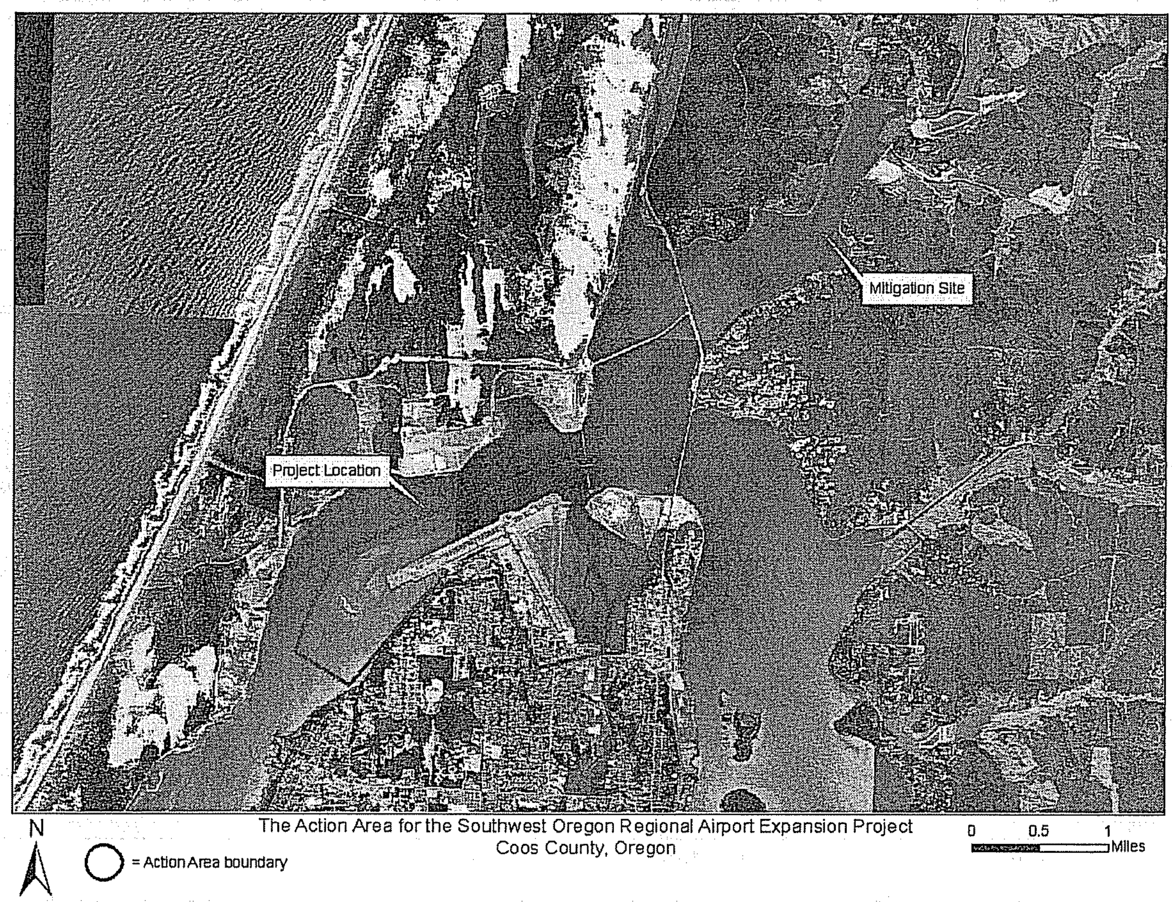
The impact reduction measures, described here as part of the proposed action, are intended to reduce adverse effects on ESA-listed species and their habitats. The NMFS regards these impact reduction measures as integral components of the proposed action and expects that all proposed project activities will be completed consistent with those measures. We have completed our effects analysis accordingly. Any project activity that deviates from these impact reduction measures will be beyond the scope of this consultation and will not be exempted from the prohibition against take as described in the attached ITS. Further consultation will be required to determine what effect the modified action may have on listed species or critical habitats.

The NMFS relied on the foregoing description of the proposed action, including all stated impact reduction measures, to complete this consultation. To ensure that this consultation remains valid, NMFS requests that the action agency or applicant keep NMFS informed of any changes to the proposed action.

**Action Area**

'Action area' means all areas to be affected directly or indirectly by the Federal action and not merely the immediate area involved in the action (50 CFR 402.02). The action area is defined as the footprint of the existing airport and adjacent bank, substrate, and aquatic areas of the Coos Bay Estuary and Pony Slough. The action area extends 500 feet upstream from the project site and 1,500 feet downstream from the downstream end of the project site in Coos Bay due to potential impacts from stormwater discharge, turbidity and contaminant dispersion, and habitat loss. The action area also incorporates the mitigation site which includes the immediate footprint of the site and the waters of Haynes Inlet surrounding the site out to a distance of approximately 300 feet. The airport is on Coos Bay in North Bend, Coos County, Oregon. The site is in Township 25 South, Range 13 West, Sections 8, 9, and 10.

**Figure 1.** Location of the two construction areas within Coos Bay for the Southwest Oregon Regional Airport Expansion Project.



The Pacific Fishery Management Council (PFMC) designated EFH for groundfish (PFMC 2005), coastal pelagic species (PFMC 1998), and Chinook salmon (*O. tshawytscha*), coho salmon, and Puget Sound pink salmon (PFMC 1999). The action area includes areas designated as EFH for various life-history stages of groundfish, coastal pelagics, and Chinook salmon and coho salmon (Table 1).

The action area is used by adult and juvenile OC coho salmon for migration and making the transition between the marine and freshwater environments. The OC coho salmon were listed under the ESA, protective regulations were issued and critical habitat was designated on February 4, 2008 (70 FR 7816).

**Table 1.** Species with designated EFH found in waters of Oregon and Washington

| **Groundfish Species** | Blue rockfish (*S. mystinus*) | Rougheye rockfish (*S. aleutianus*) | Flathead sole (*Hippoglossoides elassodon*) |
|---|---|---|---|
| Leopard shark (*Triakis semifasciata*) | Bocaccio (*S. paucispinis*) | Sharpchin rockfish (*S. zacentrus*) | Pacific sanddab (*Citharichthys sordidus*) |
| Soupfin shark (*Galeorhinus zyopterus*) | Brown rockfish (*S. auriculatus*) | Shortbelly rockfish (*S. jordani*) | Petrale sole (*Eopsetta jordani*) |
| Spiny dogfish (*Squalus acanthias*) | Canary rockfish (*S. pinniger*) | Shortraker rockfish (*S. borealis*) | Rex sole (*Glyptocephalus zachirus*) |
| Big skate (*Raja binoculata*) | Chilipepper (*S. goodei*) | Silvergray rockfish (*S. brevispinus*) | Rock sole (*Lepidopsetta bilineata*) |
| California skate (*R. inornata*) | China rockfish (*S. nebulosus*) | Speckled rockfish (*S. ovalis*) | Sand sole (*Psettichthys melanostictus*) |
| Longnose skate (*R. rhina*) | Copper rockfish (*S. caurinus*) | Splitnose rockfish (*S. diploproa*) | Starry flounder (*Platyichthys stellatus*) |
| Ratfish (*Hydrolagus colliei*) | Darkblotched rockfish (*S. crameri*) | Stripetail rockfish (*S. saxicola*) | |
| Pacific rattail (*Coryphaenoides acrolepsis*) | Grass rockfish (*S. rastrelliger*) | Tiger rockfish (*S. nigrocinctus*) | **Coastal Pelagic Species** |
| Lingcod (*Ophiodon elongatus*) | Greenspotted rockfish (*S. chlorostictus*) | Vermillion rockfish (*S. miniatus*) | Northern anchovy (*Engraulis mordax*) |
| Cabezon (*Scorpaenichthys marmoratus*) | Greenstriped rockfish (*S. elongatus*) | Widow Rockfish (*S. entomelas*) | Pacific sardine (*Sardinops sagax*) |
| Kelp greenling (*Hexagrammos decagrammus*) | Longspine thornyhead (*Sebastolobus altivelis*) | Yelloweye rockfish (*S. ruberrimus*) | Pacific mackerel (*Scomber japonicus*) |
| Pacific cod (*Gadus macrocephalus*) | Shortspine thornyhead (*Sebastolobus alascanus*) | Yellowmouth rockfish (*S. reedi*) | Jack mackerel (*Trachurus symmetricus*) |
| Pacific whiting (Hake) (*Merluccius productus*) | Pacific Ocean perch (*S. alutus*) | Yellowtail rockfish (*S. flavidus*) | Market squid (*Loligo opalescens*) |
| Sablefish (*Anoplopoma fimbria*) | Quillback rockfish (*S. maliger*) | Arrowtooth flounder (*Atheresthes stomias*) | |
| Aurora rockfish (*Sebastes aurora*) | Redbanded rockfish (*S. babcocki*) | Butter sole (*Isopsetta isolepsis*) | **Salmon** |
| Bank Rockfish (*S. rufus*) | Redstripe rockfish (*S. proriger*) | Curlfin sole (*Pleuronichthys decurrens*) | Coho salmon (*Oncorhynchus kisutch*) |
| Black rockfish (*S. melanops*) | Rosethorn rockfish (*S. helvomaculatus*) | Dover sole (*Microstomus pacificus*) | Chinook salmon (*O. tshawytscha*) |
| Blackgill rockfish (*S. melanostomus*) | Rosy rockfish (*S. rosaceus*) | English sole (*Parophrys vetulus*) | Pink salmon (*O. gorbuscha*) |

The NMFS listed southern DPS green sturgeon as threatened under the ESA on April 7, 2006 (71 FR 17757). Southern DPS green sturgeon use the action area as habitat for growth and development to adulthood and for adult feeding. The NMFS has not designated critical habitat for southern DPS green sturgeon, or issued protective regulations under section 4(d) of the ESA.

## ENDANGERED SPECIES ACT

Section 7(a)(2) of the ESA requires Federal agencies to consult with NMFS to ensure that their actions are not likely to jeopardize the continued existence of endangered or threatened species, or adversely modify or destroy their designated critical habitat. The Opinion that follows records the results of the interagency consultation for this proposed action. An ITS is provided after the Opinion that specifies the impact of any taking of OC coho salmon that will be incidental to the proposed action, reasonable and prudent measures that NMFS considers necessary and appropriate to minimize such impact, and nondiscretionary terms and conditions (including, but not limited to, reporting requirements) that must be complied with by the Federal agencies, applicants, or both, to carry out the reasonable and prudent measures.

### Biological Opinion

To complete the jeopardy analysis presented in this Opinion, NMFS reviewed the status of each listed species considered in this consultation, the environmental baseline in the action area, the effects of the action, and cumulative effects (50 CFR 402.14(g)). From this analysis, NMFS determined whether effects of the action were likely, in view of existing risks, to appreciably reduce the likelihood of both the survival and recovery of the affected listed species.

For the critical habitat adverse modification analysis, NMFS considered the status of the entire designated area of the critical habitat considered in this consultation, the environmental baseline in the action area, the likely effects of the action on the function and conservation role of the affected critical habitat, and cumulative effects. The NMFS used this assessment to determine whether, with implementation of the proposed action, critical habitat would remain functional, or retain the current ability for the primary constituent elements (PCEs) to become functionally established, to serve the intended conservation role for the species (Hogarth 2005).

#### Status of the Species and Critical Habitat

This section defines the biological requirements of the species, and reviews the status of the species and affected critical habitat relative to those requirements. The present risk of extinction faced by the listed species informs NMFS' determination of whether additional risk will 'appreciably reduce' the likelihood that they will survive or recover in the wild. The greater the present risk, the more likely it is that any additional risk resulting from the proposed action's effects on the population size, productivity (growth rate), distribution, or genetic diversity of the species (McElhany *et al.* 2000), or on the conservation value of critical habitat, will be an appreciable reduction.

**OC Coho Salmon**. This species includes all naturally-spawned populations of coho salmon in Oregon coastal streams south of the Columbia River and north of Cape Blanco, and progeny of five artificial propagation programs. The Oregon Coast Technical Recovery Team (OC-TRT) identified 56 historical populations, grouped into five major "biogeographic strata," based in consideration of historical distribution, geographic isolation, dispersal rates, genetic data, life history information, population dynamics, and environmental and ecological diversity (Lawson *et al.* 2007).

The OC-TRT concluded that, if recent past conditions continue into the future, OC coho salmon are moderately likely to persist over a 100-year period without artificial support, and have a low to moderate likelihood of being able to sustain their genetic legacy and long-term adaptive potential for the foreseeable future (Wainwright *et al.* 2007).

The following factors were identified by NMFS (2007) as limiting the recovery of OC coho salmon: Degraded floodplain connectivity and function, degraded channel structure and complexity, degraded riparian areas and large wood debris recruitment, degraded stream substrate, degraded water quality, predation, competition, and disease.

***Coos River population***. OC coho salmon occurring in the action area are part of the Coos River population that was identified as a functionally-independent population (Lawson *et al.* 2007). An independent population is defined as having minimal demographic influence from adjacent populations and is viable-in-isolation. An independent population is any collection of one or more local breeding units whose population dynamics or extinction risk over a 100-year time period is not substantially altered by exchanges of individuals with other populations (McElhany *et al.* 2000). The Coos River Population is part of the Mid-South Coast biogeographic strata defined within the OC coho salmon ESU (Lawson *et al.* 2007).

Annual spawning surveys document the Coos River population's annual abundance varies considerably from year to year (Tables 2 and 3). The recent negative trend in abundance demonstrated at the ESU level is reflected at the population level as well (Table 3). Preliminary conclusions for the 2007 spawner abundance places last year's spawner abundance at a very low level.

The number of OC coho salmon juvenile outmigrants from the Coos River population has not been studied enough to provide a reliable estimate. However, it can be back-calculated by dividing the number of returning adults by marine survival. Marine survival predictions averaged 4%, with a range of 0.5% and 11.7%, between 1970 and 1999 (PMFC 2000). In the years of overlapping data (1990-1999), the average number of outmigrants estimated by this back-calculation is 123,625, with a range of 72,067 to 1,686,360.

**Table 2.** Annual estimates of wild OC coho salmon spawner abundance in the Coos Bay system based on monitoring data collected by ODFW.

| Year | Coos Bay & Big Creek |
|---|---|
| 1990 | 2,273 |
| 1991 | 3,813 |
| 1992 | 16,545 |
| 1993 | 15,284 |
| 1994 | 14,685 |
| 1995 | 10,351 |
| 1996 | 12,128 |
| 1997 | 1,127 |
| 1998 | 3,167 |
| 1999 | 4,945 |
| 2000 | 5,386 |
| 2001 | 43,301 |
| 2002 | 35,429 |
| 2003 | 29,559 |
| 2004 | 24,116 |

**Table 3.** Estimated wild OC coho salmon abundance estimates and 95% confidence interval (CI) from the 2002 through 2007 spawning survey seasons for Coos River. Included are the number of surveys and miles surveyed.

| Year | Number Surveys | Miles | Estimate | 95% CI |
|---|---|---|---|---|
| 2002 | 32 | 29.4 | 35,688 | 13,258 |
| 2003 | 33 | 30.9 | 29,559 | 11,486 |
| 2004 | 34 | 31.8 | 24,116 | 7,446 |
| 2005 | 9 | 7.3 | 17,048 | 9,170 |
| 2006 | 23 | 20.0 | 11,266 | 4,243 |
| 2007 | 31 | 30.1 | 1,414 | 459 |

**Southern DPS Green Sturgeon.** Green sturgeon are a widely-distributed and marine-oriented species found in nearshore waters from Baja California to Canada (NMFS 2008). There are two distinct population segments defined for green sturgeon – a northern DPS with spawning populations in the Klamath and Rogue rivers and a southern DPS that spawns in the Sacramento River (NMFS 2008). The southern DPS includes all spawning populations of green sturgeon south of the Eel River in California, of which only the Sacramento River currently contains a spawning population. McLain (2006) noted that southern DPS green sturgeon were first determined to occur in Oregon and Washington waters in the late 1950s when tagged San Pablo Bay green sturgeon were recovered in the Columbia River estuary (CDFG 2002).

The green sturgeon biological review team (BRT) convened a status review update in November 2004 (BRT 2005). The majority of the BRT concluded that southern DPS green sturgeon is likely to become endangered in the foreseeable future and only one member concluded that the southern DPS is not in danger of extinction or likely to become endangered in the foreseeable future. Weighing heavily in this decision was the fact that this species only spawns in one area, the Sacramento River. The BRT felt that the blockage of green sturgeon spawning from what were certainly historic spawning areas above Shasta Dam and the accompanying decrease in spawning area with the loss of the Feather River spawning area make green sturgeon in the southern DPS at risk of extinction in the foreseeable future.

The distribution of green sturgeon is not well known, although southern DPS green sturgeon are reported to congregate in coastal waters and estuaries, including non-natal estuaries, such as Coos Bay. Beamis and Kynard (1997) suggested that green sturgeon move into estuaries of non-natal rivers to feed. Information from fisheries-dependent sampling suggests that green sturgeon only occupy large estuaries during the summer and early fall in the northwestern United States. Green sturgeon are known to enter Washington estuaries during summer (Moser and Lindley 2007). Commercial catches of green sturgeon peak in October in the Columbia River estuary, and records from other estuarine fisheries (Willapa Bay and Grays Harbor, Washington) support the idea that sturgeon are likely to be present in these estuaries from June until October (Moser and Lindley 2007).

***Coos Bay.*** Total population estimates are not available for abundance of either DPS of green sturgeon in Coos Bay; southern DPS individuals were documented to occur by sampling in a 2006 study (Israel and May 2006). Because Coos Bay is not their natal stream, southern DPS green sturgeon are likely to be present from June through October. While in the Coos Bay estuary, they are likely feeding and seeking out the deepest habitats.

**Status of OC Coho Salmon Critical Habitat.** The NMFS reviews the status of critical habitat affected by the proposed action by examining the condition and trends of PCEs of critical habitat throughout the designated area. Within the action area, critical habitat has been designated for OC coho salmon. The PCEs consist of the physical and biological elements identified as essential to the conservation of the species in the documents identifying critical habitat (Table 4).

**Table 4.** Sites (types of habitats), essential physical and biological features named as PCEs, and affected life history events in all salmon critical habitat designations.

| Site | Essential Physical and Biological Features | Affected Life History Event |
|---|---|---|
| Estuarine | Free of obstruction with water quality, water quantity, and salinity conditions supporting juvenile and adult physiological transitions between fresh- and saltwater; natural cover[a]; and forage[b]. | Juvenile and adult mobility and survival |

[a] Natural cover includes submerged and overhanging large wood, aquatic vegetation, large rocks and boulders, and side channels.

[b] Forage includes aquatic invertebrate and fish species that support growth and maturation.

Critical habitat was designated for OC coho salmon, and the action area contains one or more PCEs within the acceptable range of values required to support the biological processes for which the species use that habitat. The specific unit of OC coho salmon critical habitat that will be affected by the proposed action is the Coos Bay 5th field hydraulic unit code (HUC5

#1710030403). This watershed contains PCEs necessary for spawning, rearing and migration. The action area is identified as estuarine habitat and contains the PCEs necessary for juvenile and adult mobility and survival (Table 4). The NMFS Critical Habitat Analytical Review Team (CHART) identified the key management activities with the potential to affect the PCEs as forestry and urbanization. The CHART rated the conservation values of the HUC5 and the migratory corridor as high.

OC coho salmon adult and smolts considered in this Opinion migrate through the action area and use the area to make the physiological transition between marine and freshwater environments. Thus, the affected PCEs in the action area are those that are essential for conservation of adult and juvenile coho salmon for migration and to make the transition between these two environments (Table 4). Loss of estuarine wetlands caused by diking and filling to make those areas suitable for agricultural use, urbanization, and industrialization is the most important factor limiting salmon habitat value in the Coos Bay estuary.

**Environmental Baseline for the Action Area**

The NMFS describes the environmental baseline in terms of the biological requirements for habitat features and processes necessary to support all life stages of ESA-listed species within the action area. When the environmental baseline departs from those biological requirements, the adverse effects of a proposed action on the species or its habitat are more likely to jeopardize the listed species or result in destruction or adverse modification of a critical habitat (NMFS 1999).

The Coos Bay estuary is the second largest estuary in Oregon. It is approximately 13,300 acres in size, averaging nearly 0.6 mile wide by 15 miles long. The bay has approximately 30 tributaries. The major tributary flowing into Coos Bay is the Coos River. The Coos Bay estuary is classified as a drowned river mouth-type estuary, where winter flows discharge high volumes of sediment through the estuary. In summer, when discharge is lower, seawater inflow dominates this type of estuary. Extensive filling and diking of Coos Bay and its sloughs, estuaries, and tributaries have changed the form and function of the estuary. Approximately 90% of Coos Bay marshes have been lost to dikes and landfills (Proctor *et al.*1980). Approximately 72,000 tons of sediment, mainly silts and clays, pour into the Coos Bay estuary every year (Schultz 1990).

The waters surrounding the airport site consist of mostly shallow tidal mudflats that are exposed during most low tide occurrences. Habitat typing and mapping identified the area around the airport as: (1) Intertidal with sand and mud flats; (2) undifferentiated aquatic bed; and (3) seagrass aquatic bed. These three habitat types comprise 57.3% of the total 8,582 acres of intertidal zone within Coos Bay.

### Effects of the Action

'Effects of the action' means the direct and indirect effects of an action on the species or critical habitat, together with the effects of other activities that are interrelated or interdependent with that action, that will be added to the environmental baseline (50 CFR 402.02). The effects analysis presented in this section is based on information developed with the FAA and the applicants during the consultation process and provided by the applicants BA and supplemental information.

Based on information provided in the BA, NMFS concludes that the proposed action will have adverse effects on the aquatic environment in the action area. Two distinct areas exist in the action area. The taxiway C relocation and the Mangan mitigation site are the two areas with very distinct actions and effects on the environment. The NMFS believes the action, as proposed, is reasonably likely to have the following direct and indirect effects on the ESA-listed species and their aquatic environment: (1) Increased turbidity; (2) chemical contamination from materials staging and construction activities; (3) loss of benthic and shoreline habitat; (4) restoration of estuary functions; and (5) injury due to fish salvage.

Changes in stormwater generation and management are not expected to result in adverse effects to the local aquatic environment. Increased impervious surface and resulting stormwater management will result in discharged stormwater to Coos Bay and Pony Slough, but the proposed level of treatment and water management results in a negligible probability of an adverse effect on OC coho salmon and southern DPS green sturgeon. Approximately 76,595 square feet of increased impervious surface will result from the proposed action. The development of grassy swales, retention ponds, and an infiltration collection system will treat the 6-month, 24-hour storm; that is 90 to 95% of the annual runoff volume. Discharge will occur into Coos Bay and Pony Slough, which will have some low-intensity but insignificant effects on flow and potential contaminants.

#### <u>Effects on the Aquatic Environment</u>.

***Turbidity.*** Elevated turbidity levels will result from actions taken in both areas of the project. Actions associated with the taxiway C relocation that will cause elevated turbidity include the construction of the gravel pier. Dike removal at the Mangan mitigation site will also result in elevated turbidity.

Dry season construction of the pier will equate to less opportunity for precipitation-generated turbidity from the structure and fill area and will reduce the chances of smolts entering the work area. Construction of the pier within the early portion of the in-water work period would present a more significant delay from that already incurred by the project and would increase the likelihood of fall and winter storms affecting the work area and potentially increasing local turbidity.

During the gravel pier construction that will be used to isolate the work area, geotextile fabric will be placed during low tide and filled with unwashed aggregate. Each day the fabric will be folded up and closed around the aggregate to prevent tidal action from washing dirt off of the aggregate. It is expected that some turbidity will be generated through this process. Elevated turbidity levels will occur along the outside of the geotextile fabric from two causes: primarily due to wave action at the base of the structure, and secondarily from fine sediments escaping the geotextile fabric.

This elevated turbidity is expected to be localized, but to develop cumulatively along the face of the pier. Elevated turbidity levels will accumulate fine material and travel along the face of the pier in the direction of the water current. Turbidity plume directional movement and disbursement will be dependent on current flow. The outgoing tidal flows, combined with outgoing river flows, will carry the turbidity approximately 1,500 feet downstream from the end of the gravel pier. The gravel pier is inside a cove, therefore incoming tides will carry along the face of the pier into the back end of the cove. Most turbidity movement will be parallel to the gravel pier and then dispersed out from the pier to settle at the end of the cove. The cove area where elevated turbidity is expected to be observed is approximately 3.8 acres (185 feet wide and 900 feet long). During the incoming tide, the NMFS expects any increase in turbidity to not be detectable beyond this area. Tidal fluctuations and wind will drive the currents and disperse the suspended sediments away from the pier. Elevated turbidity levels will occur over a short time, lasting a few hours immediately after the work area is inundated by the incoming high tide. The elevated turbidity levels will occur over the 2 weeks of in-water work, twice each day in relation to the high tide cycle.

The dike removal process will create elevated turbidity in the immediate vicinity of the work. Although the removal work will occur at low tide, inundation of the work area during the high tide cycle will suspend sediments and create elevated turbidity. The placement of two silt fences will aid in controlling the suspended sediment spread, but not eliminate elevated turbidity. It is expected that the elevated turbidity levels will be observed up to 300 feet from the dike removal area. The elevated turbidity levels will occur over the 5 days of in-water work, twice each day in relation to the high-tide cycle.

**Chemical Contamination.** As with all construction activities, accidental release of fuel, oil, and other contaminants may occur as the presence of construction equipment near sensitive habitats, such as the estuary and wetlands, creates the potential for introduction of toxic materials from accidental spills, improper storage of petrochemicals, or mechanical failure. Operation of back-hoes, excavators, and other equipment requires the use of fuel, lubricants, *etc*., which, if spilled into the channel of a waterbody or into the adjacent riparian zone, can injure or kill aquatic organisms.

Based on experience with construction activities, the probability of a fuel spill, equipment malfunction, or accident is more than negligible. However, this is likely to be a short-term effect. Short-term effects of a spill could be extremely detrimental to aquatic habitat within the action area. Petroleum-based contaminants, such as fuel, oil, and some hydraulic fluids, contain poly-cyclic aromatic hydrocarbons (PAHs) which can be acutely toxic to the aquatic environment for fishes and can also cause lethal and chronic sublethal effects to aquatic organisms (Neff 1985).

Accidental spills may occur, allowing chemicals to reach Coos Bay, resulting in impacted water quality and reduced feeding opportunities for aquatic species within the action area. The large volume of water in the bay, the strong water currents and wind action, and the conservation measures proposed to minimize the amount and distance of a toxicant material spread will result in the dilution of any spill to undetectable levels in a few hours. Potential water contamination from construction activities will be controlled by the implementation of a spill containment plan. However, depending on the timing, weather conditions, and response and clean-up efficiency, adverse impacts may still occur due to the proximity to aquatic habitat.

**Loss of Benthic and Shoreline Habitat.** The fill will permanently destroy 1.23 acres of tidal estuarine habitat in Coos Bay. Habitat typing and mapping identified the area around the airport as: (1) Intertidal with sand and mud flats; (2) undifferentiated aquatic bed; and (3) seagrass aquatic bed. This proposed action will fill 1.23 acres of the total 8,582 acres of these three habitat types in the intertidal zone of Coos Bay. This loss will result in reduced abundance and diversity of prey for species inhabiting the immediate surrounding area of the Coos Bay estuary. The loss of shallow-water and benthic habitat from construction operations will eliminate the physical habitat space and the biotic community living in the 1.23 acres. Macroinvertebrates move, rest, find shelter, and feed on the substrate and organic material, as well as live within the substrate. The proposed project will physically disturb channel bottoms, eliminate the aquatic habitat, eliminate or displace established benthic communities and reduce prey availability in the vicinity of the fill placement.

**Restoration of Estuary Functions.** The applicant proposes to provide approximately 10 acres of estuarine compensatory mitigation at the Mangan mitigation site on Haynes Inlet, in the town of North Bend in Coos County, Oregon. This mitigation area is currently a 35-acre diked freshwater wetland and has been used to graze livestock since the 1940s. The mitigation action will restore portions of the area and provide similar estuarine habitat function to those that will be lost due to the filling of 1.23 acres of intertidal estuarine habitat; the conversion of 1.39 acres of freshwater wetland to intertidal wetland; and the 1.13 acres of freshwater wetland lost from the new dike construction. Approximately 8.6 acres of the total 10-acre intertidal mitigation site will function as a tidal mud flat, supporting mats of green and brown algae and provide support for a mud flat biotic community. Establishing approximately 1.44 acres of salt marsh in the mitigation area will be accomplished by planting plugs of Lyngbye's sedge (*Carex lygbyei*) and seeding of redtop (*Agrostis alba*), which are both salt marsh species. This salt marsh complex provides productive nutrient cycling and forage production in the estuarine ecosystem. Full conversion of this area will likely take several years for the salt tolerant plants to establish and mature. This is also the likely time line for most of the other estuarine biotic community.

**Effects on Species.**

***Fish salvage.*** Project activities will create fish entrapment conditions. This activity is proposed for July, but may occur in August, depending on action approval. During July and August, very few OC coho salmon smolts are expected to inhabit the action area. Adult coho salmon are not expected to be in the action area at that time. Adult southern DPS green sturgeon occurring in the action area are not likely to occur in the areas immediately adjacent to the project where fish salvage will occur, and are not likely to be entrapped or require capture.

Fish salvage is proposed to occur in the taxiway relocation area and in the Mangan mitigation area. In the taxiway C relocation area, proposed activities include constructing a gravel pier to serve as an in-water work enclosure. An area of approximately 1.23 acres will be enclosed and require fish salvage. In the process of isolating the work area, fish entrapment conditions are created and the proposed action includes seining the entrapment area to recover fish. Enclosure of the isolation area will occur at low tide and this should result in fewer trapped fish than if the entire area was enclosed at a higher tide. Some juvenile coho salmon will likely evacuate the areas to be isolated in response to disturbance of the areas and as the tide recedes, but it is reasonably certain that some smolts will be stranded or trapped and will require handling. All captured fish will be released in the open bay. Approximately 0.25 acre of intertidal area will be enclosed with the two silt curtains at the Mangan mitigation site. As stated, few coho salmon smolts are expected to be in the area during the proposed in-water work period. Seining and dip-netting are proposed methods of capture for any fish entrapped within the silt curtain deployment.

The NMFS assumes that any coho salmon smolts salvaged would experience high stress with the possibility of up to a 5% direct or delayed mortality due to injury and stress experienced in the fish salvage process. Although work area isolation is a conservation measure intended to reduce adverse effects from in-water work activities, some OC coho salmon smolts are likely to be subjected to incidental harassment, injury or death.

Based on an average of 4% survival from smolts to returning adults, back-calculated estimates from recent (last 6 years, Table 3) return numbers would suggest 35,000 to 875,000 smolts pass through the action area. It is expected almost all smolts from the Coos River OC coho salmon population will move through the estuary and into the ocean prior to this work area isolation activity (July and August); therefore, only a very small proportion of the number of individuals in the Coos population will be exposed to adverse effects. Based on experience with smolt outmigration timing and the proposed in-water work timing in July and August, the NMFS expects 0.5 % of the total smolts to still be in Coos Bay; therefore 175 to 4,375 smolts could inhabit the bay at the time work area isolation will occur. Of these smolts, few are expected to occur in the action area and the NMFS expects a smaller number to actually be trapped in the isolation areas.

The two isolation areas will have different probabilities of entrapping coho salmon smolts. At the airport site, the NMFS expects 450 smolts (10% of the highest estimate) to be entrapped with up to 23 (approximately 5%) of these dying from stress and injury due harassment from being captured and handled. At the Mangan site, the NMFS expects 219 smolts (5% of the highest estimate) to be entrapped with up to 11 (approximately 5%) of these dying from stress and injury due harassment from being captured and handled.

***Turbidity.*** Elevated turbidity levels will be the result of in-water work. The two regions of the action area will have differing causes and patterns of generating elevated turbidity. Increases in suspended sediment at a concentration of 53.5 milligrams per liter (mg/L) for a 12-hour period caused physiological stress and changes in behavior in coho salmon (Berg 1983). The NMFS expects the OC coho salmon smolts would react quicker with higher concentrations.

At the taxiway relocation area, the initial installation of the gravel pier will result in disturbance of the substrate from installation of the geotextile fabric and then placement of the coarse gravel and the resulting increased suspended sediment will reach concentrations that are likely to cause physiological stress to smolt coho salmon residing in the area. Most work will occur at low tide and the step-wise procedures described in the proposed action are intended to minimize turbidity by covering the unwashed gravel with the geotextile. Some turbidity creation will occur during this process, but NMFS expects the turbidity to be localized. Disturbed substrate at the outside base of the gravel pier will be suspended by wave action created from tidal influence, wind action, and ship wakes. This elevated turbidity will move directionally with the current and wave action.

During the outgoing tide, elevated turbidity levels are expected to be observed up to 1,500 feet from the downstream end of the gravel pier where it will disperse to an undetectable level. At the downstream end of the gravel pier and for the first 300 feet of this 1,500 feet turbidity plume, turbidity concentrations may approach and likely exceed the 53.5 mg/L levels that could cause gill irritation and behavioral response.

During the incoming tide, the highest concentrations will occur along the base of the gravel pier and as the suspended sediment is carried back into the cove, thereby limiting its dispersal. The NMFS expects the elevated turbidity concentrations within the cove will reach levels that are likely to cause gill irritation and behavioral response over approximately 3.8 acres. Turbidity will be highest at the back of the cove and dissipate as the currents flow back outwards

Any coho salmon smolts exposed to these high turbidity levels are likely to display behavioral effects, such as reduced feeding and gill-flaring, in response to pulses of suspended sediment (Berg and Northcote 1985). Gill irritation can result in increased disease exposure resulting in higher mortality rates. OC coho salmon smolts exposed to these elevated concentrations will likely move out of the area, thus forced to seek other suitable habitat. This may make them more vulnerable to predators, although the lower water visibility will assist their avoidance of predators. Adult southern DPS green sturgeon are most likely to inhabit deeper waters where project caused elevated turbidity levels are not expected to reach concentrations that would adversely affect this species.

At the Mangan mitigation site, turbidity generation will occur from the removal of the existing dike. Equipment operation and actual fill removal will occur at low tide intervals, but the work site will be inundated during each high tide event. This inundation will mobilize disturbed and exposed fine sediments during the fill removal process. Deploying two silt screens, set five feet apart, will filter some of the fine sediments. This control measure will maintain some control of the turbidity distribution, but turbidity concentrations are expected to reach gill irritation levels inside the silt screened area and the first 200 feet outside of the last screen. Any OC coho salmon smolts within this area exposed to these high levels will experience gill irritation and make a behavioral avoidance response. These smolts will likely move out to the outer edge of the turbidity line to avoid the irritation. This may make them more vulnerable to predators, although the lower water visibility will assist their avoidance of predators. Adult southern DPS green sturgeon are most likely to inhabit deeper waters where project caused elevated turbidity levels are not expected to reach concentrations that would adversely affect this species.

In July and August, when the turbidity causing project activities will occur, few (175 to 4,375) OC coho salmon smolts will occur in the bay, with even fewer in the action area. Some smolts that are late in leaving the Coos Estuary could be exposed to higher turbidity concentrations, therefore the potential for exposure and subsequent adverse effects that may lead to increased mortality due to vulnerability to predation and disease cannot be discounted. In conclusion, only a very small portion (0.5%) of the total smolts from the Coos River population of OC coho salmon will be exposed to elevated turbidity levels cause by the project. Therefore, it is reasonably certain that these effects are not likely to be significant at the population level.

***Chemical contamination.*** The potential extent of a chemical spill from the proposed project is limited because of work area isolation for construction activities and proposed conservation measures. Additionally, all work is proposed to occur during the late summer when the fewest amount of coho salmon will be present due to their limited use of the estuary at that time. Nonetheless, any exposure to these toxic chemicals could be extremely detrimental to juvenile coho salmon within the action area.

Petroleum-based contaminants, such as fuel, oil, and some hydraulic fluids, contain PAHs which can kill salmonids at high levels of exposure and can also cause lethal and sublethal adverse effects to aquatic organisms (Neff 1985). The action area is a large open bay with sufficient open space for the fish to quickly move from the toxicants. Each compound has its own specific characteristics related to mobility, toxicity, and density, therefore some compounds that may move through the water column more rapidly will expose more fish to toxic chemicals.

Mortality, harm and harassment, including reduced or less aggressive feeding, reduced growth, increased disease susceptibility and reduced survival of OC coho salmon smolts is reasonably certain to occur from chemical contamination from accidental spills, but the extent of this exposure will be limited to the few individuals in the immediate area of the spill. It is expected that the conservation measures employed to contain any spill and the large volume of water of Coos Bay will result in limiting adverse concentrations of these chemicals to 300 feet around the gravel pier. Potential dispersal patterns are expected to those described in the turbidity section. A large fuel spill is unlikely, but would degrade water quality from the spill location up to a couple of hours until it is diluted. Directional movement will depend on tidal currents, river flow, and wind/wave direction. Based on the few OC coho salmon smolts that potentially could be exposed to the contaminants, only a very small proportion of the Coos River population's total smolts will be exposed to chemical contamination. Therefore it is reasonably certain that these effects are not likely to be significant at the population level.

***Loss of benthic and shoreline habitat.*** Adult, smolt, and juvenile coho salmon from the Coos River population of OC coho salmon will be exposed to the loss of estuarine habitat resulting in impacts to available forage and decreased cover from predators. Juvenile salmonids feed on a range of invertebrates. In winter, aquatic larval forms of organisms dominate the food source (Brown 2002) while the benthic invertebrates most commonly consumed by rearing and migrating coho juvenile salmonids in an estuary are *Corophium salmonis* and *Corophium spinicorne* (amphipods) and adult *Diptera* (Bottom *et al.* 2001). Areas with rooted vegetation provide a greater density of food sources than bare mud (Brown 2002). The fill will permanently destroy approximately 1.23 acres of tidal estuarine habitat in Coos Bay and will result in reduced abundance and diversity of prey for juvenile coho salmon inhabiting the Coos Bay estuary. Habitat typing and mapping identified the area around the airport as intertidal with sand and mud flats; undifferentiated aquatic bed; and seagrass aquatic bed. Aquatic seagrass provides natural cover for coho salmon smolts. Coho salmon smolts will be more vulnerable to predation with the loss of cover.

Increased predation is also likely with the change to a riprapped shoreline that favors some predatory fish species. All Coos River population individuals whose natal streams are upstream of the project site will have some exposure to this component of the proposed action resulting in lost estuarine habitat and reduced forage. With the exception of South Slough and a few other smaller tributaries, the majority of OC coho salmon in this population are from upstream of this action area. Based on estimates from the last 6 years, the estimated number of adult OC coho salmon exposed to the lost habitat is from 1,400 to 35,000 individuals per year. OC coho salmon outmigrant numbers vary significantly depending on the year and the environmental conditions determining the survival rates. Based on an average of 4% survival from smolts to returning adults, back-calculated estimates from these return numbers would suggest 35,000 to 875,000 smolts would be exposed to this lost habitat per year.

Little is known about green sturgeon feeding other than general information. The 2002 status review (Adam *et al.* 2002) described benthic invertebrates, mollusks, and small fish as potential forage for green sturgeon. All of these prey species are likely to inhabit the habitat to be filled. Specific information about southern DPS green sturgeon use of this habitat is not known, but permanently lost habitat will result in some level of reduced forage available for green sturgeon in the airport area.

***Restoration of estuary functions.*** Proposed compensatory mitigation is expected to result in long-term beneficial habitat restoration for OC coho salmon and southern DPS green sturgeon. Full conversion of this area will likely take several years for the salt tolerant plants to establish and mature and the ecological functioning of the area to reach full potential. Forage production, nutrient cycling, water quality maintenance, natural cover through submerged plant growth; and other biotic and abiotic components of the estuarine ecosystem will be improved by re-introducing this diked pasture to tidal flushing. When this tidal flat and salt marsh reach their full ecological potential, the result for OC coho salmon and southern DPS green sturgeon is an increase in forage production, water quality, and coho salmon natural cover. This mitigation site is located in Haynes Inlet, which is approximately 2.7 miles upstream from the taxiway relocation, and in an arm of Coos Bay that is not necessarily directly benefiting all upstream segments of the Coos River coho salmon population. The resulting habitat increase from the mitigation site will provide benefits to the population overall by increasing natural cover and forage production in Haynes Inlet. Fewer individuals of the Coos River population will be exposed to this habitat, but it is likely the increased quantity of habitat will offset the losses from the airport site.

Distribution of green sturgeon in Coos Bay is likely independent of the Coos Bay tributaries. The NMFS assumes any green sturgeon inhabiting Coos Bay that would be impacted by the loss of the intertidal zone at the airport will also be benefitted by the benefits from the Mangan mitigation site due to the overall increase in forage production within this area of the bay.

***Summary of effects to OC coho salmon and southern DPS green sturgeon.*** Project-caused effects on OC coho salmon and southern DPS green sturgeon will reach adverse levels. Direct and indirect effects from project actions will adversely affect OC coho salmon due to fish salvage efforts, turbidity, chemical contamination, and habitat loss. The proposal to complete in-water work between July 1 and August 31 results in fewer OC coho salmon exposed to the activities and serves to minimize, but not eliminate, exposure to direct adverse conditions. Salvage will occur in two separate areas that will have differing probabilities of entrapping coho salmon smolts. A total of 669 OC coho salmon smolts are expected to be harassed and captured during fish salvage operations. Up to 34 of these smolts are expected to die due to injury and stress related factors. Southern DPS green sturgeon occurring in the action area are expected to inhabit the deeper waters of the bay, depending on the time of day, tidal cycle, and activity. Adverse effects from project caused elevated turbidity or chemical contamination are discountable due to green sturgeon spatial distribution. Southern DPS green sturgeon in the area are adult fish residing and feeding in the estuary. It is unlikely and considered discountable that any individuals will be captured during the fish salvage effort. Both OC coho salmon and southern DPS green sturgeon will lose habitat at the airport taxiway expansion resulting in adverse effects to both species due to permanent loss of forage at the airport site. Beneficial actions are proposed to compensate for the loss of forage and ecological functions by re-introducing approximately 10 acres of intertidal habitat to tidal flushing, but a delay of several years before the area reaches full ecological potential is expected.

**Effects on OC Coho Salmon Critical Habitat.** The action area in Coos Bay, which is designated as critical habitat for OC coho salmon, provides habitat to support successful estuarine life history requirements. OC coho salmon adults and smolts use the action area for migration and to make the physiological transition between marine and freshwater environments. Thus, the affected PCEs in the action area are those that are essential for conservation of adult and juvenile coho salmon for migration and to make this transition between these two environments. These PCEs include water quality, salinity conditions, natural cover, and forage which support juvenile and adult physiological transitions between fresh- and saltwater. The likely effects of the project on these essential features are described below.

1. Water Quality. Suspended sediment levels will be increased over background due to fine sediment mobilized by construction activities. While the impact on habitat is great enough to adversely affect some OC coho salmon smolts, it will not occur on a large enough spatial or temporal scale to significantly disrupt their normal behavioral patterns. Few smolts will occur in the action area at the time elevated turbidity levels will occur and the elevated turbidity levels will be short-term, lasting a few hours at a time during the two weeks of in-water work. A large fuel spill is unlikely, but would degrade water quality from the spill location up to 300 feet for up to a couple of hours until it is diluted. Directional movement will depend on tidal currents, river flow, and wind/wave direction. Because these impacts are short term and temporary or are unlikely, the water quality PCE will not be functionally changed.

2. Salinity Conditions. Salinity conditions will be improved within the Haynes Inlet portion of the Coos Bay 5th field due to the Mangan mitigation site development. This area is not accessible to OC coho salmon unless this proposed action occurs. The mitigation site

is located in Haynes Inlet where reintroduction of river flows and tidal currents to approximately 10 acres of previously inaccessible intertidal habitat will provide a complex and varying salinity gradient, which is necessary to aid adult and smolt OC coho salmon making the transition between the marine and freshwater environments.

3. Natural Cover. 1.23 acres of natural cover will be permanently lost due to the filling of intertidal habitat. An additional area (10 acres) will be restored at the Mangan mitigation site. The additional acres of habitat reintroduced to tidal influence is likely a reasonable offset to the acres lost at the airport site.

4. Forage. Food resources will be permanently lost in the 1.23 acres of the airport fill site. Additional forage production will be available in the Mangan mitigation site once the area reaches functioning condition, perhaps in 1 to 2 years. While the impact on habitat is great enough to result in some OC coho salmon smolts being adversely affected, it will not disrupt normal behavior patterns. Because the mitigation site will provide additional benthic habitat in the Coos Bay 5th field watershed, the food resources PCE will not be functionally changed.

***Summary of effects to OC coho salmon critical habitat.*** Information presented in the status and baseline sections of this opinion show that the Coos Bay estuary has been altered, but conditions still support successful migration and transition from freshwater to saltwater environments. Four PCEs will be affected, but will not be functionally changed because effects will be small-scale, short-term, unlikely, or sufficiently offset by the proposed mitigation. Potential short-term effects to the water quality PCE include increased turbidity concentrations and toxic material contamination from PAHs due to spill, equipment failure, or accident. These are expected to be short-term and localized. Salinity conditions will be improved in the action area at the Mangan mitigation site where tidal flow and fluctuation will be reintroduced to 10 acres of intertidal habitat. Forage production and natural cover will be lost from the filling of 1.23 acres and this will be replaced with the 10 acre mitigation site within the same watershed. Since the effects will not adversely change the habitat functions at the site scale, the effects from the proposed project will not adversely change functions at the 5th field watershed scale either.

**Cumulative Effects**

Between 2000 and 2006, the population of Coos County increased by 3.2%.[1] Thus, NMFS assumes that future private and state actions will continue within the action area, increasing as population density rises. As the human population in the action area continues to grow, demand for agricultural, commercial, or residential development is also likely to grow. The effects of new development caused by that demand are likely to reduce the conservation value of the habitat within the action area. However, NMFS is not aware of any specific future non-Federal activities within the action area that would cause greater effects to a listed species or a designated critical habitat than presently occurs.

## Conclusion

After reviewing the status of OC coho salmon and designated critical habitat, the environmental baseline for the action area, the effects of the proposed action, and cumulative effects, NMFS concludes that the proposed action is not likely to jeopardize the continued existence of southern DPS green sturgeon or OC coho salmon, and is not likely to destroy or adversely modify OC coho salmon designated critical habitat. These conclusions are based on the following considerations.

The suspended sediment and contaminant spill threats from the proposed action will expose OC coho salmon smolts to adverse water quality conditions that may reduce survival due to increased susceptibility to disease, predation, and physiological response to toxicants. However, only a very small percentage of Coos River coho salmon smolts will still be in the estuary during July and August. These two threats to southern DPS green sturgeon are discountable because of their deep-water habitat use.

The proposed action will result in harassment of up to 669 smolt OC coho salmon due to capture and handling. Effects on abundance and productivity at the population scale will be insignificant because such a small proportion of the total Coos River population's smolt population will be affected (approximately 0.07 to 1.9%, based on 6-year high and low population estimates). No specific future non-Federal activities have been identified within the action area that would cause greater effects to a listed species or a designated critical habitat than presently occurs.

The limiting factor to OC coho salmon that will be affected from this project is the loss of intertidal estuarine habitat including sand and mud flats, undifferentiated aquatic bed, and seagrass aquatic bed. As proposed, 1.23 acres of intertidal habitat will be permanently filled and approximately 10 acres of intertidal habitat will be restored for fish use by relocating a dike. Within these 10 acres of intertidal habitat, the potential exists for all three habitat types to develop after several years of tidal flow exposure. As part of the proposed action, this habitat replacement is expected to offset the habitat loss at the taxiway relocation site; therefore, the proposed action will not result in a net decrease in intertidal habitat. The lag time between the mitigation site reaching its full ecological potential and the immediate habitat loss will cause adverse impacts to OC coho salmon and southern DPS green sturgeon due to loss of available cover for OC coho salmon and reduced forage available to both species.

Four critical habitat PCEs will be affected, but will not be functionally changed because effects will be localized and short-term, beneficial, or replaced by compensatory mitigation in the same watershed. The actions will not adversely affect the estuary habitat functions within the 5$^{th}$ field watershed. The critical habitat would remain functional and retain its current ability for the PCEs to become functionally established.

## Reinitiation of Consultation

Reinitiation of formal consultation is required and shall be requested by the Federal agency or by NMFS where discretionary Federal involvement or control over the action has been retained or is authorized by law and: (a) If the amount or extent of taking specified in the ITS is exceeded;

(b) if new information reveals effects of the action that may affect listed species or designated critical habitat in a manner or to an extent not previously considered; (c) if the identified action is subsequently modified in a manner that has an effect to the listed species or designated critical habitat that was not considered in the biological opinion; or (d) if a new species is listed or critical habitat is designated that may be affected by the identified action (50 CFR 402.16).

To reinitiate consultation, contact the Oregon State Habitat Office of NMFS and refer to the NMFS Number assigned to this consultation (2008/03298).

**Incidental Take Statement**

Section 9 of the ESA and Federal regulation pursuant to section 4(d) of the ESA prohibit the take of endangered and threatened species, respectively, without a special exemption. Take is defined as to harass, harm, pursue, hunt, shoot, wound, kill, trap, capture or collect, or to attempt to engage in any such conduct. Harm is further defined by NMFS to include significant habitat modification or degradation that results in death or injury to listed species by significantly impairing essential behavioral patterns, including breeding, feeding or sheltering. Harass is defined by Fish and Wildlife Service as an intentional or negligent actions that create the likelihood of injury to listed species to such an extent as to significantly disrupt normal behavior patterns which include, but are not limited to, breeding, feeding or sheltering. Incidental take is defined as take that is incidental to, and not the purpose of, the carrying out of an otherwise lawful activity. Under the terms of section 7(b)(4) and section 7(o)(2), taking that is incidental to and not intended as part of the agency action is not considered to be prohibited taking under the ESA, provided that such taking is in compliance with the terms and conditions of this ITS.

**Amount or Extent of Take**

The NMFS has not prohibited take of southern DPS green sturgeon. However, the effects of the proposed action will overlap in time and space with the presence of adult and smolt OC coho salmon, and are reasonably likely to result in take of some juveniles. The action area is used as a migration corridor and as an area that both life stages use to acclimate while making the physiological transition between freshwater and saltwater. The action area is defined as the footprint of the existing airport and adjacent bank, substrate, and aquatic areas of the Coos Bay Estuary and Pony Slough. The action area extends 500 feet upstream from the project site and 1,500 feet downstream from the downstream end of the project site in Coos Bay due to potential impacts from turbidity, contaminant dispersion, and habitat loss. The mitigation site includes the immediate footprint of the site and the waters of Haynes Inlet surrounding the site out to a distance of approximately 300 feet. The Coos Bay estuary plays a critical role in the survival and recovery of ESA-listed OC coho salmon by providing refuge, nutrients and conditions in which juvenile and adult salmon change physiologically.

While adults will not be present in the bay during construction and very few smolts are expected, both life-stages will be exposed to the long-term, continuing adverse effects of the project. The action area provides migration and vital estuarine habitat in fair condition. Incidental take caused by the adverse short- and long-term effects will include the following: (1) Death or injury of smolts from work area isolation and fish salvage; (2) increased vulnerability to predation of juvenile coho salmon displaced from the action area during construction, changed habitat characteristics favoring predators, and lost natural cover; (3) death or significant impairment of essential behaviors from increased turbidity and exposure to PAHs; and (4) reduced growth and survival from reduced feeding opportunities due to lost forage production in the area until the mitigation site's ecological potential is reached in 2 years. Outmigrating OC coho salmon smolts from most of the Coos River population use the action area for migration and to acclimate to saltwater conditions. Within this action area, the area that incidental take may occur includes an area 300 feet downstream from the gravel pier construction, approximately 3.8 acres inside the cove adjacent to the gravel pier, and approximately 200 feet outside the silt screen placement surrounding the Mangan mitigation site. Incidental take within that area that meets the terms and conditions of this incidental take statement will be exempt from the taking prohibition.

Some coho salmon smolts will likely evacuate the action area in response to work area isolation activities, but it is reasonably certain that some individuals will be trapped within the work isolation area. These trapped individuals will be stranded during dewatering. Death and injury of captured smolts is reasonably certain to occur. However, only a small number of individuals are likely to be exposed to or displaced by work area isolation due to the July and August implementation. The process of work area isolation for the proposed action is reasonably certain to cause incidental take (capture) of 669 individual OC coho salmon smolts, up to 34 of which may die.

The distribution and abundance of fish that occur within an action area are affected by habitat quality, competition, predation and the interaction of processes that influence genetic, population, and environmental characteristics. These biotic and environmental processes interact in ways that may be random or directional, and may operate across far broader temporal and spatial scales than are affected by the proposed action. Thus, the distribution and abundance of fish within the action area cannot be attributed entirely to habitat conditions, nor can NMFS precisely predict the number of fish that are reasonably certain to be injured or killed if their habitat is modified or degraded by the proposed action.

Here, the best available indicators for the extent of take is the 1.23 acres of intertidal aquatic habitat that is to be permanently modified by the action, and increased turbidity measured within the 3.8 acres of the cove at 300 feet downstream from the end of the gravel pier and 200 feet outside the last silt screen at the Mangan site. These are the best indicators of the likely take pathways associated with this action, are proportional to the anticipated amount of harm and harassment, and are the most practical and feasible indicators to measure.

In the accompanying Opinion, NMFS determined that this level of incidental take is not likely to jeopardize OC coho salmon. The area of intertidal habitat modified, extent of suspended sediment, and the number of juveniles captured or killed by work area isolation (up to 669 smolts captured or 34 smolts killed) are the thresholds for reinitiating consultation. Exceeding any of these limits will trigger the reinitiation provisions of this Opinion.

### Reasonable and Prudent Measures

The following measures are necessary and appropriate to minimize the impact of incidental take of listed species from the proposed action:

The FAA shall:

1. Minimize incidental take from construction by applying permit conditions to avoid or minimize disturbance to aquatic habitats.

2. Avoid or minimize the likelihood of incidental take caused by work area isolation.

3. Avoid or minimize long-term take from the loss of eel grass by planting eel grass in the mitigation area.

4. Ensure completion of a monitoring and reporting program to confirm that the take exemption for the proposed action is not exceeded, and that the terms and conditions in this incidental take statement are effective in minimizing incidental take.

### Terms and Conditions

The measures described below are non-discretionary, and must be undertaken by the FAA or, if an applicant is involved, must become binding conditions of any permit or grant issued to the applicant, for the exemption in section 7(o)(2) to apply. The FAA has a continuing duty to regulate the activity covered by this incidental take statement. If the FAA (1) fails to assume and implement the terms and conditions or (2) fails to require an applicant to adhere to the terms and conditions of the incidental take statement through enforceable terms that are added to the permit or grant document, the protective coverage of section 7(o)(2) may lapse. To monitor the impact of incidental take, the FAA or applicant must report the progress of the action and its impact on the species to the NMFS as specified in the incidental take statement.

1. To implement reasonable and prudent measure number 1 (construction), the FAA shall ensure that:

    a. <u>Timing of In-water Work</u>. Work below the oridinary high tide will be completed during the period of July 1 through August 31. All in-water work must be completed within these dates unless otherwise approved in writing by NMFS.
    b. <u>Minimum Area.</u> Construction impacts are confined to the minimum area necessary to complete the project.
    c. <u>Cessation of Work</u>. Project operations will cease under high flow conditions that may inundate the project area, except for efforts to avoid or minimize resource damage.

d. Fish Screens. All water intakes used, including pumps used to isolate any in-water work area, will have a fish screen installed, operated and maintained according to NMFS' fish screen criteria.[2]

e. Pollution and Erosion Control Plan. A pollution and erosion control plan will be prepared and carried out to prevent pollution related to construction operations. The plan must be available for inspection upon request by the FAA or NMFS.

   i. Plan contents. The pollution and erosion control plan must contain the pertinent elements listed below, and meet requirements of all applicable laws and regulations.

      1. Practices to prevent erosion and sedimentation associated with access roads, stream crossings, construction sites, haul roads, equipment and material storage sites, fueling operations and staging areas.
      2. A description of any hazardous products or materials that will be used, including procedures for inventory, storage, handling, and monitoring.
      3. A spill containment and control plan with notification procedures, specific clean up and disposal instructions for different products, quick response containment and clean up measures that will be available on the site, proposed methods for disposal of spilled materials, and provisions for employee training on spill containment.
      4. Practices to prevent construction debris from dropping into any stream or waterbody, and to remove any material that does drop with a minimum disturbance to the streambed and water quality.

   ii. Inspection of erosion controls. During construction, all erosion controls must be inspected daily to ensure they are working adequately.[3] If inspection shows that the erosion controls are ineffective, work crews must be mobilized immediately to make repairs, install replacements, or install additional controls as necessary.

   iii. Sediment must be removed from each erosion control once it has reached 1/3 of the exposed height of the control.

f. Pre-construction Activity. Before significant[4] alteration of the project area, the following actions must be completed:

   i. Marking. Flag the boundaries of clearing limits associated with site access and construction to prevent ground disturbance of riparian vegetation, wetlands, and other sensitive features beyond the flagged boundary.

   ii. Emergency erosion controls. Ensure that the following materials for emergency erosion control are on site:

---

2 National Marine Fisheries Service, *Juvenile Fish Screen Criteria* (revised February 16, 1995) and *Addendum: Juvenile Fish Screen Criteria for Pump Intakes* (May 9, 1996) (guidelines and criteria for migrant fish passage facilities, and new pump intakes and existing inadequate pump intake screens) *(http://www.nwr.noaa.gov/1hydrop/hydroweb/ferc.htm).*

3 'Working adequately' means no turbidity plumes are evident during any part of the year.

4 'Significant' means an effect can be meaningfully measured, detected or evaluated.

1. A supply of sediment control materials (*e.g.*, silt fence, straw bales).[5]
2. An oil-absorbing floating boom whenever surface water is present.

g. Heavy Equipment. Use of heavy equipment will be restricted as follows:
   i. Select equipment that will have the least adverse effects on the environment (*e.g.*, minimally-sized, low ground pressure equipment).
   ii. Ensure that only enough supplies and equipment to complete a specific job will be stored on site.
   iii. Complete vehicle cleaning, maintenance, refueling and fuel storage in the vehicle staging area placed 150 feet or more from any stream, waterbody or wetland.
   iv. Inspect all vehicles operated within 150 feet of any stream or wetland daily for fluid leaks before leaving the vehicle staging area. Repair any leaks detected in the vehicle staging area before the vehicle resumes operation. Document inspections in a record that is available for review on request by FAA or NMFS.
   v. Before operations begin, and as often as necessary during operation, steam clean all equipment that will be used below ordinary high water until all visible external oil, grease, mud, and other visible contaminants are removed. Complete all cleaning in the vehicle staging area.

h. Vehicle staging. Vehicle staging, cleaning, maintenance, refueling, and fuel storage must take place in a vehicle staging area placed 150 feet or more from any stream, waterbody or wetland.

i. Stationary power equipment. Stationary power equipment (*e.g.*, generators, cranes) operated within 150 feet of any stream, waterbody or wetland must be diapered to prevent leaks, unless otherwise approved in writing by NMFS.

j. Site Preparation. Native materials will be conserved for site restoration. If possible, native materials must be left where they are found. Materials that are moved, damaged or destroyed must be replaced with a functional equivalent during site restoration.

k. Earthwork. Earthwork (including excavation, filling and compacting) will be completed as quickly as possible.

l. Site Stabilization. Stabilize all disturbed areas, including obliteration of temporary roads, following any break in work unless construction will resume within 4 days.

m. Source of Materials. Boulders, rock, woody materials, and other natural construction materials used must be obtained outside riparian areas.

---

[5] When available, certified weed-free straw or hay bales must be used to prevent introduction of noxious weeds.

2. To implement reasonable and prudent measure number 2 (work area isolation), the FAA shall ensure that:

   a. Fish Salvage. Before, and intermittently during, isolation of in-water work areas, fish trapped in the area must be captured using a hand-net, seine, or other methods as are prudent to minimize risk of injury, then released at a safe release site under the supervision of a qualified fishery biologist.
      i. If an isolated pool is affected by work area isolation the entire pool must be salvaged for fish prior to isolation.
      ii. Handle ESA-listed fish with extreme care, keeping fish in water to the maximum extent possible during seining or hand-netting and transfer procedures to prevent the added stress of out-of-water handling.
      iii. Ensure water quality conditions are adequate in buckets or tanks used to transport fish by providing circulation of clean, cold water, using aerators to provide dissolved oxygen, and minimizing holding times.
      iv. Release fish into a safe release site as quickly as possible, and as near as possible to capture sites.
      v. Do not transfer ESA-listed fish to anyone except NMFS personnel, unless otherwise approved in writing by NMFS.
      vi. Obtain all other Federal, state, and local permits necessary to conduct the capture and release activity.
   b. Salvage Notice. The following notice is included as a permit condition and shall be provided to the applicant and the contractor and posted at the work site:

      NOTICE: If a sick, injured or dead specimen of a threatened or endangered species is found in the project area, the finder must notify NMFS through the contact person identified in the transmittal letter for this Opinion, or through the NMFS Office of Law Enforcement at 1-800-853-1964, and follow any instructions. If the proposed action may worsen the fish's condition before NMFS can be contacted, the finder should attempt to move the fish to a suitable location near the capture site while keeping the fish in the water and reducing its stress as much as possible. Do not disturb the fish after it has been moved. If the fish is dead, or dies while being captured or moved, report the following information: (1) NMFS consultation number; (2) the date, time, and location of discovery; (3) a brief description of circumstances and any information that may show the cause of death; and (4) photographs of the fish and where it was found. The NMFS also suggests that the finder coordinate with local biologists to recover any tags or other relevant research information. If the specimen is not needed by local biologists for tag recovery or by NMFS for analysis, the specimen should be returned to the water in which it was found, or otherwise discarded.

3. To implement reasonable and prudent measure number 3 (eel grass planting), the FAA shall ensure that:

    a. Identify areas within the Mangan mitigation site that are suitable for eel grass production.
    b. Plant eel grass in the identified suitable habitat.

4. To implement reasonable and prudent measure number 4 (monitoring and reporting) the FAA shall:

    a. Turbidity Monitoring. Complete turbidity monitoring as follows.
        i. Equipment. Use an appropriate and regularly calibrated turbidometer to quantify change as nephelometic turbidity units (NTU), or use a visual observation based on any detectable change.
        ii. Interval. A turbidometer reading, or visual observation, must be taken as often as necessary to ensure that each work area is not contributing excessive sediment to the stream.
            1. Whenever in-water work is in progress, or when precipitation has occurred within seven days, a sample must be taken at least twice each day, at approximately 10:00 a.m. and again at 2:00 p.m.
            2. When in-water work is not in progress and no precipitation has occurred within the previous seven days, a sample may be taken once each day, at approximately 2:00 p.m.
            3. Sites. Each sample consists of a turbidometer reading, or a visual observation, made at a baseline site upstream of each work area, and a corresponding reading or observation made within the 3.8 acres of the cove, within 300 feet downstream from the end of the gravel pier and 200 feet outside the last silt screen at the Mangan site.
        iii. Compliance.
            1. Compare results from the baseline and compliance sites for each sample to determine whether turbidity increased below the work area.
            2. If turbidity increased by 5 NTUs, or to any visible extent, take corrective action to reduce turbidity, including any work necessary to repair, replace or reinforce sediment controls, and continue to monitor every 4 hours.
            3. If the turbidity does not return to baseline level within 24 hours, contact NMFS and cease work until turbidity returns to baseline.
        iv. Reporting. Prepare and submit a summary of the turbidity monitoring, including a photograph of the baseline and compliance sites; a copy of turbidity measurements or observations with the date and time that each was taken; other relevant sampling conditions; and description of any sediment control failure, sediment release, and correction efforts.
    b. Implementation Monitoring Report. Complete implementation monitoring and submit a monitoring report to NMFS describing the FAA' progress and success in

meeting the terms and conditions contained in this Opinion by March 1 of the year following construction. The content of the monitoring report will include:

- i. Project name
- ii. Project location by 6th field HUC
- iii. FAA contact person(s)
- iv. Starting and ending dates for work completed
- v. Photos, within construction areas, of the riparian vegetation and the stream channel before, during, and after project completion.
  1. Include general views and close-ups showing details of the project and project area, including pre- and post-construction.
  2. Label each photo with date, time, project name, and a comment about the subject.
- vi. Other data as follows:
  1. A summary of pollution and erosion control inspection results, including a description of any erosion control failure, contaminant release, and efforts to correct such incidences.
  2. Dates work ceased due to high flows.
  3. Status of compliance with NMFS' fish screen criteria.
  4. Isolation of in-water work area and fish capture and release.
     - a. Supervisory fish biologist – name and contact information.
     - b. Methods of work area isolation and take minimization.
     - c. Habitat conditions before, during and within 1 week after completion of work area isolation.
     - d. Means of fish capture.
     - e. Number of OC coho salmon captured.
     - f. Location and condition of OC coho salmon released.
     - g. Any incidence of observed injury or mortality.

c. Site Restoration.

- i. Post-construction report showing as-built conditions, including photo points, construction and any variation from the approved plan, to be submitted within 60 days of the completion of construction.
- ii. Final area reintroduced to tidal flow at the Mangan mitigation site.
- iii. Final linear distance breached in the dike.
- iv. Planting composition and density.
- v. Copy of the legal agreement conveying mitigation site responsibilities.

d. Extent of Take. At project completion, report the total acres of intertidal habitat filled, the total acres of estuary restored, all turbidity measurements and the results of fish salvage operations.

e. Reporting. On an annual basis for 5 years after completing the proposed action, the FAA shall ensure submittal of a monitoring report to NMFS describing the applicant's success in meeting their habitat restoration goals of intertidal habitat restoration. This report will include the following information:

i. Project identification.

- (1). Project name.
- (2) Starting and ending dates of work completed for this project.
- (3) The FAA contact person.

ii. Intertidal and freshwater habitat development at the Mangan site. Documentation of the following conditions:

(1) Any changes in survival and coverage of the willow plantings.
(2) A plan to inspect and, if necessary, replace failed plantings.
(3) Intertidal habitat rehabilitation will be documented by mapping habitats established for 5 years.
(4) Monitoring report of survival and spread of Lyngbye's sedge and redtop.
(5) Report the identified potential eel grass habitat in #ii(3) and monitoring survival and spread of eel grass.
(6) Benthic invertebrate monitoring to document colonization of the mitigation area with marine/estuarine species.
(7) Tidal influence area achieved based on the highest measured tide.

iii. A plan to inspect and, if necessary, replace failed plantings to achieve 100% survival at the end of the first year, and 80% survival or 80% coverage after 5 years (including both plantings and natural recruitment) of native species in the salt marsh area; control invasive non-native vegetation; and protect plantings from wildlife damage and other harm.

f. Monitoring reports shall be submitted to:

Portland, OR 97232-2182

## MAGNUSON-STEVENS FISHERY CONSERVATION AND MANAGEMENT ACT

The consultation requirement of section 305(b) of the MSA directs Federal agencies to consult with NMFS on all actions, or proposed actions that may adversely affect EFH. Adverse effects include the direct or indirect physical, chemical or biological alterations of the waters or substrate and loss of, or injury to, benthic organisms, prey species and their habitat, and other ecosystem components, if such modifications reduce the quality or quantity of EFH. Adverse effects to EFH may result from actions occurring within EFH or outside EFH, and may include site-specific or EFH-wide impacts, including individual, cumulative, or synergistic consequences of actions (50 CFR 600.810). Section 305(b) also requires NMFS to recommend measures that may be taken by the action agency to conserve EFH.

The Pacific Fishery Management Council (PFMC) designated EFH for groundfish (PFMC 2005), coastal pelagic species (PFMC 1998), and Chinook salmon, coho salmon, and Puget Sound pink salmon (PFMC 1999). The proposed action and action area for this consultation are described in the Introduction to this document. The action area includes areas designated as EFH for various life-history stages of groundfish (PFMC 2005), coastal pelagic species (PFMC 1998), and Chinook salmon and coho salmon (PFMC 1999).

Based on information provided in the BA and the analysis of effects presented in the ESA portion of this document, NMFS concludes that proposed action will have the following adverse effects on EFH designated for groundfish, coastal pelagic species, and Chinook salmon and coho salmon:

1. Water Quality. Suspended sediment levels will be increased over background due to fine sediment mobilized by construction activities. While the impact on habitat is great enough to adversely affect some MSA-managed species, it will not occur on a large enough spatial or temporal scale to significantly disrupt their normal behavioral patterns. The elevated turbidity levels will be short-term, lasting a few hours at a time during the 2 weeks of in-water work. A large fuel spill is unlikely, but would degrade water quality from the spill location up to 300 feet for up to a couple of hours until it is diluted. Directional movement will depend on tidal currents, river flow, and wind/wave direction. Because these impacts are short term and temporary or are unlikely, the water quality of the action area will not be functionally changed.

2. Salinity Conditions. Salinity conditions will be improved within the Haynes Inlet portion of the Coos Bay 5th field due to the Mangan mitigation site development. This area is not accessible to MSA-managed species unless this proposed action occurs. The mitigation site is located in Haynes Inlet where reintroduction of river flows and tidal currents to approximately 10 acres of previously inaccessible intertidal habitat will provide a complex and varying salinity gradient, which is necessary to aid adult and smolt salmon making the transition between the marine and freshwater environments. Other MSA-managed species will have access to this intertidal habitat.

3. Natural Cover. An unknown area of eelgrass beds, which is natural cover for MSA-managed species, will be permanently lost due to the filling of intertidal habitat. This could be up to 1.23 acres of natural cover. An additional area, possibly up to 10 acres, will be developed at the Mangan mitigation site. Although neither maximum is likely, the additional acres of habitat reintroduced to tidal influence is likely a reasonable offset to the acres lost at the airport site.

4. Forage. Food resources will be permanently lost in the 1.23 acres of airport relocation fill site. Additional forage production will be available in the Mangan mitigation site once the area reaches functioning condition, perhaps in 1 to 2 years. While the impact on habitat is great enough to result in some MSA-managed species being adversely affected, it will not disrupt normal behavior patterns. Because the mitigation site will provide additional benthic habitat in the Coos Bay 5th field watershed, the food resources for MSA-managed species will not be functionally changed.

**EFH Conservation Recommendations**

The following two conservation measures are necessary to avoid, mitigate or offset the impact of the proposed action on EFH. These conservation recommendations are a subset of the ESA terms and conditions.

1. Minimize adverse effects from construction by applying permit conditions to avoid or minimize disturbance to aquatic habitats as described in Term and Condition 1 in the accompanying Opinion.
2. Ensure completion of a monitoring and reporting program as described in Term and Condition 3, except for 3.b.vi.4 (isolation of in-water work area and fish capture and release), in the accompanying Opinion to confirm the action is meeting its objective of minimizing habitat modification from permitted activities. Recommended EFH monitoring and reporting components are pollution and erosion control, final area of intertidal habitat filled; area of intertidal habitat reintroduced to tidal influence, success of plant establishment, and species composition and abundance of invertebrates in the intertidal mitigation site.

**Statutory Response Requirement**

Federal agencies are required to provide a detailed written response to NMFS' EFH conservation recommendations within 30 days of receipt of these recommendations [50 CFR 600.920(j) (1)]. The response must include a description of measures proposed to avoid, mitigate or offset the adverse affects of the activity on EFH. If the response is inconsistent with the EFH conservation recommendations, the response must explain the reasons for not following the recommendations. The reasons must include the scientific justification for any disagreements over the anticipated effects of the proposed action and the measures needed to avoid, minimize, mitigate or offset such effects.

In response to increased oversight of overall EFH program effectiveness by the Office of Management and Budget, NMFS established a quarterly reporting requirement to determine how many conservation recommendations are provided as part of each EFH consultation and how many are adopted by the action agency. Therefore, in your statutory reply to the EFH portion of this consultation, we ask that you clearly identify the number of conservation recommendations accepted.

**Supplemental Consultation**

The FAA must reinitiate EFH consultation with NMFS if the proposed action is substantially revised in a way that may adversely affect EFH, or if new information becomes available that affects the basis for NMFS' EFH conservation recommendations [50 CFR 600.920(k)].

## DATA QUALITY ACT DOCUMENTATION AND PRE-DISSEMINATION REVIEW

Section 515 of the Treasury and General Government Appropriations Act of 2001 (Public Law 106-554) (Data Quality Act) specifies three components contributing to the quality of a document. They are utility, integrity and objectivity. This section of the Opinion addresses these Data Quality Act (DQA) components, documents compliance with the DQA, and certifies that this EFH consultation has undergone pre-dissemination review.

**Utility:** Utility principally refers to ensuring that the information contained in this consultation is helpful, serviceable and beneficial to the intended users.

This consultation concludes that the Coos Bay airport expansion will adversely affect EFH, and includes conservation recommendations to the action agency to avoid, minimize or otherwise offset those adverse modifications. The FAA may authorize and fund this action in accordance with its authority to oversee aviation guidelines. The intended users are the FAA and the Southwest Oregon Regional Airport.

Individual copies were provided to the above-listed entities. This consultation will be posted on the NMFS Northwest Region website (http://www.nwr.noaa.gov). The format and naming adheres to conventional standards for style.

**Integrity:** This consultation was completed on a computer system managed by NMFS in accordance with relevant information technology security policies and standards set out in Appendix III, 'Security of Automated Information Resources,' Office of Management and Budget Circular A-130; the Computer Security Act; and the Government Information Security Reform Act.

**Objectivity:**

***Information Product Category:*** Natural Resource Plan.

***Standards:*** This consultation and supporting documents are clear, concise, complete, and unbiased; and were developed using commonly accepted scientific research methods. They adhere to published standards including the NMFS ESA Consultation Handbook, ESA Regulations, 50 CFR 402.01, *et seq.*, and the MSA implementing regulations regarding EFH, 50 CFR 600.920(j).

***Best Available Information:*** This consultation and supporting documents use the best available information, as referenced in the Literature Cited section. The analyses in this Opinion/EFH consultation contain more background on information sources and quality.

***Referencing:*** All supporting materials, information, data and analyses are properly referenced, consistent with standard scientific referencing style.

***Review Process:*** This consultation was drafted by NMFS staff with training in ESA and MSA implementation, and reviewed in accordance with Northwest Region ESA quality control and assurance processes.

**NOAA Technical Memorandum**
**NMFS-NWFSC Series**

The Northwest Fisheries Science Center of the National Marine Fisheries Service, NOAA, uses the NOAA Technical Memorandum NMFS-NWFSC series to issue scientific and technical publications. Manuscripts have been peer reviewed and edited. Documents published in this series may be cited in the scientific and technical literature.

The NMFS-NWFSC Technical Memorandum series of the Northwest Fisheries Science Center continues the NMFS-F/NWC series established in 1970 by the Northwest & Alaska Fisheries Science Center, which has since been split into the Northwest Fisheries Science Center and the Alaska Fisheries Science Center. The NMFS-AFSC Technical Memorandum series is now being used by the Alaska Fisheries Science Center.

# Executive Summary

On 27 November 2007, the National Marine Fisheries Service (NMFS) received a petition seeking to list southern eulachon (*Thaleichthys pacificus*), as a threatened or endangered species under the Endangered Species Act (ESA) of 1973. NMFS evaluated the petition to determine whether the petitioner provided substantial information as required by the ESA to list a species. Additionally, NMFS evaluated whether information contained in the petition might support the identification of a distinct population segment (DPS) that may warrant listing as a species under the ESA. NMFS determined that the 27 November 2007 petition did present substantial scientific and commercial information, or cited such information in other sources, that the petitioned action may be warranted and, subsequently, NMFS initiated an updated status review of eulachon in Washington, Oregon, and California.

The Eulachon Biological Review Team (BRT)—consisting of scientists from the Northwest Fisheries Science Center, Alaska Fisheries Science Center, Southwest Fisheries Science Center, U.S. Fish and Wildlife Service, and U.S. Forest Service—was formed by NMFS, and the team reviewed and evaluated scientific information compiled by NMFS staff from published literature and unpublished data. Information presented at a public meeting in June 2008 in Seattle, Washington, and data submitted from state agencies and other interested parties were also considered. The BRT also reviewed additional information submitted to the ESA Administrative Record.

The BRT was charged with consideration of the following questions:

1. Consider, consistent with the criteria defined by the joint USFWS-NMFS DPS policy (61 FR 4722; 7 February 1996), whether eulachon warrant delineation into one or more DPSs.
2. Once the DPS structure for eulachon has been delineated, assess the level of extinction risk facing the species (including any DPS in the United States) throughout all of its range.
3. In articulating the assessed level of extinction risk, describe the BRT's confidence that the species or DPS is: at high risk of extinction, at moderate risk, or neither.
4. In the BRT's evaluation of extinction risk, please include a consideration of the threats facing the species/DPS that may or may not be manifested in the current demographic status of populations. Please document the BRT's consideration of these threats according to the statutory listing factors (ESA section 4(a)(1)(A)–(C), and (E)): the present or threatened destruction, modification, or curtailment of its habitat or range; overutilization for commercial, recreational, scientific, or educational purposes; disease or predation; and other natural or man-made factors affecting its continued existence. In describing the threats facing the species/DPS, please distinguish between threats (e.g., human actions or natural events) and limiting factors (e.g., the physical, biological, or

chemical processes that result in demographic risks to the species/DPS), and qualitatively rank, if possible, the severity of identified threats to the species' persistence. The consideration of the inadequacy of existing regulatory mechanisms (section 4(a)(1)(D)) will be conducted by the regional office or offices in concert with the evaluation of efforts being made to protect the species.

5. If the BRT determines that the species or delineated DPS is at neither moderate nor high risk throughout all of its range, please consider whether it is at moderate or high risk throughout a significant portion of its range.

Guidance on what constitutes a DPS is provided by the joint USFWS-NMFS policy on vertebrate populations. To be considered distinct, a population, or group of populations, must be discrete from the remainder of the species to which it belongs and significant to the species to which it belongs as a whole. Discreteness and significance are further defined by the services in the following policy language (USFWS-NMFS 1996, p. 4,725):

> Discreteness: A population segment of a vertebrate species may be considered discrete if it satisfies either one of the following conditions:
>
> 1. It is markedly separated from other populations of the same taxon as a consequence of physical, physiological, ecological, or behavioral factors. Quantitative measures of genetic or morphological discontinuity may provide evidence of this separation.
> 2. It is delimited by international governmental boundaries within which differences in control of exploitation, management of habitat, conservation status, or regulatory mechanisms exist that are significant in light of section 4(a)(1)(D) of the Act.
>
> Significance: If a population segment is considered discrete under one or more of the above conditions, its biological and ecological significance will then be considered in light of congressional guidance (see Senate Report 151, 96th Congress, 1st Session) that the authority to list DPSs be used sparingly while encouraging the conservation of genetic diversity. In carrying out this examination, the services will consider available scientific evidence of the discrete population segment's importance to the taxon to which it belongs. This consideration may include, but is not limited to, the following:
>
> 1. Persistence of the discrete population segment in an ecological setting unusual or unique for the taxon,
> 2. Evidence that loss of the discrete population segment would result in a significant gap in the range of a taxon,
> 3. Evidence that the discrete population segment represents the only surviving natural occurrence of a taxon that may be more abundant elsewhere as an introduced population outside its historic range, or
> 4. Evidence that the discrete population segment differs markedly from other populations of the species in its genetic characteristics.

After consideration of the all available scientific data, the eulachon BRT has determined that the petitioned unit of eulachon that spawn in rivers in Washington, Oregon, and California is not a species under the ESA, as it does not meet all the biological criteria to be considered a DPS as defined by the joint USFWS-NMFS 1996 policy on vertebrate populations. However, the BRT has determined that eulachon spawning in Washington, Oregon, and California rivers are part of a DPS that extends beyond the conterminous United States and that the northern boundary of the DPS occurs in northern British Columbia south of the Nass River (most likely) or in southern British Columbia north of the Fraser River (less likely). The BRT found it difficult to establish a clear northern terrestrial or river boundary for this DPS in light of the fact that the BRT believes the northern boundary is essentially determined by oceanographic processes. However, it was the majority opinion of the BRT that the northern boundary of the DPS is south of the Nass River on the north coast of British Columbia. The BRT proposes that this DPS be termed the southern DPS of eulachon. The BRT also concluded that the eulachon spawning in the Nass River and further north consist of at least one additional (northern) DPS.

The BRT qualitatively ranked threats to the southern DPS of eulachon subpopulations that spawn in the Klamath River, Columbia River, Fraser River, and British Columbia coastal rivers south of the Nass River. In each case, the BRT ranked climate change impacts on ocean conditions as the most serious threat to persistence of eulachon. Climate change impacts on freshwater habitat and eulachon bycatch were scored as moderate to high risk in all subareas of the DPS, and dams and water diversions in the Klamath and Columbia rivers and predation in the Fraser and British Columbia coastal rivers were also ranked within the top four threats in their respective regions.

The BRT was concerned that although eulachon are a relatively poorly monitored species, the weight of the available information indicates that the southern DPS of eulachon has experienced an abrupt decline in abundance throughout its range. Considering this large decline, in addition to other risk factors, the BRT determined that the southern DPS of eulachon is at moderate risk of extinction throughout all of its range.

# Acknowledgments

The status review of eulachon (*Thaleichthys pacificus*) was conducted by a team of scientists. NMFS gratefully acknowledges the commitment and efforts of the Eulachon Biological Review Team (BRT) members and thanks them for generously contributing their time and expertise to the development of this status review.

The Eulachon BRT relied on comments and informational reports submitted by the public and by state, tribal, and federal agencies. The authors acknowledge the efforts of all who contributed to this record, especially the Washington Department of Fish and Wildlife (WDFW), Oregon Department of Fish and Wildlife (ODFW), California Department of Fish and Game, and Department of Fisheries and Oceans Canada (DFO).

Numerous individual fishery scientists and managers provided information that aided in preparation of this document and deserve special thanks. We particularly thank Dr. Doug Hay, Nearshore Consulting, Nanaimo, British Columbia (Scientist Emeritus, Pacific Biological Station, DFO); Brad James, WDFW; Olaf Langness, WDFW; and Tom Rien, ODFW; for information, data, opinions, and advice.

We also thank Megan Moody, Nuxalk Nation, Bella Coola, British Columbia; Andy Lecuyer, Environmental Advisor, Rio Tinto Alcan Inc., Kemano, British Columbia; Michael R. Gordon, M. R. Gordon & Associates Ltd., North Vancouver, British Columbia; and Irene Martin, Skamokawa, Washington, for providing documents or steering us toward those who could.

We also thank five anonymous scientists whose peer review of an earlier version of this document provided added clarity.

# Introduction: Summary of Information Presented by the Petitioner

In 1999 the National Marine Fisheries Service (NMFS) received a petition (Wright 1999) to list eulachon (*Thaleichthys pacificus*) in the Columbia River and its tributaries as a threatened or endangered species under the U.S. Endangered Species Act (ESA) of 1973. NMFS determined that the 1999 eulachon petition failed to present substantial scientific and commercial information indicating that the petitioned action may be warranted (NMFS 1999).

On 27 November 2007, NMFS received a new petition seeking to list eulachon in Washington, Oregon, and California as a threatened or endangered species under the ESA (Cowlitz Indian Tribe 2007). NMFS evaluated the petition to determine whether the petitioner provided substantial information to list a species as required by the ESA. Additionally, NMFS evaluated whether information contained in the petition might support the identification of a distinct population segment (DPS) that may warrant listing as a species under the ESA. NMFS determined that the 27 November 2007 petition did present substantial scientific and commercial information, or cited such information in other sources, that the petitioned action may be warranted and, subsequently, NMFS initiated a status review of eulachon in Washington, Oregon, and California (NMFS 2008).

A Eulachon Biological Review Team (BRT)[1]—consisting of scientists from the Northwest Fisheries Science Center (NWFSC), Alaska Fisheries Science Center (AFSC), Southwest Fisheries Science Center, U.S. Fish and Wildlife Service (USFWS), and U.S. Forest Service—was formed by NMFS, and the team reviewed and evaluated scientific information compiled by NMFS staff from published literature and unpublished data. Information presented at a public meeting in June 2008 in Seattle, Washington, and data submitted to the ESA Administrative Record from state agencies and other interested parties were also considered.

The BRT proceeded on the directives included in the Draft BRT Eulachon Instructions Memo that was received from the NMFS Northwest Region on 19 May 2008. In the memo the BRT was charged with consideration of the following questions:

1. Consider, consistent with the criteria defined by the joint USFWS-NMFS DPS policy (61 FR 4722; 7 February 1996), whether eulachon warrant delineation into one or more DPSs.

[1] The Eulachon BRT consisted of: Jonathan Drake, Robert Emmett, Kurt Fresh, Richard Gustafson, Mindy Rowse, and David Teel, NWFSC; Matthew Wilson, AFSC; Peter Adams, SWFSC; Elizabeth A. K. Spangler, USFWS; and Robert Spangler, U. S. Forest Service.

2. Once the DPS structure for eulachon has been delineated, assess the level of extinction risk facing the species (including any DPS in the United States) throughout all of its range.
3. In articulating the assessed level of extinction risk, describe the BRT's confidence that the species or DPS is at high risk of extinction, at moderate risk, or neither.
4. In the BRT's evaluation of extinction risk, please include a consideration of the threats facing the species/DPS that may or may not be manifested in the current demographic status of populations. Please document the BRT's consideration of these threats according to the statutory listing factors (ESA section 4(a)(1)(A)–(C), and (E)): the present or threatened destruction, modification, or curtailment of its habitat or range; overutilization for commercial, recreational, scientific, or educational purposes; disease or predation; and other natural or man-made factors affecting its continued existence. In describing the threats facing the species/DPS please distinguish between threats (e.g., human actions or natural events) and limiting factors (e.g., the physical, biological, or chemical processes that result in demographic risks to the species/DPS), and qualitatively rank, if possible, the severity of identified threats to the species' persistence. The consideration of the inadequacy of existing regulatory mechanisms (section 4(a)(1)(D)) will be conducted by the regional office or offices in concert with the evaluation of efforts being made to protect the species.
5. If the BRT determines that the species or delineated DPS is at neither moderate nor high risk throughout all of its range, please consider whether it is at moderate or high risk throughout a significant portion of its range.

The Eulachon BRT submitted a summary status review document (BRT 2008) to the NMFS Northwest Region in December 2008. In April 2009 we asked a number of scientists with expertise in eulachon biology or viability analysis to review that document (BRT 2008). Substantial scientific comments received from five peer reviewers and our responses to these comments can be found in Appendix E. Numerous changes have been incorporated into the present document in response to suggestions made by the peer reviewers.

## The DPS Question: Evidence for Discreteness and Significance

The petitioner noted that early mitochondrial DNA (mtDNA) genetic information (McLean et al. 1999) suggested that eulachon did not exhibit genetic discreteness and gave little support for subdivision of population structure throughout the species' range. However, other biological data including the number of vertebrae, size-at-maturity, fecundity, river-specific spawning times, and population dynamics indicated that there is substantial local stock structure (Hart and McHugh 1944, Hay and McCarter 2000). The petitioner described these latter observations as consistent with the hypothesis that there is local adaptation and genetic differentiation among populations. Recent microsatellite genetic work (Beacham et al. 2005) appears to confirm the existence of significant differentiation among populations. The petitioner summarized these findings as indicating that although the Fraser River, mainstem Columbia River, and Cowlitz River spawning populations are genetically distinct from each other, they are more closely related to one another than either population is to the more northerly British Columbia populations (Beacham et al. 2005). Although the petitioner felt that the available information is inconclusive, the petitioner noted that eulachon may be composed of several DPSs separated by differences in run timing, spawn timing, meristics, and genetic characteristics.

The petitioner concluded that the available genetic, meristic, and life history information is inconclusive regarding the discreteness of eulachon populations. However, the petitioner argued that under the DPS policy, eulachon populations in Washington, Oregon, and California are collectively discrete from more northerly populations because they are delimited by an international governmental boundary (i.e., the U.S.-Canada border between Washington and British Columbia) across which there is a significant difference in exploitation control, habitat management, or conservation status. The petitioner noted that the United States and Canada differ in their regulatory control of commercial, recreational, and tribal or First Nations eulachon harvest, and also differ in their management of eulachon habitat. The petitioner concluded that there is no assurance that the United States and Canada will coordinate management and regulatory efforts sufficiently to conserve eulachon and their habitat, and thus the DPS should be delineated at the border between Washington and British Columbia.

The petitioner argued that the southern eulachon population segment is significant under the DPS policy because the loss of the discrete population segment would cause a significant gap in the taxon's range. The petitioner stated that eulachon have largely disappeared in rivers throughout the southern portion of their range, and that eulachon in the Columbia River probably represent the southernmost extant population for the species. The petitioner argued that the loss of the Columbia River eulachon population and any dependent coastal spawning populations could represent the loss of the species throughout its range in the United States, as well as the loss of a substantial proportion of its historical range.

## Summary of Abundance and Population Trends

The petitioner stated that although eulachon abundance exhibits considerable year-to-year variability, nearly all spawning runs from California to southeastern Alaska have declined in the past 20 years, especially since the mid-1990s (Hay and McCarter 2000). Historically, the Columbia River has exhibited the largest returns of any spawning population throughout the species' range. The petitioner noted that from 1938 to 1992, the median commercial catch of eulachon in the Columbia River was approximately 1.9 million pounds (lb). From 1993 to 2006, the median catch had declined to approximately 43,000 lb, representing a 97.7% reduction in catch from the prior period. Although there was an increasing trend in Columbia River eulachon catch from 2000 to 2003, recent catches have been extremely low. The petitioner also presented catch per unit effort (CPUE) and larval survey data (JCRMS 2006) for the Columbia River and tributaries in Oregon and Washington that similarly reflect the depressed status of Columbia River eulachon during the 1990s, a relative increase during 2001 to 2003, and a decline back to low levels in recent years.

The petitioner also noted that eulachon returns in the Fraser River showed a similar pattern to those in the Columbia River; a rapid decline in the mid-1990s, increased returns during 2001 to 2003, and a recent decline to low levels. The petitioner stated that egg and larval surveys conducted in the Fraser River since 1995 also demonstrate that, despite the implementation of fishing restrictions in British Columbia, the stock has not recovered from its mid-1990s collapse and remains at a precariously low level. An offshore index of Fraser and

Columbia rivers eulachon biomass, calculated from eulachon bycatch in an annual trawl survey of shrimp biomass off the west coast of Vancouver Island, illustrates highly variable biomass over the time series since 1973, but also reflects stock declines in the mid-1990s and in recent years, according to the petitioner. With respect to eulachon populations further south in the species' range, the petitioner noted that populations in the Klamath River, Mad River, Redwood Creek, and Sacramento River are likely extirpated or nearly so.

## Summary of Risk Factors

The petitioner described a number of threats facing eulachon range-wide and facing populations in U.S. rivers in particular. The petitioner expressed concern that habitat loss and degradation threaten eulachon, particularly in the Columbia River basin. The petitioner argued that hydroelectric dams block access to historical eulachon spawning grounds and affect the quality of spawning substrates through flow management, altered delivery of coarse sediments, and siltation.

The petitioner expressed strong concern regarding the siltation of spawning substrates in the Cowlitz River due to altered flow management and the accumulation of fine sediments from the Toutle River. The petitioner believes that efforts to retain and stabilize fine sediments generated by the 1980 eruption of Mount St. Helens are inadequate. The petitioner noted that the release of fine sediments from behind a U.S. Army Corps of Engineers (USACE) sediment retention structure (SRS) on the Toutle River has been negatively correlated with Cowlitz River eulachon returns 3 to 4 years later. The petitioner also expressed concern that dredging activities in the Cowlitz and Columbia rivers during the eulachon spawning run may entrain and kill fish, or otherwise result in decreased spawning success.

The petitioner also noted that eulachon have been shown to carry high levels of chemical pollutants (EPA 2002), and although it has not been demonstrated that high contaminant loads in eulachon result in increased mortality or reduced reproductive success, such effects have been shown in other fish species (Kime 1995). The petitioner concluded that no evidence suggests that disease currently poses a threat to eulachon, but noted that information presented in the 1999 petition (Wright 1999) to list eulachon suggested that predation by pinnipeds may be substantial.

The petitioner expressed concern that depressed eulachon populations are particularly susceptible to overharvest in fisheries where they are targeted or taken as bycatch. The petitioner acknowledged that eulachon harvest has been curtailed significantly in response to population declines, and that were it not for continued low levels of harvest, there would be little or no status information available for some populations. However, the petitioner concluded that existing regulatory mechanisms have proven inadequate in recovering eulachon stocks, and that directed harvest and bycatch may be important factors limiting the recovery of impacted stocks. The petitioner emphasized the need for further fishery-independent monitoring and research.

Finally, the petitioner concluded that global climate change is one of the greatest threats facing eulachon, particularly in the southern portion of its range where ocean warming trends may be the most pronounced. The petitioner felt that the risks facing southerly eulachon populations in Washington, Oregon, and California will be exacerbated by such a deterioration of marine conditions. According to the petitioner, these southerly populations, already exhibiting dramatic declines and impacted by other threats (e.g., habitat loss and degradation), might be at risk of extirpation if unfavorable marine conditions predominate in the future.

# The Species Question

As amended in 1978, the ESA allows listing of DPSs of vertebrates as well as named species and subspecies. Guidance on what constitutes a DPS is provided by the joint USFWS-NMFS (1996) policy on vertebrate populations. To be considered distinct, a population, or group of populations, must be discrete from the remainder of the taxon to which it belongs and significant to the taxon to which it belongs as a whole. Discreteness and significance are further defined by the services in the following policy language (USFWS-NMFS 1996, p. 4,725):

> Discreteness: A population segment of a vertebrate species may be considered discrete if it satisfies either one of the following conditions:
>
> 1. It is markedly separated from other populations of the same taxon as a consequence of physical, physiological, ecological, or behavioral factors. Quantitative measures of genetic or morphological discontinuity may provide evidence of this separation.
> 2. It is delimited by international governmental boundaries within which differences in control of exploitation, management of habitat, conservation status, or regulatory mechanisms exist that are significant in light of section 4(a)(1)(D) of the [Endangered Species] Act.
>
> Significance: If a population segment is considered discrete under one or more of the above conditions, its biological and ecological significance will then be considered in light of congressional guidance (see Senate Report 151, 96th Congress, 1st Session) that the authority to list DPSs be used sparingly while encouraging the conservation of genetic diversity. In carrying out this examination, the services will consider available scientific evidence of the discrete population segment's importance to the taxon to which it belongs. This consideration may include, but is not limited to, the following:
>
> 1. Persistence of the discrete population segment in an ecological setting unusual or unique for the taxon,
> 2. Evidence that loss of the discrete population segment would result in a significant gap in the range of a taxon,
> 3. Evidence that the discrete population segment represents the only surviving natural occurrence of a taxon that may be more abundant elsewhere as an introduced population outside its historic range, or
> 4. Evidence that the discrete population segment differs markedly from other populations of the species in its genetic characteristics.

The interagency policy states that international boundaries within the geographical range of the species may be used to delimit a distinct population segment in the United States. This criterion is applicable if differences in the control of exploitation of the species, the management of the species' habitat, the conservation status of the species, or regulatory mechanisms differ between countries that would influence the conservation status of the population segment in the United States. However, in past assessments of DPSs of marine fish, NMFS has placed the emphasis on biological information in defining DPSs and has considered political boundaries only at the implementation of ESA listings. Therefore, the BRT focused only on biological information in identifying whether DPSs of eulachon could be delineated.

# Eulachon Life History and Ecology

## Taxonomy and Species Description

### Scientific Nomenclature

Eulachon are an anadromous smelt in the family Osmeridae and are distinguished from other osmerids by having 4–6 gill rakers on the upper half of the arch (others have 8–14 gill rakers), distinct concentric striae on the operculum and suboperculum (other osmerids lack these concentric striae), and 8–11 pyloric caeca (others have 0–8 pyloric caeca) (McAllister 1963, Hart 1973, Mecklenburg et al. 2002). McAllister (1963) provides a taxonomic synonymy for the species, which was originally described from the Columbia River as *Salmo (Mallotus) pacificus* by Richardson (1836). The genus *Thaleichthys* has only one species and valid subspecies have not been described (McAllister 1963). The binomial species name is derived from Greek roots; *thaleia* meaning rich, *ichthys* meaning fish, and *pacificus* meaning of the Pacific (Hart 1973).

### Common Names

#### Native, Indian, and First Nations languages

The common name officially recognized by the American Fisheries Society (Nelson et al. 2004) for *Thaleichthys pacificus* is eulachon (pronounced you-la-kon in the United States), which is originally derived from the Chinook Indian trade language of the lower Columbia River (Hart and McHugh 1944, Moody 2008). Numerous variations include hoolakan, hooligan, hoolikan, olachan, ollachan, oolachan, oolichan, oulachan, oulachon, oulacon, ulchen, ulichan, uthlecan, yshuh (Hart and McHugh 1944), ooligan, olachen, and olachon (Moody 2008). The Yurok Tribe of the lower Klamath River call eulachon quat-ra (Larson and Belchik 1998) and the Quinault Tribe named the fish páagwáls (Olson 1936). Each First Nations group in British Columbia has a unique name for eulachon (Hay and McCarter 2000, Moody 2008). The First Nations of the lower Fraser River called eulachon swavie or chucka (Hart and McHugh 1944); and the Haisla and Tlingit of Alaska call it juk'wan or za'xwen and ssag or saak, respectively (Krause 1885, Betts 1994, Willson et al. 2006).

#### English

Besides eulachon, *Thaleichthys pacificus* is known by numerous local common English names including candlefish, small fish, savior fish, salvation fish, little fish, fathom fish (because it was sold by the fathom) (Hart and McHugh 1944), and Columbia River smelt.

# Eulachon and Human Cultural History

Eulachon were, and still are, highly important ceremonially, nutritionally, medicinally, and economically to First Nations people in British Columbia and Native American tribes in northern California and the Pacific Northwest. Many ethnographers and historians have stressed the cultural and nutritional importance of eulachon to the Tlingit of Southeast Alaska (Mills 1982, Olson and Hubbard 1984, Krause 1885, Betts 1994), Tsimshians of the north coast of British Columbia (Stewart 1975, Halpin and Seguin 1990, Martindale 2003), Haisla of Douglas Channel and Gardner Canal of British Columbia (Hawthorn et al. 1960, Hamori-Torok 1990), Haihais and Oowekeeno of Rivers Inlet in British Columbia (Hilton 1990), Nuxalk (formerly known as the Bella Coola) of the central coast of British Columbia (Kuhnlein et al. 1982, Kennedy and Bouchard 1990), Kwakwaka'wakw (formerly known as the Kwakiutl) of the north and central coast of British Columbia (Curtis 1915, Rohner 1967, Macnair 1971, Mitchell 1983, Codere 1990), Stó:lō of the Fraser River (Duff 1952), Quinault of the Washington coast (Willoughby 1889, Olson 1936), Chinook and Cowlitz on the lower Columbia River (Boyd and Hajda 1987, Byram and Lewis 2001), and Yurok on the Klamath River (Pilling 1978, Byram and Lewis 2001). In many areas, eulachon returned in the late winter and early spring when other food supplies were scarce and were known, for this reason, as savior or salvation fish (Boyd and Hajda 1987, Byram and Lewis 2001).

Major aboriginal subsistence fisheries for eulachon reportedly occurred on the Stikine, Nass, Skeena, Kitimat, Bella Coola, Kingcome, Klinaklini, Fraser (Macnair 1971, Kuhnlein et al. 1982, Mitchell 1983), and Columbia rivers (Boyd and Hajda 1987). Eulachon were eaten fresh, smoked, dried, and salted, and rendered as oil or grease. Especially to the north of the Fraser River, the fat of the eulachon was rendered into oil, or what is commonly called grease, which is solid at room temperature and was a common traditional year-round condiment with many foods, as well as a medicine for skin rashes and internal ailments among First Nations people on the central and north coasts of British Columbia and in some parts of Alaska (Kuhnlein et al. 1982). Kuhnlein et al. (1982, p. 155) stated that:

> The cultural significance of ooligan grease cannot be underestimated, as it was (and continues to be) a prominent food and gift during feasts and potlatch ceremonies. Early ethnographers among the Nuxalk and Kwakiutl people noted that it was a sign of poverty for a family to be without ooligan grease.

Eulachon grease was widely traded to First Nations such as the Haida and Nootka of Vancouver Island and First Nations in the interior of British Columbia that had no rivers with eulachon runs (Krause 1885, Green 1891, Martindale 2003). Sutherland (2001, p. 8) has stated that "by trading the grease [First Nations people] obtained wealth, prestige, and power." Ancient trade routes up the Nass and Bella Coola river valleys, in particular, and through the mountains, became known as "grease trails" after the traffic in eulachon grease, packed in wooden boxes (Collison 1941, Hart and McHugh 1944, Stewart 1977, Byram and Lewis 2001, Hirch 2003). Numerous sources describe the methods, which varied slightly from area to area, of extracting the oil by boiling the fish bodies (MacFie 1865, Lord 1866, Swan 1881, Krause 1885, Green 1891, Macnair 1971, Stewart 1977).

The largest and most important eulachon fisheries for grease production were on the Nass and Klinaklini rivers of British Columbia (Stacey 1995), although grease was produced by all the First Nations with fishing rights on eulachon rivers north of the Fraser River (Swan 1881, Macnair 1971). As many as 2,000 people annually migrated to the eulachon fishing grounds (Tsawatti) on the Klinaklini River at the head of Knight Inlet (Macnair 1971, Mitchell 1983, Stacey 1995), some traveling from as far as 402 km (250 miles) away by canoe (Codere 1990). The assemblage on the Klinaklini River included nine winter village groups of the Southern Kwakwaka'wakw (formerly known as the Southern Kwakiutl) (Mitchell 1983). A comparable assemblage of five other Southern Kwakwaka'wakw winter village groups and the bulk of the Nimpkish First Nation people from Vancouver Island congregated at Quaee at the head of Kingcome Inlet on the Kingcome River to harvest the spring run of eulachon (Mitchell 1983). Kennedy and Bouchard (1990, p. 325) in an ethnographic summary of the Bella Coola First Nation noted that "Because of their abundance and their value as a trade item, eulachons (particularly when rendered into highly valued grease) were second only to salmon in importance to the Bella Coola."

# Historical and Current Distribution

### Freshwater Spawning Distribution

Eulachon spawn in the lower portions of certain rivers draining into the northeastern Pacific Ocean ranging from northern California to the southeastern Bering Sea in Bristol Bay, Alaska (Hubbs 1925, Schultz and DeLacy 1935, McAllister 1963, Scott and Crossman 1973, Willson et al. 2006) (Table A-1 in Appendix A, Figures 1 through 3). This distribution coincides closely with the distribution of the coastal temperate rain forest ecosystem on the west coast of North America (Figure 1). Both Willson et al. (2006) and Moody (2008) have recently reviewed the coast-wide spawning distribution of eulachon in North America.

Monaco et al. (1990) and Emmett et al. (1991) summarized distribution and abundance of fishes in U.S. West Coast estuaries (see Table A-2) and based on the references cited therein described adult eulachon as common in Grays Harbor and Willapa Bay on the Washington coast, abundant in the Columbia River, common in Oregon's Umpqua River, and abundant in the Klamath River in northern California. In addition, a number of estuaries where eulachon were thought to occur in rare relative abundance included Puget Sound and Skagit Bay in Washington; Siuslaw River, Coos Bay, and Rogue River in Oregon; and Humboldt Bay in California (Monaco et al. 1990, Emmett et al. 1991). Hay and McCarter (2000) and Hay (2002) identified 33 eulachon spawning rivers in British Columbia and 14 of these were classified as supporting regular yearly spawning runs. Willson et al. (2006) and Moody (2008) list numerous rivers that support eulachon runs in Southeast and Southcentral Alaska and on the coastline of Alaska in the southeastern Bering Sea (Table A-1). McPhail and Lindsey (1970, p. 198) suggested that eulachon "apparently survived glaciation south of the ice sheet along the Pacific coast of North America" and likely "entered the Bering Sea from the south" following the Wisconsian glaciation.

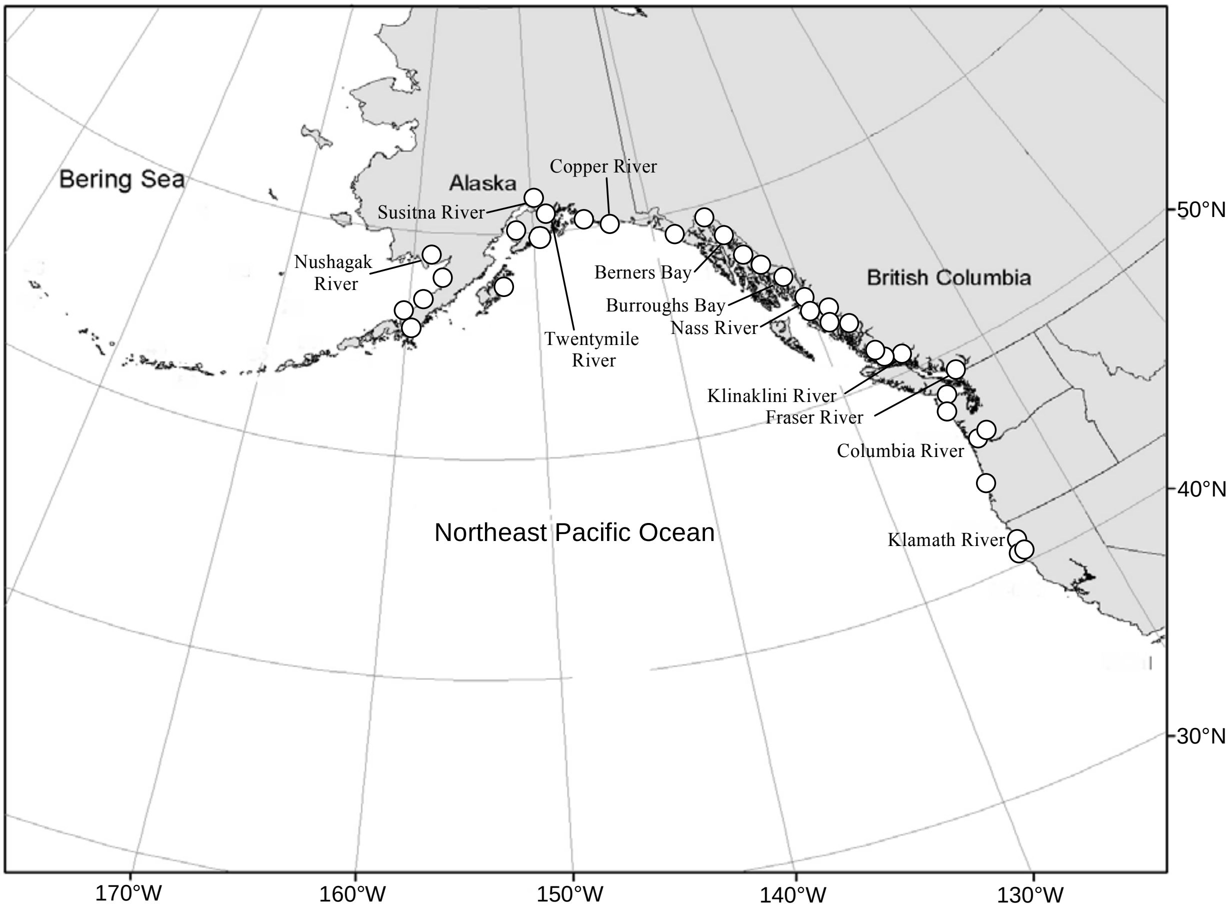

Figure 1. Distribution of eulachon spawning rivers (open circles) in the Northeast Pacific Ocean.

## California

Hubbs (1925) and Schultz and DeLacy (1935), leading ichthyologists of their day, described the Klamath River in northern California as the southern limit of the range of eulachon. Miller and Lea (1972, p. 62) in the California Department of Fish and Game's (CDFG) Guide to the Coastal Marine Fishes of California reported that the eulachon "spawns in rivers from Mad River north." More recent compilations state that large spawning aggregations of eulachon were reported to have once regularly occurred in the Klamath River (Fry 1979, Moyle et al. 1995, Larson and Belchik 1998, Moyle 2002, Hamilton et al. 2005) and on occasion in the Mad River (Moyle et al. 1995, Moyle 2002) and Redwood Creek (Ridenhour and Hofstra 1994, Moyle et al. 1995) (Table A-1, Figure 2).

In addition, Moyle et al. (1995) and Moyle (2002) state that small numbers of eulachon have been reported from the Smith River (Table A-1). CDFG's Status Report on Living Marine Resources (Sweetnam et al. 2001, p. 477–478) states that "The principal spawning run [of eulachon] in California is in the Klamath River, but runs have also been recorded in the Mad and Smith rivers and Redwood Creek." Allen et al. (2006) indicated that eulachon usually spawn no further south than the lower Klamath River and Humboldt Bay tributaries. The California

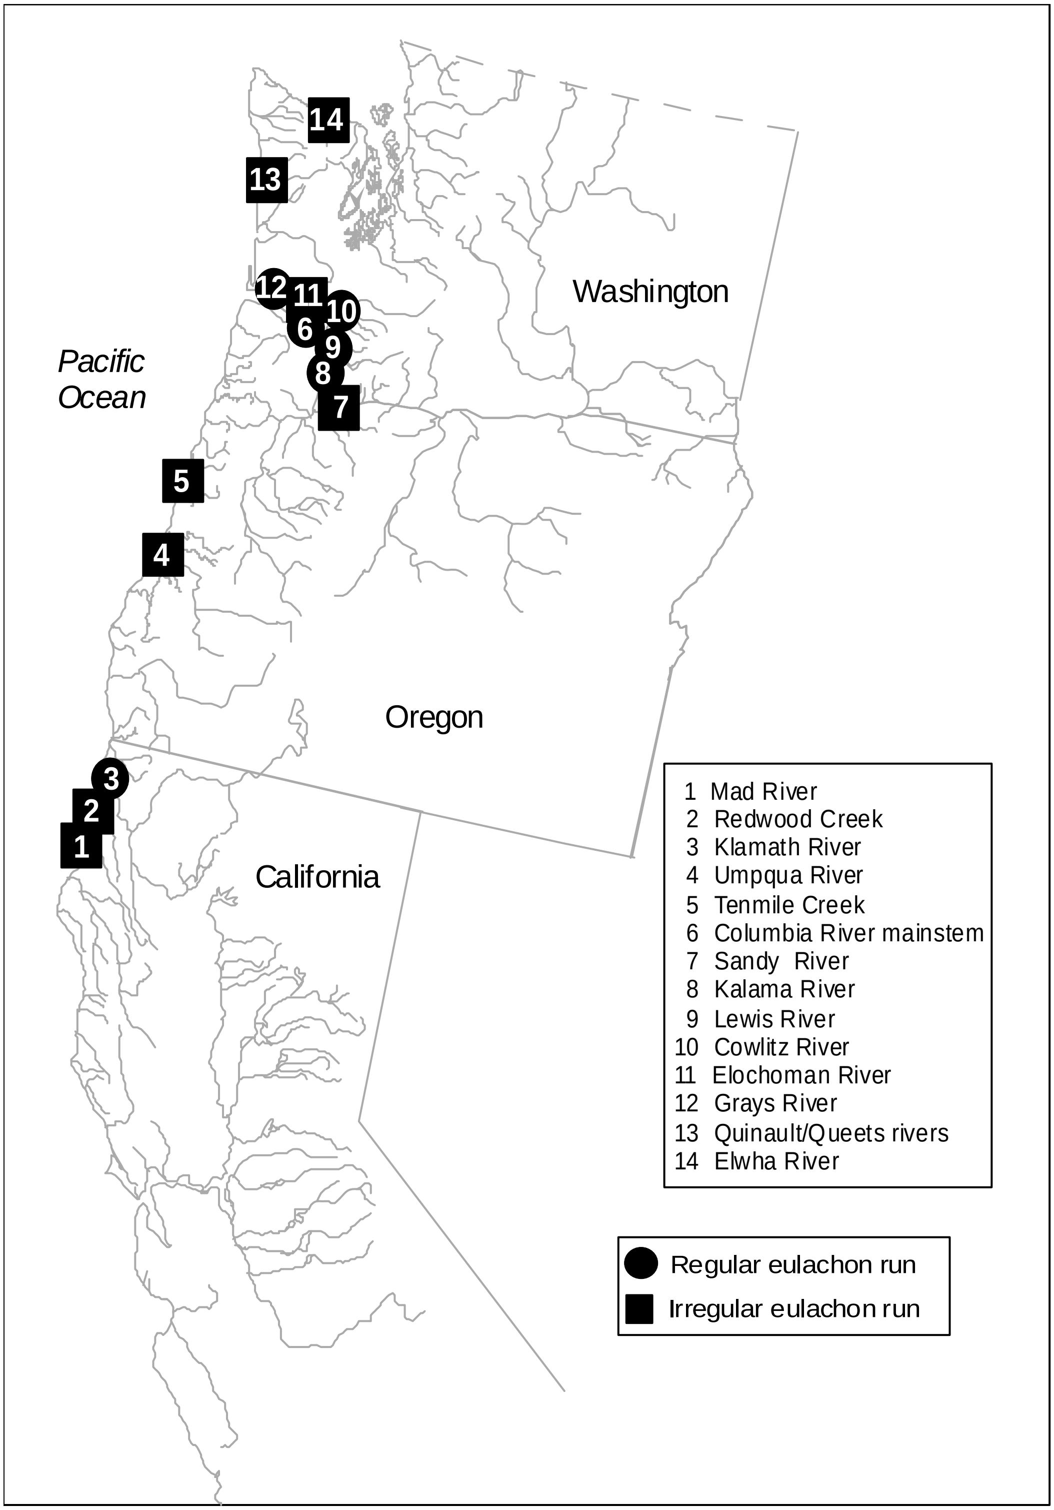

Figure 2. Eulachon spawning areas mentioned in the text in the conterminous United States.

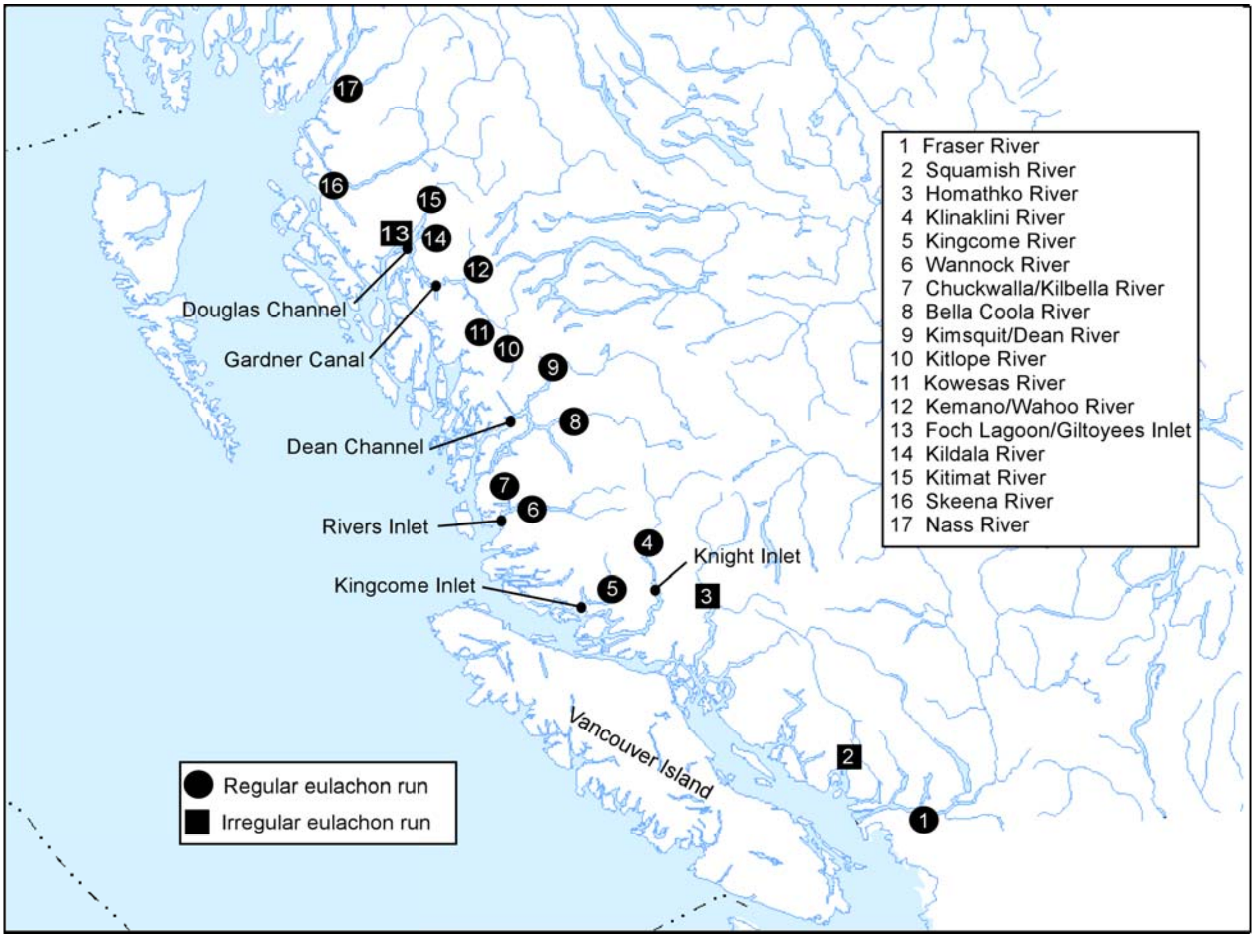

Figure 3. Major known eulachon spawning rivers in British Columbia (based on Hay and McCarter 2000 and Hay 2002).

Academy of Sciences (CAS) ichthyology collection database (online at http://research .calacademy.org/research/Ichthyology/collection/index.asp) lists eulachon specimens collected from the Klamath River in February 1916, March 1947, and March 1963, and in Redwood Creek in February 1955.

A search of available online digital newspaper resources (listed in Table B-1) revealed an early account of eulachon (aka candlefish in northern California) in the Klamath River in a newspaper article in 1879 (Appendix B). Runs large enough to be noted in available local newspaper articles occurred in the Klamath River in February 1919, March 1968, April 1963, and April 1969, in Redwood Creek in April 1963 and April 1967, and in the Mad River in April 1963 (Table A-3 and Appendix B). An early memoir by a traveler surveying timber resources on the Klamath River reported eulachon being harvested (15–20 lb in a single dip net haul) by Yurok tribal members in the early 1890s (Pearsall 1928) (Appendix C). Petersen (2006) reported on interviews with Yurok and Karuk tribal fishers on the lower Klamath River that indicated eulachon were abundant in the river in the 1960s. Petersen (2006, p. 88) stated that "one fisher remembered picking up 75 pounds of fish in one dip" and that another remembered "filling the back of a pickup truck in one hour" with eulachon in 1966.

Young (1984) collected eulachon in Redwood Creek in April 1978 and in the Klamath River in April 1978, March and April of 1979, and 1980. Bowlby (1981) documented eulachon in the diet of California sea lions (*Zalophus californianus*) through gastrointestinal content analysis and in harbor seals (*Phoca vitulina*) through scat analysis and gastrointestinal content analysis in the Klamath River during spring 1978 and 1979. One California sea lion contained 186 eulachon in its gut on 10 April 1978 when the carcass was recovered 1 km upriver from the river mouth, and sea lions "were observed at Klamath Glenn, 9.6 km upriver, while fishermen dipnetted these congregating fish from shore" (Bowlby 1981, p. 59). Eulachon have been reported to spawn at least as far as 40 km upstream on the Klamath River (Fry 1979, Hamilton et al. 2005). Larson and Belchik (1998, p. 5) noted that "In the Klamath, adults generally migrate as high as Pecwan Creek …, have been witnessed as high as Weitchpec …, but specific spawning areas are unknown."

Eulachon have been occasionally reported from other freshwater streams of California. Fry (1979, p. 90) reported that the largest eulachon run in California occurred in the Klamath River, and that eulachon occurred in "fresh water from the Gualala River, California, northward." Although Odemar (1964) has been cited as evidence that eulachon occurred in the Russian River, Odemar (1964) actually stated that "No runs of *T. pacificus* have been reported in the Russian River, or in any river south of the Mad River, and it does not appear that the fish examined off the Russian River in May 1963 were destined to spawn there."

Eulachon were not observed by Eldridge and Bryan (1972) in a larval fish survey of Humboldt Bay, California, and Barnhart et al. (1992, p. 101) stated that eulachon are "not reported in Humboldt Bay tributaries," although they are occasionally recorded in Humboldt Bay itself. Monaco et al. (1990) described eulachon as rare in Humboldt Bay and, in addition to several personal communications, cited Gotshall et al. (1980) and Young (1984) as supporting references (Table A-2). Gotshall et al. (1980, p. 229) recorded eulachon as an "occasional visitor" in winter to Humboldt Bay, California. Young (1984) stated that:

> Specimens [of eulachon] have occasionally been taken, during the spawning season, in Jolly Giant and Jacoby creeks (George Allen, pers. comm., 1980). Both of these streams empty into Humboldt Bay.

Jennings (1996) reported on observations of adult eulachon in creeks tributary to Humboldt Bay, California, in May 1977. A single spawned-out adult male eulachon was collected in a downstream migrant trap on Jolly Giant Creek, approximately 7 km south of Mad River, and a total of seven adult eulachon were observed in another downstream migrant trap in Jacoby Creek, located 8.5 km south of Mad River (Jennings 1996).

Although Minckley et al. (1986, their Table 15.1, p. 541) indicate that eulachon were native to the Sacramento River and drainages within the south California Coastal to Baja California region, no verifying references for these assertions were given. Recently, Vincik and Titus (2007) reported on the capture of a single mature male eulachon in a screw trap at RKM 228 (RM 142) on the Sacramento River.

## Coastal Oregon

Monaco et al. (1990) and Emmett et al. (1991) summarized distribution and abundance of eulachon in major Oregon estuaries and listed the Rogue River, Coos Bay, Siuslaw River, and Umpqua River as possessing records of eulachon presence. More recently, Willson et al. (2006, p. 36–37) listed the following drainages on the coast of Oregon as supporting eulachon spawning runs (based on Emmett et al. [1991] and personal communications with fish biologists of ODFW): Winchuck, Chetco, Pistol, Rogue, Elk, Sixes, Coquille, Coos, Siuslaw, Umpqua, and Yaquina rivers; and Hunter, Euchre, Tenmile (draining Tenmile Lake), and Tenmile (near Yachats, Oregon) creeks (Table A-1).

Monaco et al. (1990) described eulachon as rare in the Rogue River and, in addition to a personal communication, cited Ratti (1979b) as a supporting reference (Table A-2). Although smelt and surf smelt (*Hypomesus pretiosus*) were reported from the Rogue River estuary by Ratti (1979b), no specific mention of eulachon occurs in this report. Roffe and Mate (1984) reported the presence of otoliths representing at least 120 eulachon from harbor seal scat collected in April 1978 on the Rogue River, which represented 16.7% of the identified harbor seal prey.

Reimers and Baxter (1976) reported that adult eulachon were caught in a downstream migrant trap in the lower portion of the Sixes River in Oregon between 1964 and 1972, although dates of occurrence or numbers caught were not provided. Reimers and Baxter (1976) suggested that these adults had possibly been spawning and were headed downstream at the time of capture.

Gaumer et al. (1973) recorded the taking of 28 eulachon in June 1971 by recreational fishers at the city docks of Bandon, Oregon, in the Coquille River estuary. Kreag (1979) also lists eulachon as occurring in the marine portion of the Coquille River estuary.

Monaco et al. (1990) described eulachon as rare in Coos Bay, Oregon, and, in addition to a personal communication, cited Cummings and Schwartz (1971), Hostick (1975), Roye (1979), and Wagoner et al. (1988) as supporting references (Table A-2). Cummings and Schwartz (1971) included eulachon in their list of fishes occurring in Coos Bay and indicated that eulachon were found up to 11 km (6.8 miles) upstream of the mouth of the bay. Although whitebait smelt (*Allosmerus elongatus)* and surf smelt were reported from Coos Bay by Hostick (1975), no specific mention of eulachon occurs in this report. Roye (1979, p. 36) referenced Cummings and Schwartz (1971) in describing eulachon as occurring in the lower 14.5 km (9 miles) of the Coos Bay estuary. The final version of the draft report, cited by Monaco et al. (1990) as Wagoner et al. (1988), stated that "eulachon may have occurred in large numbers in past years [in the Coos Bay estuary], but they have apparently not been abundant enough in recent years to attract an active dipnet fishery" (Wagoner et al. 1990, p. 100). More recently, Miller and Shanks (2005) surveyed the distribution of 28 identified larval and juvenile fish species in Coos Bay for more than three years between 1998 and 2001, but did not encounter eulachon.

Two reports (Gestring 1991, ODFW 1991) were found that list eulachon as a native fish species occurring in Tenmile and North Tenmile lakes, although no further information on frequency of occurrence or abundance were provided in these reports.

OFC (1970) reported that from 4,000 to 5,000 lb of eulachon were landed by two commercial fishermen in the Umpqua River during 31 days of drift gill net fishing from late December 1966 to mid-March 1967. OFC (1970, p. 34) stated that "The fishing area extended from the Highway 101 bridge at Reedsport upstream about 4 miles." A sport fishery for eulachon also operated over this period in the Umpqua River (OFC 1970). Monaco et al. (1990) described eulachon as common in the Umpqua River estuary and, in addition to a personal communication, cited Mullen (1977), Ratti (1979a), and Johnson et al. (1986) as supporting references (Table A-2). Neither Mullen (1977) nor Ratti (1979a) mention eulachon and Johnson et al. (1986, their Table 1) list eulachon as occurring in trace amounts in their trawl and beach-seine samples from April 1977 to January 1986.

Williams (2009, p. 2) reported that the Oregon Department of Fish and Wildlife (ODFW) has "no direct observations of eulachon spawning in the Umpqua" River, but provided additional information "on eulachon observations and captures during inventories." Williams (2009, p. 2) noted that:

> two random observations of eulachon [were reported] from Little Mill Creek [a tributary of the lower Umpqua River] on December 8, 1954 and January 26, 1955. The fish found in 1954 measured 6 inches in total length.

Williams (2009, p. 3) also reported on the results of seine collections conducted during March to November from 1995 to 2003 in Winchester Bay estuary on the Lower Umpqua River, which documented the

> presence … [of eulachon] in 4 of the last 14 years. Forty-four fish were found in May 1995, 80 fish during April and July 1998, 54 fish during March and May 1999, and 2 fish during June 2003. Seining was also conducted in the lower Smith River estuary [a tributary of the Lower Umpqua] at three sites during 1999 during February and March, but no eulachon were captured.

A search of available online digital newspaper resources (listed in Appendix B) revealed anecdotal evidence that an extensive recreational fishery for eulachon occurred in the lower Umpqua River at least from 1969 to 1982 during January to April. The last reference to eulachon in the Umpqua River in these digital newspaper resources occurred in 1989 (Appendix B).

Monaco et al. (1990) described eulachon as rare in the Siuslaw River estuary and, in addition to a personal communication, cited Hutchinson (1979) as a supporting reference (Table A-2); however, we have been unable to locate a copy of this document.

WDFW and ODFW (2008) describe the occasional occurrence of small numbers of eulachon in Tenmile Creek (not be confused with the Tenmile Lakes Basin), just south of Yachats, Oregon. Between 1992 and 2008, a total of 75 eulachon were caught in traps designed to catch outmigrating salmonid smolts located 0.8 km upstream from the ocean. Eulachon were caught in 1992 (24), 1993 (6), 1994 (1), 1995 (1), 1996 (1), 2001 (26), 2003 (3), 2005 (10), 2007 (1), and 2008 (2). As reported in WDFW and ODFW (2008):

> Eulachon were seen in February (3 years), March (6 years), April (7 years) and May (1 year). The earliest observed arrival was the week of February 3 in 1992.

> The latest observed presence was the week of May 21 in 2001. Fish lengths (annual averages) ranged from 155 to 208 mm FL. Local biologists suspect the eulachon spawn in the creek based on the trapping location, fish size, and that some fish appear to be spawned out.

Although Monaco et al. (1990) describe eulachon as not found in the Yaquina River (based on several personal communications) (Table A-2), Borgerson et al. (1991) list eulachon as occurring in the Yaquina River basin, but do not elaborate further on the evidence for this opinion.

**Columbia River**

Large spawning runs of eulachon occur in the mainstem lower Columbia River and the tributary Cowlitz, Lewis, Sandy (Craig and Hacker 1940), Grays (Smith and Saalfeld 1955), Kalama, and Elochoman (DeLacy and Batts 1963) rivers and Skamokawa Creek (WDFW and ODFW 2001, 2008). Smith and Saalfeld (1955) stated that eulachon were occasionally reported to spawn up to the Hood River on the Oregon side of the Columbia River prior to the construction of Bonneville Dam in the 1930s. In times of great abundance (e.g., 1945, 1953), eulachon have been known to migrate as far upstream as Bonneville Dam (Smith and Saalfeld 1955, WDFW and ODFW 2008) and may extend above Bonneville Dam by passing through the ship locks (Smith and Saalfeld 1955). Eulachon likely reached the Klickitat River on the Washington side of the Columbia River in 1945 via this route (Smith and Saalfeld 1955).

On average, the highest incidence of spawning occurs in the Cowlitz River (Smith and Saalfeld 1955, Wydoski and Whitney 2003), although on occasion eulachon may avoid the Cowlitz entirely, due to unfavorable environmental conditions (Wydoski and Whitney 2003). Sporadic spawning runs occur in the Grays, Elochoman, Kalama, Lewis, and Sandy rivers (JCRMS 2007, 2008, 2009). Stockley (1981, p. 1) stated that "occasionally, with very large runs, smelt ascend and enter the Washougal" River on the Washington side of the Columbia River at RKM 195. Stockley and Ellis (1970) suggested that in years of low abundance eulachon may not enter the Columbia River tributaries but remain within the mainstem Columbia River. In 2001 eulachon migrated upstream to Bonneville Dam at RKM 234 and spawned in all the major tributaries of the lower Columbia River, including the Sandy River (Howell et al. 2001). In 1953 eulachon were observed spawning in Tanner Creek on the Oregon side of the Columbia River near the base of Bonneville Dam (OFC 1953, WDFW and ODFW 2008).

Craig and Suomela (1940, p. 11) stated that "smelt are reported to confine their spawning activities to the lower 5 miles of the [Sandy] river" and that "this section is characterized, especially near the mouth, by moderate riffles and an abundance of glacial silt and sand." Anderson (2009) noted that eulachon have been observed on the Sandy River, Oregon, as far upstream as Gordon Creek at RKM 20.9 (RM 13). In addition, ODFW (Williams 2009, p. 1) stated that:

> The Sandy River in Oregon is the only Oregon tributary known to support a run of eulachon. However, it is sporadic and none have been seen in the last 6 to 8 years. … Based on observed sport fishing activity in the Sandy, we believe that spawning took place from the mouth up to RM 2.5.

Williams (2009) also reported on the onetime observation by an ODFW stream surveyor in February 1991 of eulachon in Conyers Creek, a tributary of the Clatskanie River, which is in turn a tributary of the lower Columbia River on the Oregon side of the river. The stream surveyor reported that eulachon were seen holding in pools within the lower 0.8 km (0.5 mile) of Conyers Creek during a daytime flood tide, but none were observed in the main stem of the Clatskanie River.

WDFW and ODFW (2008, p. 4) indicated that eulachon "used [Grays River] more frequently than commercial landings would suggest." Furthermore, Anderson (2009, his Table 1, p. 2) stated that the normal extent of eulachon spawning on the Grays River extended to the "covered bridge (RKM 17.4)."

Smith and Saalfeld (1955, p. 22) reported that:

> The lowest suitable spawning ground on the Cowlitz is located just below Kelso and the upper limit of spawning was noted in 1946, when smelt eggs were found in river bottom samples taken upstream almost to the mouth of the Toutle River, 20 river miles [32.2 km] from the Columbia.

In describing the principle spawning reaches of eulachon in the Cowlitz River, WDFW and ODFW (2008, p. 4) stated that eulachon:

> typically move upstream about 16 miles [25.7 km] (Castle Rock/Toutle River mouth area), often up to 34 miles [54.7 km] (Toledo area), and on occasion up to 50 miles [80.5 km] upstream (Cowlitz Salmon Hatchery barrier dam). … Upstream movement during the past 15 years or so has apparently been limited to the Castle Rock/Toutle River mouth area.

Stockley (1981, p. 1) indicated that eulachon "have been known to ascend the Toutle River [tributary of the Cowlitz River] occasionally," particularly before the 1980 eruption of Mount St. Helens (WDFW and ODFW 2008). Anderson (2009, p. 3) stated that:

> Adult eulachon were observed to enter the Toutle River prior to the eruption of Mount St. Helens. … Though the Washington Department of Fish and Wildlife (WDFW) has no reports of eulachon using the Toutle River since the eruption … WDFW considers the Toutle River as potential primary habitat due to its past use and vicinity to primary Cowlitz River spawning grounds.

WDFW and ODFW (2008, p. 4) indicated that eulachon "used [the Kalama River] more frequently than commercial landings would suggest." In addition, Anderson (2009, his Table 1, p. 2) said that the normal extent of eulachon spawning on the Kalama River extended "downstream of Modrow Bridge (RKM 4.5)."

Anderson (2009, his Table 1, p. 2) indicated that the normal extent of eulachon spawning on the Lewis River extended to the "upper end of Eagle Island (RKM 18.8)." WDFW and ODFW (2008, p. 4) stated that eulachon:

> typically move upstream about 10 miles [on the Lewis River] but on occasion upstream 19.5 miles [31.4 km] to Ariel [aka Merwin] Dam. … Biologists believed that a natural sediment blockage prevented upstream movement past river mile 7

> [11.3 km] for a number of years, from 1977 until the mid-1980s. Spawning eulachon have since been observed upstream of river mile 7 [11.3 km].

Anderson (2009, p. 2) noted that “eulachon spawn within the main stem of the Columbia River, but spawning ground locations are not well known.” Smith and Saalfeld (1955) reported that spawned out and partially spawned out eulachon captured near Eagle Cliff on the main stem of the Columbia River identified this area as a eulachon spawning ground. Howell et al. (2001, p. 12) also noted that Eagle Cliff at RKM 82 “on the Washington shore [is] historically recognized as a major mainstem eulachon spawning area” and that “spawning in the main stem of the Columbia River has never been recorded upstream of Martin’s Bluff” at RKM 117. Romano et el. (2002) collected eulachon eggs between RKM 56 and RKM 118 on the Washington side of the main stem of the Columbia River; however, mapping the extent of spawning on the main stem will require much additional sampling (Anderson 2009). Anderson (2009, p. 3) noted that:

> In years of very high eulachon abundance, spawning has been observed in the main stem of the Columbia River upstream of RKM 137 as eulachon travel to the Lewis and Sandy rivers and as far as Bonneville Dam on rare occasion. Primary spawning habitat could, therefore, extend from the estuary upstream to at least as far as the Sandy River (RKM 193).

The earliest mention of eulachon in the Columbia River occurs in the journals of members of the Lewis and Clark Expedition during February and March 1806 (Gass 1807, Moulton 1990, Moring 1996) (Appendix C). Throughout the 1810s–1820s, the journals of several fur trappers and explorers (e.g., Gabriel Franchère [Franchère 1967, 1968, 1969], Robert Stuart [Rollins (ed.) 1995], Wilson Price Hunt [Rollins (ed.) 1995], Alexander Henry [Gough (ed.) 1992], and Alexander Ross [Ross 1849]) describe the appearance of large eulachon runs in the lower Columbia River and their importance to the local Native American tribes (Appendix C).

Subsequently, several contemporary references (Suckley 1860, Lord 1866, Anderson 1872, 1877, Crawford 1878, Huntington 1963) (Appendix C) indicate a major decline in Columbia River eulachon abundance occurred between the mid to late 1830s and mid to late 1860s. Similarly, several secondary references (Summers 1982, Urrutia 1998, Hinrichsen 1998, Martin 2008, 2009) cite additional sources that indicate eulachon were at low levels of abundance prior to about 1867, when eulachon were once again seen in large numbers. Anderson (1872, footnote on p. 30–31) (Appendix C) stated that eulachon:

> were formerly very abundant in spring on the lower Columbia; but suddenly, about the year 1835, they ceased to appear, and thence-forward up at least to 1858, none frequented the river. I have been informed, however, that they have since reappeared, and that there is now a regular supply as formerly.

Subsequently, Anderson (1877, p. 345) (Appendix C) said:

> Formerly resorting in enormous shoals to the estuary of the Columbia River, [eulachon] disappeared suddenly about the year 1837, and continued to absent itself for many years, until recently, when it suddenly reappeared in shoals as numerous as of yore.

Similarly, Lord (1866, p. 96) (see Appendix C) observed that:

> Some 50 years ago, vast shoals of eulachon used regularly to enter the Columbia; but the silent stroke of the Indian paddle has now given place to the splashing wheels of great steamers, and the Indian and the candle-fish have vanished together.

An early settler on the Cowlitz River, Edwin Huntington (Huntington 1963, p. 5) (Appendix C), recalled that:

> Not within the memory of the oldest white inhabitant had there been any smelt in the Cowlitz River until some time in the early sixties. I am not certain what year I first saw them, but there was a heavy run and nobody paid much attention to them—not even the Indians. … After the second or third year of their return, people began to sit up and take notice. In 1865, a young lady school teacher, Miss Baker (afterward my wife) having learned how to make hair nets, conceived the idea of making dip nets in which to catch them and soon everybody had nets and were catching them by the ton and shipping them to Portland. The Indians had a tradition that there had been smelt here many many years before, but to punish them for some offense the Sahely Tyee had taken them away and it must have been a good many years as the oldest of them did not seem to know much about tradition.

Summers (1982, p. 31) in a local history of the town of Kelso, Washington, at the confluence of the Cowlitz and Columbia rivers, related that:

> The earliest record of a smelt run was found in a 1867 diary written by W. A. L. McCorkle, a settler at Lexington. He tells of small silvery fish coming into the Cowlitz during that year and that no smelt had been observed by Americans earlier than that. Settlers came beginning 1850. Of course, the Cowlitz Indians and other tribes had caught smelt in the Cowlitz many years before the Americans came.

However, a memoir written by Peter W. Crawford (Crawford 1878, p. 369) indicates that early settlers were aware of "small numbers" of eulachon on the Cowlitz River, and that large runs were noted, after an absence of 17 years, in the spring of 1865. Crawford (1878, p. 369) (Appendix C) stated that:

> In Feby and March 1865 there appeared a strange little fish unknown to the early settlers of Cowlitz or lower Columbia River. Although the Indians declared that those little finny swarming beings of the deep had frequented the waters of the Cowlitz River before but had absented themselves for 17 years, during which period no Indian had seen a school. … The early settlers on the lower Cowlitz remember having a few such little fellows in small numbers.

Hinrichsen (1998, p. 16) reported that "According to historian Duncan Stacey, Hudson's Bay Company documents describe very low returns in the Columbia River from about 1835 to 1865." However, examination of microfilmed records from the Hudson's Bay Company Archives (Fort Vancouver Report 1826–1845 [reel #1M783] and Fort Vancouver Post Journal

1825–1836 [reel # 1M148]) did not reveal any reference to eulachon or smelt in these records. Fort Vancouver was a Hudson's Bay Company post from 1825 to 1860 near the present location of Vancouver, Washington, on the lower Columbia River. Another early reference (Swan 1881, p. 258) mentions that "eulachon are found in limited numbers at certain seasons in the Columbia River."

A search of available online digital newspaper resources (listed in Appendix B) revealed mention of eulachon in the Columbia River or "smelt" as items for sale in local fish markets in the spring of 1867. A two sentence article in the Vancouver Register (Vancouver, Washington Territory) for 6 April 1867 (Appendix B) indicates that large numbers of "smelt" were present in the Columbia River off the city of Vancouver (at about RKM 170) at that time. This newspaper article said that previously "this … fish ... [had] never before been known to come up higher than Lewis River," which indicates that eulachon were known to occur in some numbers prior to 1867 in the Lewis River or in the Columbia River, downstream of the Lewis River.

Two advertisements of "smelt" for sale in Portland, Oregon, fish markets appeared in early newspapers, one in April 1867 and another in April 1868. Since April is near the tail end of the traditional period for eulachon run timing in the Columbia River, and other species of smelt are available at that time, it is uncertain whether these advertisements (Appendix B) refer to eulachon or some other species of smelt. An advertisement of eulachon for sale (referred to as Oak Point smelt) in a local fish market appeared on 15 January 1869 in the Daily Oregonian (Portland) (Appendix B). In later years the eulachon commercial fishery commonly operated in the vicinity of Oak Point on the Lower Columbia River indicating that this advertisement of "Oak Point smelt" likely refers to eulachon and not some other smelt species.

A newspaper article published in the Daily Oregonian on 13 March 1885 (Appendix B) reported that:

> a pioneer, who resided for many years on the lower Columbia, says that there were no smelt or oolachan, as they were called by Indians, in the Columbia from the time he came here till in 1863, when they appeared in vast numbers about the middle of February, and have been plentiful every season since. In Irving's "Astoria" mention is made of the great quantities of smelt in the Columbia in 1826. Shortly after they forsook the river entirely and did not return till 1863, having been absent nearly 40 years.

**Coastal Washington**

Outside of the Columbia River Basin, eulachon have been occasionally reported from other coastal Washington rivers. Swan (1881, p. 258) noted that "eulachon are found in limited numbers at certain seasons in … Shoalwater bay [Willapa Bay], Gray's Harbor, and at the mouth of various small streams of the coast." WDFW and ODFW (2001) stated that "Washington rivers outside the Columbia Basin where eulachon have been known to spawn include the Bear, Naselle, Nemah, Wynoochee, Quinault, [and] Queets … rivers." Willson et al. (2006) listed Willapa Bay (North, Naselle, Nemah, Bear, and Willapa rivers), Grays Harbor (Humptulips, Chehalis, Aberdeen, and Wynoochee rivers), and the Copalis, Moclips, Quinault, Queets, and Bogachiel rivers as supporting eulachon spawning runs.

Monaco et al. (1990) described eulachon as common in Willapa Bay based on a personal communication (Table A-2). Smith (1941) noted that:

> A small smelt run was noted in the north fork of the Nemah River on 7 February 1941. The fish ascended the Nemah River as far as the mouth of Williams Creek, which stream they entered for a distance of about 100 yards. … An old resident of the community reported that this was the first smelt run that had occurred during his 48 years in the section.

According to WDFHMD (1992), adult eulachon "were found in the Naselle and Bear rivers, tributaries of Willapa Bay (B. Dumbauld, WDF, pers. comm.)" in 1992. WDFW and ODFW (2001, p. 12) reported "that in 1993, when the eulachon run into the Columbia River was delayed (presumably due to cold water conditions), they were noted in large abundance in the Quinault and Wynoochee rivers, outside the Columbia Basin."

Monaco et al. (1990) described eulachon as "common" in Grays Harbor and, in addition to a personal communication, cited Deschamps et al. (1970) as a supporting reference (Table A-2). Deschamps et al. (1970, p. 16) reported the capture of a single adult eulachon in a seine catch in March 1966 and stated that "It is unlikely that the Chehalis system [which drains into Grays Harbor] has a run of any consequence, although strays or feeding fish from other areas probably visit the upper harbor at times." WDFW and ODFW (2001, p. 12) reported that eulachon "were noted in large abundance in the … Wynoochee" River, a tributary of the Chehalis River, in 1993. Simenstad et al. (2001) recorded eulachon as of "rare" occurrence in sloughs of the Chehalis River estuary in 1990 and 1995.

Willoughby (1889) and Olson (1936) record the Quinault Indian Tribe as taking eulachon in the lower Quinault River with dip nets. Olson (1936, p. 36) stated that:

> The people of the lower villages often came down to the river mouth to catch smelt (komólnil) and candlefish (páagwáls). Both were taken in the surf of the beach, though the candlefish often ascend the river for several miles. There was usually a big run every three or four years, when the water was literally filled with fish. The time of the run varied, usually occurring between January and April.

The Washington Department of Fisheries annual report for 1960 (Starlund 1960) and statistical report for 1970 (Ward et al. 1971) listed commercial eulachon landings in the Quinault River in 1936 (36,315 lb [16,507 kg]), 1940 (6,917 lb [3,144 kg]), 1953 (93,387 lb [42,449 kg]), 1958 (34,387 lb [15,630 kg]), 1960 (135 lb [61 kg]), and 1961 (1,051 lb [ 477 kg]). Fiedler (1939, p. 213) also records 36,300 lb (16,500 kg) of eulachon taken by dip net in the coastal district of Washington State in 1936. WDFW and ODFW (2001, p. 12) reported that eulachon "were noted in large abundance in the Quinault" River in 1993. Quotations from unattributed sources were presented in Workman (1997) that described eulachon occurring in and about the Quinault River in January 1936 and February 1993. NWIFC (1998, p. 11) reported that "candlefish, or Columbia River smelt, were caught in significant numbers at the mouth of the Queets River for the second time in 5 years in late January [1998]." A noticeable number of eulachon make an appearance in the Queets, Quinault, and occasionally, the Moclips rivers at 5–6 year intervals and were last observed in the Quinault River in the winter of 2004–2005.[2]

Shaffer et al. (2007) reported on the capture of 58 adult eulachon in the Elwha River on Washington's Olympic Peninsula (Figure 2) between March 18 and June 28, 2005. This was the first formal documentation of eulachon in the Elwha River, although anecdotal observations suggest that eulachon "were a regular, predictable feature in the Elwha until the mid 1970s" (Shaffer et al. 2007, p. 80). Other Olympic Peninsula rivers draining into the Strait of Juan de Fuca have been extensively surveyed over many years for salmonid migrations; however, eulachon have not been observed in any of these other systems (Shaffer et al. 2007).

## Puget Sound

Girard (1858) based his description of a new species *Thaleichthys stevensi* (later synonymized with *Salmo* [*Mallotus*] *pacificus* Richardson, 1836 as *T. pacificus* [Richardson, 1836] [McAllister, 1963]) on a single specimen collected in Puget Sound by George Suckley. The published figure (Girard 1858, his Plate LXXV, his Figure 1 through Figure 4) of this single specimen is detailed enough to be identifiable as a eulachon. Later, Suckley (1860, p. 348–349) in his Report Upon the Fishes Collected on the Survey (text republished in Suckley and Cooper 1860) stated that eulachon were "a very delicious fish, in some years coming in great shoals in the bays in the lower part of Puget Sound, and along the coast near the mouth of Frazer's River." Suckley (1860, p. 348–349) also stated that eulachon were "abundant in Puget Sound" and that "several eulachon in the recent state [dried] were obtained by me from different portions of the lower end of Puget Sound;" however, these specimens were lost when in transit to "Washington city" and their identification cannot be verified. Similarly, Lord (1866, p. 96), in his The Naturalist in Vancouver Island and British Columbia, stated that "the eulachon has also disappeared from Puget's Sound."

Curiously, although these early authorities (Girard 1858, Suckley 1860, Lord 1866) describe Pacific herring (*Clupea pallasii*) and eulachon as occurring in Puget Sound, they make no mention of surf smelt, longfin smelt (*Spirinchus thaleichthys*), or Pacific sand lance (*Ammodytes hexapterus*) in Puget Sound. Swan (1881, p. 258) also stated that eulachon were found "in limited numbers at certain seasons … in the waters of Puget Sound" and they are "found on Puget Sound occasionally with the sand-smelt *Hypomesus olidus*." Since *H. olidus*, or pond smelt, is a freshwater species, Swan may have meant to refer to the abundant surf smelt.

Jordan and Starks (1895, p. 793) also listed eulachon as "abundant in spring" in Puget Sound, although they did not obtain specimens themselves. They cite a local fisherman as reporting "that this species buries itself in the sand of the beach," which indicates that the fish referred to by the local fisherman were not eulachon, but were possibly either surf smelt or Pacific sand lance. Both surf smelt and Pacific sand lance are currently common in Puget Sound and spawn on Puget Sound beaches, and Pacific sand lance are locally known as "candlefish" (Penttila 2007). Therefore, there is substantial reason to believe that mention of abundant eulachon in Puget Sound in some nineteenth century references (Suckley 1860, Lord 1866,

[2] L. Gilbertson, Quinault Indian Nation, Taholah, WA. Pers. commun., 27 June 2008.

Jordan and Starks 1895) results from misidentification with either the common longfin smelt or surf smelt, neither of which were mentioned in Suckley (1860) or Lord (1866).

DeLacy et al. (1972) gathered available fish collection records for Puget Sound from academic and fisheries agencies sources and indicated that between 10 and 49 reports of eulachon exist in these records for the San Juan Islands. However, no more than 10 reports of eulachon specimens exist for each of the Juan de Fuca Strait, Everett, Seattle, central Puget Sound, and south Puget Sound regions (DeLacy et al. 1972). Monaco et al. (1990) described eulachon as rare in Puget Sound and, in addition to a personal communication, cited Miller and Borton (1980) as a supporting reference. Miller and Borton (1980) list five eulachon specimens collected in Puget Sound (one each in Port Susan, off Everett, and in Carr Sound, and two at Carkeek Park), which are deposited in the University of Washington Fish Collection, and seven eulachon specimens reported in the University of Washington Boat Log (one each at Golden Gardens, Port Madison, Herron Island, Penn Cove, and three in or near Carr Inlet). Currently, 12 specimens of eulachon collected in Puget Sound are deposited in the University of Washington Fish Collection (searchable database at http://www.washington.edu/burkemuseum/collections/ichthyology/index.php).

Miller and Borton (1980) also reported a personal communication dated 22 April 1976 from a biologist with the Puyallup Tribe indicating that eulachon "spawn in Wapato Creek, 1 mile upstream from the mouth of the Puyallup River." Fiedler (1941, p. 463) recorded 10,200 lb (4,636 kg) of eulachon landed in Puget Sound in 1938 in a commercial fishery using drag bag net gear. The precise location of this fish catch is not recorded (Fiedler 1941).

There are some records of transplant efforts to Puget Sound rivers from Columbia River source populations. An article in a Centralia, Washington, newspaper in 1932 (Centralia Daily Chronicle, 1 February 1932, p. 2, col. 8) (Appendix B) reported that:

> Another attempt will probably be made this year by the state fisheries department to transplant Columbia River smelt to streams flowing into Puget Sound. Attempts have been made in the past and a large number of smelt were planted in the Nisqually River several years ago. Floyd [Lloyd] Royal of the state biological department is making a study of the matter here, and it is probable that smelt spawn will be hatched in the state hatchery on the Kalama river and the young smelt planted in both the Snohomish and Skagit rivers if the attempt to hatch them proves successful.

Similarly, Wendler and Nye (1962, p. 9) stated that:

> A smelt transplant was initiated in 1959 from the Lewis River to the Puyallup River.... Approximately 4,500 fish were transplanted with an estimated egg potential of 40 million. This was considered a minimal number to plant for a species which requires mass spawning for successful reproduction. However, a measure of success may be seen if Columbia River smelt are present in the Puyallup during the spring of 1962.

A recent WDFW technical report entitled Marine Forage Fishes in Puget Sound (Penttila 2007, p. 19) presents detailed data on the biology, status, and trends of surf smelt and longfin smelt in Puget Sound, but states that "there is virtually no life history information within the

Puget Sound basin" available for eulachon. Similarly, detailed notes provided by WDFW and ODFW (2008) as part of this review, do not provide evidence of spawning stocks of eulachon in Puget Sound rivers. Interestingly, a newspaper account in The Daily Oregonian of Portland for 4 March 1876, cautions the public "against buying Puget Sound smelt [a likely reference to surf smelt] for Columbia River smelt [eulachon]" (Appendix B).

Monaco et al. (1990) described eulachon as rare in Skagit Bay and, in addition to a personal communication, cited Miller and Borton (1980) as a supporting reference (Table A-2). Miller and Borton (1980) report on a total of 20 eulachon specimens collected in the San Juan Islands, southern Strait of Georgia, and Strait of Juan de Fuca and recorded in boat logs and museum collection records; however, samples from Skagit Bay were not included in this list.

The Nooksack River has been frequently listed as supporting a run of eulachon (WDFW and ODFW 2001, Wydoski and Whitney 2003, Willson et al. 2006, Moody 2008); however, Anchor Environmental (2003, p. 27) stated that:

> Longfin smelt [*Spirinchus thaleichthys*] are also called "hooligans" and are sometimes mistaken for eulachon. Eulachon occurrence and spawning has not [been] documented in the Nooksack River.

The run of hooligans into the Nooksack River commonly occurs in November, which is outside of the normal spawn timing period for eulachon, and these fish have recently been positively identified as longfin smelt.[3]

**British Columbia**

Hay and McCarter (2000, their Table 1) listed a total of 33 eulachon spawning rivers in British Columbia; however, only about 14 of these river systems were thought to have regular yearly eulachon returns (Table A-1). These 14 river systems and the estuaries or inlets they are associated with from south to north are the Fraser River (Strait of Georgia), Klinaklini River (Knight Inlet), Kingcome River (Kingcome Inlet), Wannock River (Rivers Inlet), Chuckwalla/Kilbella rivers (Rivers Inlet), Kimsquit and Dean rivers (Dean Channel), Bella Coola River (Dean Channel), Kemano/Wahoo rivers (Gardner Canal), Kowesas River (Gardner Canal), Kitlope River (Gardner Canal), Kildala River (Douglas Channel), Kitimat River (Douglas Channel), Skeena River (Chatham Sound), and Nass River (Portland Inlet) (Hay and McCarter 2000, Hay 2002).

Many of these distributions were discovered or verified during a series of ichthyoplankton surveys of eulachon larvae on the mainland coast of British Columbia (McCarter and Hay 1999). These surveys "suggested the occurrence of eulachon spawning in … rivers not previously known to support eulachon spawning" (McCarter and Hay 1999, p. 8). In particular, small spawning runs of eulachon may be detected through ichthyoplankton surveys "that might be missed by conventional fishing techniques (gill nets or seine nets) on adults" (McCarter and Hay 2003, p. 17). Willson et al. (2006) and Moody (2008) recently listed numerous rivers in British Columbia thought to support eulachon runs and these distribution data, essentially the same as in Hay and McCarter (2000), are provided in Table A-1.

---

**Fraser River**—Early reference to eulachon being caught by First Nations groups on the Fraser River in 1827–1830 appear in the journals of the Hudson's Bay Company post Fort Langley, located on the south bank of the lower Fraser River near the Salmon River (MacLachlan 1998) (Appendix C). According to Swan (1881, p. 258) eulachon "taken in Fraser's River near the boundary line between Washington Territory and British Columbia are superior to those taken further south, and are sold in the Victoria market, where their excellence is highly prized."

Recent surveys of the Fraser River indicate that eulachon primarily spawn in the lower 50 km (Hay et al. 2002), although earlier studies reported spawning occurred at least up to RKM 100 (McHugh 1940), and perhaps as far upstream as Hope, more than 150 km from Vancouver, British Columbia (Moody 2008). McHugh (1940) surveyed eulachon egg distribution in the Fraser River using a bottom dredge and determined that spawning in 1940 occurred mainly between the towns of Mission and Chilliwack, over a distance of about 13 km. Samis (1977, p. 1) stated that "localized areas of spawning may occur in the north and south arms of the Fraser River, in the Pitt and Alouette rivers, and in other tributaries." However, similar to the findings of Hart and McHugh (1944), Samis (1977) found the highest concentration of eulachon eggs in the Fraser River in May 1976 to occur upstream of Mission, adjacent to Nicomen Island. Higgins et al. (1987, p. 2) noted that "potential [eulachon] spawning sites exist in the lower Fraser River adjacent to Barnston, McMillan, and Matsqui islands (Samis 1977), which are approximately 100 km, 130 km, and 175 km from the Fraser River mouth, respectively." Interannual variation in spawning locations in the Fraser River occur (Hay and McCarter 2000, Hay et al. 2002), with most spawning being above New Westminster in 1995, below New Westminster in 1996, and in the tributary Pitt River in 1999 (Hay and McCarter 2000).

**Other British Columbia rivers**—Outside of the Fraser River, only limited aspects of the biology of eulachon have been studied in other spawning rivers in British Columbia, including: the Kingcome (Berry and Jacob 1998), Wannock (Berry and Jacob 1998, Moody 2008), Bella Coola (Moody 2008), Kemano (Lewis et al. 2002, Ecometrix 2006), Kitimat (Pedersen et al. 1995, Kelson 1997, Ecometrix 2006), Skeena (Lewis, 1997, Stoffels 2001), and Nass (Langer et al. 1977) rivers.

Eulachon were normally located no further upstream in the Kemano River, British Columbia, than RKM 2.7, about 1.5 km above saltwater, although they have been rarely observed up to RKM 4.3 (Lewis et al. 2002). Eulachon spawning is limited to the lower 1.6 km of the nearby Wahoo River (Lewis et al. 2002). Stoffels (2001, p. 4) described areas of the lower mainstem Skeena River and several tributaries (Table A-1) and stated that:

> The eulachon spawn in the main stem Skeena, with high value spawning grounds around the lower Skeena River Islands and around the mouth of the Kwinitsa River (D. De Leeuw, WLAP, pers. comm.). Eulachon also spawn throughout the Ecstall River system, almost up to Johnston Lake and in the Khyex, the Scotia, the Khtada, Kasiks, Gitnadoix and other tributaries in the vicinity (Don Roberts, Terrace, pers. comm.).

Eulachon reportedly spawn upriver in the Nass River to about RM 32 (RKM 51.5), which is the near the limit of tidal influence (Langer et al. 1977).

Although eulachon are not thought to maintain populations in island rivers (Hay and McCarter 2000), anomalous spawning events have reportedly occurred in the Somass, Nimpkish (Hay and McCarter 2000), and Kokish rivers (Willson et al. 2006) on Vancouver Island, as well as in "unnamed rivers on Haida G'waii [Queen Charlotte Islands]" (Willson et al. 2006, p. 35).

**Alaska**

Moffitt et al. (2002) indicated that at least 35 rivers in Alaska have spawning runs of eulachon, including one in a glacial stream on Unimak Island, the first island in the Aleutian Island chain off the western end of the Alaska Peninsula. According to Moffitt et al. (2002, p. 3), "this is probably the only island in Alaska with a glacial river of the type similar to mainland systems used for spawning." Armstrong and Hermans (2007, p. 2) stated that "no eulachon runs in island rivers have been reported in Southeast [Alaska]." Aspects of the biology of eulachon have been studied in the following Alaska rivers: the Stikine (Franzel and Nelson 1981), Taku (Flory 2008b), Chilkoot (Betts 1994), Chilkat (Mills 1982, Betts 1994), Copper (Moffitt et al. 2002), Eyak, Alaganik (Moffitt et al. 2002, Joyce et al. 2004), Twentymile (Kubik and Wadman 1977, 1978, Spangler 2002, Spangler et al. 2003), and Susitna (Barrett et al. 1984, Vincent-Lang and Queral 1984).

Both Willson et al. (2006) and Moody (2008) listed numerous other Alaska rivers thought to support eulachon runs and these distribution data are provided in Table A-1. In some years, commercial harvests have occurred on eulachon in the Copper, Stikine, Unuk, Chickamin, and Bradfield rivers (Moffitt et al. 2002, Armstrong and Hermans 2007). Jordan and Gilbert (1899, p. 439) indicated that eulachon occurred in the "Nushagah [Nushagak] River" that flows into Alaska's Bristol Bay in the southeastern Bering Sea. Other more recent compilations also list the Nushagak River as supporting a run of eulachon (Mecklenburg et al. 2002, Willson et al. 2006). The Nushagak River is the northern most system reported to support a run of eulachon.

Larval plankton surveys suggest that the upstream limit of eulachon distribution in the Taku River occurs at about RKM 44 (Flory 2008b). During exceptionally large runs, eulachon have reportedly been seen "at Bull Slough, near the Tulsequah River in Canada" (Flory 2008b, p. 16). Tidal influence affects the Taku River up to about RKM 35 (Flory 2008b). Eulachon were observed from the mouth of the Susitna River up to about RKM 80 in 1982 and 1983, although the greatest concentration of spawning occurred within the lower 46.6 km of the main channel of the Susitna River (Barrett et al. 1984).

**Physical characteristics of spawning rivers**

Hay and McCarter (2000, p. 12) noted that some eulachon rivers are "large or turbid, with high sediment loads; others are small and clear." Despite these apparent differences, they recognized that "virtually all [eulachon rivers] have spring freshets, which are characteristic of rivers draining large snow packs or glaciers." Although this is true of most rivers supporting eulachon in British Columbia and Alaska (Hay et al. 2002), many eulachon rivers in the lower Columbia River basin and on the coasts of California, Oregon, and Washington are not fed by extensive snowmelt or glacial runoff. However, most systems that support eulachon and are not fed by snowmelt still possess extensive spring freshets. Hay and McCarter (2000, p. 12) suggested that the apparent requirement for snow pack or glacier-fed spring freshets may be the reason why "there are no known eulachon spawning rivers found on any large coastal islands, including Vancouver Island, Queen Charlotte Islands, Kodiak, or any of the small coastal islands in northern British Columbia or southeastern Alaska."

The lack of eulachon larvae in waters examined during ichthyoplankton surveys off Vancouver Island and the Queen Charlotte Islands in April and May (Hay and McCarter 1997) "reinforce the conclusion that eulachon spawning is mainly confined to coastal rivers that have a distinct spring freshet and drain major glaciers or snowpacks" (McCarter and Hay 2003, p. 16). Typically, eulachon spawn well before the spring freshet, near the seasonal flow minimum, especially on the mainland coast of British Columbia (Lewis et al. 2002); however, Fraser River eulachon appear to spawn during the height of the freshet (Stables et al. 2005). In many rivers, eulachon spawning appears to be timed so that egg hatching will coincide with peak spring river discharge (Flory 2008b).

## Marine Distribution

Although they spend 95–98% of their lives at sea (Hay and McCarter 2000), little is known concerning the saltwater existence of eulachon. They are reported to be present in the "food rich" and "echo scattering layer" of coastal waters (Barraclough 1964, p. 1,337), and "in near-benthic habitats in open marine waters" of the continental shelf between 20 and 150 m depth (Hay and McCarter 2000, p. 14). Hay and McCarter (2000, their Figure 5) illustrated the offshore distribution of eulachon in British Columbia as determined in research trawl surveys, which indicate that most eulachon were taken at around 100 m depth, although some were taken as deep as 500 m and some at less than 10 m. Schweigert et al. (2007, p. 11) stated that "the marine distribution of adults in British Columbia includes the deeper portions of the continental shelf around Dixon Entrance, Hecate Strait, Queen Charlotte Sound, and the west coast of Vancouver Island, generally at depths of 80–200 m." Mueter and Norcross (2002) reported eulachon were present in 32% of triennial bottom trawl surveys on the upper slope and continental slope in the Gulf of Alaska between 1984 and 1996 and were caught at depths down to 500 m in the Kodiak, Yakutat, and southeast areas of Alaska. Armstrong and Hermans (2007) indicated that eulachon are commonly caught in trawls in the coastal fjords of Southeast Alaska. Further information on eulachon distribution in research bottom trawl surveys is below and in Table A-4 and Table A-5.

Smith and Saalfeld (1955, p. 12) reported the occasional capture of eulachon in the offshore "otter trawl fishery," particularly in November to January near the mouth of the Columbia River "as the mature smelt approach the Columbia River." Emmett et al. (2001) reported the capture of small numbers of eulachon by nighttime surface trawls targeted on pelagic fishes off the Columbia River in April to July of 1998 and 1999. About 10% of hauls in 1999 contained from one to a maximum of eight eulachon (Emmett et al. 2001). Eulachon also occur as bycatch in some U.S.-based groundfish fisheries (Bellman et al. 2008) off the U.S. West Coast and more commonly in the California and Oregon ocean shrimp (*Pandalus jordani*) fisheries (NWFSC 2008). The Pacific Fishery Management Council has prohibited at-sea directed harvest of eulachon in U.S. West Coast waters and eulachon are not an actively managed or monitored species (PFMC 2008); therefore there is a paucity of data on at-sea distribution of eulachon off the U.S. West Coast.

## U.S. West Coast groundfish trawl surveys

Fishery-independent surveys conducted off the U.S. West Coast that provide data on distribution or abundance of eulachon in the ocean are very limited (Table A-4). The Northwest and Alaska Fisheries Center (NWAFC, before it split into NWFSC and AFSC) and AFSC conducted groundfish trawl surveys on the continental slope (at depths of 184–1,280 m) periodically from 1984 to 1987, and annually beginning in 1988. Continental shelf (at depths of 55–183 m) surveys were conducted triennially from 1977 to 2001 by the NWAFC and AFSC. The NWFSC assumed responsibility for the slope portion of the groundfish survey starting in 1998 and expanded the depth coverage to include the continental shelf as well as the continental slope in 2003. Many of these groundfish surveys report catch as occurring in one of five International North Pacific Fisheries Commission (INPFC) statistical areas. These INPFC areas from north to south are: 1) Vancouver (U.S.-Canada border to lat 47°30′N), 2) Columbia (lat 47°30′ to 43°00′N), 3) Eureka (lat 43°00′ to 40°30′N), 4) Monterey (lat 40°30′ to 36°00′N), and 5) Conception (lat 36°00′N to the U.S.-Mexico border) (Figure 4).

Eulachon were reported in the triennial groundfish bottom trawl surveys on the U.S. West Coast continental shelf in 1977 (Gabriel and Tyler 1980), 1980 (Coleman 1986), 1983 (Weinberg et al. 1984), 1986 (Coleman 1988), 1989 (Weinberg et al. 1994a, 1994b), 1992 (Zimmermann 1994, Zimmermann et al. 1994), 1995 (Wilkins 1998, Wilkins et al. 1998), 1998 (Shaw et al. 2000, Wilkins and Shaw 2000), and 2001 (Weinberg et al. 2002, Wilkins and Weinberg 2002) (Table A-4). These surveys targeted rockfish from 1977 to 1986, and were subsequently designed to estimate Pacific hake (*Merluccius productus*) and juvenile sablefish (*Anoplopoma fimbria*) abundance, as well as other commercially important groundfish (Weinberg et al. 1994a). However, these groundfish surveys were designed to sample bottom dwelling species and capture only a small and erratic portion of the pelagic distribution of eulachon.

The 1977 shelf groundfish survey recorded eulachon in six of nine assemblages off the Washington and Oregon coasts, being most abundant within the Nestucca Intermediate Assemblage (90–145 m) off Oregon (Gabriel and Tyler 1980). Trawl surveys in 1980–1986 occurred between Monterey Bay, California, and either Northern Vancouver Island (1980), Estevan Point, Vancouver Island (1983), or the U.S.-Canada border (1986) at depths of 55–366 m (Coleman 1986, 1988, Weinberg et al. 1984). From 1989 to 2001 triennial groundfish bottom trawl surveys covered all West Coast INPFC areas from Vancouver to Monterey, inclusive. In 1980 eulachon were recorded as the fifteenth most common fish encountered at depths of 55–183 m in the INPFC Eureka area, but were not recorded within the top 20 species encountered in the INPFC Vancouver, Columbia, or Monterey areas (Coleman 1986).

Latitudinal and longitudinal range and minimum, maximum, and mean depth distribution of eulachon captured in the triennial surveys from 1989 to 2001 are provided in Table A-4. Eulachon were found into the far south Monterey INPFC area in the 1989 survey but were not recorded in either the Monterey or Eureka INPFC areas in surveys conducted between 1992 and 2001. Mean depth of occurrence of eulachon in these surveys varied between 137 and 147 m, with minimum depths of 59–79 m and maximum depths of 322–466 m (Table A-4).

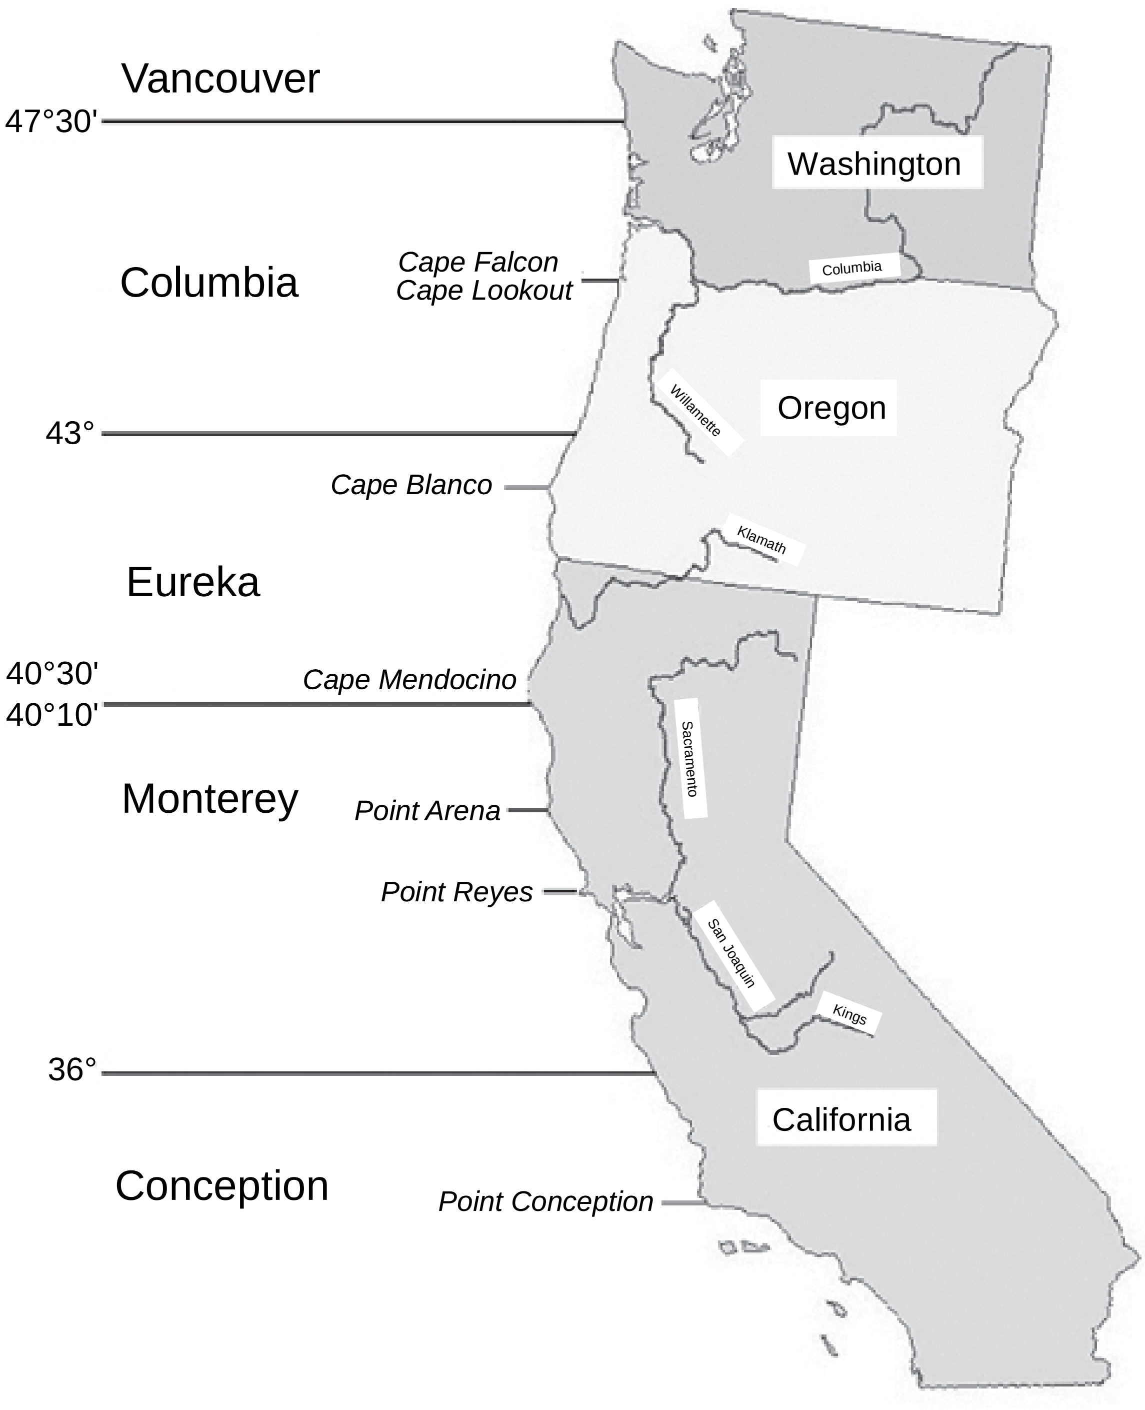

Figure 4. INPFC statistical areas off the U.S. West Coast. Modified from Pacific Fishery Management Council Web site at http://www.pcouncil.org/wp-content/uploads/georock.pdf.

Eulachon were occasionally sampled in West Coast upper continental slope groundfish trawl surveys conducted between 1984 and 1999 by the NWAFC and AFSC (Raymore and Weinberg 1990, Parks et al. 1993, Lauth et al. 1997, Lauth 1997a, 1997b, 1999, 2000) and between 1999 and 2002 by the NWFSC (Builder Ramsey et al. 2002, Keller et al. 2005, 2006a, 2006b). These surveys covered habitat between 183 and 1,280 m from the U.S.-Canada border to lat 30°30′N (Lauth et al. 1997, Lauth 1997a, 1997b, 1999, 2000, Keller et al. 2005, 2006a, 2006b), although annual surveys prior to 1997 covered only a portion of the area each year (Table A-4). This depth range is deeper than is preferred by eulachon (Hay and McCarter 2000), so these surveys likely missed the vast majority of eulachon, which occur on the continental shelf and not the slope.

Minimum, maximum, and mean depths of eulachon captured during the 1989–2002 survey years are given in Table A-4; however, eulachon were seldom encountered at these depths (below 183 m) and their reported occurrence in trawl hauls ranged from 6% of trawls conducted between 1989 and 1993 to fewer than 1% of all trawls in 2001. Presumably, eulachon were not encountered during the NWFSC 1999 bottom survey of the U.S. West Coast continental slope, as this species is not included in the comprehensive list of species encountered (Builder Ramsey et al. 2002). Eulachon were captured as deep as 608 m during the 2001 survey (Keller et al. 2005).

Starting in 2003, the NWFSC conducted combined slope and shelf surveys for groundfish between depths of 55 and 1,280 m (Keller et al. 2007a, 2007b, 2008) off the U.S. West Coast (Table A-4). Sampling in these slope and shelf surveys, in contrast to the NWAFC and AFSC triennial bottom trawl surveys (discussed above), did not extend into the Canadian portion of the Vancouver INPFC area where the triennial surveys had encountered the majority of eulachon. Currently, eulachon abundance in the Canadian portion of the Vancouver INPFC is tracked by the Department of Fisheries and Oceans Canada (DFO) during the annual surveys of shrimp biomass off the west coast of Vancouver Island (DFO 2008a). Eulachon were found at depth extremes of 51 to 237 m in the NWFSC surveys, with mean depths of 119 to 130 m during the three survey years (Table A-4) (Keller et al. 2007a, 2007b, 2008); however, eulachon biomass estimates were not presented in these survey documents. Some eulachon were found as far south as 34°N in the INPFC Conception area in 2003 and 2004 (Keller et al. 2007a, 2007b), a southern distribution that had not been recorded in groundfish surveys since 1989 (Weinberg et al. 1994a) (Table A-4). Pacific hake trawl surveys in U.S. and Canadian waters off the Pacific Coast have also reported incidental catch of eulachon (Fleischer et al. 2005, 2008), although details on catch location were not provided.

### Alaska trawl surveys

Latitudinal and longitudinal range and minimum, maximum, and mean depth distribution of eulachon captured in AFSC bottom trawl surveys in the Gulf of Alaska (triennially from 1984 to 1996, biennially from 1999 to 2007), Eastern Bering Sea (annually from 1982 to 2008), and Aleutian Islands (triennially from 1983 to 1997, biennially from 2000 to 2006) regions of Alaska are summarized in Table A-5. Eulachon are a common species in the Gulf of Alaska trawl surveys (Stark and Clausen 1995, Martin and Clausen 1995, von Szalay et al. 2008) and are particularly abundant in the Chirikof and Kodiak INPFC areas (von Szalay et al. 2008). In the

2007 trawl survey, eulachon were present in about 31% of the hauls under 300 m deep and 9% of hauls below that depth, although none were seen deeper than 700 m (von Szalay et al. 2008).

Eulachon distribution and abundance were also incidentally reported in two summer echo integration-trawl (EIT) surveys of prespawning walleye pollock (*Theragra chalcogramma*) on the Gulf of Alaska continental shelf in 2003 (Shumagin Islands to Prince William Sound) and 2005 (Islands of Four Mountains to south Prince William Sound) (Guttormsen and Yasenak 2007). Eulachon were the fourth and third most abundant species by numbers of fish caught in midwater trawls in the Gulf of Alaska in 2003 (10% of total) and 2005 (18% of total), respectively. Eulachon constituted 6.6% of the fish caught during EIT bottom trawls in 2003 in the Gulf of Alaska, but were not recorded in bottom trawls in 2005 (Guttormsen and Yasenak 2007).

Marine distribution maps of eulachon captured in AFSC research bottom trawl surveys of the Eastern Bering Sea continental shelf between 2001 and 2007 are provided in Nebenzahl (2001), Acuna et al. (2003), Acuna and Kotwicki (2004, 2006), Lauth and Acuna (2007a, 2007b), and Acuna and Lauth (2008). Abundance estimates for eulachon are not generally provided in these documents as they are "not adequately represented in the samples," which is "due to the bottom sampling nature of the survey" (Nebenzahl 2001, p. 27).

**Ichthyoplankton surveys**

Ichthyoplankton surveys in the northeastern Pacific Ocean commonly report the capture of osmerid larvae, but few studies have identified smelt larvae to the species level (Waldron 1972, Richardson and Pearcy 1977, Doyle et al. 2002, Auth and Brodeur 2006, Parnell et al. 2008). It is also possible that by the time eulachon reach the open ocean where these ichthyoplankton surveys occur, they may have grown sufficiently to be able to avoid capture in slowly towed, fine-mesh ichthyoplankton nets.

**Mixed stock genetic analysis**

Beacham et al. (2005) used variation at 14 microsatellite DNA loci to examine the stock composition of trawl and research surveys in marine areas off British Columbia. Using a genetic baseline data set of eulachon populations in eight rivers in Washington and British Columbia, they estimated the proportional composition of three marine-caught samples. A sample of 184 eulachon was collected during a shrimp research survey near Nootka Sound off the west coast of Vancouver Island in May of 2000. The largest proportions of fish were estimated to be from the Columbia River (56.6%, SD = 10.4) and Fraser River (37.5%, SD = 10.1). Populations in other rivers were estimated to contribute less than 6% to the sample. A sample of 100 eulachon sampled as bycatch in a shrimp trawl fishery near Chatham Sound (off British Columbia's north coast) in March 2001 was estimated to be largely fish from the British Columbia central mainland (51.6%, SD = 13.8) and from the Nass River (37.4%, SD = 10.9). Columbia (1.7%, SD = 2.4) and Fraser (2.1%, SD = 3.6) rivers contributed a small fraction to the sample. A third sample of 200 fish taken in research shrimp surveys in Queen Charlotte Sound in March 2001 was comprised of substantial proportions of Columbia, Fraser, British Columbia central mainland, and Skeena rivers, all contributing between 22.1% (SD = 5.9) and 27.1% (SD = 6.9).

Beacham et al. (2005) concluded that although eulachon marine migrations are largely unknown, there is spatial structure to the distributions of fish from different rivers. Their data indicate that Queen Charlotte Sound is an area inhabited by eulachon from very diverse origins including fish from nearby rivers as well as from more northern and southern sources. Analysis of samples in the south (off Vancouver Island) were dominated by Columbia River and Fraser River fish, whereas eulachon in the most northern marine region sampled, Chatham Sound, were largely from British Columbia coastal rivers north of the Fraser River.

# Life History Stages

### Eggs

Eulachon eggs from the Columbia River are reported to be approximately 1 mm in diameter (Parente and Snyder 1970, WDFW and ODFW 2001). In the Fraser River, eggs have been variously reported to "have an average diameter between 0.03 and 0.04 inches [0.76–1.02 mm] after preservation in formalin" (Hart and McHugh 1944, p. 9), to measure " less than 1.0 mm diameter" (Hay and McCarter 2000, p. 18), or to be "small (≈0.8 mm)" (Hay et al. 2002, p. 20). According to Garrison and Miller (1982, p. 119), "the eggs show considerable irregularity in shape and have numerous oil globules in the yolk." This irregularity in shape likely refers to unfertilized eggs.

Mature eggs are reported to have an outer sticky membrane that turns inside out after the broadcast spawned eggs are fertilized and remains attached to the egg by a short stalk, which serves to adhere the egg to particles of sand or other substrates (McHugh 1940, Hart and McHugh 1944, Smith and Saalfeld 1955, Hay and McCarter 2000). Hay et al. (2002, p. 18) speculated that as eulachon eggs may attach to small sediment particles and appear to develop while being actively carried downstream by river currents that "the mobile incubation (or 'tumble' incubation) may even have a selective advantage because it may spread the eggs over a broad space, thereby reducing predation and optimizing environmental conditions."

Pedersen et al. (1995) found no significant relationship between egg weight and female body length in the Kitimat River, British Columbia. Eggs weighed 0.26–0.58 mg with a mean and standard error of 0.43 ± 0.01 mg (n = 58) (Pedersen et al. 1995). Similarly, Hay and McCarter (2000) reported eggs from the Fraser River to weigh 0.36–0.68 mg (0.51 ± 0.01 mg, n = 106) in 1995 and 0.30–0.68 mg (0.44 ± 0.01 mg, n = 100) in 1996 in the Fraser River. Mean eulachon egg weight in the Kemano River, British Columbia, was estimated at 0.43 mg (± 0.16 SD, n = 429) (Lewis et al. 2002).

Smith and Saalfeld (1955) reported that eulachon eggs from the Columbia River required 388, 378, and 370 daily cumulative degree Fahrenheit days (equivalent to 198, 192, and 188 degree Celsius days) to hatch in the Naselle River Hatchery, Kalama River Hatchery, and the University of Washington School of Fisheries hatchery, respectively. In hatchery conditions, Smith and Saalfeld (1955) reported eggs taken from the Cowlitz River hatched in 19 days at temperatures that varied from 9.4 to 12.7ºC. These data led Smith and Saalfeld (1955) to estimate that eulachon eggs would hatch in 30–40 days, given the usual water temperatures in February and March in the Cowlitz River. Assuming similar thermal requirements for incubation, Langer et al. (1977) estimated that it would take 30–40 days for eulachon eggs to hatch in the Nass River, British Columbia. Artificially spawned and incubated eulachon eggs from the Cowlitz River hatched in 21–25 days when reared at 6.5–9.0ºC (Parente and Snyder 1970). Berry and Jacob (1998 p. 4) reported the incubation period in the Kingcome River in Kingcome Inlet, British Columbia "to be approximately 21 days." Flory (2008b, p. 3) cited a personal communication indicating that the incubation period for eulachon in Southeast Alaska ranges from four to six weeks, longer than the typical three to five weeks common in more southern regions.

Lewis et al. (2002) estimated that the number of accumulated thermal units (ATUs, one ATU equal to one degree Celsius for one day) between the peak of adult spawning and larval migration for eulachon in the Kemano River, British Columbia, in 1990 to be 204 degree-days based on daily recorded temperatures. In 1997 the number of ATUs to reach 50% larval hatch were estimated to be 340 in the Kemano River and 235 in the nearby Wahoo River (Lewis et al. 2002). Duration of egg incubation in the Kemano River was calculated at 50 days (Lewis et al. 2002). Similarly, 51% of eulachon larvae hatched in the Kitimat River, British Columbia, in 1993 after accumulating 258 ATUs and 87% of hatch occurred at an estimated 307 ATUs (Pedersen et al. 1995). The shortest duration of incubation of eulachon eggs from deposition to hatch was 35–39 days, the earlier time period equating to approximately 168 ATUs (Pedersen et al. 1995).

In the Twentymile River in Southcentral Alaska, incubation was estimated during three time periods at 47–50 days, which equated to between 294 and 321 ATUs, based on calculations using mean daily water temperatures (Spangler 2002, Spangler et al. 2003). Moody (2008, p. 3) reported that earlier studies had found eulachon eggs from the Bella Coola River hatched in 54 days at about 6ºC, equivalent to about 340 ATUs. Howell (2001) reported that 400ºC ATUs (752ºF ATUs) were accumulated prior to hatching, after a minimum of 47 days, by eulachon eggs stripped from Cowlitz River broodstock and incubated at a constant temperature of 48ºC under artificial hatchery conditions. The anomalously high number of ATUs required for hatching in this experiment may have been an artifact of the experimental conditions (Howell 2001).

Pedersen et al. (1995) postulated that incubation requirements may vary with latitude, and Spangler (2002) and Spangler et al. (2003) noted that, in general, the number of ATUs required for eulachon egg incubation appears to increase with increasing latitude.

Parente and Snyder (1970) provide the only published observations on eulachon embryonic development, which is typical of teleost fishes. In laboratory conditions at temperatures ranging from 6.5°C to 9°C; a blastodisc appears at 3 hours after fertilization, cleavage is occurring by 30 hours, invagination of the gastrula is in process at 60 hours, and the head and auditory capsule are apparent at 120 hours. At 300 hours (12–13 days) a weak heart beat is present, which is stronger by 400 hours. By this time the yolk sac is about one-half its original size. The active embryo begins hatching at about 500 hours (20–21 days) and all eggs under observation hatched within 5 days of each other (Parente and Snyder 1970).

## Larvae

Newly hatched larvae are transparent, slender, and about 4–8 mm in length in the Columbia River (Parente and Snyder 1970, WDFW and ODFW 2001), 4.0–6.5 mm in the Fraser River (Hay et al. 2002), and 4–6 mm in the Kemano River (Lewis et al. 2002). Eulachon larvae are reported to be feeble swimmers and are rapidly carried downstream to estuarine portions of rivers and inlets within hours or days of hatching (McHugh 1940, Hart and McHugh 1944, Smith and Saalfeld 1955, Parente and Snyder 1970, Samis 1977, Howell 2001). In the Columbia River, larval eulachon are usually located near the bottom during their downstream migration (Smith and Saalfeld 1955, Howell et al. 2001). Larval nutrition is provided by the yolk sac prior to first feeding (WDFW and ODFW 2001). Spangler et al. (2003) detected higher levels of downstream drifting larval eulachon during low light intensity periods at night than during the day in the Twentymile River, Alaska. Care must be taken in many parts of the range that larval eulachon in rivers are not confused with superficially similar cottid (sculpin) larvae (Kelson 1997, Flory 2008b).

Ichthyoplankton surveys indicate that larval eulachon may be retained for weeks or months in estuaries (McCarter and Hay 1999, 2003), especially in inlets or fjords on the British Columbia mainland coast (McCarter and Hay 2003). These surveys also indicate that eulachon larvae are mostly present in the top 15 m of the water column, with few larvae occurring below 20 m (McCarter and Hay 1999, Hay and McCarter 2000). Hay and McCarter (2000, p. 19) showed that newly hatched larvae were about 3.6–8 mm in length and that in mainland inlets on the British Columbia coast “mean eulachon larval size (mm) generally increased at each sampling station in a seaward direction away from eulachon spawning rivers.” Although larvae disperse seaward from their spawning rivers, they also “appear to be retained in inlets” and fjords to some degree on the British Columbia coast (Hay and McCarter 2000, p. 21). Ichthyoplankton surveys also showed that larvae were smaller in shallow water than those captured in deeper depths (McCarter and Hay 1999, Hay and McCarter 2000). During the period from April to August, larval eulachon on the central British Columbia coast were estimated to grow from an initial size of 3–4 mm to 30–35 mm in length (McCarter and Hay 1999, 2003).

Robinson et al. (1968b, their Table I) determined that almost all eulachon larvae in the Strait of Georgia, off the Fraser River during daylight on 6 June 1967, were distributed in the top 6.5 m of the water column, with the greatest density (50–150 larvae/$m^3$) occurring between 1.7 and 3.5 m depth. McCarter and Hay (1999) found that eulachon larvae (mostly ≤15 mm in length) in mainland inlets on the central coast of British Columbia were mainly found within the top 15 m of the water column during springtime plankton tows and suggested that larval densities were greater near the surface at night than during daytime tows.

## Juveniles

Information on the distribution and ecology of juvenile eulachon is scanty, owing to these fish being too small to occur in most fisheries and too large to occur in ichthyoplankton surveys (Hay and McCarter 2000). Eulachon that range 30–100 mm in length, exhibit schooling behavior, and have developed pigmentation and lateral scales are generally classified as juveniles (Hay and McCarter 2000). Barraclough (1964) sampled juvenile eulachon in the Strait of Georgia in winter and spring with midwater trawls and shrimp trawls and indicated that Fraser

River eulachon may spend their first year of life in the Strait of Georgia; however, observer data indicate that virtually no eulachon were caught as bycatch in the late 1990s in the Strait of Georgia shrimp fishery (Hay et al. 1999a). A larger mesh size is used in commercial shrimp trawls, compared to the mesh size used in Barraclough's (1964) studies (Hay and McCarter 2000), suggesting that juvenile eulachon may be present in coastal waters but are difficult to detect without a directed effort. Hay and McCarter (2000, p. 22) reported that "it seems that … [juveniles] disperse to open, marine waters within the first year of life and perhaps within the first few months."

## Adults and Spawners

### Age composition

The two common methods of estimating age in eulachon, either through counting rings on scales or on otoliths, have not been validated for any population of eulachon (Ricker et al. 1954, DeLacy and Batts 1963, Higgins et al. 1987, Hay and McCarter 2000, Moffitt et al. 2002, Clarke et al. 2007). Age as determined from scales is typically one to three years less than age determined from otolith increments (Ricker et al. 1954, Langer et al. 1977, Higgins et al. 1987). Several early studies expressed doubt as to the reliability of using otolith rings to determine eulachon age (Smith and Saalfeld 1955, DeLacy and Batts 1963). Consequently, the determination of age from scales and otoliths are not considered reliable methods by many researchers (Ricker et al. 1954, Hay and McCarter 2000, Hay et al. 2003, Clarke et al. 2007). Clarke et al. (2007, p. 1,480) noted that many dark bands or pseudo-annuli are present in whole and polished otoliths "that have been interpreted as winter growth zones in past ageing attempts" and that "sectioned otoliths viewed under transmitted light can reveal fewer zones," indicating some of the problems with this ageing methodology.

In some cases "there is no corresponding increase in size (length or weight) with putative [increase in] age" (Hay and McCarter 2000, p. 15). Higgins et al. (1987) also reported overlap in fork lengths (FL) between putative age classes of eulachon. However, in the Twentymile River, Alaska, eulachon body length has been shown to increase with age in both males and females, as expected (Spangler 2002). Beamish and McFarlane (1983) highlighted the importance of proving that a technique for ageing a species is accurate (age validation). Age validation "requires either a mark-recapture study or the identification of known-age fish in the population" (Beamish and McFarlane 1983, p. 741). It is important to point out that age validation is different than determining the precision of an ageing technique by assessing the level of agreement among several age readers. Despite the acknowledged problems with age determination in eulachon, numerous studies have reported age composition of spawning populations of eulachon based on examination of growth increments on either scales or otoliths and these data are presented in Table A-6.

Although age determination of eulachon is admittedly difficult and uncertain, adult spawners are variously reported to be 3–4 years old (Smith and Saalfeld 1955) or 3–5 years old (WDFW and ODFW 2001) in the Columbia River; 2–3 years old (McHugh 1939, Ricker et al. 1954) or mostly 3 years old, with some 2-, 4-, and 5-year-olds in the Fraser River (Hay et al. 2005); and mostly age 3 (Hay and McCarter 2000, Hay 2002) or 2–5 years old (Schweigert et al. 2007) in British Columbia. The majority of adult eulachon on the Columbia River are reported to return at age 3, although some are purported to be up to 9 years old (WDFW and ODFW 2001). Wydoski and Whitney (2003, p. 106) also stated that some eulachon "may live for 9 years;" however, these age estimates are based on the unvalidated otolith methodology.

Clarke et al. (2007) examined seasonal changes in trace elements incorporated into otoliths to estimate age structure of eulachon populations in the Columbia, Fraser, Kemano, Skeena, and Copper rivers. It has been shown that barium (Ba) and calcium (Ca) are incorporated into the aragonitic matrix of fish otoliths in proportion to their concentration in the environment (Bath et al. 2000). Barium concentrations are normally about three times greater in deep ocean waters than in surface waters; however, for about 3 months during the summer, wind-driven upwelling of deep barium-rich waters occurs off the west coast of North America and "these upwelling events should therefore impart a seasonal barium peak … in … [eulachon] otoliths" (Clarke et al. 2007, p. 1,481). As expected, Clarke et al. (2007) found that eulachon otoliths had low Ba:Ca levels in the outer region of the otolith in February and March and high levels in the summer. Clarke et al. (2007, p. 1,488) used laser-ablation inductively coupled plasma mass spectrometry to reconstruct the Ba:Ca profile of eulachon otoliths and stated that:

> a single age class of fish was observed to spawn in the systems examined in this study. Only 3-year-old eulachon were observed from the spawning populations in the Fraser and Kemano rivers, and the majority of fish for the Columbia, Skeena, and Copper rivers were also composed of a single age class; 2-, 3- and 4-year-olds from the Columbia, Skeena, and Copper rivers, respectively.

These data suggest that populations to the south spawn at an earlier age than more northern populations. Clarke et al. (2007, p. 1,489) concluded that "seasonal fluctuations in Ba:Ca observed in this study suggests that, to date, many eulachon have been aged incorrectly" and that "Ba:Ca variations appear to match expected annual shifts in ambient chemistry and so offer a more reliable annual marker for ageing."

Analyses of size frequencies have also been used to estimate age of at-sea (Ricker et al. 1954, Barraclough 1964, Hay and McCarter 2000, Hay et al. 2003, Clarke et al. 2007) and in-river (McHugh 1939) eulachon. These methods have identified age 1+ and age 2+ eulachon in the ocean (Barraclough 1964, Hay et al. 2003) and indicate that "the largest size mode [in the ocean] corresponds to the size modes observed in spawning rivers" (Hay et al. 2003, p. 5). Size frequency analysis indicates that most eulachon in British Columbia are spawning at age 3 (Hay and McCarter 2000).

**Body size**

Eulachon are reportedly the largest species of smelt in the family Osmeridae on the west coast of North America (Scott and Crossman 1973). Published reports of maximum eulachon body length of 305 mm (Clemens and Wilby 1967, Miller and Lea 1972) are likely in error (Miller and Lea 1976, Mecklenburg et al. 2002). Specimens of 254 mm (Miller and Lea 1976, Mecklenburg et al. 2002) from the Bering Sea represent the maximum known length for eulachon. Mean lengths of male and female eulachon in the Twentymile and Susitna rivers of Southcentral Alaska are greater than 200 mm FL (Table A-7), much larger than mean lengths in rivers further south (Spangler 2002, Spangler et al. 2003). These authors also noted that the mean weight of eulachon in the Susitna and Twentymile rivers was greater than in eulachon spawning in more southern rivers (Spangler 2002, Spangler et al. 2003) (Table A-8).

Moffitt et al. (2002) found mean length of male eulachon on the Copper River to be significantly longer than females in all years analyzed from 1998 to 2002. There were also significant differences in length among years for both male and female eulachon from the Copper River. Male eulachon were also found to be significantly longer and heavier than female eulachon in the Twentymile River, Alaska, in 2000 and 2001 (Spangler 2002, Spangler et al. 2003). Male eulachon were significantly larger than females in the Kemano River, British Columbia, and both sexes were significantly longer than eulachon in the nearby Wahoo River (Lewis et al. 2002).

Length of pelvic and pectoral fins of female eulachon from the Fraser River were both 14.3% of the standard body length, compared to 17.6% for pelvic fins and 15.8% for pectoral fins in male eulachon (McHugh 1939, Hart and McHugh 1944). By comparison, Langer et al. (1977) found that lengths of pelvic and pectoral fins of female eulachon in the Nass River were 11.1% and 11.8% of the standard body length, compared to 13.4% for pelvic fins and 12.7% for pectoral fins in male eulachon. Both sexes of eulachon in the Nass River apparently possess "relatively smaller fins than do Fraser fish" (Langer et al. 1977, p. 33). Craig (1947, p. 3) stated that among Columbia River tributaries:

> fishermen consistently claim to find larger smelt in the runs comprising the Lewis and Sandy river populations than those in the Cowlitz River stocks. Such size variation has been statistically proven sound in 1946 when large samples of fish were measured from both the Cowlitz and Sandy rivers.

Clarke et al. (2007, p. 1,484) found significant differences in length and weight of eulachon from five river systems (Columbia, Fraser, Kemano, Skeena, and Copper) and found a trend towards larger fish in more northerly populations "and the largest fish were from Alaska and northern British Columbia." Clarke et al. (2007) suggested that eulachon likely spawn after reaching a minimum fork length of 160 mm and a body weight greater than 30 g and that these size thresholds are obtained at an earlier age in southern latitudes and later in the far north. Available data on eulachon body length and weight from throughout the species' range are compiled in Table A-7 and Table A-8, respectively.

### Vertebrae meristics

Hart and McHugh (1944) and DeLacy and Batts (1963) attempted to identify stocks of eulachon based on differences in the number of vertebrae present in adult fish on the spawning grounds. Hart and McHugh (1944, p. 6) counted vertebrae, which varied from 65 to 72 per fish, in eulachon samples from the Nass River, Rivers Inlet, Knight and Kingcome inlets, and Fraser River and found:

> the Fraser river run to differ in average vertebral number from the runs to the more northern parts of the province.… This indicates that mixing between the runs to the Fraser and more northerly rivers cannot be extensive because, if it were, any differences in vertebral count would soon be eliminated.

Similarly, DeLacy and Batts (1963, p. 33) counted vertebrae, which also varied from 65 to 72 per fish, in eulachon samples taken between 1953 and 1962 in the lower Columbia River and its tributaries and reported that "an indication of heterogeneity was found among eight collections of smelt made in 1956 from the Cowlitz, Kalama, and Sandy rivers." Based on these data, DeLacy and Batts (1963, p. 33) stated that their study found "scant evidence of heterogeneity in the total Columbia River smelt population;" however, "there is enough suggestion of heterogeneity to justify further exploration of the possibility that smelt do move to the spawning grounds in some nonrandom fashion."

### Sexual dimorphism

There are a number of morphological differences between male and female eulachon at maturity. Mean length is in general longer in males than in females (McHugh 1939, Higgins et al. 1987, Lewis et al. 2002, Spangler 2002, Spangler et al. 2003, Cambria Gordon 2006). Although age-2 males were statistically greater in length than the same age females on the Nass River in 1971, length of age-3 through age-5 fish did not vary between the sexes (Langer et al. 1977). Mean weight of males was statistically greater than that of females in the Twentymile River, Alaska, in 2000 and 2001 (Spangler 2002, Spangler et al. 2003) and in the Kemano River, British Columbia, from 1988 to 1998 (Lewis et al. 2002). However, mean lengths and weights of male and female eulachon in the Fraser River from 1995 to 2001 as reported by Hay et al. (2002, their Table 3) did not show consistent differences between the sexes. McHugh (1939) was also unable to detect significant difference in size between males and female eulachon from the Fraser River.

Males differ from females in having numerous tubercles on the body, head, and fins, and particularly along the lateral line (McHugh 1939, Hart and McHugh 1944, McAllister 1963, McPhail and Lindsey 1970, Spangler et al. 2003). In males, "the muscles of the body wall have undergone considerable development, so that the body wall is considerably thicker, and the whole fish is more firm and rigid than the female" (McHugh 1939, p. 21). Females are smoother in appearance with far fewer tubercles and do not possess the mass of muscle along the lateral line (McAllister 1963, Spangler et al. 2003). The pelvic fins are also larger at the base and longer in male compared to female eulachon; the ends of the pelvic fins often reach as far posterior as the level of the anus in males, but are much shorter in females (McHugh 1939, Hart and McHugh 1944, McAllister 1963, McPhail and Lindsey 1970, Spangler et al. 2003, Cambria Gordon 2006). Hart and McHugh (1944, p. 4) reported that female eulachon have a more tapered form than male eulachon. Spangler (2002) found females retained teeth to a greater degree (84.0–96.9%) than did males (3.4–32.4%) in the Twentymile River, Alaska.

### Proximate analysis

The very high fat content of eulachon led many Native American tribal groups in Southeast Alaska and First Nations in British Columbia, especially to the north of the Fraser River, to render the fat of the eulachon into oil or "grease" (Kuhnlein et al. 1982, Hay and McCarter 2000). Several early studies investigated the chemical characteristics of eulachon oil with regard to its nutritional qualities (Brocklesby and Denstedt 1933, Brocklesby 1941, Bailey et al. 1952). However, Clark and Clough (1926, p. 505) were the first to publish on the proximate composition of eulachon flesh and they reported that a single sample of the edible portion of fresh eulachon from the Columbia River contained 11.2% fat, 13.2% protein, and 1.4% ash. Although Clark and Clough (1926) studied the composition of Columbia River eulachon, these results were subsequently republished in Babcock (1927) as typical for British Columbia. Stansby (1976) found the mean (and range) of percent moisture, oil, protein, and ash in the raw muscle of 16 eulachon specimens from the Columbia River to be 79.6% (76.5–81.3), 6.3% (4.6–9.0), 14.6% (13.2–15.3), and 1.3% (1.1–1.4), respectively. Stansby's (1976) data were also reported in Sidwell (1981).

Whole unprocessed eulachon sampled in Knights Inlet on the British Columbia coast contained 16.7% fat and 72.3% moisture (Kuhnlein et al. 1996). Mean percent values for eulachon caught at sea in the Gulf of Alaska were 18.8% oil (as total lipid), 11.9% protein, 1.6% ash, and 68.1% moisture (Payne et al. 1999). Similar mean values for sea-caught eulachon in the eastern Bering Sea were 19.9% oil (as total lipid), 12.5% protein, 1.5% ash, and 66.7% moisture (Payne et al. 1999). Of 14 species of forage fish in the Gulf of Alaska and Bering Sea, eulachon had the highest oil content (16.8–21.4%) and the lowest moisture content (64.6–70.8%) (Payne et al. 1997, 1999). No significant differences in composition of eulachon were seen between the Gulf of Alaska and the Bering Sea when fish of a common size range collected in the same season of the year were compared (Payne et al. 1999).

In the Gulf of Alaska, eulachon were found to have the lowest mean moisture content (64%), lowest mean ash content as a percentage of dry mass (4%), highest dry mass energy value (7.7 kcal/g), and highest wet mass energy value (2.6 kcal/g) among 18 fish and 5 squid species analyzed (Perez 1994). These energetic values were obtained using bomb calorimetry (Perez 1994). Payne et al. (1999) derived a mean value for eulachon wet mass energy of 2.47 kcal/g derived from calculations of caloric content using energy coefficients for protein and oil from Gulf of Alaska eulachon. These eulachon energy values were the highest in relation to moisture content of the 13 forage fish analyzed (Payne et al. 1999). Similarly, Anthony et al. (2000) reported that eulachon had the highest mean lipid content (50% of dry mass) among 39 forage fish species analyzed in the Gulf of Alaska. Eulachon also had a much higher water content as a percent of wet mass (71%) than would be expected given its high lipid content (Anthony et al. 2000). A sample of 34 eulachon (141–202 mm standard length [SL]) also had the second highest mean energy density, after northern lampfish (*Stenobrachius leucopsarus*): 6.5 kcal/g (27.2 kJ/g) dry mass or 1.8 kcal/g (7.49 kJ/g) wet mass (Anthony et al. 2000).

Iverson et al. (2002) examined fat content and fatty acid composition in 26 species of fish and invertebrates in Prince William Sound, Alaska. Fat content of 20 eulachon samples taken in spring were uniformly the highest in fat content and ranged 15–25% fat with a mean value of 19% fat (Iverson et al. 2002). The next highest fat content was found in adult herring, which ranged 7–20% fat with a mean value of 14% fat (Iverson et al. 2002). Eulachon possessed unique fatty acid signatures that "differed most from all other finfish, cephalopod, or crustacean species studied" (Iverson et al. 2002, p. 177). Eulachon in Prince William Sound had "extremely high levels of 18:1n-9, moderately high levels of 14:0 and 16:1n-7, and extremely low levels of polyunsaturated fatty acids such as 20:5n-3 and 22:6n-3" (Iverson et al. 2002, p. 177). The dietary source of this unique fatty acid signature in eulachon is currently unknown (Iverson et al. 2002).

The apparent differences in fat content between eulachon samples in the Columbia River (6.3% fat; Stansby 1976), Knight Inlet on the British Columbia coast (16.7% fat, Kuhnlein et al. 1996), and in the Gulf of Alaska (19% fat, Payne et al. 1999, Iverson et al. 2002) likely had a significant impact on American Indian and First Nations uses for these fish. MacLachlan (1998, p. 183) stated that:

> On the northern coast, eulachon were a major source of oil, but on the Fraser, as on the Columbia, they were eaten fresh or smoked whole. A difference in oil content may have been the basis of this difference in use.

# Reproduction and Development

### Sex Ratio

Many studies have reported that sex ratios in eulachon are either biased in favor of males (Smith and Saalfeld 1955, Kubik and Wadman 1977, 1978, Franzel and Nelson 1981, Higgins et al. 1987, Lewis 1997, Lewis et al. 2002, Moffitt et al. 2002, Spangler 2002, Spangler et al. 2003) or are highly variable depending on time and location of sampling (McHugh 1939, Hart and McHugh 1944, Langer et al. 1977, Pedersen et al. 1995). On the other hand, Hay and McCarter (2000) and Hay et al. (2002) report that the ratio of spawning male to female eulachon in their gill net samples from the Fraser River in 1995–2002 was approximately 1 to 1, with the exception of 1998 when the sex ratio was 1.7 to 1.

All reports of eulachon sex ratio should be viewed with caution, as proportions of male to female eulachon have been reported to vary with fishing gear type, distance upriver, distance from the river shoreline, time of the day, and migration time (McHugh 1939, Langer et al. 1977, Moffit et al. 2002, Lewis et al. 2002, Spangler 2002, Spangler et al. 2003). Langer et al. (1977, p. 33) reported that "sex ratios varied with location, within the duration of the run, and between years in the Nass River." Lewis (1997) suggested that sex ratios skewed in favor of males may be due to longer residence time of male eulachon in freshwater compared to females. Moffit et al. (2002) postulated that as spawning commences, females may avoid the riverbank and disperse to the center of the river, thus skewing sex ratios calculated from dip net sampling along riverbanks. Spangler (2002) and Spangler et al. (2003) reported that sampling with different gear types (gill nets versus dip nets) resulted in different sex ratios in the Twentymile River, Alaska. However, Franzel and Nelson (1981) reported that fishing gear did not significantly change the sex ratio of eulachon captured in the Stikine River, Alaska.

Mc Hugh (1939) and Hart and McHugh (1944) reported that the sex ratio varied during the fishing season in 1939 and 1941 in the Fraser River; males predominated in the early part of the eulachon run, but in the latter part females came to predominate. A similar situation may obtain in the Columbia River basin, where WDFW and ODFW (2001, p. 15) stated that analysis of sex ratios indicated that "female return timing is skewed later than that of males," although females never appear to dominate. Pedersen et al. (1995, p. 16) reported that earlier studies in the Nass River had found "a changing sex ratio during the spawning season," whereas another study based on daily monitoring had found 55% males and 45% females. Lewis et al. (2002) also reported changing sex ratios over the duration of the eulachon run in the Kemano River, British Columbia; however, there appeared to be two pulses of female returns, and males rather than females appeared to dominate the later part of the run. The proportion of males was also found to increase as the run progressed in 1971 on the Nass River (Langer et al. 1977) and at Flag Point Channel on the Copper River in 1998 and 2000–2002 (Moffit et al. 2002).

The overall sex ratio reported by Smith and Saalfeld (1955) for the Columbia River basin was 4.5 males to 1 female. Similarly, Higgins et al. (1987) and Rogers et al. (1990) found a sex ratio of 3.4 males to 1 female in Fraser River samples collected in April 1986 and Rogers et al. (1990) reported the ratio to be 5.9 to 1 in 1988. Sex ratios in the early 1930s in Cowlitz River dip net, Lewis River dip net, and Columbia River gill net samples were 3.2 to 1, 12.3 to 1, and 6.8 to 1, respectively (Smith and Saalfeld 1955). In 1946 sex ratios in commercial fisheries were 10.5 to 1 in the Cowlitz River and 2.8 to 1 in the Sandy River, which may reflect the bias in the fishery for the more marketable male eulachon (Smith and Saalfeld 1955). Since males dominate the early part of the run in the Columbia River, they are more prevalent in both the sport and commercial fisheries, which preferentially target the first fish to return (WDFW and ODFW 2001).

Sex ratio of male to female eulachon in the Kemano River, British Columbia, ranged from 1.1 to 1 to 10.7 to 1 with a mean of 4.4 to 1 between 1989 and 1997; however, when weighted by fish abundance over the duration of the run, the true sex ratio was estimated at 1.6 to 1 (Lewis et al. 2002, p. 72). Males predominated in upriver locations in both 1970 and 1971 in the Nass River (Langer et al. 1977). However, in the Fraser River the proportion of male to female eulachon was independent of the distance of upriver capture (along a 31 km gradient) among April 1986 (Higgins et al. 1987, Rogers et al. 1990) and April/May 1988 (Rogers et al. 1990) samples.

Franzel and Nelson (1981) found that gill net–sampled eulachon in the Stikine River, Alaska, over two years had a sex ratio of males to females of 17.5 to 1. Eulachon sex ratios on the Copper River, Alaska, and nearby systems were also dominated by males in all samples (Moffitt et al. 2002). The percentages of males at Flag Point Channel on the Copper River in 1998, 2000, 2001, and 2002 were 78%, 60%, 72%, and 69%, respectively. At 60-km Channel on the Copper River in 2002, males represented 61%–85% of the captured eulachon (Moffit et al. 2002). On the Copper River delta, the percentages of males in 1998 and 2000 were 91% and 66%, respectively, in Alaganik Slough and ranged from 82% to 98% in January to February 2001 in Ibeck Creek (Moffit et al. 2002). Eulachon collected in Twentymile River, Alaska, from May 15 to June 2, 1976, and from April 29 to June 5, 1977, had a cumulative sex ratio of 5 males to 1 female (n = 204) (Kubik and Wadman 1977) and 7.4 males to 1 female (n = 408) (Kubik and Wadman 1978), respectively. Sampling by dip net in the Twentymile River resulted in male to female ratios of 6.7 to 1 in 2000 (n = 394) and 2.1 to 1 in 2001 (n = 2,711) (Spangler 2002, Spangler et al. 2003). Barrett et al. (1984) reported average male to female sex ratios of prespawning eulachon of 1.6 to 1 in late May 1982, 1.3 to 1 in early June 1982, 1.2 to 1 in mid-May 1983, and 0.6 to 1 in mid-May and early June 1983. Spawning and postspawning ratios were higher due to the shorter stream residence time of female eulachon (Barrett et al. 1984).

Smith and Saalfeld (1955, p. 22) first hypothesized “that the type of spawning of smelt may necessitate an excess of males.” Moffitt et al. (2002, p. 26) postulated that in the case of eulachon, which broadcast-spawn eggs and sperm in fast moving rivers, “a large number of males upstream may increase the probability of egg fertilization.” Spangler et al. (2003, p. 46) also postulated that a sex ratio skewed in favor of males "may be a key element to successful spawning" and that "fertilization would increase with more available milt in the water increasing the probability of eggs being fertilized." Hay and McCarter (2000, p. 23) stated that spawning involves groups of fish and eulachons must closely synchronize the timing of spawning between sexes, because the duration of sperm viability in freshwater is short, perhaps only minutes. Interestingly, Langer et al. (1977, p. 32) reported on a second-hand observation of spawning in eulachon, suggesting that a group of males simultaneously released milt upstream of a group of females that laid their eggs as the milt drifted over the downstream female eulachon. Lewis et al. (2002, p. 83) observed spawning eulachon in the Kemano River, British Columbia and reported that:

> At night in the riffles, males lay next the females, beside them and on top of them. We observed small puffs of milt and eggs drifting in the water. We interpret this behaviour as egg laying behaviour because we had not seen it during the day and because we examined rocks at the site during daylight hours … and discovered eggs adhering to the rocks.

### Fecundity

Hart and McHugh (1944) noted that fecundity in the Fraser River ranged about 17,300–39,600 eggs in female eulachon measuring 145–188 mm SL. Average fecundity was about 25,000 eggs per female (Hart and McHugh 1944, Hart 1973). Smith and Saalfeld (1955, p. 22) report a fecundity of 20,000–60,000 for female eulachon ranging 140–195 mm length from the Columbia River. Both Clemens and Wilby (1967) and McPhail and Lindsey (1970) report fecundity to be about 25,000 eggs in an average size female. Hay and McCarter (2000) reported total fecundity range of 20,000–40,000 eggs, the number generally increasing with fish size. Depending on fish size, fecundity can range 7,000–31,000 eggs on the Columbia River (Parente and Snyder 1970, WDFW and ODFW 2001).

Mean total fecundity in Fraser River eulachon ranged from a low of about 31,200 to a high of about 34,100 when estimated between 1995 and 1998 (Hay et al. 2002). Mean relative fecundity (total fecundity divided by female body weight) of Fraser River eulachon ranged from a low of 683 eggs/g in 1995 to a high of 898 eggs/g in 1997 (Hay et al. 2002). There are significant differences in fecundity among years in Fraser River eulachon, which are likely related to "significant interannual differences in mean size (length and weight)" (Hay et al. 2002, p. 11).

Mean fecundity of 58 eulachon from the Kitimat River, British Columbia, in 1993 was about 22,900 eggs with a range of 3,242 to 47,798 (Pedersen et al. 1995). Relative fecundity in the Kitimat River was calculated at 504 eggs/g female body weight (Pedersen et al. 1995). Based on 5 years of data, mean eulachon fecundity in Kemano River, British Columbia, was about 27,000 and ranged 6,744–57,260 eggs. Mean relative fecundity of Kemano River eulachon over this 5-year data set was 544 eggs/g female body weight (Lewis et al. 2002).

Mean fecundity of eulachon in the Copper River, Alaska, was estimated at about 35,520 (range: 12,202–52,722) in 2000 and 36,200 (range: 18,645–62,855) in 2001 (Moffitt et al. 2002). From these data, Moffitt et al. (2002) estimated relative fecundity of eulachon from the Copper River in 2000 and 2001 as 790 and 792 eggs/g female body weight, respectively. Fecundity in the Twentymile River, Alaska, ranged from as low as 8,530 to as high as 67,510 and reportedly increased with increasing length, weight, and age (as determined by otolith increment analysis) (Spangler 2002, Spangler et al. 2003).

### Homing

Smith and Saalfeld (1955, p. 12) examined migration behavior of eulachon in the Columbia River and its tributaries and stated that:

> The so-called "homing instinct," influencing fish to return as adults to the stream in which they were hatched, has not been established for smelt. … The irregularity of the runs into the various tributaries virtually precludes the existence of a home tributary influence.

McCarter and Hay (1999) and Hay and McCarter (2000) argue that both the short time eulachon larvae spend in the natal freshwater environment and their small size would preclude their ability to imprint on a spawning river. Eulachon larvae are very small, 4–6 mm in length, weigh only a few mg at hatching, and are flushed into the estuarine environment almost as soon as they rise into the water column. Hay and McCarter (2000, p. 13) noted that eulachon larvae are so small that they "may lack the necessary physiological tissue (i.e., olfactory rosette and associated nervous system memory capacity)" to imprint on the freshwater natal spawning river. However, eulachon larvae may spend weeks to months in nearby estuarine environments where they grow significantly in size and may develop the capacity to imprint on large estuaries and eventually home to these areas as adults (McCarter and Hay 1999, Hay and McCarter 2000). These considerations would suggest that large river estuaries, inlets, and fjords may serve as the smallest stock structure unit for eulachon (McCarter and Hay 1999, 2003, Hay and McCarter 2000, Hay 2002, Hay and Beacham 2005).

### Spawn Timing

McCarter and Hay (1999, p. 12) emphasized that:

> Based on concepts developed from observation of spawning of Pacific salmon, the timing of [eulachon] spawning runs should be biologically adapted to each river. If so, and if the same model is applied to eulachons, then each population would be adapted to each river.

However, several authors emphasize that there is no clear latitudinal (Hay and McCarter 2000, Cambria Gordon 2006) or other pattern (Hay et al. 2002) apparent in eulachon spawn timing (Table A-9, Figure 5). Over the whole range of eulachon from northern California to the southeastern Bering Sea, Hay and McCarter (2000, p. 17) noted that:

> the most southern runs (i.e., the California and the Columbia River runs) are early, beginning in late January, whereas some of the Alaska runs are much later (May), although not too dissimilar to [eulachon in] the Fraser [River, which run in April through May].

However, eulachon have been known to spawn as early as January in rivers on the Copper River delta of Alaska (Moffitt et al. 2002), as late as May in northern California, and from January to April in various subbasins of the Columbia River (Table A-9, Figure 5, and Figure 6). Analysis

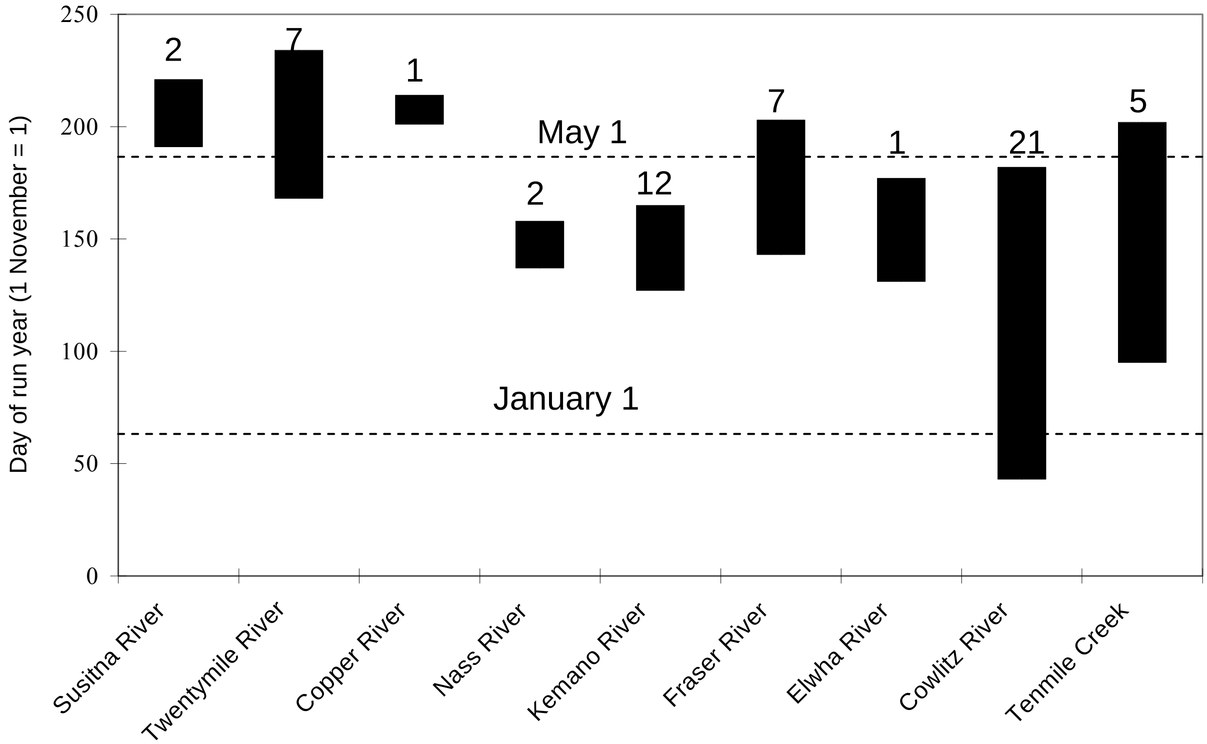

Figure 5. Duration of reported eulachon spawn timing in various river systems arranged north to south from left to right on the x-axis. Dates of spawn timing have been converted relative to the day of the run year beginning on November 1. Numbers above plots indicate the total years of data available for each system. Data from Barrett et al. (1984, reported in Spangler et al. 2003), ADFG (1972, 1973, 1974, reported in Spangler et al. 2003), Kubik and Waldman (1977, 1978), Spangler (2002), Spangler et al. (2003), Morstad (1998, reported in Spangler et al. 2003), Langer et al. (1977), Lewis et al. (2002), Hay et al. (2003), Shaffer et al. (2007), B. James,[4] and WDFW and ODFW (2008).

of spawn timing as a stock identifier in eulachon is also complicated by observed variation in the duration of spawn timing from year to year, the presence of multiple spawning runs in some rivers, and observations of eulachon returning earlier in recent years in some systems relative to historical data (Moody 2008).

## California

Historically, eulachon runs in northern California were said to start as early as December and January and peak in abundance during March and April (Table A-9). Larson and Belchik (1998, p. 5) reported that:

> The timing of the Klamath, Redwood Creek, and Mad River spawning migrations were similar to the Columbia's runs, which usually begin in December and January (S. King, ODFW, pers. comm.). The Klamath run continued until around May with peak occurrence between March and April.

[4] B. James, WDFW, Vancouver, WA. Pers. commun., 12 May 2008.

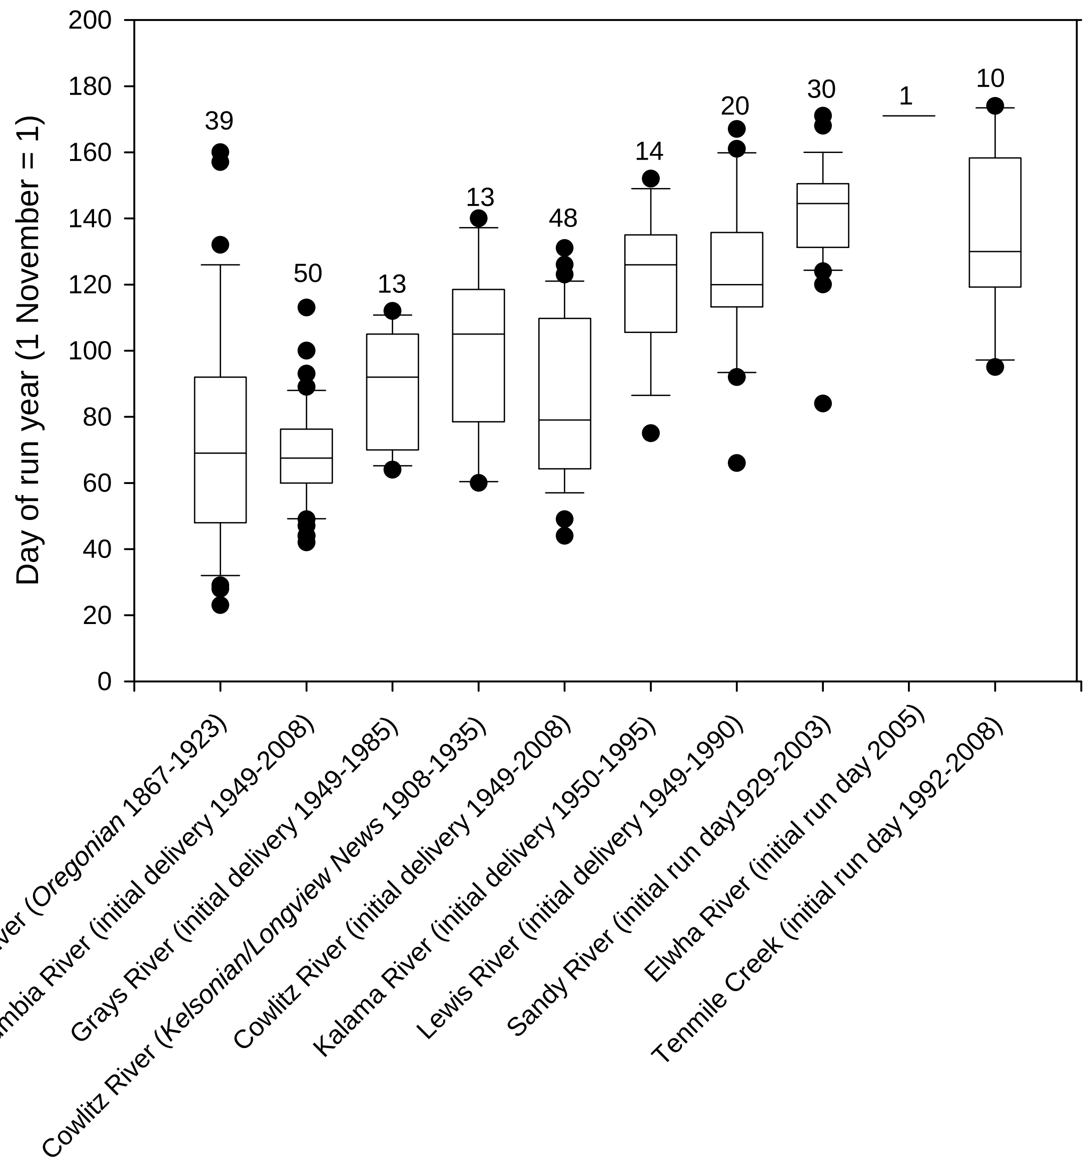

Figure 6. Box plots of the initial day of river entry in various river systems as reported in local newspapers (Appendix B and Smith et al. 1953), commercial fishery deliveries (B. James[5]), Shaffer et al. (2007), and WDFW and ODFW (2008). Dates of initial river entry or fishery delivery have been converted to the day of the run year beginning on November 1. Numbers above plots indicate the total years of data available for each data set.

Similarly, Young (1984) reported on the collection or observation of adult eulachon in the Klamath River and Redwood Creek in April 1978 and in the Klamath River in March and April in both 1979 and 1980. Young (1984, p. 62) further stated that eulachon begin their migration in the Klamath River "in January in small numbers well before the main spawning runs (more than one may occur) in March and April, and then continuing on a smaller scale."

[5] See footnote 4.

**Columbia River and tributaries**

Smith and Saalfeld (1955, p. 24) noted that eulachon "may be found in the Columbia River between late December and mid-May." Howell and Uusitalo (2000, p. 3) documented that historically eulachon migration into the Columbia River "begins in December, peaks in February, and continues through May." Bargmann et al. (2005, p. 22) stated that "peak [eulachon] abundance [in the Columbia River] is usually in February, but may be as late as April."

Initial arrival of eulachon in the Columbia River and its tributaries can be estimated from historical landings data in the commercial fishery (WDFW,[6] Howell and Uusitalo 2000) (Figure 6). Documented eulachon landings in the Columbia River have occurred as early as December 13 and as late as February 21 with an average date of around January 8 for the years 1949 to 2008, based on data supplied by WDFW.[7] Based on newspaper accounts of eulachon in the fish markets of Portland, Oregon, from 1867 to 1923 (Appendix B), the earliest date of appearance of eulachon in the Portland markets was November 23 and the mean date of initial appearance was February 12 (Figure 6).

Similarly, documented eulachon landings in the Cowlitz River have occurred as early as December 13 and as late as March 11 with an average date of around January 25 for the years 1949 to 2008, based on data supplied by WDFW.[8] Newspaper accounts of initial appearance of eulachon in the Cowlitz River between 1908 and 1935 were summarized in Smith et al. (1953) and give the earliest date of January 30. In the Grays River between 1949 and 1985, initial eulachon landings occurred as early as January 3 with an average initial date of February 20, based on data supplied by WDFW.[9] In the Kalama River between 1950 and 1995, initial eulachon landings occurred as early as January 14 with an average initial date of April 1, based on data supplied by WDFW.[10] In the Lewis River between 1949 and 1990, initial eulachon landings occurred as early as January 5 with an average initial date of April 16, based on data supplied by WDFW.[11]

WDFW and ODFW (2008) provided the initial arrival dates of eulachon in the Sandy River, Oregon, for the years 1929 to 2008, although no run was recorded in 48 of the 79 years. The earliest appearance of eulachon on the Sandy River occurred on January 23 (the next earliest being February 28) and the latest on April 21, with an average data of initial appearance of about March 21 (Figure 6). Craig (1947, p. 3) stated that eulachon "runs into the Sandy and Lewis rivers normally occur later than those in the Cowlitz." Smith and Saalfeld (1955, p. 13) also noted that "the Cowlitz fish [appear] in the early part of the season, and the Sandy fish nearly two months later." Comparison of average dates of initial landings in the commercial fishery in the Cowlitz River (January 25) and in the Sandy River (March 21) confirm that a nearly two-month period separates the average run timing in these two tributaries (Figure 6).

## British Columbia

On the mainland coast of British Columbia, earliest eulachon spawning occurs in the far north in February to early March in the Nass River, and the latest spawning occurs in April and May in the Fraser River in the far south (Table A-9, Figure 5). This pattern of spawn timing is reversed from the apparent overall range-wide pattern of eulachon spawning earlier in the south and later in the north (Hay and McCarter 2000). Early researchers variously stated that eulachon enter and spawn in rivers in British Columbia "from the middle of March to the middle of May" (Hart and McHugh 1944, p. 7) or "during March, April, and May" (Clemens and Wilby 1967, p. 123). Hart and McHugh (1944, p. 7) also affirmed that "The time of appearance is fairly constant from year to year in each locality and the runs are apparently of progressively shorter duration from south to north." Similarly, McCarter and Hay (2003, p. 16) noted that:

> In some rivers, such as the Kitimat or Kemano, the time of spawning is relatively early, beginning in early March and in others, such as the Fraser or Klinaklini, the timing is later, beginning in April or May.

**Fraser River**—The early journals of Fort Langley, a Hudson's Bay Company post on the lower Fraser River, indicate that eulachon were observed in the Fraser River on 28–29 April 1828, 14 April 1829, and 4 May 1830 (MacLachlan 1998) (Appendix C). McHugh (1939) suggested that the presence of spent fish in the catch indicated that spawning may occur throughout the two-month period from early April until late May in the Fraser River. Hart and McHugh (1944) sampled eulachon on the Fraser River 12 April–19 May 1939 and 4 April–8 May 1940. Ricker et al. (1954, p. 1) noted that historically the eulachon fishery operated in the Fraser River "between the middle of March and the middle of May, from the mouth of the river up to Mission and Matsqui." More recently, Hay et al. (2002, p. 20) stated that eulachon enter the Fraser River "in late March and April to spawn" and Stables et al. (2005) recorded the capture of eulachon by trawl net in late April and early May of both 2001 and 2002.

**Kitimat River**—In 1993 eulachon spawned in the lower 4 km of the Kitimat River March 20–30 (Pedersen et al. 1995). Peak spawning in 1997 occurred March 7–19 (Kelson 1997).

**Kemano River**—Lewis et al. (2002) reported that eulachon run timing in the Kemano River extended from late March to early April in 1980 and typically lasted from March 22 to April 10 between the years 1988 and 1998. Females entered the Kemano River in two distinct pulses separated in time by from several days up to 10 days (Lewis et al. 2002). Typically the run duration was about 15 days in the Kemano River, "ranging from 4 to 20 days" and "over the 11 year study [1988–1998] there was a trend for the eulachon run to begin and end earlier" perhaps in "response to changing sea temperatures" (Lewis et al. 2002, p. 68).

**Skeena River**—Adult eulachon were present in the Skeena River March 10–20, 1997 (Lewis 1997). Historically, the Skeena River eulachon run was reported to occur between early February and late March (Lewis 1997).

**Nass River**—Swan (1881) noted that two spawning runs of eulachon appear in the Nass River, one that normally begins between March 16 and 22, but sometimes occurs as late as March 28 to April 4, and a second run that enter the river towards the end of June. Langer et al.

(1977, p. 45) verified that eulachon typically enter the Nass River in mid-March, peaking in late March, and the run may extend into mid-April and may consist of "two overlapping spawning waves."

### Alaska

Moffitt et al. (2002, p. 3) stated that "eulachon enter river systems from January through early July" in Alaska. Eulachon typically spawn in early April in the Taku River in Southeast Alaska and may migrate beneath river ice to reach the spawning grounds (Flory 2008b). Franzel and Nelson (1981) reported that the eulachon run in the Stikine River, Alaska, in 1979 and 1980 occurred in early April soon after spring breakup and lasted for up to 3 to 4 weeks. Marston et al. (2002, p. 231) reported that eulachon spawning runs in 1995–1997 in the Antler and Berners rivers in Berners Bay in Southeast Alaska began between May 3–6 and lasted 10–12 days, "although spent fish or a few late spawners remained in the rivers until the end of May." More recently, eulachon have spawned in mid to late April in Berners Bay rivers (Flory 2008a), spawning 26 April–14 May 2004 in the Antler River in particular (Eller and Hillgruber 2005).

**Chilkat and Chilkoot rivers**—Krause (1885) indicated that two runs of eulachon occurred in the Chilkat River region of Southeast Alaska, a February run and a separate run in late April to mid-May. The later run was characterized as larger in both numbers and individual fish size (Krause 1885). Mills (1992, p. 8) stated that the main eulachon run occurred "between mid and late May" on the Chilkat River. Betts (1994, p. 19) reported that both the Chilkat and Chilkoot rivers supported two runs of eulachon, "a small run in February, and en masse most commonly in mid-May." Eulachon harvest on the Chilkat River occurred 1–7 May 1990 and 6–16 May 1991 (Betts 1994). On the nearby Chilkoot River, harvest occurred 6–9 May 1990 and 9–16 May 1991 (Betts 1994). Betts (1994) also reported that salmon fishwheels on the Chilkat River caught eulachon 7 May–17 June 1991. Eulachon reportedly spawn in several rivers in the Yakutat region of Alaska in March to early June (Rogers et al. 1980).

**Copper River delta**—Eulachon run timing in the Copper River, Alaska, and in nearby rivers of the Copper River delta is variable, and in many cases two runs separated by weeks to months have been observed in the same rivers (Moffitt et al. 2002, Joyce et al. 2004) (Table A-9). Eulachon were observed in the Eyak River on the western Copper River delta 16–23 June 2002, but did not appear in Ibeck Creek in 2002, a tributary of the Eyak (Joyce et al. 2004). In 2003 there were two separate eulachon runs observed in the Eyak River, February 15–22 and June 9–13. Eulachon were observed in the tributary Ibeck Creek 28 January–17 March 2001 (Moffitt et al. 2002) and 15 February–1 March 2003 (Joyce et al. 2004). On the central Copper River delta, eulachon were present in Alaganik Slough as early as 9 February 2001 (Moffitt et al. 2002), 9–16 June 2002, and during two periods in 2003, February 23–26 and May 29 to June 15 (Joyce et al. 2004). In the Copper River itself, eulachon were present as early as May 19 and as late as May 24 at Flag Point Channel between 1998 and 2002, and the duration of the run lasted 8–14 days (Moffitt et al. 2002). Eulachon were present at Flag Point 20 May–2 June 1998, 19–28 May 2000, 19–30 May 2001, 24 May–6 June and 16–24 June in 2002, and 1–5 March and 17–19 April 2003 (Joyce et al. 2004). Eulachon were also present at 37-mile Bridge on the Copper River 16–23 June 2003 (Joyce et al. 2004).

**Twentymile River**—The eulachon run in the Twentymile River "spanned a period of 25 days between May 13 and June 6" in 1976 (Kubik and Wadman 1977, p. 37) and "44 days from April 23 to June 5" in 1977 (Kubik and Wadman 1978, p. 54) (Table A-9). Spangler (2002) and Spangler et al. (2003) cited an additional 7 years of observations in the Twentymile River where the spawn period ranged 18–54 days. Eulachon were captured in the Twentymile River by dip nets 4 May–21 June and 17 April–9 June in 2000 and 2001 (Spangler 2002, Spangler et al. 2003). Spangler (2002, p. 27) stated that "the eulachon run lasts over a longer period of time in the Twentymile River than in any other river for which data are available." In contrast, other researchers have stated that the duration of eulachon spawning migrations decreases from south to north (Hart and McHugh 1944, Scott and Crossman 1973).

**Susitna River**—Based on the presence of adults, two runs of eulachon were observed on the Susitna River in Southcentral Alaska in 1982 (May 16–30 and June 1–8) and 1983 (May 10–17 and May 19 to June 8) (Barrett et al. 1984, Vincent-Lang and Queral 1984). Initial eulachon run timing likely precedes these early dates for the first run, as fish were present as soon as sampling was possible following ice breakup in both years (Vincent-Lang and Queral 1984). Actual spawning occurred on the Susitna River May 21–31 and June 4–9 in 1982, and May 15–22 and May 23 to June 5 in 1983 (Barrett et al. 1984).

### Multiple spawning runs

A number of rivers are reported to have two or even more separate spawning runs of eulachon, including the Chilkat River (Krause 1885, Betts 1994), Chilkoot River (Betts 1994), Copper River (Moffitt et al. 2002, Joyce et al. 2004), and Susitna River (Vincent-Lang and Queral 1984) in Alaska, and the Nass River (Swan 1881, Langer et al. 1977) and Kingcome River (Berry and Jacob 1998) in British Columbia. Based on adult run timing, Langer et al. (1977) suggested there could be up to three waves of spawning on the Nass River. Berry and Jacob (1998, p. 4) reported that there appeared to be four waves of eulachon spawning activity in the Kingcome River, British Columbia, in 1997, "with peaks on April 2, April 15, April 21, and May 2." There may also have been an earlier eulachon spawning event in March and a later one in early June in the Kingcome River (Berry and Jacob 1998), based on the presence of eggs and larvae; however, experience in other river systems raises the possibility that some of these eggs and larvae may have been confused with those of sculpins (cottids) (Kelson 1997). Indications of eulachon spawning in May and June, based on egg and larval presence, in the Kitimat (Pedersen et al. 1995), Skeena (Lewis 1997), and other rivers on the central and north coast of British Columbia are suspect, due to the presence of sculpin larvae in these rivers that may have been misidentified as eulachon larvae (Kelson 1997).

## Semelparity versus Iteroparity

Numerous references (McPhail and Lindsey 1970, Hart 1973, Scott and Crossman 1973, Samis 1977, Garrison and Miller 1982, Lewis et al. 2002) cite Barraclough (1964) as evidence that eulachon may be iteroparous. In fact, Barraclough (1964, p. 1,337) noted that the presence of dead eulachon found in the Columbia and Fraser rivers indicates many die after spawning. The evidence in Barraclough (1964, p. 1,337) that eulachon may be iteroparous occurs in the statement that: "spent eulachon in good condition caught by trawlers in the Strait of Georgia off the mouth of the Fraser River suggest that some eulachon recover after spawning, and may spawn a second time." However, it is uncertain whether the spent eulachon observed at the mouth of the Fraser River, as reported by Barraclough (1964), recovered and lived long enough to spawn in a subsequent season. Some additional secondary sources indicate that some eulachon are iteroparous (WDFW and ODFW 2001, Mecklenburg et al. 2002, LCFRB 2004b). According to WDFW and ODFW (2001, p. 4), "although adults can repeatedly spawn, most die after spawning." Mecklenburg et al. (2002, p. 175) stated that "most [eulachon] die after spawning, but some survive to spawn once more."

Earlier authorities (McHugh 1939, Hart and McHugh 1944, Clemens and Wilby 1946, Ricker et al. 1954, Smith and Saalfeld 1955) reported that eulachon were semelparous (spawn once in their lifetime and die soon after spawning). McHugh (1939) and Hart and McHugh (1944) noted that the outer edge of the scales in spawning eulachon in the Fraser River were resorbed and showed a characteristic clear margin. This region of the scale is commonly called a spawning mark or spawning check. However, these authors found no eulachon with a previous year's spawning check and "concluded that none of the fish examined had spawned in a previous year" (McHugh 1939, p. 21). Similarly, Langer et al. (1977, p. 39) stated that "since no spawning checks were noted on any scales from the Nass River, repeat spawning is probably minor or nonexistent on the Nass." Eulachon in the Kemano River also showed no evidence of spawning checks on the otoliths (Lewis et al. 2002). Smith and Saalfeld (1955, p. 25) reported that:

> All available evidence indicates that smelt die after one spawning. In all spawning studies where live smelt were allowed to spawn in the confines of [a] hatchery trough, death followed extrusion of the spawn. In addition, commercial fisherman, who fish in the Columbia River after the smelt run, report the tremendous abundance of dead smelt on the river bottom.

The evidence is strong that most, if not all, eulachon in the southern portion of the range (south of about 54°N latitude) are semelparous (Hay and McCarter 2000, Hay 2002, Hay et al. 2002, 2003), "although there may be some iteroparity (survive spawning) at higher latitudes, in Alaska" (Hay et al. 2003, p. 2). Hay et al. (2002, 2003) presented three lines of evidence for semelparity in eulachon from British Columbia: 1) direct observation of postspawning mortality in the form of beached and floating carcasses in many rivers, 2) only eulachon with well developed teeth are found at sea, whereas all spawning eulachon observed in the Fraser River have undergone substantial tooth loss and resorption, and 3) the largest size class of eulachon in British Columbia are found in rivers during the spawning runs and are much larger than any eulachon caught anywhere in the nearby ocean. However, retention of teeth in significant numbers of spawning eulachon in the Twentymile River, Alaska (Spangler 2002, Spangler et al. 2003), indicates that some of these fish may survive spawning, return to the sea, and begin feeding again. Teeth retention rates in spawning eulachon in the Twentymile River were 84% and 97% for females, and 3% and 32% for males in 2000 and 2001, respectively (Spangler 2002, Spangler et al. 2003).

Although age determination in eulachon has not been validated (see above discussion in the Age Composition subsection, p. 35), Lewis et al. (2002) examined age composition as estimated from otolith increments of prespawning eulachon captured in a fishery and postspawning carcasses on the Kemano River and reported that the carcass sample had:

> a greater proportion of fish age 5 years [than did the prespawning sample] (31% versus 21%) and a lower proportion age 3 (18% versus 41%) and 4 years (51% versus 38%). Based on these data, we reject the null hypothesis that Kemano River eulachon are semelparous.

However, Clarke et al. (2007) reported that the pattern of seasonal oscillations in barium and calcium deposited in eulachon otoliths (see discussion in Age Composition subsection on page 36) and the lack of a freshwater strontium signal in otoliths of spawners indicate that eulachon are semelparous. Comparison of length frequencies of eulachon at sea and in the Kemano River also indicate that Kemano River eulachon are semelparous, and are estimated to spawn at age 3 (Clarke et al. 2007). Otoliths of eulachon that had spawned in freshwater in a previous season would be expected to show a corresponding decrease in the strontium to calcium ratio representative of this time spent in freshwater; however, this was not evident in otolith samples from any of five river systems (Clarke et al. 2007). Strontium to calcium ratios are much higher in bony structures of fish secreted while in the marine compared to freshwater environment, have been used to detect migration of fish between these two environments in many studies, and can detect exposure to freshwater conditions of as little as 6 hours. This study "supports the hypothesis that [eulachon] are semelparous" (Clarke et al. 2007, p. 1,490).

## Spawn Behavior

### Selection of spawn substrate

Eulachon eggs were reportedly preferentially laid on sand in both the Fraser (McHugh 1940, Hay et al. 2002) and Nass rivers (Langer et al. 1977). Eggs were primarily found attached to pea-sized gravel and only secondarily on sand in the Columbia River (Smith and Saalfeld 1955). Eggs laid in areas of silt or organic debris reportedly suffer much higher mortality than those laid over sand or gravel (Langer et al. 1977). Although eulachon eggs are most commonly laid on a sand substrate, eggs have been found on silt, gravel to cobble–sized rock, and organic detritus (Smith and Saalfeld 1955, Langer et al. 1977, Vincent-Lang and Queral 1984, Lewis et al. 2002).

### Estuary spawning

Based on movements of adult eulachon tracked with gastrically implanted radio tags in the Twentymile River, Spangler (2002) and Spangler et al. (2003) speculated that a portion of the eulachon population in this river may have spawned in the estuary. Some tagged fish moved in and out of the lower river and did not move upstream of the tagging site. Spangler et al. (2003, p. 52) stated that "if fish are capable of spawning in the estuary, larval sampling [and thus abundance estimation methodology] could be missing a segment of the population leading to erroneous results." However, Armstrong and Hermans (2007, p. 4) cite an unpublished study indicating that eulachon egg survival is reduced on exposure to salinities of 16 ppt and greater, and thus successful spawning in estuarine salinities greater than this is unlikely.

### Spawn migration

According to Spangler et al. (2003, p. 2), "There are no consistently reported environmental factors known to influence spawning run timing of adult eulachon throughout their range." These factors include water temperature, tide height, and river discharge rates (Spangler 2002, Spangler et al. 2003). However, both water temperature and river discharge rate are cited as factors that may initiate upriver migration of eulachon in local river basins (Ricker et al. 1954, Smith and Saalfeld 1955, Langer et al. 1977).

**Spawn temperature**

It is apparent that "the temperature at which eulachon spawning runs commence varies by geographic area" (Spangler 2002, p. 71); however, a clear pattern is not readily discernible. Columbia River eulachon are reported to spawn at temperatures between 4ºC and 10ºC and that the spawning migration is inhibited at temperatures less than 4ºC (WDFW and ODFW 2001). In 2001, most eulachon avoided the Columbia River until mid-February when the temperature rose above 4ºC (Howell et al. 2001). Spawning in the Fraser River reportedly occurs "at temperatures exceeding 6 or 7ºC whereas temperatures in northern rivers, which sometimes are ice covered during spawning, are much lower" (Hay et al. 2003, p. 2). Mean, minimum, and maximum water temperatures during spawning in the Kemano River in March-April between 1992 and 1998 were 3.1ºC, 1.1ºC, and 6.5ºC, respectively (Lewis et al. 2002). Langer et al. (1977, p. 18) reported that "1971 temperature records from the Nass [River] indicated that peak [eulachon] migration was occurring at temperatures as low as 0–1°C." During the 8-day peak eulachon migration in the Nass River in 1971, the mean daily water temperature ranged from 0.3 to 2.0°C (Langer et al. 1977, their Table 6). Temperature at the onset of the eulachon run in the Twentymile River, Alaska, ranged 2.8–6.0°C (Spangler 2002, Spangler et al. 2003); however, over the entire spawning run temperatures varied "from 1.6°C to 12.7°C in 2000 and from 0.5°C to 10.7°C in 2001" (Spangler et al. 2003, p. 28). Eulachon spawned in the Susitna River, Alaska, in 1982 and 1983 when temperatures ranged about 6–11°C (Barrett et al. 1984, Vincent-Lang and Queral 1984).

**Spawning under ice**

Swan (1881, p. 260) stated that eulachon arrive in the Nass River "about the time the ice begins to break up" and that in "some years the ice remains solid until after the fish are caught, in which case holes have to be cut in the ice to put down the nets." Langer et al. (1977, p. 43) documented this under-ice eulachon fishery on the Nass River in 1969 and stated that "adult migration occurs at colder river temperatures than previously recorded." Hay and McCarter (2000) also noted that spawning may occur under the ice in some northern British Columbia rivers. Eulachon reportedly migrate, and presumably spawn, under the ice on the Unuk River in Southeast Alaska, and this under-ice migratory behavior may have also occurred in the past on the Twentymile River in Southcentral Alaska (Spangler 2002, Spangler et al. 2003). Flory (2008b) reported that in April 2006 on the Taku River in Southeast Alaska, "eulachon schools were observed up river [before ice break up], indicating the fish moved underneath the ice [to] access spawning grounds (E. Jones, pers. comm.)."

**Spawning at night or under low light levels**

Several authors indicate that eulachon mainly spawn at night (Smith and Saalfeld 1955, Parente and Snyder 1970, Lewis 1997) or under low light conditions (Spangler 2002), and this has been suggested as possible predator avoidance behavior (Spangler et al. 2003). Smith and

Saalfeld (1955) reported that captive eulachon always deposited eggs at night, and when partially spent eulachon were captured at night in the Cowlitz River, freshly deposited eggs were sampled on the river bottom the next morning. Lewis et al. (2002, p. 74) reported that "female eulachon migrated into the [Kemano] river to spawn in darkness on high tides, retreating by day to the lower river" and that egg drift was greatest at night in the Kemano River.

#### Tidal level during spawning

Periods of low river discharge and high tides are associated with peak adult eulachon migration in both the Nass River, British Columbia (Langer et al. 1977), and the Twentymile River, Alaska (Spangler 2002, Spangler et al. 2003). Higgins et al. (1987, p. 6) were unable to discriminate between interacting effects of light and tide on eulachon migration in the Fraser River but did note that fishing success was best "at dusk on the high slack tide." Lewis et al. (2002) also suggested that eulachon spawning may be tied to nighttime high tides, and noted that "higher tides reduced water velocity, allowing eulachon to swim further upstream."

#### Flow velocity and depth during spawning

In the Kemano River, British Columbia, eulachon preferred water velocities from 0.1 to 0.7 m/s (Lewis et al. 2002). Earlier studies on Kemano eulachon indicated that many eulachon are unable to maintain long-term position in the stream at flow velocities greater than 0.3 m/s (Lewis et al. 2002). In the Susitna River, Alaska, "water velocities ranging from 0.5 to 2.5 feet/s [0.2–0.8 m/s] are most commonly utilized for spawning" (Vincent-Lang and Queral 1984, p. 5).

McHugh (1940) found the heaviest concentration of eulachon eggs in the Fraser River at a depth of 25 feet (7.6 m). Likewise, Langer et al. (1977) reported eggs to be more abundant at depths greater than 4 m than in shallower waters in the Nass River, British Columbia. In the Columbia River, larval eulachon were recovered in waters from 3 inches (0.1 m) to more than 20 feet (6.1 m) in depth and spent adults have been caught as deep as 75 feet (22.9 m) (Smith and Saalfeld 1955). However, eulachon may live long enough after spawning to be swept far downstream from the spawning grounds, so the presence of spent eulachon may not indicate that spawning occurred in the vicinity. In the Kemano River, British Columbia, eulachon preferred depths between 0.5 and 2.3 m, but used available habitat from 0.2 to more than 4 m in depth (Lewis et al. 2002). In the Susitna River, Alaska, "depths ranging from 0.5 to 3.0 feet [0.2–0.9 m] are most commonly utilized for spawning" (Vincent-Lang and Queral 1984, p. 5).

## Trophic Interactions

### Diet

Larval and juvenile eulachon are planktivorous (WDFW and ODFW 2001). Barraclough (1967) and Robinson et al. (1968b) examined stomach contents of larval (5–15 mm FL) eulachon caught in surface trawls in the Strait of Georgia in early June of 1966 and 1967, respectively. Although 5–8 mm FL larvae still possessed a yolk sac, larvae as small as 6 mm FL had fed on copepod nauplii. Other stomach contents of larval (≤15 mm FL) eulachon in the Strait of Georgia included phytoplankton, centric diatoms, copepod metanauplii, copepod eggs, barnacle eggs, rotifers, cladocerans (*Podon* sp.), ostracods, and polychaete larvae (Barraclough 1967, Robinson et al. 1968b).

Barraclough (1967), Barraclough and Fulton (1967), and Robinson et al. (1968a, 1968b) examined stomach contents of postlarval and juvenile (20–69 mm FL) eulachon caught in surface trawls in the Strait of Georgia in early June 1966, July 1966, May 1967, and June 1967. Stomach contents of eulachon in the Strait of Georgia included phytoplankton, barnacle eggs, barnacle nauplii, copepod eggs, copepod nauplii, copepods (*Pseudocalanus* sp., *Acartia longiremis*, *Acartia* sp., *Microcalanus pygmaeus*, *Calanus* sp.), cladocerans, ostracods, mysiids, larvaceans (*Oikopleura* sp.), and in one case a larval eulachon (Barraclough 1967, Barraclough and Fulton 1967, Robinson et al. 1968a, 1968b). Larger specimens of eulachon (91–157 mm FL) collected in the Strait of Georgia had consumed barnacle eggs, copepods (*Pseudocalanus* sp., *Acartia longiremis*, *Calanus* sp.), cladocerans, and gammaridean amphipods (Robinson et al. 1968a, 1968b).

Smith and Saalfeld (1955, p. 12) stated that the only recognizable prey found in stomachs of adult eulachon captured off Washington in 1948 were abundant "remains of the cumacean, *Cumacea dawsoni*." Other authorities have reported that juvenile and adult eulachon eat primarily "euphausiids and copepods" (Hart 1973, p. 149) or "euphausiids, crustaceans, and cumaceans" (Scott and Crossman 1973, p. 323). Hay (2002, p. 100) stated that "eulachon stomachs from offshore waters indicate that [they] mainly consume the euphausiid *Thysanoessa spinifera*." Yang et al. (2006) examined the stomach contents of 39 eulachon from a single haul in the Gulf of Alaska in 2001 that ranged in size from 160 to 210 mm FL. Food items and their percent of total stomach content weight included mysids (2.7%), cumaceans (2.1%), hyperiid amphipods (5.9%), the euphausiid *T. inermis* (25.8%), other euphausiids (40.8%), larvaceans (1.7%), teleost fish (13.8%), undetermined fish remains (2.6%), and unidentified material (4.6%) (Yang et al. 2006).

## Predators

### Marine mammals

Numerous pinnipeds prey on eulachon both at sea and during eulachon spawning runs, including: 1) Stellar sea lions (*Eumetopias jubatus*) (Beach et al. 1981, 1985, Jeffries 1984, Bigg 1988, Marston et al. 2002, Womble 2003, Sigler et al. 2004, Womble and Sigler 2006, Womble et al. 2005, 2009), 2) California sea lions (Beach et al. 1981, 1985, Bowlby 1981, Jeffries 1984), 3) northern fur seals (*Callorhinus ursinus*) (Clemens et al. 1936, Spalding 1964, Antonelis and Fiscus 1980, Antonelis and Perez 1984), and 4) harbor seals (Fisher 1947, 1952, Spalding 1964, Pitcher 1980, Beach et al. 1981, 1985, Bowlby 1981, Jeffries 1984, Roffe and Mate 1984, Olesiuk 1993, Marston et al. 2002). Other nonpinniped marine mammal predators on eulachon include baleen whales, beluga whales (*Delphinapterus leucas*) (Moore et al. 2000, Rugh et al. 2000, Speckman and Piatt 2000), humpback whales (*Megaptera novaeangliae*) (Marston et al. 2002, Witteveen et al. 2004), killer whales (*Orcinus orca*), harbor porpoises (*Phocoena phocoena*) (Jeffries 1984), Dall's porpoises (*Phocoenoides dalli*) (Kajimura et al. 1980, Stroud et al. 1981, Jeffries 1984), and white-sided dolphins (*Lagenorhyncus obliquidens*) (Morton 2000).

## Birds

Numerous authors (WDFW and ODFW 2001, Spangler 2002, Willson and Marston 2002, Marston et al. 2002, Maggiulli et al. 2006) report large numbers of gulls (*Larus* spp.), terns (*Sterna* spp.), ducks (Anatidae), bald eagles (*Haliaeetus leucocephalus*), shorebirds (Scolopacidae), corvids, and other birds feeding on live and dead eulachon during spawning events. Documented bird predators on spawning aggregations of eulachon in various river systems are summarized in Table A-10.

Ormseth et al. (2008, their Table 2) listed the estimates of eulachon contribution to seabird diets (percent weight of eulachon in the predator's diet) based on a mass-balance ecosystem model derived from predator diet data in the Gulf of Alaska for the following birds: kittiwakes (*Rissa* spp.) (4.3%), murres (*Uria* spp.) (3.0%), puffins (*Fratercula* spp.) (6.1%), cormorants (*Phalacrocorax* spp.) (3.0%), gulls (*Larus* spp.) (8.2%), shearwaters (*Puffinus* spp.) (5.0%), and albatross/jaeger (3.5%).

## Fish

Numerous fish species have been recorded as consuming eulachon, including spiny dogfish (*Squalus acanthias*) (Chatwin and Forrester 1953, Jones and Geen 1977), green sturgeon (*Acipenser medirostris*) (Fry 1979), Pacific cod (*Gadus macrocephalus*) (Hart 1949, Yang 1993, Yang and Nelson 2000, Yang et al. 2006), walleye pollock (Yang 1993, Yang and Nelson 2000, Yang et al. 2006), Pacific halibut (*Hippoglossus stenolepis*) (Scott and Crossman 1973, Yang 1993, Yang and Nelson 2000, Yang et al. 2006), sablefish (Yang 1993, Buckley et al. 1999, Yang and Nelson 2000, Yang et al. 2006), Pacific hake (Alton and Nelson 1970, Outram and Haegele 1972, Livingston 1983, McFarlane and Beamish 1985, Rexstad and Pikitch 1986, Buckley and Livingston 1997, Buckley et al. 1999), rougheye rockfish (*Sebastes aleutianus*) (Yang and Nelson 2000), and arrowtooth flounder (*Atheresthes stomias*) (Kabata and Forrester 1974, Yang 1993, Buckley et al. 1999, Yang and Nelson 2000, Yang et al. 2006).

Larval and juvenile eulachon have also been reported to be the occasional prey of Pacific herring, surf smelt, Pacific sand lance, kelp greenling (*Hexagrammos decagrammus*), threespine stickleback (*Gasterosteus aculeatus*), steelhead (*Oncorhynchus mykiss*), Chinook salmon (*O. tshawytscha*), sockeye salmon (*O. nerka*), coho salmon (*O. kisutch*), chum salmon (*O. keta*), and pink salmon (*O. gorbuscha*) salmon in the Strait of Georgia (Barraclough 1967, Barraclough and Fulton 1967, Robinson et al. 1968b). Juvenile white sturgeon (*Acipenser transmontanus*) in the Columbia River are known to consume large quantities of eulachon eggs during spawning events (McCabe et al. 1993). Marston et al. (2002) reported that coho salmon and Dolly Varden (*Salvelinus malma*) may also feed on eulachon eggs and larvae. In addition, juvenile eulachon may occasionally consume larval eulachon (Barraclough 1967, p. 26).

## Other predators

Marston et al. (2002) noted that terrestrial mammals such as bears (*Ursus* spp.), wolves (*Canis lupus*), river otters (*Lontra canadensis*), and mink (*Mustela vison*) likely prey on eulachon either during or after spawning events.

### Parasites

Compilations of parasites and fish hosts in British Columbia (Margolis and Arthur 1979, Kabata 1988, McDonald and Margolis 1995, Gibson 1996) listed two trematodes (*Pronoprymna petrowi* and *Lecithaster gibbosus*), a cestode (*Phyllobothrium* sp.), a nematode (*Contracaecum* sp.), and a parasitic pennellid copepod (*Haemobaphes disphaerocephalus*) as known parasites on eulachon. The trematode *L. gibbosus* was found in stomachs of juvenile eulachon collected in the Strait of Georgia with 29–59 mm FL (Robinson et al. 1968a, 1968b, Barraclough 1967). Similarly, the trematode *P. petrowi* was found in the stomachs of juvenile eulachon collected in the Strait of Georgia with 32–38 mm FL (Barraclough 1967). Arai (1967, 1969) reported the trematode *L. gibbosus*, a larval cestode *Phyllobothrium* sp, and a larval nematode *Contracaecum* sp. in eulachon from Burke Channel, an inlet on the south mainland coast of British Columbia. Hoskins et al. (1976) reported the occurrence of the parasitic copepod *Haemobaphes diceraus* on a eulachon host, from Port Hardy on Vancouver Island, British Columbia. Kabata (1988) and McDonald and Margolis (1995) described another pennellid copepod (*H. disphaerocephalus*) as parasitic on eulachon from British Columbia. Kabata (1988) noted that the report of *H. diceraus* infecting eulachon by Hoskins et al. (1976) occurred before *H. disphaerocephalus* was described as a separate species. The pennellid copepods in the genus *Haemobaphes* attach themselves headfirst to the bulbous arteriosus of the host fish with the body protruding from the gill arch (McDonald and Margolis 1995).

## Information Relating to the Species Question

### Approaches to Addressing Discreteness and Significance

The BRT considered several kinds of information to delineate potential DPS structure in eulachon. To address the discreteness criteria, the BRT primarily considered patterns of genetic variation among eulachon sampled from various locations along the coast, patterns of variation in life history and morphology, and ecological and environmental differences between eulachon populations. Comparison of spawning distribution, spawn timing, meristic variation in vertebral counts, elemental analysis of otoliths, and genetic variation have also been cited as evidence for stock discrimination in eulachon (Hay and McCarter 2000, Beacham et al. 2005, Hay and Beacham 2005). For the significance criteria, the BRT focused primarily on ecological differences among populations and on whether loss of such populations would create a significant gap in the range of the species.

#### Life history and morphology

Isolation between populations may be reflected in several variables, including differences in life history variables (e.g., spawning timing, seasonal migrations), spawning location, parasite incidence, growth rates, morphological variability (e.g., morphometric and meristic traits), and demography (e.g., fecundity, age structure, length and age at maturity, mortality rates), among others. Although some of these traits may have a genetic basis, they are usually also strongly influenced by environmental factors over the lifetime of an individual or over a few generations. Differences can arise among populations in response to environmental variability among areas and can sometimes be used to infer the degree of independence among populations or subpopulations. Begg et al. (1999) have emphasized the necessity to examine the temporal stability of life history characteristics in order to determine whether differences between populations persist across generations.

### Persistence of spawn location and spawn timing

Eulachon generally spawn in rivers that are glacier fed or have peak spring freshets. It has been argued that the rapid movement of eggs and larvae by these freshets to estuaries makes it likely that eulachon imprint and home to an estuary into which several rivers drain rather than to individual spawning rivers (McCarter and Hay 1999, Hay and McCarter 2000). Thus the estuary has been invoked as the likely geographic stock unit for eulachon (McCarter and Hay 1999, 2003, Hay and McCarter 2000, Hay 2002, Hay and Beacham 2005) (Table A-1).

Variation in spawn timing among rivers has been cited as indicative of local adaptation in eulachon (Hay and McCarter 2000), although the wide overlap in spawn timing and river entry timing among rivers makes it difficult to discern distinctive geographic patterns in this trait. In general, eulachon spawn earlier in southern portions of their range than in rivers to the north. River entry and spawning begins as early as December and January in the Columbia River system and as late as June in Southcentral Alaska (Table A-9, Figure 5, and Figure 6). However, they have been known to spawn as early as January in rivers on the Copper River delta of Alaska and as late as May in northern California. The general spawn timing pattern is reversed along the coast of British Columbia, where the earliest spawning occurs in the Nass River in the far north in February to early March and the latest spawning occurs in the Fraser River in April and May in the far south (Table A-9, Figure 5). There is also some evidence that different waves or runs of eulachon may occur in some basins, based on run-time separation (Table A-9).

These differences in spawn timing result in some populations spawning when water temperatures are as low as 0–2°C, and sometimes under ice (Nass River, Langer et al. 1977), whereas other populations experience spawning temperatures of 4–7°C (Cowlitz River, Smith and Saalfeld 1955) (Table A-11).

### Morphology

Differences in the mean number of vertebrae in eulachon from northern and southern rivers in British Columbia have been cited as indicative of population separation (Hart and McHugh 1944, Hay and McCarter 2000), although no differences were evident in population means between the Fraser and Columbia rivers (Hay and McCarter 2000) (Figure 7). However, meristic differences such as these can vary with environmental conditions and it is impossible to determine the underlying causes of these differences from the available data. It has often been shown that the number of vertebrae formed during early development is subject to modification by temperature such that the average vertebral number in fish populations is greater in the northern versus the southern portion of the range and the mean vertebral number in a population may also vary from year to year within a population (McHugh 1954, Waldman 2005). In addition, morphometric and meristic differences between groups of fish are often subtle and relating such differences to a specific degree of isolation among populations can be difficult.

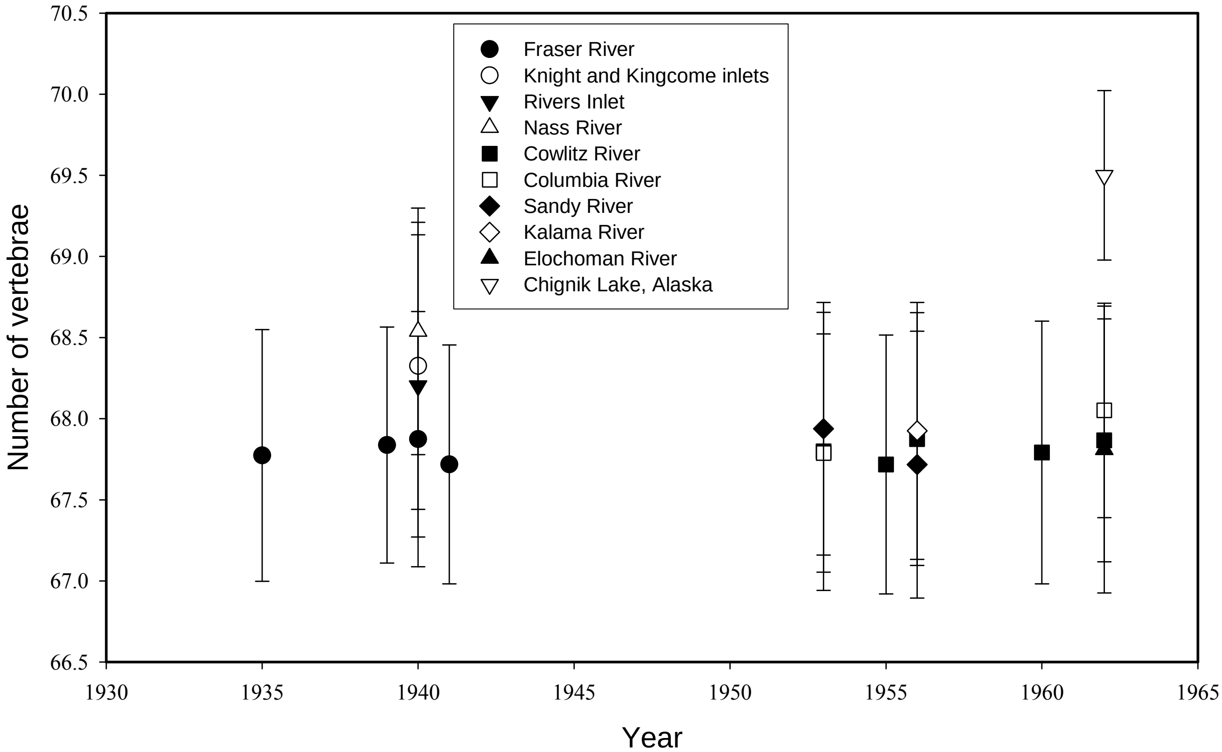

Figure 7. Comparison of mean and standard deviations of eulachon vertebral counts in various rivers. Data from DeLacy and Batts (1963) for the Columbia River, its tributaries, and Chignik Lake. Data from Hart and McHugh (1944) for rivers in British Columbia.

Coastwide, there appears to be an increase in both mean length and weight of eulachon at maturity with an increase in latitude (Table A-7, Table A-8, and Figure 8). Mean eulachon fork length and weight at maturity range from upwards of 215 mm and 70 g in the Twentymile River in Alaska to 175 mm and 37 g in the Columbia River. Although eulachon obtain a larger body size in the northern portion of their range compared to populations in the south, this relationship may be somewhat obscured by problems associated with the ageing of this species (Hay and McCarter 2000). Most Pacific herring also exhibit a latitudinal cline in mean size-at-age, such that Pacific herring in southern locations (e.g., California) exhibit small size and Pacific herring in the north (e.g., Bering Sea) obtain a far larger size at a similar age (Stout et al. 2001a, Gustafson et al. 2006). This pattern is typical of many vertebrate ectotherms where higher rearing temperatures result in reduced size at a given stage of development (Lindsey 1966, Atkinson 1994).

### Otolith chemistry

Hay and McCarter (2000) and Hay and Beacham (2005) reported on attempts to use differences in the elemental makeup of eulachon otoliths (earbones) to detect stock structure among various rivers on the coast of British Columbia. Significant variation occurred in the elemental analysis associated with the date of the laboratory elemental analysis. Despite these sources of potential error, the results indicated that there were differences in the elemental

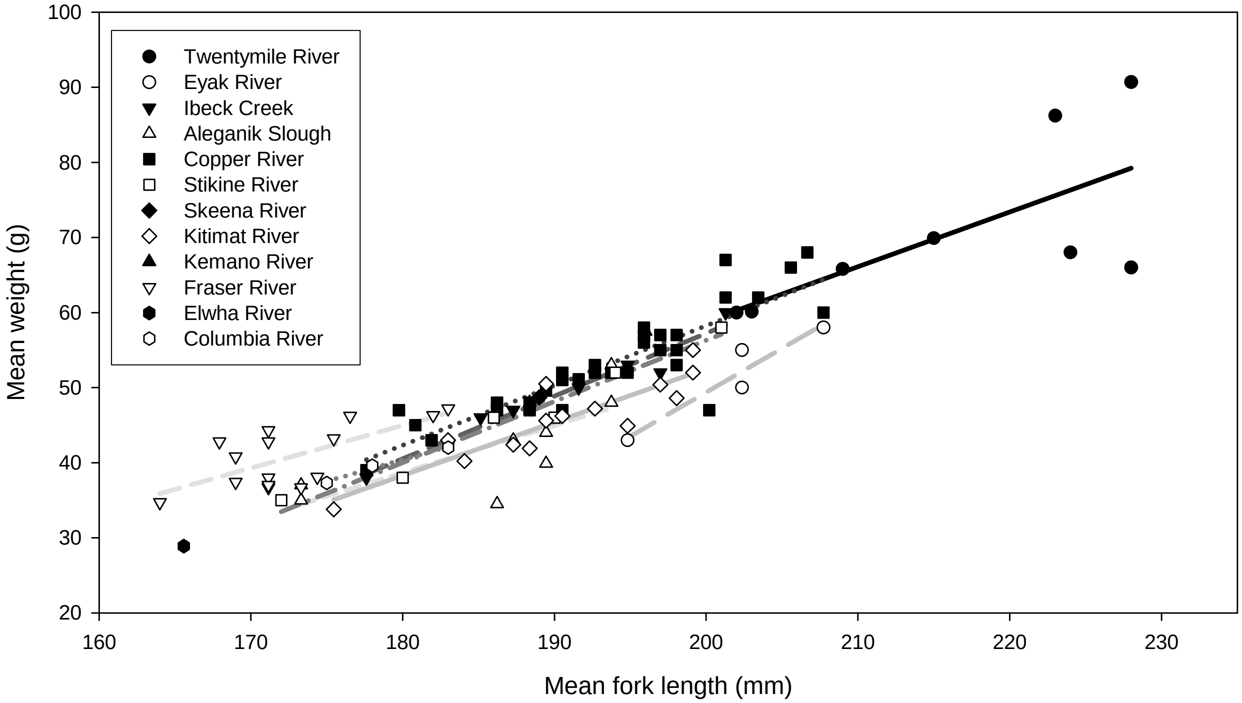

Figure 8. Length-weight relationship of eulachon from various rivers. Standard linear regressions fit the data to lines for each population that has multiple observations. Standard lengths and total lengths have been converted to fork length using equations published in Buchheister and Wilson (2005).

composition of eulachon otoliths over a broad geographic range, but that "elemental analysis was not useful to distinguish between closely adjacent stocks" (Hay and Beacham 2005, p. 10).

## Age composition

Age determination of eulachon has been difficult to validate and estimates of age based on otolith or scale increments may not be accurate (Ricker et al. 1954, Hay and McCarter 2000). However, in general, studies using otolith aging techniques have concluded that some eulachon spawn at age 2 or age 5, but most are age 2 or age 3 at spawning (Willson et al. 2006). Recently, Clarke et al. (2007) pioneered a method to estimate eulachon age at spawning from analysis of variations in barium and calcium in the otoliths. This study indicated that age structure of spawners in the southern areas may be limited to one, or at most, two year classes (Clarke et al. 2007). According to Clarke et al. (2007):

> The number of Ba:Ca peaks measured in the eulachon populations varied; eulachon captured in Barkley Sound, located off the west coast of Vancouver Island (ocean), had 1.5 and 2.5 peaks, Fraser River eulachon were all characterized by 3 peaks, and Columbia River eulachon exhibited 2 or 3 peaks. All of the fish in the Kemano and Skeena rivers examined were characterized by 3 peaks in Ba:Ca with the exception of two Skeena River fish that had 4 peaks. Fish collected from the Copper River in Alaska had 3 or 4 peaks. The number of

peaks in Ba:Ca observed in eulachon otoliths increased with increasing latitude, suggesting that the age at maturity is older for northern populations.

## Genetic differentiation

The analysis of the geographical distribution of genetic variation is a powerful method of identifying discrete populations. In addition, such analysis can sometimes be used to estimate historical dispersals, equilibrium levels of migration (gene flow), and past isolation. Commonly used molecular genetic markers include protein variants (allozymes), microsatellite loci (variable numbers of short tandem DNA repeats), and mtDNA.

One widely used method of population analysis is sequence or restriction fragment length polymorphism (RFLP) analysis of mtDNA, which codes for several genes that are not found in the cell nucleus. mtDNA differs from nuclear DNA (nDNA) in two ways. One way is that recombination is lacking in mtDNA, so that gene combinations (haplotypes) are passed unaltered from one generation to the next, except for new mutations. A second way is that mtDNA is inherited from only the maternal parent in most fishes, so that gene phylogenies correspond to female lineages. These characteristics permit phylogeographical analyses of mtDNA haplotypes, which can potentially indicate dispersal pathways for females and the extent of gene flow between populations (Avise et al. 1987). Although the lack of recombination allows for some types of analysis that are difficult to conduct with other markers (e.g., microsatellites), inferences of population structure (or lack thereof) from mtDNA are limited by the fact that the entire mitochondrial genome is inherited genetically as a single locus. Mitochondrial studies are therefore most useful for detecting deep patterns of population structure, and may not be very powerful for detecting structure among closely related populations.

Microsatellite DNA markers can potentially detect stock structure on finer spatial and temporal scales than can other DNA or protein markers, because of higher levels of polymorphism found in microsatellite DNA (reflecting a high mutation rate). Relatively high levels of variation can increase the statistical power to detect stock structure, particularly among closely related populations. In addition, microsatellite studies usually involve analysis of multiple genetic loci, which increases the power to detect differentiation among populations.

The BRT reviewed four published genetic studies of genetic population structure in eulachon. One of these studies (McLean et al. 1999) used RFLP analysis to examine variation in mtDNA. The other studies (McLean and Taylor 2001, Kaukinen et al. 2004, Beacham et al. 2005) analyzed microsatellite loci. Additional detail on two of these studies can be found in McLean (1999).

McLean et al. (1999) examined mtDNA variation in two fragments (each containing two genes NADH-5/NADH-6 and 12S/16S rRNA) in 285 eulachon samples collected at 11 freshwater sites ranging from the Columbia River to Cook Inlet, Alaska, and also in 29 ocean-caught fish captured in the Bering Sea. Samples were taken at two sites (Columbia and Cowlitz rivers) in two years and all other locations were sampled in single years. Overall, 37 mtDNA composite haplotypes were observed in the study. Two haplotypes were found in all sampling locations and together accounted for approximately 67% of the samples in the study. Eight additional haplotypes were present at multiple sites and the remaining 27 haplotypes were "private" (found only in one location).

An analysis of the nucleotide substitutions separating the 37 haplotypes revealed that the haplotypes were all closely related, with the number of substitutions ranging between 1 and 13. The mtDNA haplotypes clustered into two major groups and the frequencies of the two haplotype groups differed among sampling sites, particularly in the Alaska and Bering Sea collections compared to samples from further south, although these differences were not statistically significant. Approximately 97% of mtDNA variation occurs within populations and about 2% is found among regions ($F_{ST} = 0.023$). McLean et al. (1999) also found that genetic distance among sampling locations was correlated with geographic distance ($r^2 = 0.22$, $P = 0.0001$). Based on these results, McLean et al. (1999) concluded that there was little genetic differentiation among distinct freshwater locations throughout the eulachon range. However, McLean et al. (1999) noted that association of geographic distance and genetic differentiation among eulachon populations suggested an emerging population subdivision throughout the range of the species.

In a later study, McLean and Taylor (2001) used five microsatellite loci to examine variation in the same set of populations as McLean et al. (1999). The populations in the Columbia and Cowlitz rivers were represented by 2 years of samples with a total sample size of 60 fish from each river. However, several populations were represented by very few samples including just 5 fish from the 3 rivers in Gardner Canal and just 10 fish from the Fraser River. Results from a hierarchical analysis of molecular variance test were similar to that of the McLean et al. (1999) mtDNA study, with 0.85% of variation occurring among large regions and 3.75% among populations within regions.

Tests of differentiation were significant among several pairs of populations in the microsatellite study (27% of tests after correction for multiple comparisons), particularly comparisons that included populations in the Columbia and Cowlitz rivers and those with the Nass River sample and samples taken further south. $F_{ST}$ (a commonly used metric to evaluate population subdivision) was estimated as 0.047 when sample sites were considered separately, and was significantly different from zero. In contrast to the mtDNA analysis, genetic distances among populations using these five microsatellite loci were not correlated with geographic distances. Overall, however, McLean and Taylor (2001) concluded that their microsatellite results were mostly consistent with the mtDNA findings of McLean et al. (1999) and that both studies indicated that eulachon have some degree of population structure.

The most extensive study of eulachon, in terms of sample size and number of loci examined, is that of Beacham et al. (2005). Beacham et al. (2005) examined microsatellite DNA variation in eulachon collected at 9 sites ranging from the Columbia River to Cook Inlet, Alaska, using the 14 loci developed by Kaukinen et al. (2004). Sample sizes per site ranged from 74 fish in the Columbia River to 421 from the Fraser River. Samples collected in multiple years were analyzed from populations in the Bella Coola and Kemano rivers (2 years of sampling) and also in the Nass River (3 years of sampling).

Beacham et al. (2005) observed much greater microsatellite diversity within populations than that reported by McLean and Taylor (2001) and all loci were highly polymorphic in all of the sampled populations. Significant genetic differentiation was observed among all comparisons of the nine populations in the study and $F_{ST}$ values for pairs of populations ranged from 0.0014 to 0.0130. A cluster analysis of genetic distances showed genetic affinities among the populations in the Fraser, Columbia, and Cowlitz rivers and also among the Kemano, Klinaklini, and Bella Coola rivers along the central British Columbia coast. In particular, there was evidence of a genetic discontinuity north of the Fraser River, with Fraser and Columbia/Cowlitz samples being approximately 3–6 times more divergent from samples further to the north than they were to each other (Figure 9). Similar to the mtDNA study of McLean et al. (1999), Beacham et al. (2005) also found that genetic differentiation among populations ($F_{ST}$) was correlated with geographic distances (r = 0.34, $P < 0.05$).

Beacham et al. (2005) found stronger evidence of population structure than the earlier genetic studies, and concluded that their results indicated that management of eulachon would be appropriately based at the level of the river drainage. In particular, the microsatellite analysis showed that populations of eulachon in different rivers are genetically differentiated from each other at statistically significant levels. The authors suggested that the pattern of eulachon differentiation was similar to that typically found in studies of marine fish, but less than that observed in most salmon species.

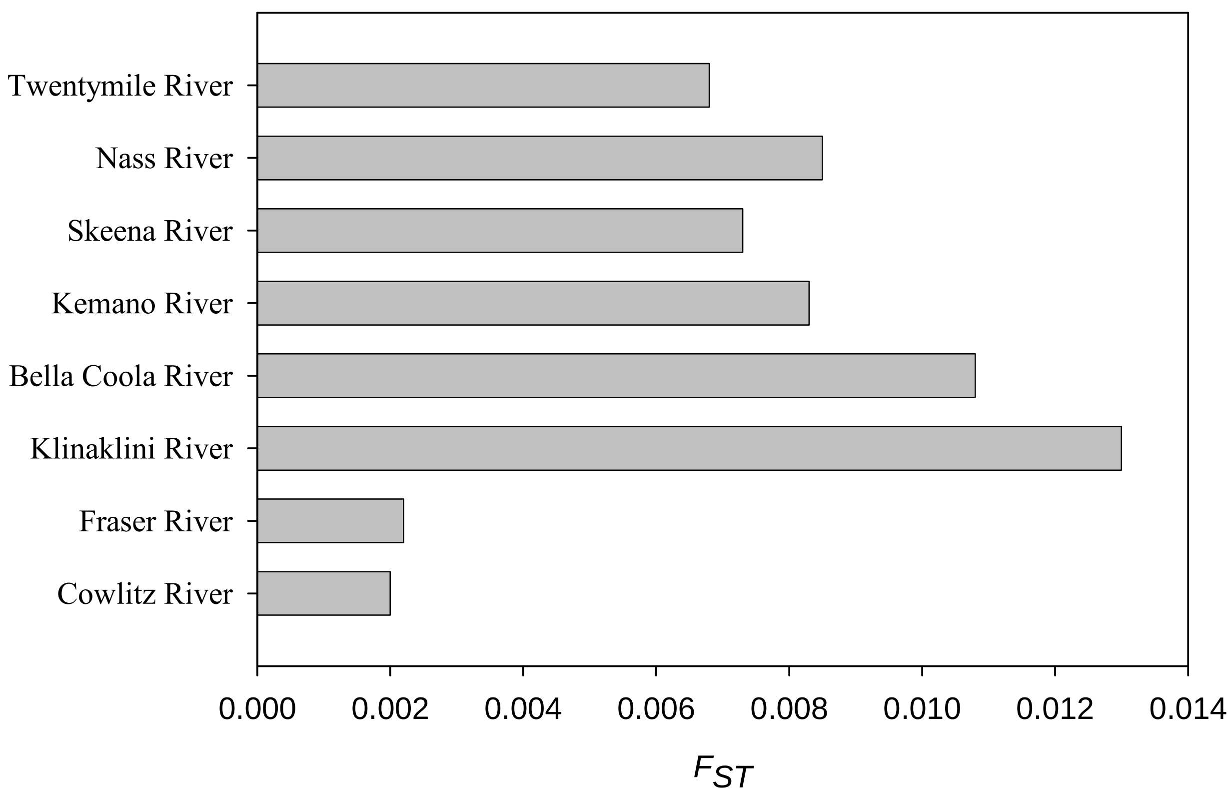

Figure 9. Comparison of $F_{ST}$ (a measure of genetic distance) values of the Columbia River eulachon sample to other samples. Data are from Beacham et al. (2005, their Table 4). See Beacham et al. (2005, their Figure 1) for sampling locations.

Although Beacham et al. (2005) found clear evidence of genetic structure among eulachon populations, the authors also noted that important questions remained unresolved. The most important one in terms of identifying a DPS or DPSs for eulachon is the relationship between temporal and geographic patterns of genetic variation. In particular, Beacham et al. (2005) found that year-to-year genetic variation within three British Columbia coastal river systems was similar to the level of variation among the rivers, which suggests that patterns among rivers may not be temporally stable. However, in the comparisons involving the Columbia River samples, the variation between the Columbia samples and one north-of-Fraser sample from the same year was approximately five times greater than a comparison within the Columbia from two different years. Taken together, there appears to be little doubt that there is some genetic structure within eulachon and that the most obvious genetic break appears to occur in southern British Columbia north of the Fraser River. To fully characterize genetic relationships among eulachon populations, additional research will be needed to identify appropriate sampling and data collection strategies.

### Ecological features

The analysis of ecological features or habitat characteristics may be informative in identifying population segments that occupy unusual or distinctive habitats, relative to the biological species as a whole. One of the criteria that may be useful for evaluating discreteness as articulated in the joint DPS policy (USFWS-NMFS 1996) relates to the population being "markedly separated from other populations of the same taxon as a consequence of … ecological … factors." In addition, the persistence of a discrete population segment in an ecological setting unusual or unique for the taxon is also a factor identified in the joint DPS policy that may provide evidence of the population's significance. Oceanographic and other ecological features may also contribute to demographic isolation between marine populations.

**Freshwater (spawning) environment**—The presumed fidelity with which eulachon return to their natal river, estuary, inlet, or area implies a close association between a specific stock and its freshwater or estuarine environment. Differences in life history strategies among eulachon populations or stocks may have arisen, in part, in response to selective pressures of different freshwater and estuarine environments. If the boundaries of distinct freshwater or estuarine habitats coincide with substantial differences in life histories, it would suggest a certain degree of local adaptation. Therefore, identifying distinct freshwater, terrestrial, and climatic regions may be useful in identifying eulachon DPSs.

The Environmental Protection Agency has established a system of ecoregion designations based on soil content, topography, climate, potential vegetation, and land use for the conterminous United States (Omernik 1987) and Alaska (Gallant et al. 1995). Historically, the distribution of eulachon in Washington, Oregon, and California corresponds closely with the Coastal Range Level III Ecoregions as defined in Omernik and Gallant (1986) and Omernik (1987). Similarly, Environment Canada (2008) has established a system of ecozones and ecoregions in Canada. Ecozones in Canada have been described as "areas of the earth's surface representative of large and very generalized ecological units characterized by interactive and adjusting abiotic and biotic factors." Each ecozone consists of numerous ecoregions that are described as "a part of a province characterized by distinctive regional ecological factors, including climatic, physiography, vegetation, soil, water, fauna, and land use" (Environment Canada 2008).

**Coastal range ecoregions of the United States**—Extending from the Olympic Peninsula through the Coast Range proper and down to the Klamath Mountains and the San Francisco Bay area, this region is influenced by medium to high rainfall levels due to the interaction between marine weather systems and the mountainous nature of the region. Topographically, the region averages about 500 m in elevation, with mountain tops under 1,200 m. These mountains are generally rugged with steep canyons. Between the ocean and the mountains lies a narrow coastal plain composed of sand, silt, and gravel. Tributary streams are short and have a steep gradient; therefore, surface runoff is rapid and water storage is relatively short term during periods of no recharge.

These rivers are especially prone to low flows during times of drought. Regional rainfall averages 200–240 cm per year, with generally lower levels along the southern Oregon coast. Average annual river flows for most rivers in this region are among the highest found on the West Coast when adjusted for watershed area. Peak flow of coastal rivers occurs during winter rain storms common in December and January. Snow melt adds to the surface runoff in the spring, providing a second flow peak (spring freshet), and there are long periods when the river flows are maintained at a level of at least 50% of peak flow. During July or August there is usually little or no precipitation; this period may expand to 2 or 3 months every few years. River flows are correspondingly at their lowest and temperatures at their highest during August and September, with the exception of glacier fed systems. The region is heavily forested primarily with Sitka spruce (*Picea sitchensis*), western hemlock (*Tsuga heterophylla*), and western red cedar (*Thuja plicata*). Forest undergrowth is composed of numerous types of shrubs and herbaceous plants.

**Terrestrial ecozones and ecoregions of Canada**—All rivers that support regular runs of eulachon in British Columbia are within the Pacific Maritime Ecozone, which consists of 14 ecoregions (Figure 10). The Lower Mainland, Pacific Ranges, and Coastal Gap ecoregions contain rivers supporting regular runs of eulachon as defined in Hay and McCarter (2000) and Hay (2002), and two rivers, the Nass and the Skeena, drain out of the Nass Basin Ecoregion (Environment Canada 2008).

The Lower Mainland Ecoregion (196 in Figure 10) is dominated by the Fraser River and occupies the Fraser River valley from Chilliwack and the Cascade Range foothills downstream to the Fraser River delta and northward from there to incorporate the Sunshine Coast. Mean summer and winter air temperatures in this region are 15°C and 3.5°C, respectively. At sea level, less than 10% of winter precipitation falls as snow, although maximum precipitation occurs in the winter. Mean annual precipitation in the Fraser River valley ranges from 200 cm in the Cascade foothills to 85 cm at the river's mouth. Douglas fir (*Pseudotsuga menziesii*) dominates native forest stands with an understory typically containing hollyleaved barberry, aka tall Oregon grape (*Mahonia aquifolium*), salal (*Gaultheria shallon*), and mosses. Disturbed sites are commonly dominated by stands of red alder (*Alnus rubra*). Drier natural sites consist of mixed stands of Pacific madrone (*Arbutus menziesii*), Douglas fir, western hemlock, and occasionally, Pacific dogwood (*Cornus nuttallii*). Wetter areas contain mixtures of western red cedar, Douglas fir, and western hemlock. Soils consist of unconsolidated clay-like and silty

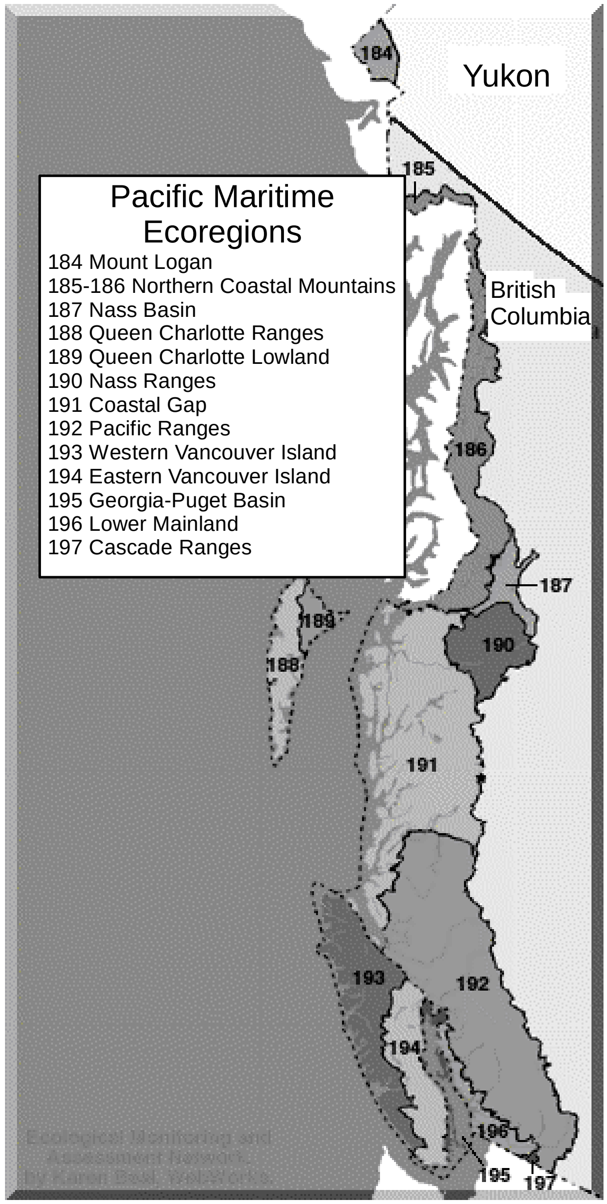

Figure 10. Ecoregions in the Pacific Maritime Ecozone of British Columbia. Map modified from online source: http://ecozones.ca/english/zone/PacificMaritime/ecoregions.html.

marine deposits, silty alluvium, glacial till, and glaciofluvial deposits. Eastern hills in the ecoregion up to 310 m in height are formed from bedrock outcrops of Mesozoic and Paleozoic age.

The Pacific Ranges Ecoregion (192 in Figure 10) extends from the southern extent of the steeply sloping irregular Coast Mountains at the U.S.-Canada border to Bella Coola in the north. These mountains range from sea level to as high as 4,000 m and are made up of granite and crystalline gneisses. Many rivers in this region originate in expansive ice fields, and numerous glaciers extend into the lowlands. Many steep-sided, transverse valleys bisect these mountains and terminate in inlets or fjords. Mean summer and winter air temperatures in this region are

13.5°C and –1°C, respectively. Mean annual precipitation in this ecoregion ranges from 340 cm at high elevations to 150 cm at sea level. This ecoregion consists of three main regions distinguished by altitude: an alpine zone above 1,800 m, a subalpine zone between 900 and 1,800 m, and a coastal forest zone below 900 m. The coastal forest zone is dominated by stands of western red cedar, western hemlock, and Pacific silver fir (*Abies amabilis*) and in drier sites by Douglas fir and western hemlock.

The Coastal Gap Ecoregion (191 in Figure 10) extends from Dean Channel north to the border between British Columbia and Alaska and is bounded by the taller Pacific Ranges to the south and the Boundary Ranges to the north. The low-relief mountains in this ecoregion consist of the Kitimat Ranges, which rarely reach higher than 2,400 m and are made up of granitic rocks and crystalline gneisses. Although many inlets and fjords bisect this mountainous coastline and terminate in steep-sided, transverse valleys, glaciers are less common and smaller than in areas to the south and north of this ecoregion. Mean summer and winter air temperatures are 13°C and –0.5°C, respectively. This ecoregion has the highest mean annual precipitation in British Columbia, ranging from 200 cm on the coast to more than 450 cm at high elevations. At sea level, the forests are dominated by western red cedar, yellow cedar (*Chamaecyparis nootkatensis*), and western hemlock. Some Sitka spruce and shore pine (*Pinus contorta* var. *contorta*) are also present with red alder being common on disturbed sites. Low-lying bogs and stream fens are common types of wetlands. Forests in upland areas are dominated by western red cedar and western hemlock, whereas Pacific silver fir and western hemlock are found in areas with poorer drainage.

The Nass Basin Ecoregion (187 in Figure 10) lies between the interior and coastal portions of the Coast Mountains in west-central British Columbia and is an area of low relief composed of folded Jurassic and Cretaceous sediments that is almost encircled by mountains. The Nass Basin is drained by the Nass and Skeena rivers to the ocean through large gaps in the Coast Mountains and consists of a gently rolling landscape generally below 750 m in altitude. Mean summer and winter air temperatures in this region are 11.5°C and –9.5°C, respectively. Mean annual precipitation ranges up to 250 cm at higher elevations to 150 cm in the lowlands. The moist montane zone is dominated by western red cedar and western hemlock, whereas forests in the subalpine zone contain subalpine fir (*Abies lasiocarpa*), lodgepole pine (*Pinus contorta* var. *latifolia*), and Engelmann spruce (*Picea engelmannii*).

**Oceanic environment**—Ware and McFarlane (1989) built on previous descriptions of oceanic domains in the northeast Pacific Ocean by Dodimead et al. (1963) and Thomson (1981) to identify three principal fish production domains: 1) a southern Coastal Upwelling Domain, 2) a northern Coastal Downwelling Domain, and 3) a central Subarctic Domain (aka the Alaskan Gyre) (Figure 11). The boundary between the Coastal Upwelling Domain and Coastal Downwelling Domain occurs where the eastward flowing Subarctic Current (aka the North Pacific Current) bifurcates to form the north-flowing Alaska Current and the south-flowing California Current in the vicinity of a transitional zone between the northern tip of Vancouver Island and the northern extent of the Queen Charlotte Islands (Figure 11). Similarly, Longhurst (2006) identifies an Alaska Downwelling Coastal Province and a California Current Province within the Pacific Coastal Biome.

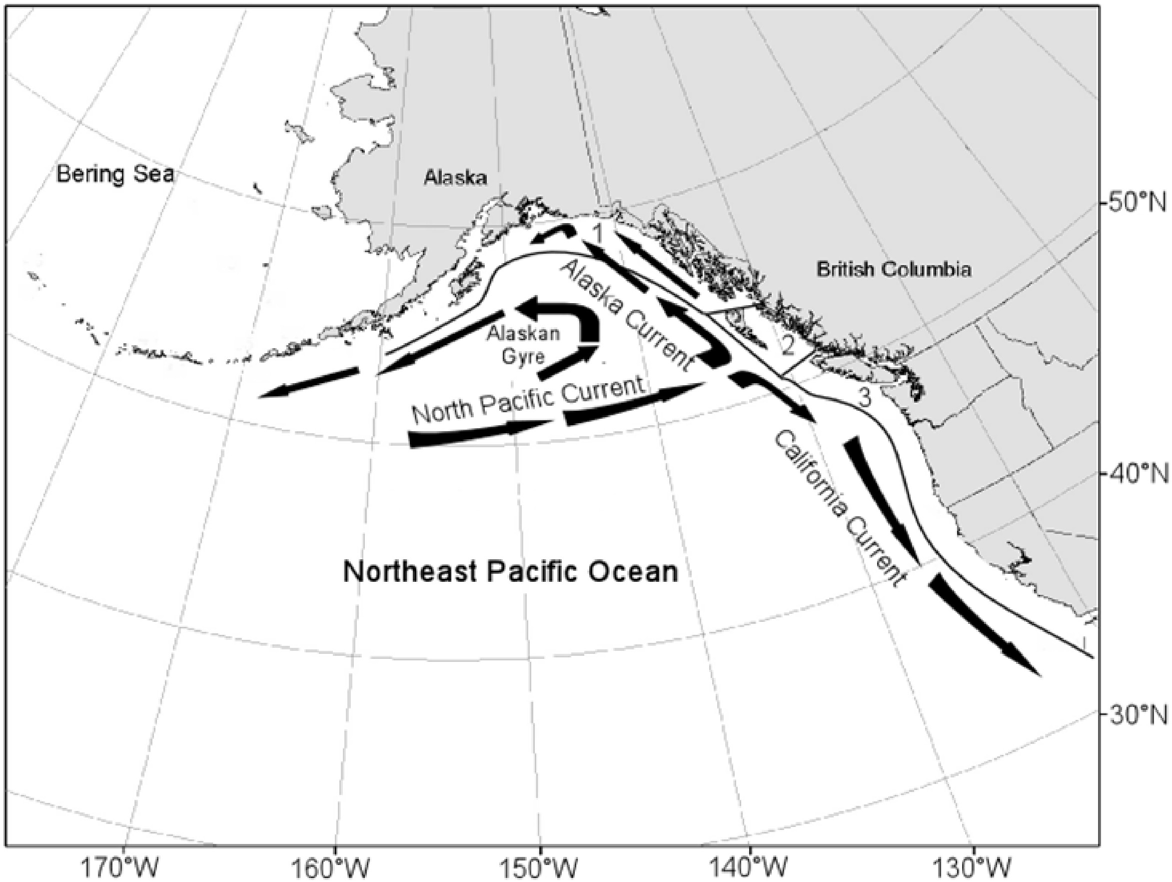

Figure 11. Approximate locations of oceanographic currents, oceanic domains (Ware and McFarlane 1989), and coastal provinces (Longhurst 2006) in the Northeast Pacific Ocean. 1–Alaska Coastal Downwelling Province (aka Coastal Downwelling Domain), 2–Transition Zone, and 3–California Current Province (aka Coastal Upwelling Domain).

Longhurst's (2006) work provides a worldwide ecological geography of the sea that identifies 4 primary oceanic biomes and 51 biogeochemical provinces based mainly on differences in regional physical processes that act on regional patterns of phytoplankton growth that are partially defined by "the interaction between light, nutrients, mixing, and stability in the upper part of the water column." This scheme to partition the ocean into provinces differs from previous attempts by relying on oceanographic features that drive phytoplankton ecology rather than on biogeography of species or water current patterns alone (Longhurst 2006). The steps taken and data analyzed to define biogeochemical provinces in the ocean are detailed in Longhurst (2006).

Within Longhurst's (2006) Pacific Coastal Biome, ocean distribution of eulachon spans the Alaska Downwelling Coastal Province and the northern portion of the California Current Province (Figure 11). Longhurst (2006) places the boundary between the Alaska Coastal Downwelling Province and the California Current Province between the Queen Charlotte Islands at 53°N latitude and the northern end of Vancouver Island at 47–48°N latitude, where the eastward flowing North Pacific Current encounters the North American continent and bifurcates to form the north-flowing Alaska Current and south-flowing California Current. Different modes of physical forcing and nutrient enrichment characterize these provinces.

The Alaska Coastal Downwelling Province spans the coastal boundary region from the Aleutian Islands east and south to the Queen Charlotte Islands (Haida Gwai'i) at about 53°N latitude and extends seaward to the Alaska Current velocity maximum (Longhurst 2006). The continental shelf in this region is dominated by nearly year-round onshore downwelling winds. Large amounts of precipitation and runoff from melting glaciers along the mountainous Alaska coast is another feature of this province. In summer and fall, when runoff is at maximum, waters in the fjord-like coastline and in the Alaska Coastal Current are usually highly stratified in both temperature and salinity. Following the spring phytoplankton bloom, stratification in the top layers of the water column limits nutrient availability and leads to subsequent nutrient depletion. Occasional wind events lead to temporary local upwelling of nutrients and subsequent phytoplankton blooms.

The northern extent of the California Current Province (aka California Upwelling Coastal Province) begins where the eastward flowing North Pacific Current splits near Vancouver Island near 47–48°N latitude, creating the southward flowing California Current and northward flowing Alaska Coastal Current (Longhurst 2006). The southern boundary of this province occurs off the southwest tip of Baja California, where the North Equatorial Current begins. Seasonal wind-driven upwelling is a dominate feature of this province, especially in the northern portion of the province. This process carries nutrients onshore where they are upwelled along the coast, leading to high primary production that lasts through much of the spring and summer. Nearshore upwelling also results in higher salinities and lower temperatures compared to offshore locations.

A widely recognized Transition Pacific Zone (Ware and McFarlane 1989, BC Ministry of Sustainable Resource Management 2002) occurs between the Alaska Coastal Downwelling and California Current provinces whose "northern boundary is indistinct and approximately coincident with the southern limit of the Alaskan Current" (BC Ministry of Sustainable Resource Management 2002, p. 35). This zone is characterized as a mixing area between boreal plankton communities to the north and temperate plankton communities to the south, and incorporates the waters of Queen Charlotte Sound and Hecate Strait (i.e., north of Vancouver Island and inshore of the Queen Charlotte Islands). In the summer, the California Current may affect the southern portion of this transition zone with the inshore Davidson Current flowing south in the summer and north in the winter (BC Ministry of Sustainable Resource Management 2002).

### Marine zoogeographic provinces

Marine zoogeography attempts to identify regional geographic patterns in marine species' distribution and delineate faunal provinces or regions based largely on the occurrence of endemic species and of unique species' assemblages (Ekman 1953, Hedgpeth 1957, Briggs 1974, Allen and Smith 1988). These province boundaries are usually coincident with changes in the physical environment such as temperature and major oceanographic currents. Similar to the above ecological features category, boundaries between zoogeographic provinces may indicate changes in the physical environment that are shared with the species under review.

Ekman (1953), Hedgpeth (1957), and Briggs (1974) summarized the distribution patterns of coastal marine fishes and invertebrates and defined major worldwide marine zoogeographic zones or provinces. Along the coastline of the boreal eastern Pacific, which extends roughly from Point Conception, California, to the eastern Bering Sea, numerous schemes have been proposed for grouping the faunas into zones or provinces. A number of authors (Ekman 1953, Hedgpeth 1957, Briggs 1974, Allen and Smith 1988) have recognized a zoogeographic zone within the lower boreal eastern Pacific that has been termed the Oregonian Province.

Another zone in the upper boreal eastern Pacific has been termed the Aleutian Province (Briggs 1974). However, exact boundaries of zoogeographic provinces in the eastern boreal Pacific are in dispute (Allen and Smith 1988). Briggs (1974) and Allen and Smith (1988) reviewed previous literature from a variety of taxa and from fishes, respectively, and found the coastal region from Puget Sound to Sitka, Alaska, to be a gray zone or transition zone that could be classified as part of either of two provinces: Aleutian or Oregonian (Figure 12). The southern boundary of the Oregonian Province is generally recognized as Point Conception, California, and the northern boundary of the Aleutian Province is similarly recognized as Nunivak in the Bering Sea or perhaps the Aleutian Islands (Allen and Smith 1988).

Briggs (1974) placed the boundary between the Oregonian and Aleutian provinces at Dixon Entrance, based on the well-studied distribution of mollusks, but indicated that distributions of fishes, echinoderms, and marine algae gave evidence for placement of this

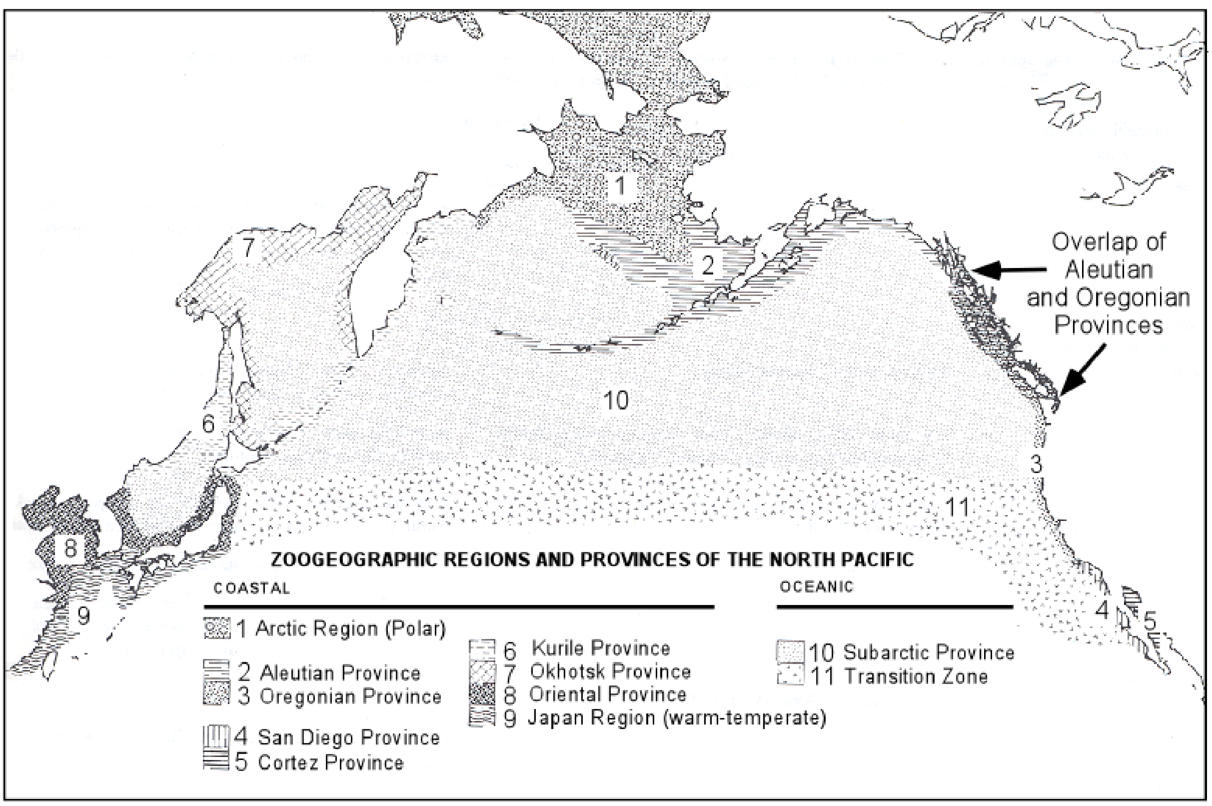

Figure 12. Marine zoogeographic provinces of the North Pacific Ocean. Modified after Allen and Smith (1988).

boundary in the vicinity of Sitka, Alaska. Briggs (1974) placed strong emphasis on the distribution of littoral mollusks (due to the more thorough treatment this group has received) in placing a major faunal break at Dixon Entrance. The authoritative work by Valentine (1966) on distribution of marine mollusks of the northeastern Pacific shelf showed that the Oregonian molluscan assemblage extended to Dixon Entrance with the Aleutian fauna extending northward from that area. Valentine (1966) erected the term Columbian Subprovince to define the zone from Puget Sound to Dixon Entrance.

Several lines of evidence suggest that an important zoogeographic break for marine fishes occurs in the vicinity of Southeast Alaska. Peden and Wilson (1976) investigated the distributions of inshore fishes in British Columbia and found Dixon Entrance to be of minor importance as a barrier to fish distribution. A more likely boundary between these fish faunas was variously suggested to occur near Sitka, Alaska, off northern Vancouver Island, or off Cape Flattery, Washington (Peden and Wilson 1976, Allen and Smith 1988). Chen (1971) found that of the more than 50 or more rockfish species belonging to the genus Sebastes occurring in northern California, more than two-thirds do not extend north of British Columbia or Southeast Alaska. Briggs (1974, p. 278) stated that “about 50 percent of the entire shore fish fauna of western Canada does not extend north of the Alaskan Panhandle.” In addition, many marine fish species common to the Bering Sea extend southward into the Gulf of Alaska, but apparently occur no further south (Briggs 1974). Allen and Smith (1988, p. 144) noted that “the relative abundance of some geographically displacing [marine fish] species suggest that the boundary between these provinces [Aleutian and Oregonian] occurs off northern Vancouver Island.”

Blaylock et al. (1998) examined the distribution of more than 25 species of parasites in 432 juvenile and adult Pacific halibut sampled over much of its North American range and found evidence of three zoogeographic zones as determined by parasite clustering; northern, central, and southern. Similar to studies with other invertebrates, Blaylock et al. (1998, p. 2,269) found a breakpoint between zoogeographic zones in the vicinity of the Queen Charlotte Islands.

### Other marine fish DPS designations

It is also useful to briefly review the size and complexity of other designated DPSs of marine fish that have undergone the status review process and have thus been considered both discrete and significant to their respective biological species. DPSs have been designated for portions of the range of Pacific herring (NMFS 2000, 2005, 2008b), Pacific hake, Pacific cod, walleye pollock (NMFS 2000), copper rockfish (*Sebastes caurinus*), quillback rockfish (*S. maliger*), brown rockfish (*S. auriculatus*) (NMFS 2001), bocaccio (*S. paucispinis*) (NMFS 2002), and smalltooth sawfish (*Pristis pectinata*) (NMFS 2003).

Several marine fish DPSs cover large geographic areas (e.g., Pacific cod and walleye pollock DPSs extend from Puget Sound to Southeast Alaska, two West Coast DPSs of bocaccio rockfish were designated off Washington and Oregon [the northern DPS] and off California and Mexico [the southern DPS], and all smalltooth sawfish in U.S. waters were designated a separate DPS). At slightly smaller geographic scales, a Southeast Alaska Pacific herring DPS (Carls et al. 2008) and DPSs of Pacific hake and Pacific herring in Georgia Basin (Puget Sound and the straits of Georgia and Juan de Fuca) were established as separate from coastal hake and herring (Gustafson et al. 2000, Stout et al. 2001a) (Figure 13). Three DPSs each of copper and quillback rockfish (Puget Sound Proper DPS, Northern Puget Sound DPS, and Coastal DPS) and two of brown rockfish (Puget Sound Proper DPS and Coastal DPS) have also been delineated (Stout et al. 2001b). Many of these marine fish DPSs include a number of identifiable subpopulations with numerous isolated spawning locations and a substantial level of life history and ecological diversity (Gustafson et al. 2000, 2006, Stout et al. 2001a, Carls et al. 2008).

## Evaluation of Discreteness and Significance for Eulachon

In past evaluations of distinct population boundaries for marine fish (Gustafson et al. 2000, 2006, Stout et al. 2001a), spawn timing, spawning distribution, tagging, biogeography, ecological factors, seasonal migration patterns, parasite incidence, genetic population structure, morphometrics, meristics, and demographic data (growth rate, fecundity, etc.) have been evaluated for evidence of DPS discreteness and significance. The BRT examined similar evidence for eulachon and found evidence that was informative included genetic data, differences in spawning temperatures and length-at-maturity and weight-at-maturity of eulachon between northern and southern rivers, ecological features of both the oceanic and terrestrial environments occupied by eulachon, and biogeography.

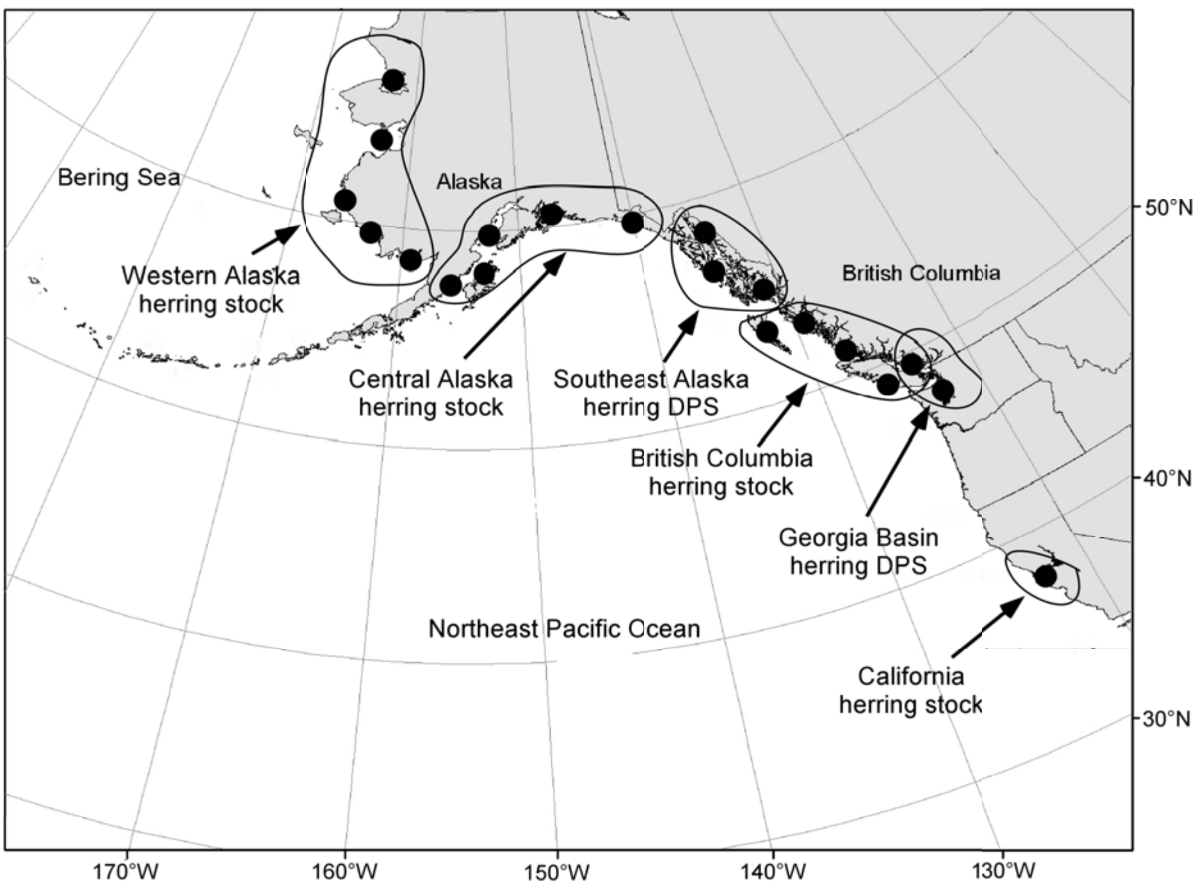

Figure 13. Major stocks of Pacific herring in the Northeast Pacific in relation to the Georgia Basin Pacific herring DPS (Stout et al. 2001a, Gustafson et al. 2006) and the Southeast Alaska Pacific herring DPS (Carls et al. 2008).

To allow for expressions of the level of uncertainty in identifying the boundaries of a discrete and significant eulachon population, the BRT adopted a likelihood point method, often referred to as the FEMAT method, because it is a variation of a method used by scientific teams evaluating options under the Forest Plan (Forest Ecosystem Management: An Ecological, Economic, and Social Assessment Report of the Forest Ecosystem Management Assessment Team, or FEMAT) (FEMAT 1993). This method was previously used in the DPS decisions for Southern Resident killer whales (Krahn et al. 2004) and Pacific herring (Gustafson et al. 2006). In this approach, each BRT member distributes 10 "likelihood" points among a number of proposed DPSs, reflecting their opinion of how likely that proposal correctly reflects the true DPS boundary. Thus if a member were certain that the DPS that contains eulachon from California, Oregon, and Washington included all spawning aggregations from the Fraser to the south, he or she could assign all 10 points to that proposal. A member with less certainty about DPS boundaries could split the points among two, three, or even more DPS proposals (Table 1).

The BRT ultimately considered six possible DPS configurations or scenarios that might conceivably incorporate eulachon that spawn in Washington, Oregon, and California rivers. Each BRT member distributed his or her 10 likelihood points amongst these six scenarios. Other possible geographic configurations that incorporated the petitioned unit were contemplated but not seriously considered by the BRT. The BRT did not attempt to divide the entire species into DPSs, but rather focused on evaluating whether a DPS could be identified that contains eulachon that spawn in Washington, Oregon, and California. The geographic boundaries (Figure 14) of possible DPSs considered in this evaluation were:

1. The entire biological species is the ESA species (i.e., there is no apparent DPS structure)
2. One DPS inclusive of eulachon in Southeast Alaska to northern California
3. One DPS south of the Nass River/Dixon Entrance
4. One DPS inclusive of eulachon in the Fraser River to California
5. One DPS south of the Fraser River (i.e., one DPS in Washington, Oregon, and California)
6. Multiple DPSs of eulachon in Washington, Oregon, and California

The distribution of likelihood points among these six scenarios is presented in Table 1. Scenario 1 (no DPS structure) received about 12% of the total likelihood points. Scenarios 2 (one DPS inclusive of eulachon in Southeast Alaska to northern California) and 5 (one DPS south of the Fraser River) received no support on the BRT. There was also very little support on the BRT for multiple DPSs of eulachon in the conterminous United States; only about 4% of the likelihood points were placed in scenario 6 (multiple DPSs of eulachon in Washington, Oregon, and California).

All remaining likelihood points (84%) were distributed among scenarios supporting a DPS at a level larger than the petitioned unit of Washington, Oregon, and California. Scenario 3 (one DPS south of the Nass River/Dixon Entrance) received about 57% of the total likelihood points and all but one BRT member placed between 5 and 10 points in this DPS scenario. Scenario 4 (one DPS inclusive of eulachon in the Fraser River to California) received significant

Table 1. Worksheet for evaluating potential of DPS or DPSs of eulachon (*Thaleichthys pacificus*) that incorporate spawning populations in California, Oregon, and Washington using the "likelihood point" method (FEMAT 1993).

| | Likelihood points | |
|---|---|---|
| **Scenario** | **Number[a]** | **Percentage[b]** |
| 1) Entire species (no DPS structure) | 11 | 12.2 |
| 2) One DPS south of Yakutat Forelands | — | — |
| 3) One DPS south of Nass River and Dixon Entrance | 51 | 56.7 |
| 4) One DPS, Fraser River and south | 24 | 26.7 |
| 5) One DPS south of Fraser River | — | — |
| 6) Multiple DPSs in Washington, Oregon, and California | 4 | 4.4 |

[a]Each BRT member distributes 10 likelihood points among the 6 DPS scenarios. Placement of all 10 points in a given scenario reflects 100% certainty that this is the DPS configuration that incorporates eulachon from Washington, Oregon, and California. Distributing points between scenarios reflects uncertainty in whether a given scenario reflects the true DPS delineation.
[b]Nine of 10 BRT members in attendance.

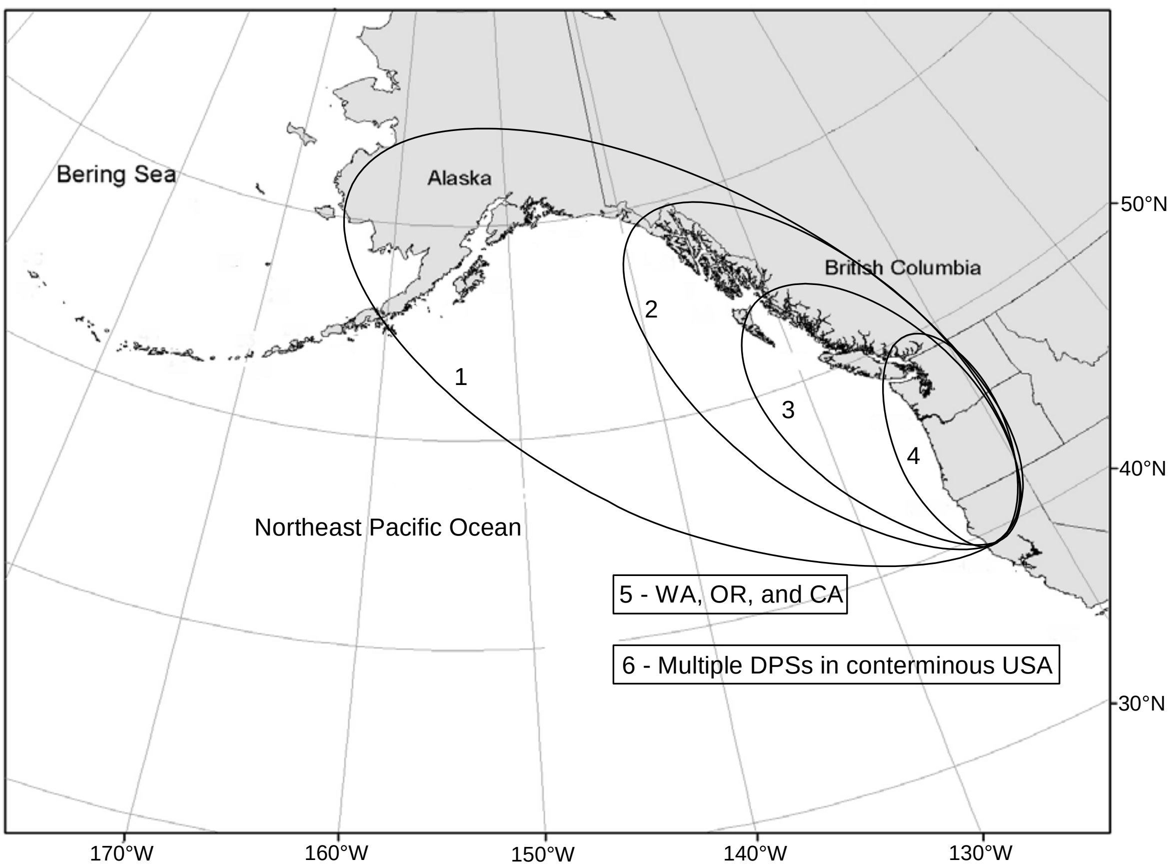

Figure 14. Geographic boundaries of possible eulachon DPSs considered by the BRT: 1) the entire biological species is one DPS, 2) one DPS south of the Yakutat Forelands (Southeast Alaska to northern California), 3) one DPS south of the Nass River (i.e., south of Dixon Entrance), 4) one DPS that includes the Fraser River and south, 5) one DPS south of the Fraser River (i.e., one DPS in Washington, Oregon, and California), and 6) multiple DPSs of eulachon in Washington, Oregon, and California.

support with about 27% of all points placed in this scenario and all but two members placed from 2 to 5 of their likelihood points in this DPS scenario. In discussing the evidence for these alternative scenarios, the BRT focused on the following factors.

In considering the discreteness and significance criteria (USFWS-NMFS 1996), the BRT concluded that the weight of the available evidence indicated that there are multiple discrete populations of eulachon. In particular, the most comprehensive genetic study of eulachon that has been published to date (Beacham et al. 2005) found reasonably strong evidence of a genetic break between eulachon spawning in the Fraser and Columbia rivers compared to those spawning in rivers further north in British Columbia and Alaska, and also found that nearly all sampled populations were differentiated statistically from each other. Earlier genetic studies (McLean et al. 1999, McLean and Taylor 2001) also found some evidence of population structure, although the evidence was less compelling than that reported by Beacham et al. (2005). However, these earlier studies were characterized by fewer loci and smaller sample sizes than the later study and therefore likely had less power to detect population structure. Overall, the BRT believed the results to be largely consistent among the studies, when differences in sample size and power are taken into account. The BRT did note, however, that there was some uncertainty about the genetic population structure due to the small number of temporally replicated samples in all of the studies, and this uncertainty is reflected in the proportion of the likelihood points that were placed in the no DPS structure category (Table 1).

In addition to the genetic data, the BRT considered the strong ecological and environmental break that occurs between the California Current and Alaska Current oceanic domains as contributing evidence for discreteness, a factor that was also important for identifying DPS structure in Pacific cod (Gustafson et al. 2000), killer whales (Krahn et al. 2004), and Southeast Alaska Pacific herring (Carls et al. 2008). The BRT also considered, but did not weigh heavily, the latitudinal differences in spawn timing, body size, and vertebral counts among samples from different rivers. Similar latitudinal patterns in life history characters were considered but did not weigh heavily in DPS decisions for Pacific cod, walleye pollock (Gustafson et al. 2000), and Pacific herring (Stout et al. 2001a). Overall, the BRT believed the genetic and ecological data provided strong evidence that eulachon south of the Nass River were discrete from those in the Nass River and northward, but that there was also evidence (from the genetic data) suggesting that Fraser and Columbia River groups may be discrete from more northern groups.

In evaluating the significance criteria, the BRT focused primarily on criteria 1 (ecological setting), criteria 2 (evidence that loss would result in a significant gap in the range of the species), and criteria 4 (markedly differs in genetic characteristics). After carefully discussing all of the available data, the BRT concluded that there was evidence supporting the significance criteria under either scenario 3 (one DPS south of the Nass River/Dixon Entrance) or scenario 4 (one DPS inclusive of eulachon in the Fraser River to California). In particular, there is evidence under either scenario for a significant break in ecological setting, and loss of a putative DPS defined by either boundary would without question result in a significant gap (or reduction) in the range of the overall species. The BRT also considered whether the available genetic data provided any evidence for “markedly different” populations, but concluded that although the genetic data provides evidence for discreteness (lack of gene flow) there was little evidence to support the existence of deep intraspecific phylogenetic breaks that the BRT believed were necessary to be considered “marked.”

In summary, the BRT believed the evidence most strongly supported scenario 3, but that there was also some evidence for scenarios 4 and 1. The factors supporting each of the top three scenarios are summarized below.

### Scenario 3

This scenario designated one DPS south of the Nass River/Dixon Entrance (57% support). Supporting factors were:

1. Beacham et al. (2005) found strong evidence that populations of eulachon in different rivers are genetically differentiated from each other at statistically significant levels and the authors suggested that the pattern of eulachon differentiation was similar to that typically found in studies of marine fish but less than that observed in most Pacific salmon species.
2. A major ecological break occurs in the coastal ocean biome between the Coastal Downwelling Province (Ware and McFarlane 1989, Longhurst 2006) to the north and the California Current Province (Ware and McFarlane 1989, Longhurst 2006) to the south. The northern boundary of the transition zone that separates these provinces occurs in the vicinity of the Dixon Entrance at the northern end of the Queen Charlotte Islands. The coastal distribution of eulachon south of the Dixon Entrance occupies an ecologically discrete area that is a combination of this transition zone and the northern California Current Province (Longhurst 2006).
3. Dixon Entrance is also the approximate northern boundary that separates two major marine zoogeographic provinces (Oregonian and Aleutian Provinces) (Briggs 1974), further supporting the ecological discreteness of marine waters south of Dixon Entrance.
4. Stocks of eulachon from the Columbia River to the Klinaklini River in British Columbia experienced a nearly simultaneous collapse in 1994 (Hay and McCarter 2000, Hay 2002), stayed at low levels throughout the 1990s, experienced a rebound in 2001–2003, and subsequently declined to near record low levels of abundance (Hay 2002, JCRMS 2007). The nearly synchronous demographic responses of all eulachon stocks south of the Nass River to what are likely coast-wide changes in ocean condition, strongly suggest that these stocks occupy a common ocean rearing environment. Stocks of eulachon from the Nass River and north remained relatively healthy throughout this period of decline of more southern stocks. Not until 2003 did eulachon stocks in southern Southeast Alaska begin to show serious declines. These demographic patterns are similar to those seen in Pacific salmon stock abundance that fluctuates in opposite directions in the Alaska and California Current domains (Hare et al. 1999), which has been correlated with the Pacific Decadal Oscillation (PDO) (Mantua and Hare 2002).
5. A major break in terrestrial ecoregions also occurs along the north coast of British Columbia in the vicinity of the Nass River, with both the Nass and Skeena rivers draining the interior Nass Basin Ecoregion (Environment Canada 2008). Evidence of a natural biological boundary coinciding with the international boundary separating Southeast Alaska and British Columbia (Dixon Entrance/Nass River) also supported delineation of

- Different biological zones are apparent along the coast, probably a result of both thermal (north-south) and salinity (east-west) gradients.
- A thermal gradient is clearly evident through British Columbia and Southeast Alaska.
    - o Temperatures in Southeast Alaska are colder than in British Columbia.
    - o Southeast Alaska has tidewater glaciers, British Columbia does not, chilling the water and increasing turbidity and possibly nutrients.
    - o Southeast Alaska mainland topography is heavily influenced by snowfields and glaciers; this is less prevalent in British Columbia.

6. Eulachon spawning in rivers on the north coast of British Columbia (e.g., Nass River) experience significantly colder temperatures at spawning (often spawning under ice) than eulachon spawning to the south, particularly in the Klinaklini, Fraser, and Columbia rivers (Hay and McCarter 2000) (Table A-11). Hochachka and Somero (2002, p. 292, 317) emphasized that habitat temperature plays a "strong and frequently dominant role … in governing the distribution patterns of organisms" and that "temperature differences of a few degrees Celsius have sufficient effects on proteins to favor adaptive change." The dominant role that temperature plays on ectothermic organisms, affecting "essentially every aspect of an organism's physiology" (Hochachka and Somero 2002, p. 290), suggests that these 2–4°C temperature differences experienced by adult eulachon and their gametes during spawning (Table A-11) are a strong indicator of potential physiological differences between eulachon south of the Nass River and those in the Nass River and northward.

Items 2–5 above support a discrete and significant eulachon population south of the Nass River/Dixon Entrance on the basis of being "markedly separated on the basis of ecological features" and Item 6 supports a discrete eulachon population south of the Nass River/Dixon Entrance on the basis of being "markedly separated on the basis of physiological features."

### Scenario 4

This scenario designated one DPS inclusive of eulachon in the Fraser River to California (27% support). Supporting factors were:

1. The available genetic data indicate that a substantial genetic break occurs between eulachon populations from the Fraser River and those from rivers further to the north (see Genetic Differentiation subsection, p. 61). In particular, the largest genetic discontinuity appears to be in southern British Columbia rather than northern British Columbia.
2. In contrast to systems to the north of the Fraser River, the Columbia, Fraser, and Klamath rivers have many physiographic and habitat features in common; all three are large rivers with wide valleys, drain extensive interior basins, are fed by spring snow melt, and do not drain off extensive ice sheets.

Average length-at-maturity and weight-at-maturity in eulachon from the Columbia and Fraser rivers and southern rivers in general are smaller than eulachon from more northern rivers (Figure 8). However, this pattern is typical in many vertebrate poikilotherms (ectotherms), where higher temperatures lead to reduced size at a given stage of development (Atkinson 1994, Lindsey 1966), so the BRT did not weight this evidence very heavily.

**Scenario 1**

This scenario designated no DPS structure (12% support). Supporting factors were:

1. There was a lack of apparent discrete differences in many eulachon life history traits (Hay and McCarter 2000, Hay and Beacham 2005); however, similar uniformity in life history characters over large geographic distances was evident in previous marine fish reviews of Pacific cod, walleye pollock (Gustafson et al. 2000), and Pacific herring (Stout et al. 2001a).
2. Another reason BRT members put some support in this scenario was uncertainty about how strongly to weight the genetic study of Beacham et al. (2005). In particular, although the BRT concluded that the study as a whole clearly supported the existence of discrete genetic populations of eulachon, the BRT was also somewhat concerned about the limited temporal replication in the study.

Given the previous DPS structure established for marine fishes, such as Pacific herring, Pacific cod, Pacific hake, and walleye pollock (Gustafson et al. 2000, 2006, Stout et al. 2001a), it seems unlikely that there would be an absence of DPS structure across the more than 2,800 km range of eulachon, an anadromous species with similar among-population genetic differentiation, as these purely marine fishes. Pacific herring, which exhibit genetic variation similar to eulachon when compared over the same geographic range (Beacham et al. 2002, 2005, Small et al. 2005), have had DPSs delineated at the geographic level of the Georgia Basin (Stout et al. 2001a) and Southeast Alaska (Carls et al. 2008), based to a large degree on marked differences in ecological features of their habitats. For example, the estimated mean $F_{ST}$ value for Pacific herring over 13 microsatellite DNA loci and 83 sampling sites ranging from California to Southeast Alaska was 0.0032 (Beacham et al. 2002), whereas a similar estimated mean $F_{ST}$ value over 14 loci and 9 eulachon sampling sites ranging from the Columbia River to Southcentral Alaska was 0.0046 (Beacham et al. 2005).

Although nowhere near the same quantity or quality of data exists for eulachon as for the economically more valuable Pacific herring, it is likely that if data comparable to that for Pacific herring were available, an even finer DPS structure for the anadromous eulachon might become apparent. In addition, the biological heterogeneity of eulachon as seen in “the geographical discontinuity of different spawning runs, different spawning times, and the apparent homing of each run to individual rivers” (Hay and McCarter 2000, p. 36) strongly argues against the lack of DPS structure.

## BRT DPS Determination

In conclusion, it was the majority opinion of the BRT that eulachon from Washington, Oregon, and California are part of a DPS that extends beyond the conterminous United States and that the northern boundary of the DPS occurs in northern British Columbia south of the Nass River (most likely) or in southern British Columbia north of the Fraser River (less likely). The BRT proposes that this DPS be termed the southern DPS of eulachon. Although it was not the

BRT's objective to subdivide the entire biological species of eulachon into DPSs throughout their range, the identification of a southern DPS of eulachon indicates that at least one, and possibly more than one, additional DPS or DPSs of eulachon occur north of the Skeena River on the north coast of British Columbia and in Alaska.

Although the BRT could not with any certainty identify multiple populations or DPSs of eulachon within the region south of Dixon Entrance/Nass River, it acknowledged the possibility that significant stock structuring does exist within this region and that a finer DPS structure might be revealed by further information on the behavior, ecology, and genetic population structure of eulachon. The BRT also recognized that the DPS that includes eulachon from California, Oregon, and Washington may represent fish that are uniquely adapted to survive at the southern end of the species' range.

# The Extinction Risk Question

Information considered in evaluating the status of a DPS can generally be grouped into two categories: 1) demographic information reflecting the past and present condition of subpopulations (e.g., data on population abundance or density, population trends and growth rates, number and distribution of populations, exchange rates of individuals among populations, and ecological, life history, or genetic diversity among populations) and 2) information on past factors for decline as well as threats faced by the DPS (e.g., habitat loss and degradation, overutilization, disease, climate change). The demographic risk data reviewed by the BRT are summarized in this document. This document also contains a narrative summary of threats faced by the DPS.

Evaluating extinction risk of a species includes considering the available information concerning the abundance, growth rate and productivity, spatial structure and connectivity, and diversity of a species and assessing whether these demographic criteria indicate that it is at high risk of extinction, at moderate risk, or neither. A species at very low levels of abundance and with few populations will be less tolerant to environmental variation, catastrophic events, genetic processes, demographic stochasticity, ecological interactions, and other processes (e.g., Gilpin and Soulé 1986, Meffe and Carroll 1994, Caughley and Gunn 1996). A rate of productivity that is unstable or declining over a long period of time may reflect a variety of causes, but indicates poor resiliency to future environmental variability or change (e.g., Lande 1993, Foley 1997, Middleton and Nisbet 1997).

For species at low levels of abundance, in particular, declining or highly variable productivity confers a high level of extinction risk. A species that is not widely distributed across a variety of well-connected habitats will have a diminished capacity for recolonizing locally extirpated populations and is at increased risk of extinction due to environmental perturbations and catastrophic events (Schlosser and Angermeier 1995, Hanski and Gilpin 1997, Tilman and Lehman 1997, Cooper and Mangel 1999). A species that has lost locally adapted genetic and life history diversity may lack the characteristics necessary to endure short-term and long-term environmental changes (e.g., Hilborn et al. 2003, Wood et al. 2008).

The demographic risk criteria described above are evaluated based on the present species status in the context of historical information, if available. However, there may be threats or other relevant biological factors that might alter the determination of the species' overall level of extinction risk. These threats or other risk factors are not yet reflected in the available demographic data because of the time lags involved, but are nonetheless critical considerations in evaluating a species' extinction risk (Wainwright and Kope 1999).

Forecasting the effects of threats and other risk factors into the foreseeable future is rarely straightforward, and usually necessitates qualitative evaluations and the application of informed professional judgment. This evaluation highlights those factors that may exacerbate or ameliorate demographic risks so that all relevant information may be integrated into the determination of overall extinction risk for the species. Examples of such threats or other relevant factors may include climatic regime shifts that portend favorable temperature and marine productivity conditions, an El Niño event that is anticipated to result in reduced food quantity or quality, or recent or anticipated increases in the range or abundance of predator populations.

In considering the status of eulachon, we evaluated both qualitative and quantitative information. Qualitative evaluations included aspects of several of the risk considerations outlined above, as well as recent, published assessments of the status of eulachon populations by agencies, reviewed below. Additional information presented by the petitioners was considered, as discussed under the Introduction: Summary of Information Presented by the Petitioner section above.

## Abundance and Carrying Capacity

### Absolute Numbers

The absolute number of individuals in a population is important in assessing two aspects of extinction risk. For small populations that are stable or increasing, population size can be an indicator of whether the population can sustain itself into the future in the face of environmental fluctuations and small-population stochasticity; this aspect is related to the concept of minimum viable populations (MVP) (Gilpin and Soulé 1986, Thompson 1991). For a declining population, present abundance is an indicator of the expected time until the population reaches critically low numbers; this aspect is related to the concept of "driven extinction" (Caughley 1994). In addition to total numbers, the spatial and temporal distribution of adults is important in assessing risk to a species or DPS.

Several aspects of eulachon biology indicate that large aggregations of adult eulachon are necessary for maintenance of normal reproductive output. Eulachon are a short-lived, high-fecundity, high-mortality forage fish, and such species typically have extremely large population sizes. Research from other marine fishes (Sadovy 2001) suggests that there is likely a biological requirement for a critical threshold density of eulachon during spawning to ensure adequate synchronization of spawning, mate choice, gonadal sterol levels, and fertilization success. Since eulachon sperm may remain viable for only a short time, perhaps only minutes, sexes must synchronize spawning activities closely, unlike other fish such as Pacific herring (Hay and McCarter 2000, Willson et al. 2006).

In most samples of spawning eulachon, males greatly outnumber females (although many factors may contribute to these observations) (Willson et al. 2006), and in some instances congregations of males have been observed simultaneously spawning upstream of females that laid eggs as milt drifted downstream (Langer et al. 1977). Sadovy (2001, p. 100) noted that "the idea that, if a population drops below some critical density, the intrinsic rate of population increase may not be realized because breeding activity may cease, cannot be readily dismissed and a number of possible Allee effects have been noted" in marine fishes. Sadovy (2001, p. 101) further noted that "aggregating behaviour presumably reflects some biological imperative for sociality during the reproductive season."

In addition, the genetically effective population size of eulachon may be much lower than the census size. Although eulachon exhibit high fecundity (7,000–60,000 eggs; mean ≈30,000), survival from egg to larva may vary widely (3–5% in the Kemano River to approximately 1% in the Wahoo River [Willson et al. 2006]) and may be less than 1% in large egg masses. Larvae are small (4–8 mm long), are rapidly carried by currents to the sea, and rear in the pelagic zone similarly to many marine pelagic fish larvae where the extent of mortality during the transition phase from larva to juvenile is high. In marine species, under conditions of high fecundity and high mortality associated with pelagic larval development, local environmental conditions may lead to random "sweepstake recruitment" events where only a small minority of spawning individuals contribute to subsequent generations (Hedgecock 1994). Hauser and Carvalho (2008) report that "data available so far suggest that the scope for sweepstake recruitment may be higher in larger populations, as the $N_e/N$ [ratio of effective size to census size] is lower in larger populations."

Large spawning aggregations of adult eulachon may also be necessary to withstand predation pressure associated with large congregations of predators that target returning adults, and to produce enough eggs and pelagic larvae to swamp out predation in the ocean (Bailey and Houde 1989). Multiple species of predators (sea lions, harbor seals, gulls, bald eagles, ducks, sturgeon, porpoises, killer whales, etc.) commonly congregate at eulachon spawning runs and "local observers often judge arrival of fish by the conspicuous arrival of many predators" (Willson et al. 2006).

## Historical Abundance and Carrying Capacity

Knowing the relationship of present abundance to present carrying capacity is important for evaluating the health of populations, but the fact that a population is near its current capacity does not necessarily signify full health. A population near capacity implies that short-term management may not be able to increase fish abundance.

The relationship of current abundance and habitat capacity to historical levels is an important consideration in evaluating risk. Knowledge of historical population conditions provides a perspective for understanding the conditions under which present populations evolved. Historical abundance also provides the basis for scaling long-term trends in populations. Comparison of present and past habitat capacity can also indicate long-term population trends and problems of population fragmentation. For eulachon, current and historical abundance data and information was available in the form of spawner biomass (pounds or metric tons) or total spawner counts (numbers of adult fish), offshore juvenile eulachon biomass estimates (metric tons), mean eulachon larval density, CPUE, commercial-recreational-subsistence fisheries landings, ethnographic studies, and anecdotal qualitative information.

## Trends in Abundance

Short-term and long-term trends in abundance are primary indicators of risk. Trends may be calculated from a variety of quantitative data, which are discussed in detail in specific subsections below. Interpretation of trends in terms of population sustainability is difficult for several reasons. First, eulachon are harvested in fisheries and shifting harvest goals or market conditions directly affect trends in spawning abundance and catch. Second, environmental fluctuations on short timescales affect trend estimates, especially for shorter trends.

## Recent Events

A variety of factors, both natural and human-induced, affect the degree of risk facing eulachon populations. Because of time lags in these effects and variability in populations, recent changes in any of these factors may affect current risk without any apparent change in available population statistics. Thus consideration of these effects must go beyond examination of recent abundance and trends, but forecasting future effects is rarely straightforward and usually involves qualitative evaluations based on informed professional judgment. Events affecting populations may include natural changes in the environment or human-induced changes, either beneficial or detrimental. Possible future effects of recent or proposed conservation measures have not been taken into account in this analysis, but we have considered documented changes in the natural environment. A key question regarding the role of recent events is: Given our uncertainty regarding the future, how do we evaluate the risk that a population may not persist?

It is generally accepted that important shifts in ocean-atmosphere conditions occurred about 1977 and again in 1998 that affected North Pacific marine ecosystems. Several studies have described decadal-scale oscillations in North Pacific climatic and oceanic conditions (Mantua and Hare 2002). These changes have been associated with recruitment patterns of several groundfish species and Pacific herring (McFarlane et al. 2000). As discussed in this report, increases in eulachon in the Columbia, Fraser, and Klinaklini rivers in 2001–2002 may be largely a result of the more favorable ocean conditions for eulachon survival during the transition from larvae to juvenile when these broods entered the ocean in 1998–2000.

One indicator of the ocean-atmosphere variation for the North Pacific is the PDO index; Figure 15 shows that from fall 2007 to mid-summer 2009 (time period E on the graph) monthly PDO values were negative, whereas PDO values were mostly positive in time period D from 2002 to fall of 2007 and during most of the previous two decades (time period B). One exception is time period C, which corresponds with 1998–2000 when good ocean conditions for survival of larval eulachon led to the increased run strength noted in 2001–2002. PDO values were generally negative for a long period from the 1950s to the late 1980s (time period A). Recently negative PDO values are associated with relatively cool ocean temperatures off the Pacific Northwest and positive values are associated with warmer, less productive conditions (Mantua and Hare 2002).

Coupled changes in climate and ocean conditions have occurred on several different time scales and have influenced the geographical distributions, and hence local abundance, of marine fishes. On time scales of hundreds of millennia, periodic cooling produced several glaciations in the Pleistocene Epoch (Imbrie et al. 1984, Bond et al. 1993). Since the end of this major period of cooling, several population oscillations of pelagic fishes, such as anchovies (*Engraulis mordax*) and sardines (*Sardinops sagax*), have been noted on the west coast of North America (Baumgartner et al. 1992). These oscillations, with periods of about 100 years, have presumably occurred in response to climatic variability. On decadal time scales, climatic variability in the North Pacific and North Atlantic oceans has influenced the abundances and distributions of widespread species, including several species of Pacific salmon (*Oncorhynchus* spp.) (Francis et

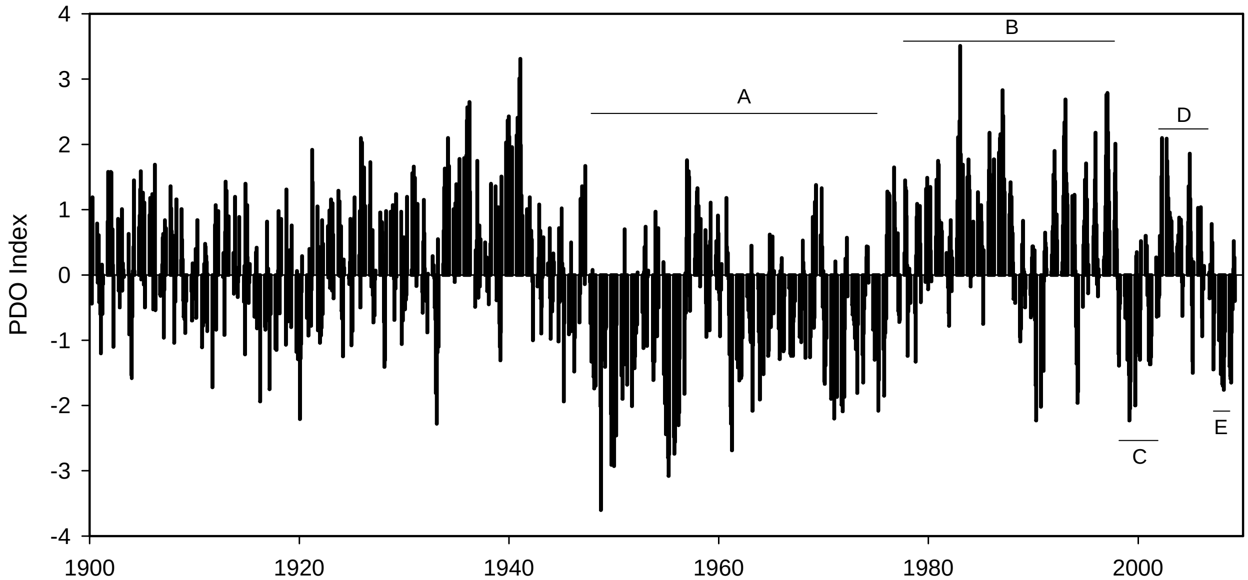

Figure 15. Monthly values for the PDO index, which is based on sea surface temperatures in the North Pacific Ocean, poleward of 20º N. A through E are time periods discussed in the text. Data source: online at http://jisao.washington.edu/pdo/PDO.latest.

al. 1998, Mantua et al. 1997) in the North Pacific, and Atlantic herring (*Clupea harengus*) (Alheit and Hagen 1997) and Atlantic cod (*Gadus morhua*) (Swain 1999) in the North Atlantic. At this time, we do not know whether recent shifts in climate and ocean conditions represent a long-term shift in conditions that will continue affecting stocks into the future or short-term environmental fluctuations that can be expected to be reversed in the near future. Although recent conditions appear to be within the range of historic conditions under which eulachon populations have evolved, the risks associated with poor climate conditions may be exacerbated by human influence on these populations (Lawson 1993).

None of the elements of risk outlined above are easy to evaluate, particularly in light of the great variety in quantity and quality of information available for various populations. Two major types of information were considered: previous assessments that provided integrated reviews of the status of eulachon in our region and data regarding individual elements of population status, such as abundance, trend, and habitat conditions.

A major problem in evaluations of risk for eulachon is combining information on a variety of risk factors into a single overall assessment of risk facing a population. Conducting an overall assessment of extinction risk involves the consideration of a wide variety of qualitative and quantitative information concerning the threats and demographic risks affecting a species' persistence. Moreover, the type and spatial-temporal coverage of the information available often varies within and among populations. This presents a substantial challenge of integrating disparate types of information into an assessment of a species' overall level of extinction risk. Usually such assessments necessitate qualitative evaluations based on informed professional judgment. In this review, we have used a risk-matrix approach through which the BRT members applied their best scientific judgment to combine qualitative and quantitative evidence regarding multiple risks into an overall assessment.

# Status Assessments

### Official Status in California, Oregon, and Washington

In California eulachon are classified on the Fish Species of Special Concern List as a Class 3 Watch List species (see http://www.dfg.ca.gov/wildlife/nongame/ssc/fish.html). This list was most recently updated in 1995. Class 3 Watch List species are defined as:

> taxa occupying much of their native range, but were formerly more widespread or abundant within that range. … The populations of such species need to be assessed periodically (i.e., every 5 years) and included in long-term plans for protected waterways (e.g., ADMAs [aquatic diversity management areas]).

In Oregon, eulachon are not listed as a state threatened, endangered, or candidate species, nor are they on the state sensitive species list. However, eulachon are on the list of Strategy Species in Oregon's Nearshore Strategy (ODFW 2006, p. 26). These species are defined in the following manner:

> Strategy species are nearshore species that were identified by the Nearshore Team to be in greatest need of management attention. Identification as a strategy species does not necessarily mean the species is in trouble. Rather, those identified as a strategy species have some significant nearshore management/conservation issue connected to that species that is of interest to managers.

ODFW (2006, p. 28) further refers to eulachon under the category of Notes on Conservation Needs as:

> Forage fish. Vulnerable freshwater spawning and nursery grounds. Columbia River population has declined. Other distinct population segments (DPS) may have experienced similar declines.

In Washington, eulachon are classified by the WDFW (online at http://wdfw.wa.gov/wlm/diversty/soc/candidat.htm) as a State Candidate Species, which are defined as:

> fish and wildlife species that the department will review for possible listing as State Endangered, Threatened, or Sensitive. A species will be considered for designation as a State Candidate if sufficient evidence suggests that its status may meet the listing criteria defined for State Endangered, Threatened, or Sensitive.

### Status in Canada

The Province of British Columbia examined the conservation status of eulachon in 2000 and again in 2004 and in both instances assigned eulachon to its blue list. According to the British Columbia Conservation Data Centre (2008, online at http://www.env.gov.bc.ca/atrisk/red-blue.html) the blue list:

> Includes any indigenous species or subspecies considered to be of Special Concern (formerly Vulnerable) in British Columbia. Taxa of Special Concern have characteristics that make them particularly sensitive or vulnerable to human activities or natural events. Blue-listed taxa are at risk, but are not Extirpated, Endangered, or Threatened.

Eulachon are also considered a Group 1 high priority candidate species for review in British Columbia by the Committee on the Status of Endangered Wildlife in Canada (COSEWIC). According to the COSEWIC Web site (http://www.cosewic.gc.ca/eng/sct0/assessment_process_e.cfm), "Group 1 contains species of highest priority for COSEWIC assessment. Wildlife species suspected to be extirpated from Canada would also be included in this group." A recent bid to conduct a COSEWIC review has been awarded in Canada and a final product is due in November 2010 (see information online at http://www.cosewic.gc.ca/eng/sct2/sct2_4_e.cfm).

Pickard and Marmorek (2007) reported out the results of a DFO workshop whose purpose was to determine research priorities and recovery strategies for eulachon in the wake of the recent coastwide decline. They stated that:

> Recent information indicates that eulachon are declining in many parts of the west coast of North America, though the reasons for this decline and possible remedies are not well understood. In 1994 the Columbia, Fraser, and Klinaklini rivers suffered sudden drastic declines (Hay 1996). Since then First Nations have reported that fish are absent or at very low levels in many other British Columbia eulachon spawning rivers including: the Kemano, Kitimat, Wannock, Bella Coola, Nass, Skeena, Chilcoot, Unuk, Kitlope, and Stikine (Moody 2007, Hay 2007).

According to Schweigert et al. (2007, p. 13):

> In recent years, particularly since 1994, eulachon abundance has declined synchronously in many rivers and virtually disappeared in California. This decrease has been noticeable in the PNCIMA [Pacific North Coast Integrated Management Area] region, with very poor runs in Douglas Channel, Gardner Canal, Dean/Burke channels, and Rivers Inlet areas in the past 5 years. It is suspected that these declines may be related to large-scale climate change. Recent studies suggest rivers that normally experience spring freshet events may gradually be changing to summer and fall freshets that may impair eulachon spawning runs.

### Other Status Assessments

Musick et al. (2000, p. 11) assessed the status of eulachon following American Fisheries Society criteria to define extinction risk in marine fishes (Musick 1999), and classified eulachon in the Columbia River as threatened based on "commercial landings [that] have declined from average of 2.1 million lb annually from 1938 to 1989 to 5,000 lb in 1999, a decline > 0.99." In addition, Musick et al. (2000, p. 11) stated that "other DPSs from British Columbia to northern California may have declines similar to that observed in the Columbia River."

Hay and McCarter (2000) conducted a review of the status of eulachon for the Canadian Stock Assessment Secretariat of Fisheries and Oceans Canada and concluded at that time that "the widespread decline in the southern part of the range warrants a COSEWIC classification of 'threatened' in Canadian waters." This conclusion was based on:

> Available evidence [which] suggests that several rivers in the central coast of British Columbia may be extirpated, while others have declined severely. Only the Nass maintains normal or near-normal runs, although the Fraser, while markedly lower in recent decades and especially since 1994, still has regular, but diminished runs. The Columbia River, with the world's largest eulachon run, declined sharply in 1993, and has remained low since. Apparently all runs in California have declined and several runs that once were large have not been seen in more than 20 years.

## General Demographic Indicators

Within the range of the DPS, the BRT examined abundance related information in the published literature; data provided by DFO, WDFW, and ODFW; analyses of available abundance data both past and present summarized in Moody (2008); and information and presentations provided by eulachon experts from DFO, WDFW, ODFW, the Cowlitz Indian Tribe, and the Yurok Indian Tribe assembled during a scientific technical meeting at the NWFSC in June 2008. Information on eulachon abundance fell into the general categories of 1) fisheries-independent scientific surveys of adults, offshore juveniles, and outmigrant larvae; 2) commercial fisheries-dependent landings; 3) recreational fisheries-dependent landings; 4) First Nations subsistence fisheries landings; 5) ethnographic studies; 6) anecdotal qualitative information; and 7) traditional ecological knowledge.

In addition, the BRT reviewed the results of a fuzzy logic expert system developed by Moody (2008) to estimate a past and present relative abundance status index for eulachon in several areas of the southern DPS of eulachon. Moody's (2008) expert system uses catch data to determine the exploitation status of a fishery and combines this with other data sources such as spawning stock biomass estimates, CPUE data, test fishery catches, larval survey data, or anecdotal comments on run size to estimate the relative abundance status index. This index was produced using designed heuristic rules and by adjusting weighting parameters (Moody 2008).

Although humans have exploited eulachon populations for centuries, the perceived abundance of the resource and its low commercial value has resulted in limited regulation of past commercial and recreational fisheries, limited recording of past catches, and until recently a lack of assessment surveys of spawning abundance. The BRT recognized that the lack of direct estimates of eulachon abundance based on fishery-independent surveys (spawning stock biomass estimates or escapement counts) prior to 1993 makes it very difficult to quantify trends in eulachon abundance. Since the mid-1990s, monitoring of this resource has improved and a handful of data sets are now available that track eulachon spawning stock abundance and offshore juvenile abundance or provide an indication of run strength in several subareas of the DPS.

## Data Availability

### Fisheries-independent scientific surveys

There are few direct estimates of spawning biomass of eulachon from rivers within the DPS, although all of these data sets began to be collected after the perceived decline in run sizes occurred in the early 1990s. Spawner biomass (pounds or metric tons) or total spawner counts (numbers of adult fish) are available for the Fraser River (1996–2009), Klinaklini River (1995), Kingcome River (1997), Wannock/Kilbella rivers (2005–2006), Bella Coola River (2001–2004), Kitimat River (1993–1996, 1998–2005), and Skeena River (1997). Even though the results of most of these studies are only available in gray literature reports, they were regarded by the BRT as constituting the best scientific and commercial data available for recent eulachon abundance in the DPS and were heavily weighted in the BRT's risk analysis. The BRT was cognizant of the fact that abundance estimates always contain observational error. These factors were taken into account when evaluating the data sets.

Offshore juvenile eulachon biomass estimates were available for Queen Charlotte Sound (1998–2009), West Coast Vancouver Island (1973, 1975–1983, 1985, 1987–2009), and the U.S. West Coast (1995, 1998, 2001). Data for Queen Charlotte Sound and West Coast Vancouver Island were collected by DFO as part of offshore shrimp biomass assessments. Eulachon juvenile biomass data for the U.S. West Coast were available from AFSC triennial groundfish bottom trawl surveys on the continental shelf (55–500 m) in 1995 (Wilkins 1998), 1998 (Wilkins and Shaw 2000), and 2001 (Wilkins and Weinberg 2002).

CPUE data for eulachon were also available off the U.S. West Coast in AFSC triennial groundfish bottom trawl surveys over the continental shelf in depths of 55–366 m (1989, 1992) or 55–500 m (1995, 1998, 2001) and in certain INPFC statistical areas in AFSC groundfish bottom trawl surveys over the continental slope in depths of 183–1,280 m (1989–1999). However, as mentioned previously, these groundfish surveys were designed to sample bottom dwelling species and capture only a small and erratic portion of the pelagic distribution of eulachon.

Mean eulachon larval density data were available in the mainstem Columbia River (1996–2009), Cowlitz River (1986, 1994–2004, 2006–2009), Grays River (1998–2001, 2004–2006, 2008, 2009), Elochoman River (1997–2001, 2003, 2008), Kalama River (1995–2002), Lewis River (1997–2003, 2007–2009), and Sandy River (1998–2000, 2003).

Data from a Fraser River test fishery were available for the years 1995–1998 and 2000–2005 and are reported as number of fish caught. CPUE data were available from the Columbia River (1988–2008), Kemano River (1988–2006), and Kitimat River (1994–2006).

### Commercial fisheries–dependent landings

Commercial fisheries landings in pounds or metric tons of eulachon were available for the Klamath River (1963), Umpqua River (1967), Columbia River (1888–1892, 1894–1913, 1915–2009), Fraser River (1881–1996), Kitimat River (1969–1971), and Skeena River (1900–1916, 1919, 1924, 1926–1927, 1929–1932, 1935, 1941).

In some areas of the southern DPS of eulachon where escapement counts or estimates of spawning stock biomass are unavailable, catch statistics provide the only available quantitative data source that defines the relative abundance of eulachon occurrence that may be otherwise evident only by simple run-strength observation. However, inferring population status or even trends from yearly changes in catch statistics requires assumptions that are seldom met, including similar fishing effort and efficiency, assumptions about the relationship of the harvested portion to the total portion of the stock, and statistical assumptions such as random sampling.

**First Nations and Indian tribal subsistence fisheries landings**

First Nations subsistence fisheries landings in pounds or metric tons of eulachon were available for a number of rivers in British Columbia including the Fraser River (1975–1987, 1991), Klinaklini River (1947, 1949, 1950, 1952, 1959–1973, 1977), Kingcome River (1950, 1957, 1960, 1961, 1963, 1966), Wannock River (1967, 1968, 1971), Bella Coola River (1945, 1946, 1948–1989, 1995, 1998), Kemano River (1969–1973, 1988–2006), and Kitimat River (1969–1972).

**Recreational fisheries–dependent landings**

Recreational fisheries for eulachon are even more poorly documented that those for commercial and subsistence purposes. A popular recreational dip net fishery for eulachon has a long history on the Columbia River, particularly in tributary rivers such as the Cowlitz and on occasion the Sandy River. Catch records are not maintained for this fishery, although it has been estimated at times to equal the commercial catch (WDFW and ODFW 2001). A similar recreational dip net fishery occurred in the past on the Fraser River, and landings data exist for a portion of this fishery in the vicinity of Mission, British Columbia, for the years 1956, 1963–1967, and 1970–1980 (Moody 2008, p. 49, her Figure 2.22).

**Ethnographic studies**

Numerous ethnographic studies emphasize the nutritional and cultural importance of eulachon to coastal mainland Indian tribes and First Nations. The BRT examined ethnographic sources that describe historical distributions and relative abundance of eulachon fisheries within the boundaries of the DPS. Many of the statements in these sources as to the historical distribution and abundance of eulachon consisted of traditional ecological knowledge or were anecdotal in nature.

**Anecdotal qualitative information**

Anecdotal information is defined in the present context as information based on personal observation, case study reports, or random investigations rather than systematic scientific evaluation. This category includes memoirs of pioneers, fur trappers, and explorers; newspaper articles; and interviews with local fishers.

The BRT examined a variety of primary sources (e.g., accounts of early explorers, surveyors, fur trappers, and settlers and newspaper articles) and secondary sourced (e.g., agency fisheries reports and journal articles that cite personal communications) that describe historical distributions and relative abundance of eulachon within the boundaries of the DPS. The BRT also examined documents (e.g., Larson and Belchik 1998, Hay and McCarter 2000, Moody 2008) that cited interviews with local fishers or personal communications from local fisheries managers in their attempt to qualitatively characterize eulachon run strength. Many statements in these sources as to the historical distribution of eulachon were largely anecdotal in nature.

### Traditional ecological knowledge

Although there is a largely untapped store of knowledge on eulachon residing in the culture and traditions of Native American Indian Tribes and First Nations in Canada, the BRT did not separately consider traditional ecological knowledge sources in its deliberations; however, the BRT did examine secondary sources that presented information on eulachon presence and run size that was gathered from interviews with traditional local fishers.

## Summary of Regional Demographic Data

To facilitate evaluation of eulachon distribution and abundance, the BRT analyzed the available demographic information on a subpopulation basis, arranged geographically into separate major estuaries, which have been postulated to be the smallest area that likely supports a biological stock (McCarter and Hay 1999, Hay and McCarter 2000, Hay 2002). These major areas are 1) Klamath River, 2) Columbia River (Cowlitz, Grays, Lewis, Kalama, Sandy rivers, etc.) in the United States, 3) Fraser River, 4) Knight Inlet (Klinaklini River), 5) Kingcome Inlet (Kingcome River), 6) Rivers Inlet (Wannock and Kilbella/Chuckwalla rivers), 7) Dean Channel (Bella Coola and Kimsquit rivers), 8) Gardner Canal (Kemano, Kowesas, and Kitlope rivers), 9) Douglas Channel (Kitimat and Kildala rivers), and 10) Skeena River in British Columbia.

Eulachon are periodically noted in small numbers in several rivers and creeks on the Washington and Oregon coast. Documentation of these irregular occurrences of eulachon is usually anecdotal and it is uncertain how these fish are related demographically to eulachon in rivers such as the Fraser and Columbia where consistent annual runs occur. Occasionally large runs are noticed, usually by the abundance of predatory birds and marine mammals that accompany these runs, in coastal rivers such as the Queets and Quinault. Usually these large run events are separated in time by periods greater than the generation time of eulachon. We do not know enough about the biology of eulachon to know if these eulachon run events represent self-sustaining populations or are simply stray individuals from larger eulachon systems. It is possible that these populations may exist at levels of abundance that would not be detected by the casual observer, only to become noticed in years of high abundance. Further research on the source and sustainability of eulachon that occasionally appear in these coastal creeks and rivers is needed to fully assess the status of these eulachon aggregations.

### Offshore juvenile abundance estimates

Four fisheries-independent indices of juvenile offshore biomass are available that indicate status of stock mixtures: 1) a West Coast Vancouver Island eulachon biomass index (Figure 16); 2) a Queen Charlotte Sound eulachon biomass index (Figure 17); 3) estimates of CPUE, biomass, or number of eulachon reported in a series of groundfish bottom trawl surveys conducted on the continental shelf and slope of the U.S. West Coast by NMFS's NWAFC and

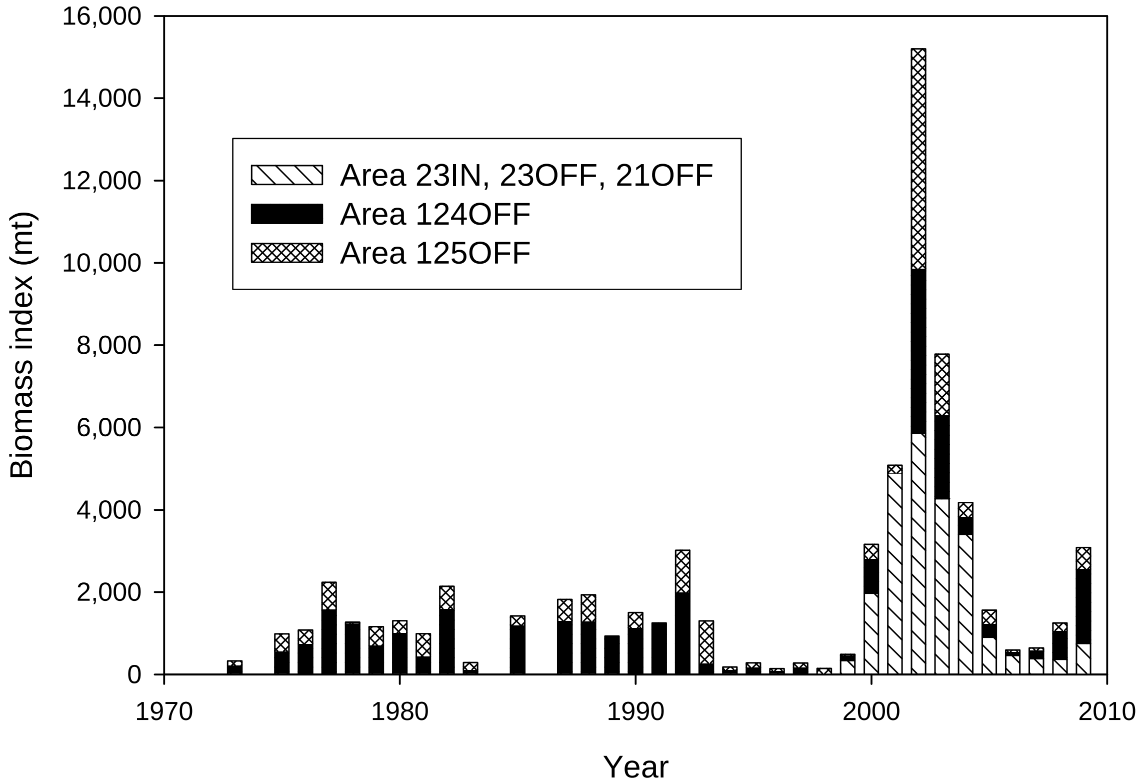

Figure 16. West coast Vancouver Island offshore eulachon biomass index. See Figure 21 for geographic locations of DFO shrimp management areas 23IN, 23OFF, 21OFF, 124OFF, and 125OFF. Data from Hay et al. (2003) and DFO west coast Vancouver Island shrimp survey bulletins (2000–2009), online at http://www-ops2.pac.dfo-mpo.gc.ca/xnet/content/Shellfish/shrimp/surveys/surveys.htm?

AFSC and more recently by NWFSC (Table 2 through Table 5, Figure 18, and Figure 19); and 4) the AFSC Gulf of Alaska bottom trawl biomass estimates for eulachon (Figure 20). The latter two groundfish surveys were designed to sample bottom-dwelling species and capture only a small and erratic portion of the pelagic distribution of eulachon. In addition, none of these four indices provides information on spawning stock biomass and each incorporates juvenile biomass derived from 2 to 4 broodyears; however, these indices are useful predictors for potential future run sizes.

DFO (2008a, p. 11) describes the west coast Vancouver Island eulachon biomass index as follows (Figure 16):

> The offshore biomass index is based on an annual trawl survey conducted in late April or early May by Fisheries and Oceans Canada, Science Branch. The survey initially was designed to index shrimp abundance but since eulachon also are caught by this survey, a eulachon index is possible. It is important to note that this is a biomass index and not a biomass estimate and that eulachon caught in this survey include stocks from both the Fraser River, and the Columbia River, and possibly other areas. This survey has been conducted since 1973 and provides an annual index of offshore abundance for the lower west coast Vancouver Island (areas 121, 23, 123, 124, and 125) [Figure 21].

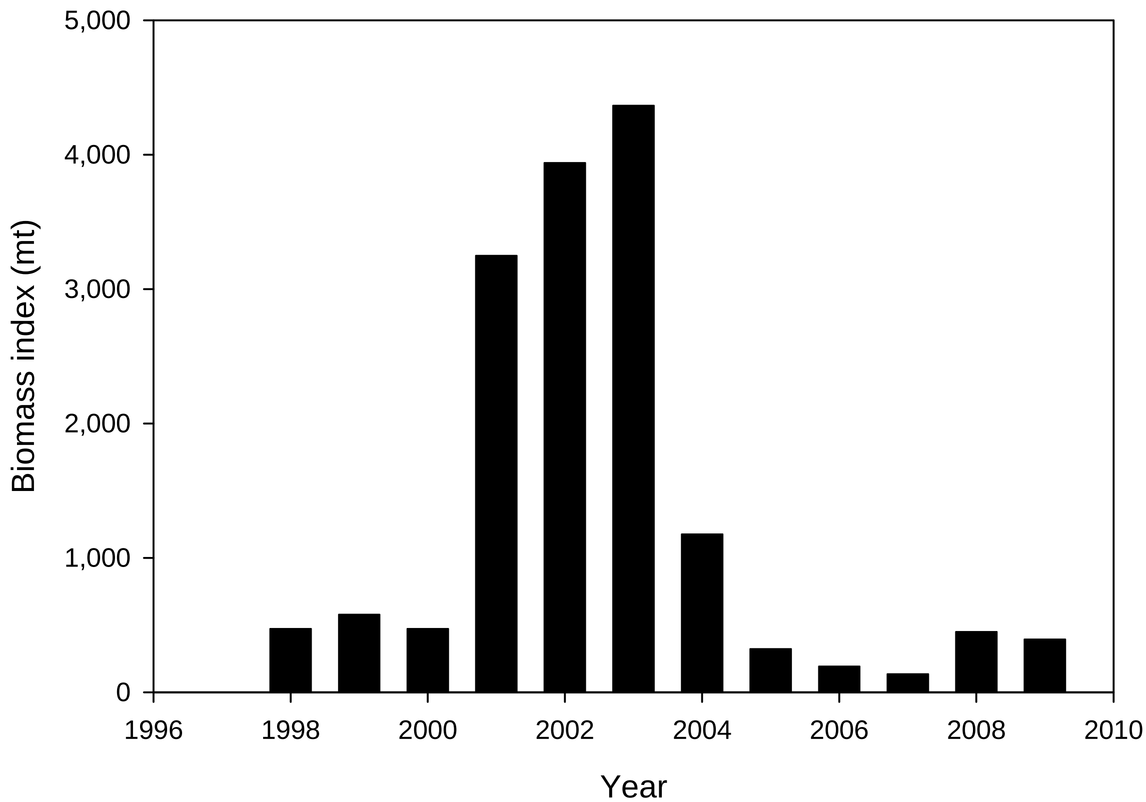

Figure 17. Queen Charlotte Sound offshore eulachon biomass index. Data from DFO Queen Charlotte Sound shrimp survey bulletins (2000–2009), online at http://www-ops2.pac.dfo-mpo.gc.ca/xnet/content/Shellfish/shrimp/surveys/surveys.htm?

DFO (2009a, p. 3) stated that "the eulachon biomass indices for 2009 increased in all SMAs [shrimp management areas] surveyed [off west coast Vancouver Island] compared to 2008 indices" (Figure 16). Biomass increased "from 353.7 t in 2008 to 720.8 t in 2009" in SMAs 23OFF+21OFF, "from 697.8 t in 2008 to 1810.1 t in 2009" in SMA 124OFF, and "from 184.9 t in 2008 to 520.0 t in 2009" in SMA 125OFF (DFO 2009a, p. 3) (Figure 21).

In a similar manner, a Queen Charlotte Sound eulachon biomass index (Figure 17) is derived from eulachon caught in the fishery-independent shrimp survey that is conducted in May of each year in SMA Queen Charlotte Sound. Data indicate that "the 2008 estimate of 451.5 t is a significant increase from the record low 137.1 t in 2007" (DFO 2008b, p. 2); however, "eulachon biomass on the shrimp grounds decreased slightly to 394.8 t in 2009 from 451.5 t in 2008" (DFO 2009b, p. 2). As reported in DFO (2009b, p. 3) "the shrimp trawl fishery in SMA Queen Charlotte Sound will remain closed due to eulachon conservation concerns in central British Columbia rivers" (Figure 21).

The history and location of groundfish trawl surveys conducted by the NWAFC, AFSC, and NWFSC in Alaska and off the U.S. West Coast were described in the above Marine Distribution subsection. Mean CPUE (kg/ha) data for eulachon in select INPFC statistical areas (Table 2) were published in various AFSC groundfish bottom trawl surveys conducted between

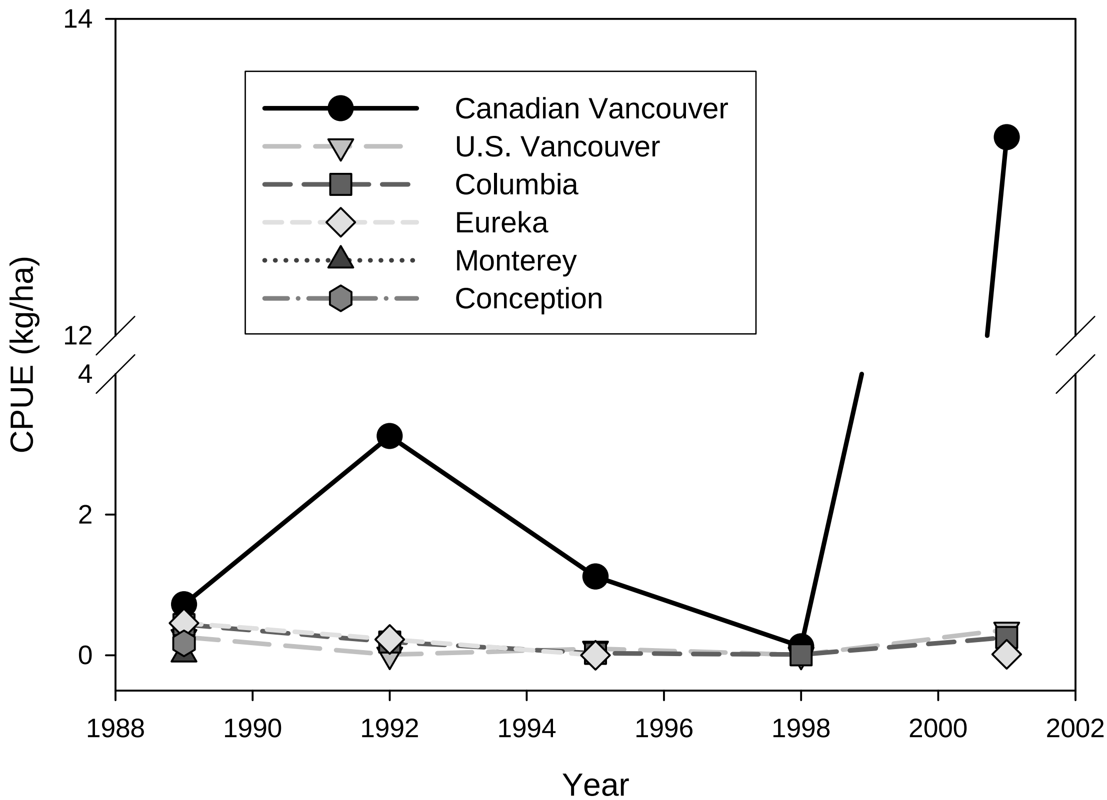

Figure 18. Mean CPUE (kg/ha) of eulachon in INPFC statistical areas (Figure 4) off the U.S. West Coast, as reported in AFSC triennial groundfish bottom trawl surveys on the continental shelf in depths of 55–366 m (1989 and 1992) or 55–500 m (1995–2001) in 1989 (Weinberg et al. 1994), 1992 (Zimmermann 1994), 1995 (Wilkins 1998), 1998 (Wilkins and Shaw 2000), and 2001 (Wilkins and Weinberg 2002).

1989 and 1999 on the U.S. West Coast continental slope between depths of 183 and 1,280 m (Lauth et al. 1997, Lauth 1997b, 1999, 2000).

As mentioned previously, this depth range is deeper than preferred by eulachon and it is likely that these continental slope surveys missed the vast majority of eulachon in the area. The 1977 triennial groundfish survey recorded eulachon in six of nine assemblages on the continental shelf off the Washington and Oregon coasts, being most abundant within the Nestucca Intermediate Assemblage (90–145 m), where they constituted 3.5% of the total biomass and had a mean CPUE of 28.6 lb/haul (13 kg/haul) (Gabriel and Tyler 1980). In 1980 eulachon were recorded as the 15th most common fish encountered (0.69 kg/ km trawled) in the shallow stratum (55–183 m) in the INPFC Eureka area, but were not recorded within the top 20 species encountered in the INPFC Vancouver, Columbia, or Monterey areas (Coleman 1986). Triennial surveys conducted in 1989–2001 provided mean CPUE (kg/ha) data for eulachon (Table 3, Figure 18) in INPFC statistical areas off the U.S. West Coast (Weinberg et al. 1994b, Zimmermann 1994, Wilkins 1998, Wilkins and Shaw 2000, Wilkins and Weinberg 2002).

Biomass and total number of fish (Table 5) estimates for eulachon were published for surveys conducted in 1995 (Wilkins 1998), 1998 (Wilkins and Shaw 2000), and 2001 (Wilkins

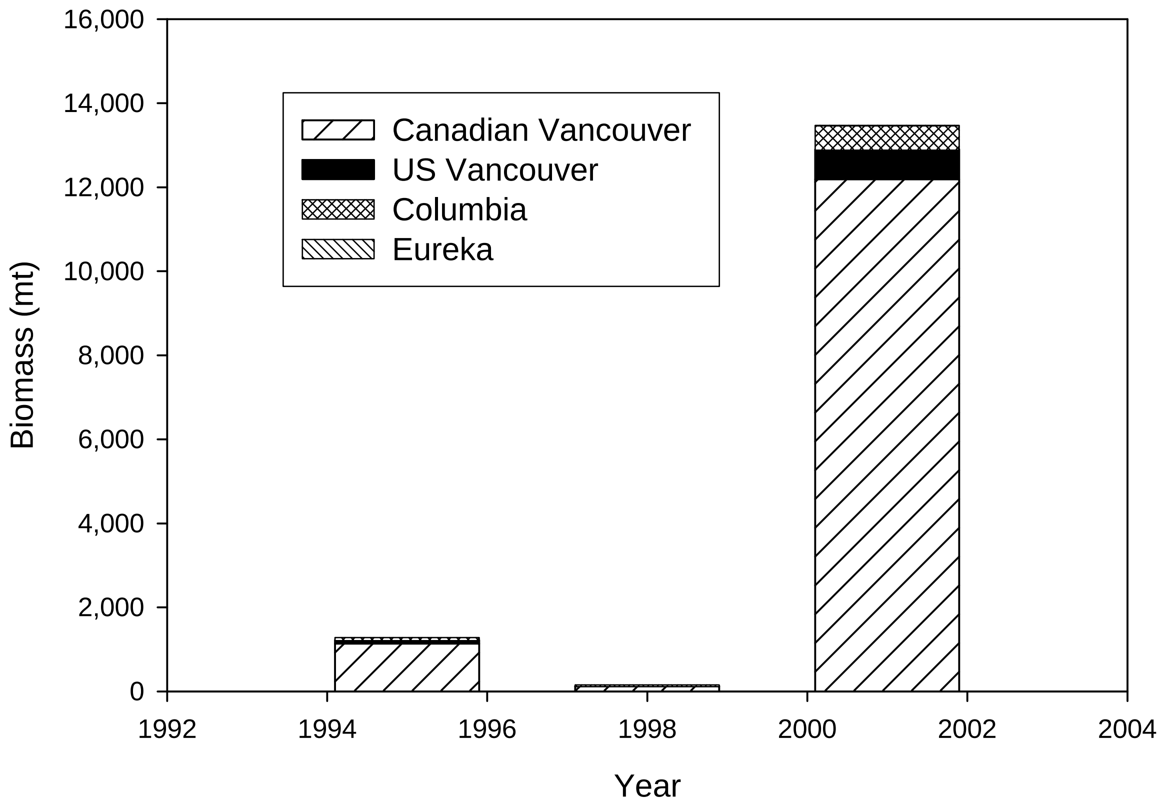

Figure 19. Estimated biomass (mt) of eulachon in INPFC statistical areas (Figure 4) off the U.S. West Coast as reported in AFSC triennial groundfish bottom trawl surveys on the continental shelf in depths of 55–500 m in 1995 (Wilkins 1998), 1998 (Wilkins and Shaw 2000), and 2001 (Wilkins and Weinberg 2002).

and Weinberg 2002). Between 80% and 90% of the eulachon biomass in these surveys occurred in the Canadian portion of the Vancouver INPFC area (Table 4, Figure 19). As stated previously, these groundfish surveys were designed to sample bottom-dwelling species and only capture a small and erratic portion of the pelagic distribution of eulachon.

Although unlikely to include eulachon from the southern DPS, the AFSC Gulf of Alaska bottom trawl estimates for eulachon (Figure 20) are a useful indicator of fluctuations in abundance in the Alaska Current for comparison with conditions in the California Current.

**Oregon marine recreational fisheries survey data**

ODFW (Williams 2009) (Table 6) provided a:

> summary for catches of eulachon in the marine sport fishery. The Oregon Recreational Boat Survey (ORBS) is our ocean boat sampling project. The survey is responsible for sampling sport catches from boats, focusing on ocean catches. Estimates of harvest are produced based on this sampling and are used for in-season management of quota species. Sampling takes place at a lesser extent in estuaries and that information is catalogued, but not used routinely. The

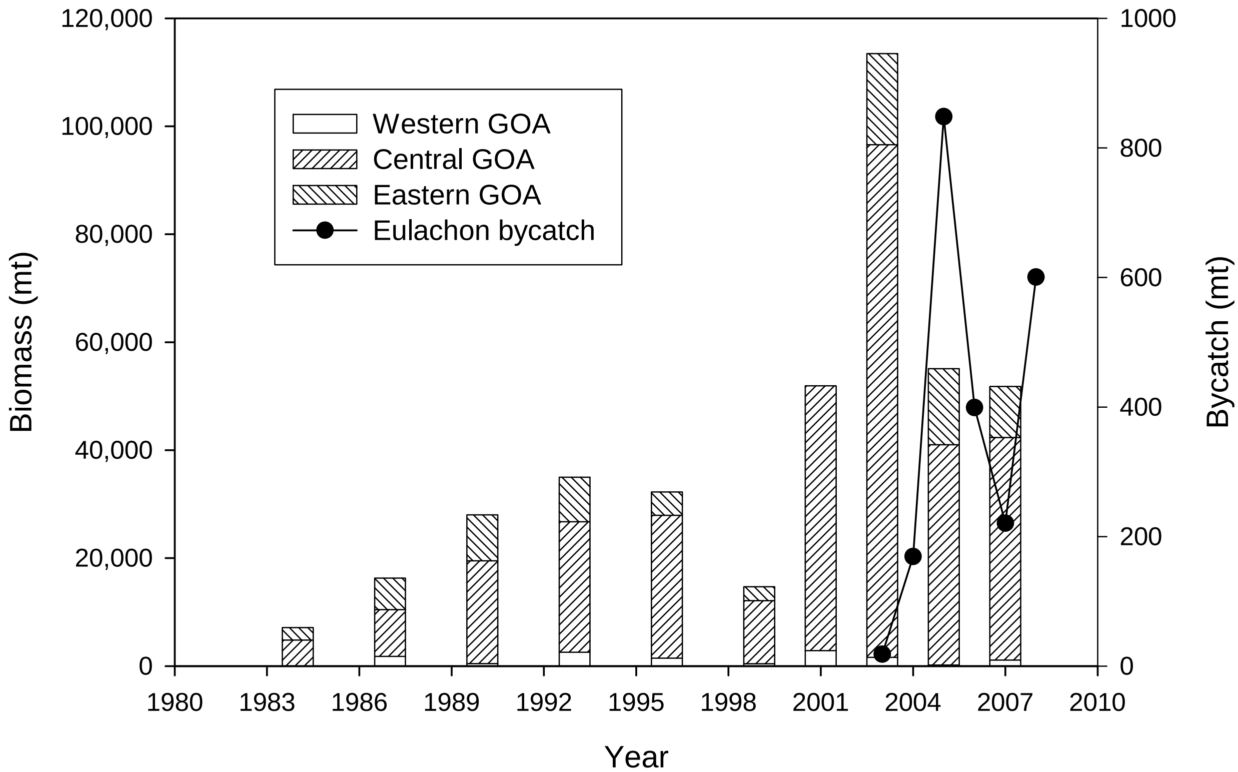

Figure 20. AFSC bottom trawl survey biomass estimates for eulachon and fishery incidental catch (bycatch) of eulachon in the Gulf of Alaska. Data from Ormseth and Vollenweider (2007) and Ormseth et al. (2008).

> Marine Recreational Finfish Statistical Survey (MRFSS) was formed by NMFS and operated by the Pacific States Marine Fisheries Commission. This survey was conducted at all saltwater access points including beaches, estuaries, man-made structures (e.g., jetties), and docks. It was a comprehensive survey that was intended to produce harvest trends over a number of years. … Beginning in 1994, ORBS estimates for ocean boats superseded those generated by the old MRFSS program because ORBS methodology generates more accurate estimates. In particular, MRFSS is weak in capturing pulse, or short-term, fisheries like smelt (the PSE [proportional statistical error] for the annual eulachon estimates range from 73 to 100). Hence, the summary is best regarded as an indicator of eulachon presence in the sport fishery, not absolute numbers.

**Northern California**

There has been no long-term monitoring program for eulachon in California, making the assessment of historical abundance and abundance trends difficult. Within California, large spawning aggregations of eulachon were reported to have once regularly occurred in the Klamath River (Fry 1979, Moyle et al. 1995, Larson and Belchik 1998, Moyle 2002, Hamilton et al. 2005) and on occasion in the Mad River (Moyle et al. 1995, Moyle 2002) and Redwood Creek (Moyle et al. 1995) (Table A-1, Figure 2). In addition, Moyle et al. (1995) and Moyle (2002) stated that small numbers of eulachon have been reported from the Smith River

(Table A-1). CDFG's Status Report on Living Marine Resources (Sweetnam et al. 2001, p. 477–478) stated that "The principal spawning run [of eulachon] in California is in the Klamath River, but runs have also been recorded in the Mad and Smith rivers and Redwood Creek." Allen et al. (2006) indicated that eulachon usually spawn no further south than the lower Klamath River and Humboldt Bay tributaries.

Eulachon were of great cultural and subsistence importance to the Yurok Tribe on the lower Klamath River (Trihey and Associates 1996) and the Yurok people consider eulachon to be a Tribal Trust Species along with spring and fall Chinook salmon, coho salmon, steelhead, Pacific lamprey (*Lampetra tridentata*) , and green sturgeon (*Acipenser medirostris*) (Trihey and Associates 1996, Larson and Belchik 1998). Eulachon once supported popular recreational fisheries in northern California rivers, but were never commercially important in California. The only reported commercial catch of eulachon in northern California occurred in 1963 when a combined total of 56,000 lb (25 mt) was landed from the Klamath River, the Mad River, and Redwood Creek. According to Larson and Belchik (1998, p. 4):

> Literature regarding … [eulachon] specific to the Klamath River Basin is limited to accounts of mere presence and qualitative descriptions of the species. Though integral components of Yurok culture, eulachon … have not been of commercial importance in the Klamath and are … totally unstudied as to their run strengths.

Larson and Belchik (1998, p. 6) also reported that according to accounts of Yurok tribal elders:

> The last noticeable runs of eulachon were observed [in the Klamath River] in 1988 and 1989 by tribal fishers. Most fishers interviewed perceived a decline in the mid to late 1970s, while about a fifth thought it was in the 1980s. A minority of those interviewed noticed declines in the 1950s and 1960s.

Larson and Belchik (1998, p. 7) further stated that:

> In December 1988 and May 1989, a total of 44 eulachon were identified in outmigrant salmonid seining operations in and above the Klamath River estuary (CDFG unpublished seining data). Though only selected sites are seined and salmonids are the targeted species, no eulachon have been positively identified since at least 1991 (M. Wallace, CDFG, pers. commun.).

As detailed in Larson and Belchik (1998), the Yurok Tribal Fisheries Program spent more than 119 hours of staff time from February 5 to May 6, 1996, sampling for eulachon in the lower Klamath River at 5 different sites where eulachon had been noted in the past without encountering a single eulachon. However, one eulachon was captured by a Yurok tribal member near the mouth of the Klamath River in 1996 (Larson and Belchik 1998). Sweetnam et al. (2001, p. 478), in the CDFG Status Report on Living Marine Resources, stated that "In recent years, eulachon numbers seem to have declined drastically, so they are now rare or absent from the Mad River and Redwood Creek and scarce in the Klamath River." CDFG (Sweetnam et al. 2001, p. 478) also stated that "the eulachon and its fishery have been largely ignored in the past" in California, and perhaps the perceived lack of eulachon in the Klamath River, currently and in the recent past, represent a low point in a natural cycle. In January 2007 six eulachon were reportedly caught by tribal fishermen on the Klamath River.[12]

The BRT was concerned that there are almost no scientifically obtained abundance data available for eulachon in the Klamath River or any other basin in northern California. Ethnographic studies, pioneer diaries, interviews with local fishers, personal communications from managers, and newspaper accounts are therefore the best information available that provide documentation of eulachon occurrence in the Klamath River and other rivers on the northern California coast.

The BRT discussed several possible interpretations of the available information. In particular, the BRT discussed the possibility that historically runs of eulachon in the Klamath River were episodic and perhaps only occasionally large enough to be noticed. The BRT also considered the possibility that eulachon still occur in low but viable numbers in northern California rivers but are not frequently observed because of the absence of a formal monitoring program. The BRT also discussed the possibility that some eulachon may spawn in estuarine environments and are not observed in the riverine environment.

The BRT concluded, however, that explanations that posit the absence of sustained Klamath River eulachon runs historically are less consistent with the available information than the hypothesis that Klamath River eulachon runs used to be regular and large enough to be readily noticeable and now are at most small and sporadic. In particular, various accounts written by CDFG personnel (Fry 1979, Sweetnam et al. 2001, CDFG 2008), Yurok Tribal Fisheries Department personnel (Larson and Belchik 1998), the National Resource Council's Committee on Endangered and Threatened Fishes in the Klamath River Basin (NRC 2004), or available academic literature (Moyle et al. 1995, Moyle 2002, Hamilton et al. 2005) universally describe accounts of the past occurrence of eulachon in the Klamath River and their subsequent decline. Based on the available information, the BRT was therefore unable to estimate the historical abundance of eulachon in northern California, but the BRT found no reason to discount the veracity of these anecdotal sources, which span a period of approximately 100 years and are nearly universal in their description of noticeable runs of eulachon having once ascended the Klamath River.

Likewise, although the BRT was concerned about the absence of a contemporary monitoring program for eulachon, the information available strongly indicated that noticeable runs of eulachon are not currently spawning in Klamath River or other northern California rivers. In particular, the BRT thought it likely that if eulachon were returning in any substantial numbers, it would be reported by residents or those engaged in recreation, research, or management on rivers in northern California. The BRT noted that large eulachon runs tend to attract the attention of fishermen, and the previous runs on the Klamath River were readily noticeable (e.g., "the fish moved up in huge swarms, followed by large flocks of feeding seabirds" [Moyle 2002, p. 240]). The BRT therefore concluded that the available information was most readily interpreted as indicating that noticeable, regularly returning runs of eulachon used to be present in the Klamath River, but have been rare or sporadic for a period of several decades.

[12] D. Hillemeier, Yurok Tribal Fisheries Department, Klamath, CA. Pers. commun., 23 June 2008.

Although the BRT was reasonably confident that eulachon have declined substantially in northern California, it is also clear that they have not been totally absent from this area in recent years.  In particular, recent reports from Yurok tribal fisheries biologists of a few eulachon being caught incidentally in other fisheries on the Klamath in 2007 indicates eulachon still on occasion enter the Klamath River in low numbers.

**Columbia River**

The Columbia River and its tributaries support the largest eulachon run in the world (Hay et al. 2002).  Despite its size and the importance of the fishery (Appendix B and Appendix D), estimates of adult spawning stock abundance are unavailable and the primary information sources on trends in Columbia River eulachon abundance are catch records.  In addition to regular returns to mainstem spawning locations in the Columbia River and on the Cowlitz River (most years), eulachon are known to spawn in the following lower Columbia River tributaries: Grays River (common use), Skamokawa Creek (infrequent use), Elochoman River (periodic use), Kalama River (common use), Lewis River (common use), and Sandy River (common use in large run years) (Table A-1, Figure 2) (WDFW and ODFW 2008).

Commercial fishery records begin in 1888 (Table 7 through Table 9, Figure 22) and local newspapers record catches in the Columbia River as early as 1867 (see Appendix B).  A large recreational dip net fishery for which catch records are unavailable has existed in concert with commercial fisheries, and the importance of the eulachon run to local Indian tribes was documented as early as the Lewis and Clark Expedition (Burroughs 1961, WDFW and ODFW 2001).  The Joint Columbia River Management Staff (JCRMS 2007) stated that "limited past creel census information suggest that the recreational catch may equal the commercial landings in some years when smelt are abundant for a long period of time."

The BRT did not have confidence in the fishery landings, particularly prior to 2001 in the Columbia River as an accurate index of the actual abundance of the species.  Landings are influenced by market conditions, fishing effort, weather, and many other factors other than actual fish abundance (WDFW and ODFW 2008).  After implementation in 2000 of the interim Joint State Eulachon Management Plan (WDFW and ODFW 2001), the commercial fishery landings have become a relatively accurate index of the trend in the run size of eulachon returning to the Columbia River.  For instance, eulachon returns increased during 2001–2003, dropped slightly in 2004, then dropped dramatically in 2005, which is reflected in both the commercial landings and CPUE data collected during 2001–2007.  This pattern was also essentially identical to that seen in offshore eulachon abundance indices (Figure 16 and Figure 17) and in abundance and catch records in several other rivers (e.g., Fraser and Klinaklini rivers) in the DPS.  JCRMS (2007) has concluded that recent commercial landings "do provide a useful measure of the relative annual run strength."  In particular, state fisheries managers of Columbia River eulachon use commercial landings to judge whether population trends are upward, neutral, or downward (JCRMS 2007).

Although not useful for estimating an accurate trend, the long-term landings data do indicate that commercial catch levels were consistently high (>500 mt and often >1,000 mt) for the three-quarters of a century period from about 1915 to 1992 (Table 9, Figure 22).  Catches

Table 7. Eulachon (aka Columbia River smelt) landings (pounds) from the Columbia River and tributary commercial fisheries. Prior to 1936, data were commonly reported by state; after that time data were reported by river basin, but not by individual state.

Table 7 continued. Eulachon (aka Columbia River smelt) landings (pounds) from the Columbia River and tributary commercial fisheries. Prior to 1936, data were commonly reported by state; after that time data were reported by river basin, but not by individual state.

| Year | Columbia River | Grays River | Cowlitz River | Kalama River | Lewis River | Sandy River | Oregon only[a] | Washington only | Total | Source |

[a]Some Oregon commercial smelt catch values may be statewide smelt catch and may include an unknown number of noneulachon smelt caught in coastal streams.
[b]Official landings data were not located for 1893 and 1914; however, newspapers (Appendix B) and local periodicals (Appendix D) recorded that substantial eulachon landings did occur in the Columbia River basin in those years.
[c]Crawford (1894, p. 5) reported landings that equated to a monetary value of $3,000. At an average of one cent per pound, this equates to approximately 300,000 pounds of eulachon.

Table 8. Eulachon landings from the Columbia River and tributary commercial fishery and total numbers of fish in the catch, assuming a range of 10.8 to 12.3 eulachon per pound, based on the mean reported weight of eulachon in the Columbia River of 37 to 42 g. Landings data from sources listed in Table 7.

| Year | Total landings (pounds) | Number of fish at 10.8 per pound | Number of fish at 12.3 per pound |

[a]Official landings data were not located for 1893 and 1914; however, newspapers (Appendix B) and local periodicals (Appendix D) recorded that substantial eulachon landings did occur in the Columbia River basin in those years.
[b]Landings of unknown size occurred but data were not recorded (Hay 2002).

declined greatly to 233 mt in 1993 and to an average of less than 40 mt between 1994 and 2000. From 2001 to 2004, the catches increased to an average of 266 mt, before falling to less than 5 mt from 2005 to 2008. Fishing restrictions were instituted in 1995, so the low catches after that time are in part due to these restrictions (Figure 23 and Figure 24). Nonetheless, the steep decline in 1993 and subsequent low abundance as indexed by the fishery is generally accepted by fishery managers as indicating a marked decline in the abundance of the stock (Bargmann et al. 2005). The WDFW and ODFW Joint Columbia River Management Staff (JCRMS 2007) concluded that "run sizes [of Columbia River eulachon], as indexed by commercial landings, remained relatively stable for several decades until landings dropped suddenly in 1993 and remained low for several years thereafter." Following this period of time, "Due to reduced seasons during 1995–2000, landings are not completely comparable with previous years; however, it is apparent that the abundance of smelt in the Columbia River Basin was much reduced during 1993–2000" (JCRMS 2005) (Table 7, Figure 22 through Figure 25).

A previous petition (Wright 1999) and NMFS finding on this petition (NMFS 1999) mentioned years where zero catches were reported for eulachon in the Columbia River. The present status review uncovered additional published Columbia River commercial fishery landings data in annual reports of state and federal fisheries agencies that fill in most of these gaps in the catch record (Table 7, Figure 22), with the exception of 1893 and 1914. In both cases, a survey of periodicals (Appendix D) and available online digital newspaper resources (see Appendix B) found articles describing the presence of eulachon in the Columbia River in those years.

The Columbia River eulachon commercial fishery has been managed according to the Joint State Eulachon Management Plan since 2001 (with an interim plan in effect in 2000), which provides for three levels of fishing based on parental run strength, juvenile production, and ocean productivity (WDFW and ODFW 2001, Bargmann et al. 2005). Effort in this fishery

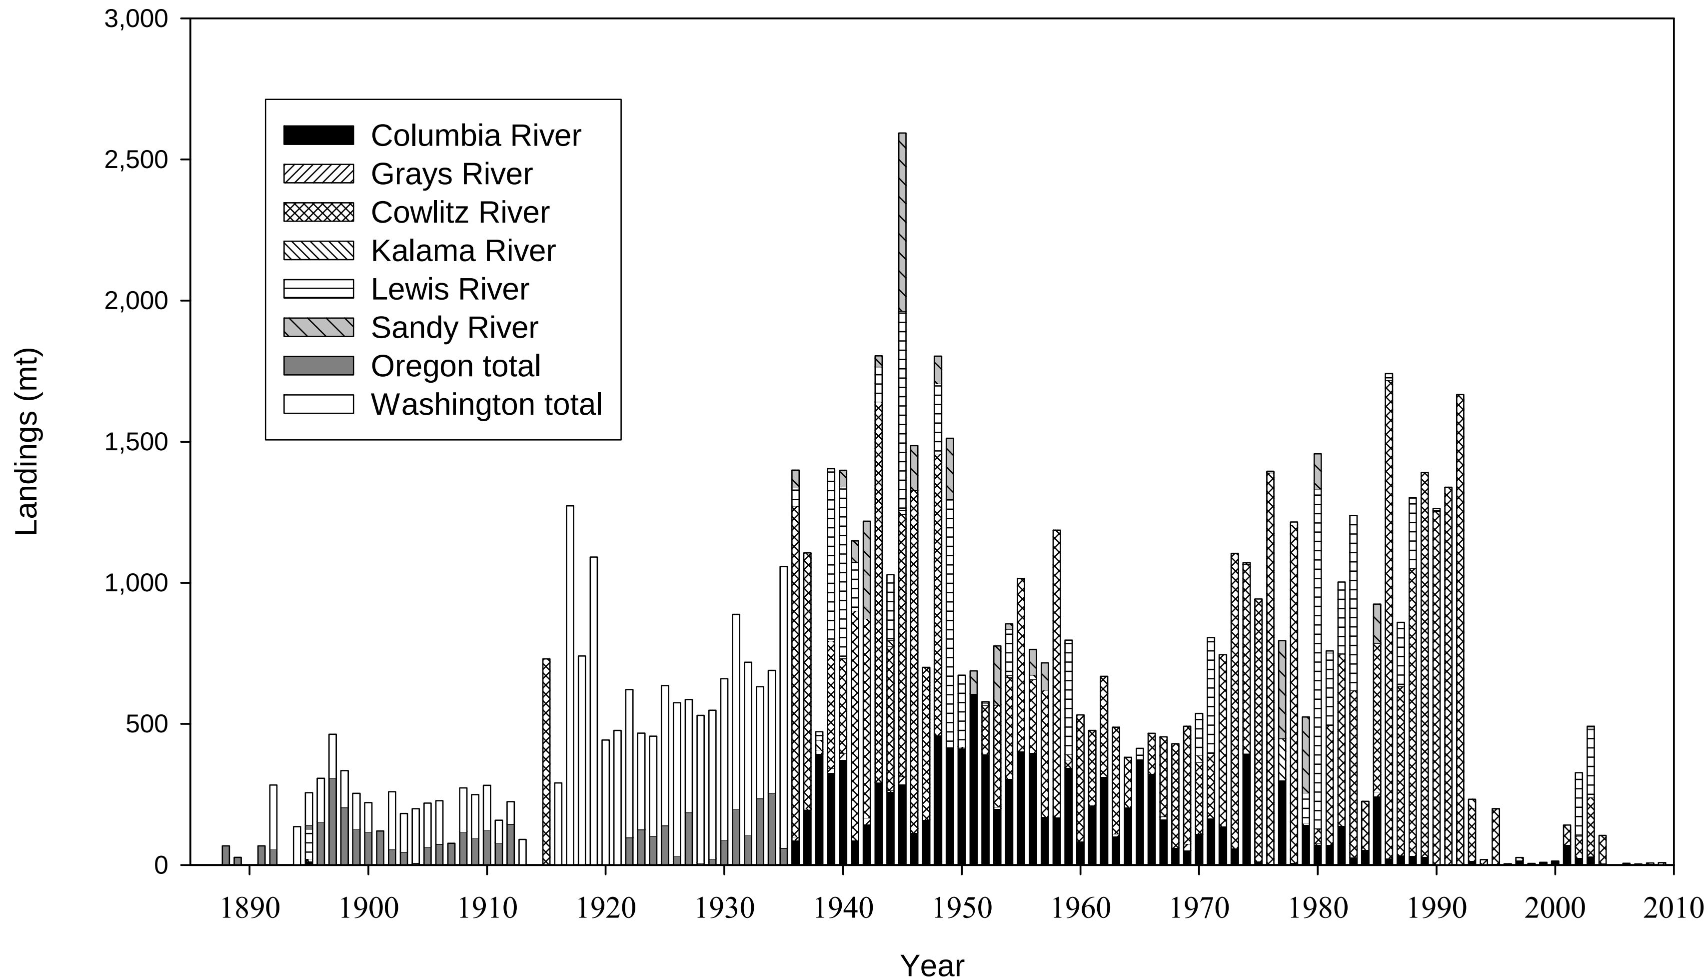

Figure 22. Commercial eulachon fishery landings in the Columbia River and tributaries from 1888 to 2009. Landings occurred in 1890 and in the Grays and Kalama rivers in many years; however, values are too small to be evident on the graph. Landings occurred in 1893 and 1914, based on newspaper and periodical sources (see Appendix B and Appendix D), but official records have not been located. Data sources listed in Table 7.

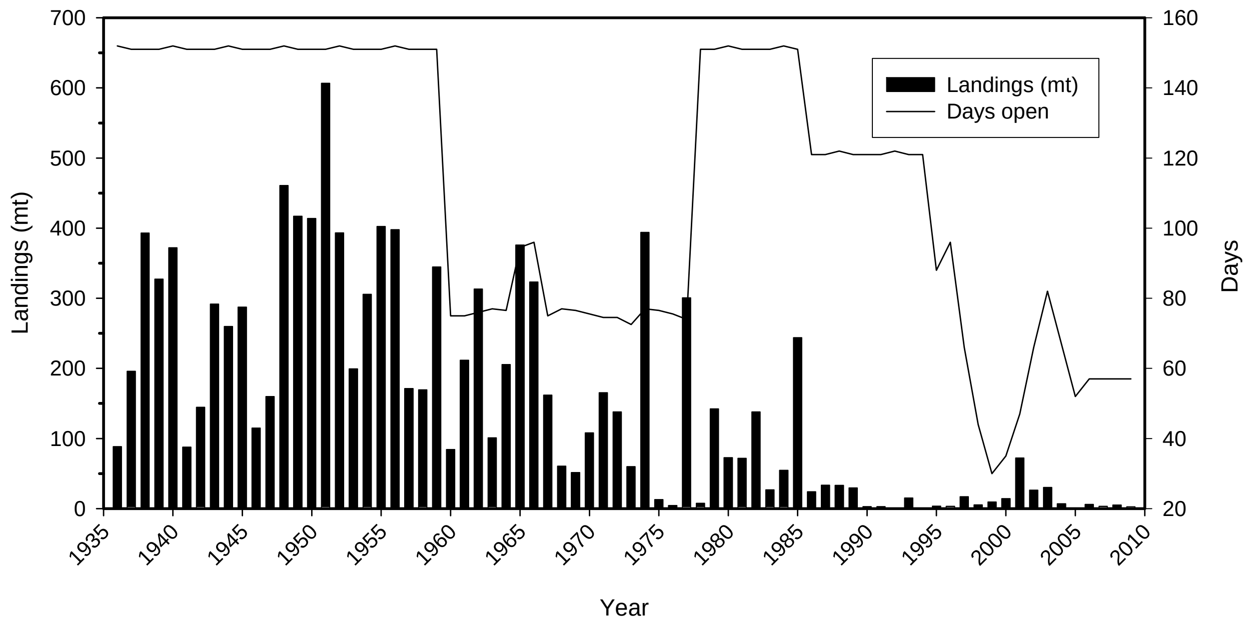

Figure 23. Commercial landings of eulachon and estimated total number of days the fishery was open in the Columbia River from 1935 to 2009.

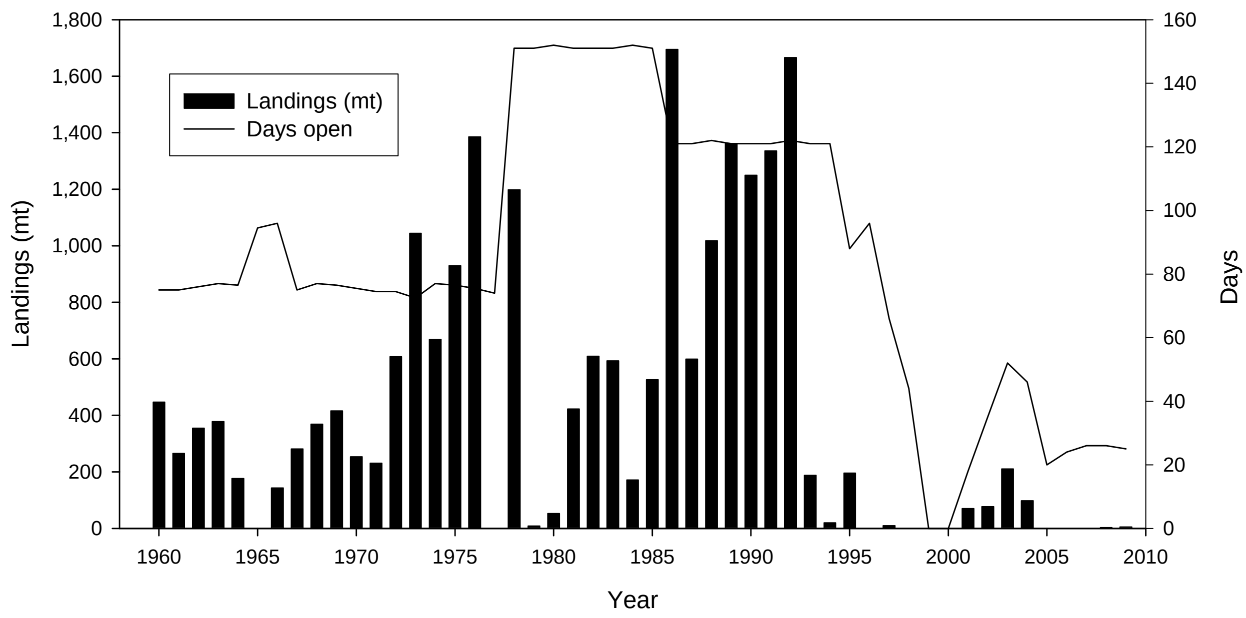

Figure 24. Commercial landings of eulachon and estimated total number of days the fishery was open in the Cowlitz River from 1960 to 2009.

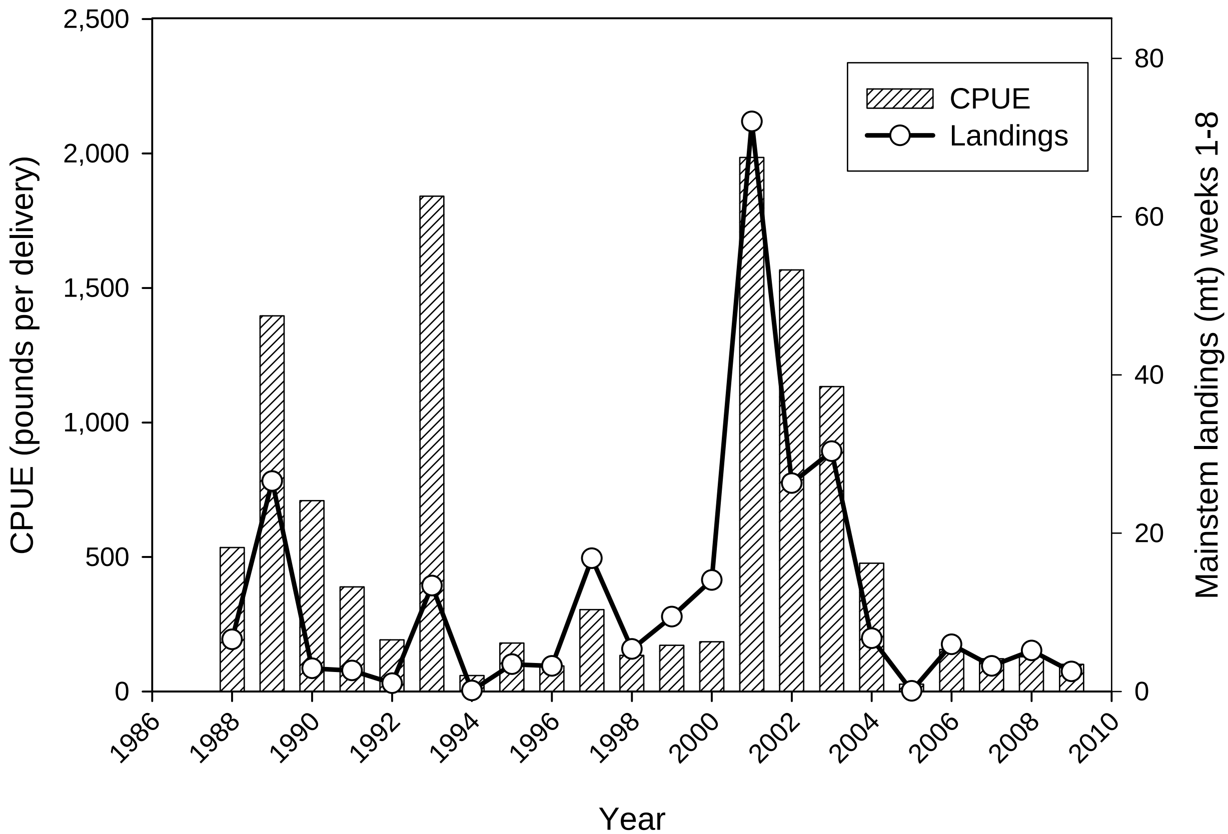

Figure 25. Columbia River commercial eulachon landings (season total may include landings during the previous December) and CPUE as pounds per delivery. Data from JCRMS (2009, their Table 17).

typically involves fewer than 10 vessels. WDFW and ODFW (2008) described these three levels of fishing: 1) Level One fisheries are the most conservative (commercial and recreational openings of 12–24 hours per week for Columbia and Cowlitz rivers) and are designed to act as a test fishery when there are indications of a poor return or great uncertainty in potential run strength, 2) Level Two fisheries (commercial and recreational openings of 2–3 days per week and potential of expansion to other tributaries) are indicated when fishery data suggest a moderate or strong run size, and 3) Level Three fisheries (commercial openings up to 4 days per week in all areas and all tributaries open to recreational fishing 4–7 days per week) may occur when abundance and productivity indicators are very strong.

The Columbia River eulachon fishery operated as a Level One test fishery in 2001; began as a Level Two fishery in 2002, switching to Level Three on February 1; operated at Level Three in 2003; started off as Level Three in 2004, with some later tributary commercial fishery restrictions; operated at Level Two in 2005 until February 23 when it was reduced to a Level One fishery; and has operated as a Level One test fishery in 2006 through 2009 (JCRMS 2005, 2006, 2007, 2008, 2009). The ability to adjust in-season fishery levels based on observed returns to the fishery, and its accurate tracking of past fluctuations in run strength, illustrates the utility of the Columbia River eulachon fishery statistics as an index of relative annual abundance (JCRMS 2007) (Figure 23 and Figure 24).

There is some information indicating that there have been periods of relatively low eulachon abundance in the past in the Columbia River. In particular, several anecdotal sources reported on a decline in the 1830s to 1860s (Suckley 1860, Lord 1866, Anderson 1872, 1877, Crawford 1878, Huntington 1963, Hinrichsen 1998, Martin 2008). Eulachon were once again seen in large numbers in the early to mid 1860s (Anderson 1872, 1877, Huntington 1963, Summers 1982, Urrutia 1998, Hinrichsen 1998, Martin 2008). Based on the available information, the BRT concluded that this information was probably accurate and likely indicated that a true and severe decline in eulachon returns and subsequent recovery occurred during that time period.

Subsequent to the decline in 1993, state and tribal fishery agencies have instituted additional monitoring efforts for Columbia River eulachon. For example, Figure 26 presents data from a larval sampling program that measures larval densities (averaged across stations and depths at selected index sites) that was initiated in 1994 for the Cowlitz River and expanded to include the Kalama River in 1995, the mainstem Columbia River in 1996, Elochoman and Lewis rivers in 1997, and Grays and Sandy rivers in 1998 (JCRMS 2005). Interannual comparison of larval densities prior to about 2003 is unreliable because "larval sampling techniques … did not include repeat sampling of the same area over the duration of the out migration period" (JCRMS 2007, p. 23), but since that time multiple surveys have been conducted each season at mainstem Columbia River sites that sample downstream of all the potential spawning locations, with the exception of Grays River. Notably, the larval densities show a peak in 2001–2002 that corresponds to a similar peak in catches (Figure 22) and offshore juvenile abundance (Figure 16 and Figure 17). Although spawning stock abundance has not been estimated using these larval surveys, the combination of data from the larval density survey and commercial and recreational landings "provides an indication of the relative run strength of eulachon in the Columbia River" (JCRMS 2007, p. 23).

The BRT had concerns about the absence of fishery-independent abundance data for Columbia River eulachon prior to the mid-1990s. The BRT agreed with state fishery managers, however, that the available catch and effort information indicate an abrupt decline in abundance in the early 1990s, and there is no evidence that the population has returned to its former level. The decline in the early 1990s appeared to coincide with a decline of eulachon in British Columbia, suggesting that a common cause, such as changing ocean conditions, was responsible for declines in both areas.

### Fraser River

Eulachon return on a regular basis to the Fraser River and on an irregular basis to the Squamish River in Howe Sound to the north (Table A-1, Figure 3) (Hay and McCarter 2000, Moody 2008). Eulachon usually begin to ascend the Fraser River at the end of March and spawning occurs in April until the middle of May. Eulachon are no longer seen spawning in some areas of the Fraser River where they used to occur. Historically, spawning occurred "primarily between Chilliwack and Mission in areas of coarse sand but also in localized areas of the North and South Arms as well as in the vicinity of the Pitt and Alouette rivers" (Higgins et al. 1987). Currently spawning is confined to areas downstream of Mission.

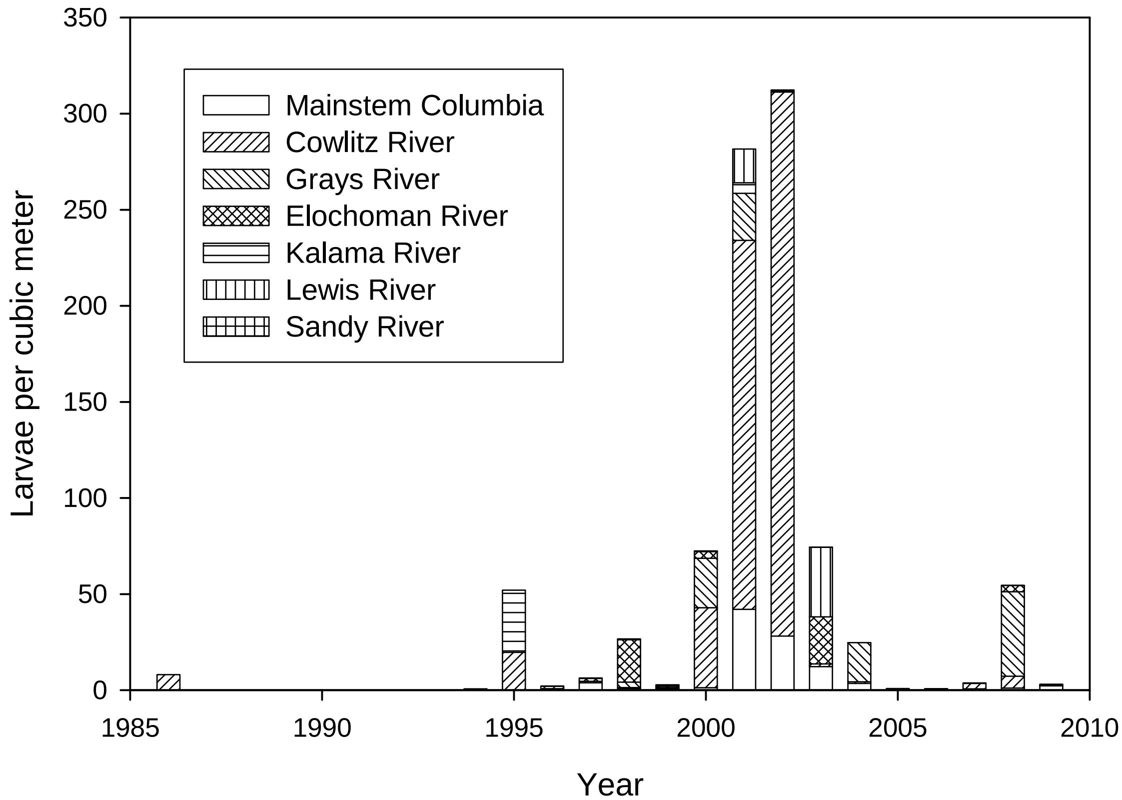

Figure 26. Columbia River larval eulachon sampling. Interannual comparisons are problematic due to inconsistent effort and methods from year to year. Larvae were encountered in the Sandy River in 1998–2000 and 2003; however, values are too small (0.1 per cubic meter) to be evident on the graph. Data from JCRMS (2008, 2009, its Table 18).

In the past, Fraser River eulachon runs supported First Nations subsistence fisheries and large commercial and recreational fisheries. Between 1941 and 1996, commercial landings averaged about 83 mt (Table 9, Table 10, and Figure 27). For much of this period, the commercial fishery landings are not a good indicator of relative abundance, since landings were largely driven by market demand (Moody 2008). In 1997 the commercial eulachon fishery was closed and commercial landings have occurred in only 2 of the last 10 years; 2002 and 2004, when 5.76 and 0.44 mt were landed, respectively (Table 9, Figure 27) (DFO 2006a). Hay et al. (2003) estimated that First Nations and recreational fisheries historically landed about 10 mt annually. Estimates of recreational fishery landings were presented in graphical form in Moody (2008, her Figure 2.22) for a portion of the Fraser River (1956, 1963–1967, 1970–1980, closed since 2005).

Moody (2008) stated that the First Nation catch amounted to 2.57 mt in 2003. However, by 2005 all First Nation, commercial, and recreational fisheries were closed due to conservation concerns (DFO 2006a). A eulachon test fishery operated on the Fraser River near New Westminster from 1995 to 2005 (with the exception of 1999) (Figure 27); however, this fishery has not operated since 2005 (DFO 2008a). This test fishery was meant to be an in-season

Table 10. Estimated eulachon spawner biomass (mt) in the north arm and south arm of the Fraser River and total number of eulachon, assuming a range of 9.9 to 13.3 eulachon per pound, based on the mean reported weight of eulachon in the Fraser River of 34 to 46 g. Biomass data online at http://www.pac.dfo-mpo.gc.ca/sci/herring/herspawn/pages/river1_e.htm.

| Year | South arm | North arm | Total biomass (mt) | Total biomass (pounds) | Number of fish at 9.9 per pound | Number of fish at 13.3 per pound |

| 2009 | 12 | 2 | 14 | 30,865 | 305,561 | 410,501 |

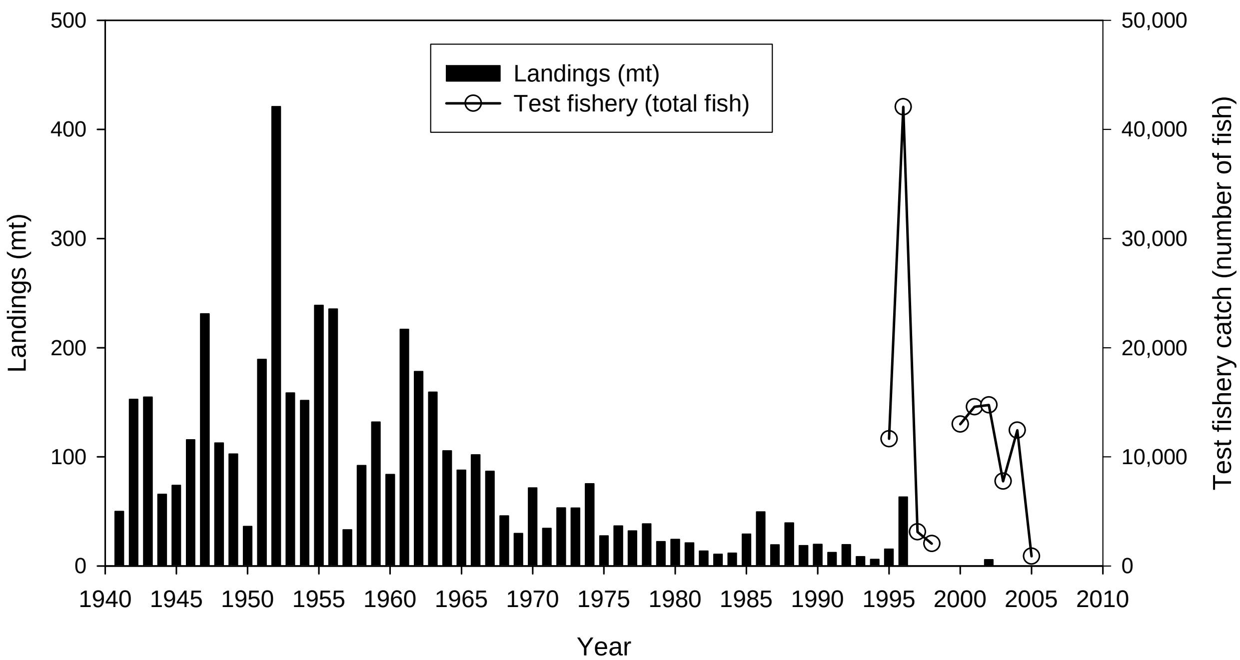

Figure 27. Eulachon landings in Fraser River commercial fishery (1940–2009) and total fish caught in Fraser River test fishery (1995–2005). Commercial fishery was closed in 1997–2001, 2003, and 2005–2009. Data from Hay (2002) and DFO (2008a).

measure of eulachon run strength and resulting data consisted of the total number of eulachon caught daily at the same site, with the same gear, over the same time period, and at similar tidal conditions (Therriault and McCarter 2005, DFO 2008a). When in operation, a catch of less than 5,000 in this test fishery was considered a conservation concern (DFO 2006a).

Table 10, Table 11, and Figure 28 present spawning stock biomass data (DFO 2008a, p. 11) that is derived from:

> an intensive sampling process [that] takes place in the Fraser River during the seven to eight weeks following spawning (April/May). This survey uses towed, small mesh nets to gather samples of eulachon eggs and larvae. The number of eggs and larvae gathered in each tow are hand counted at the Pacific Biological Station. The egg and larval count is then combined with data on the daily Fraser River discharge and historical data on eulachon fecundity (eggs produced per female) to generate an estimate of spawning stock biomass.

DFO (2008a, p. 11) stated that:

> A low spawning stock biomass for one year is cause for caution and a low spawning stock biomass for two consecutive years indicates a conservation concern. A low spawning stock biomass has been defined as less than 150 mt.

A recent population assessment of Fraser River eulachon by DFO (2007a, p. 3) stated that:

> Despite limited directed fisheries in recent years, the Fraser River eulachon stock remains at a precariously low level. This stock has failed to recover from its collapse. SSB [spawning stock biomass] estimated from the egg and larval survey conducted in 2006 was 29 tonnes. The framework documents suggest that a low SSB (<150 tonnes) for one year is cause for concern and a restriction on removals should be activated, while a low SSB for two (or more) consecutive years is more cause for alarm and should signal a halt to all removals (Hay et al. 2003, 2005). Since 2007 is the fourth consecutive year where Fraser River eulachon SSB has been below 150 tonnes, unprecedented in this short time series, no removals should be allowed in 2008.

Subsequent to this statement, spawner biomass for the 2008 and 2009 eulachon run in the Fraser River has been estimated at 10 and 14 mt, respectively (data online at http://www.pac.dfo-mpo.gc.ca/sci/herring/herspawn/pages/river1_e.htm). Figure 29 presents the Fraser River eulachon spawner abundance trend over the time period of the available data (1995–2009). A trend of 0.76 (95% CI, 0.67–0.88) for Fraser River eulachon was calculated from these data. Over the three-generation time of approximately 10 years, the overall biomass of the Fraser River eulachon population has undergone a 96.6% decline (1999, 418 mt; 2009, 14 mt). Under the International Union for the Conservation of Nature (IUCN) decline criteria (A1), a reduction in population size of this magnitude, "where the reduction or its causes may not have ceased or may not be understood or may not be reversible" (IUCN 2006), would place Fraser River eulachon in the IUCN critically endangered category (IUCN 2001, 2006).

The methodology on the Fraser River of utilizing mean egg and larval plankton density and river discharge rates (gathered throughout a seven-week outmigrant period at five locations) in combination with known relative fecundity (egg production per gram of female) and sex ratio

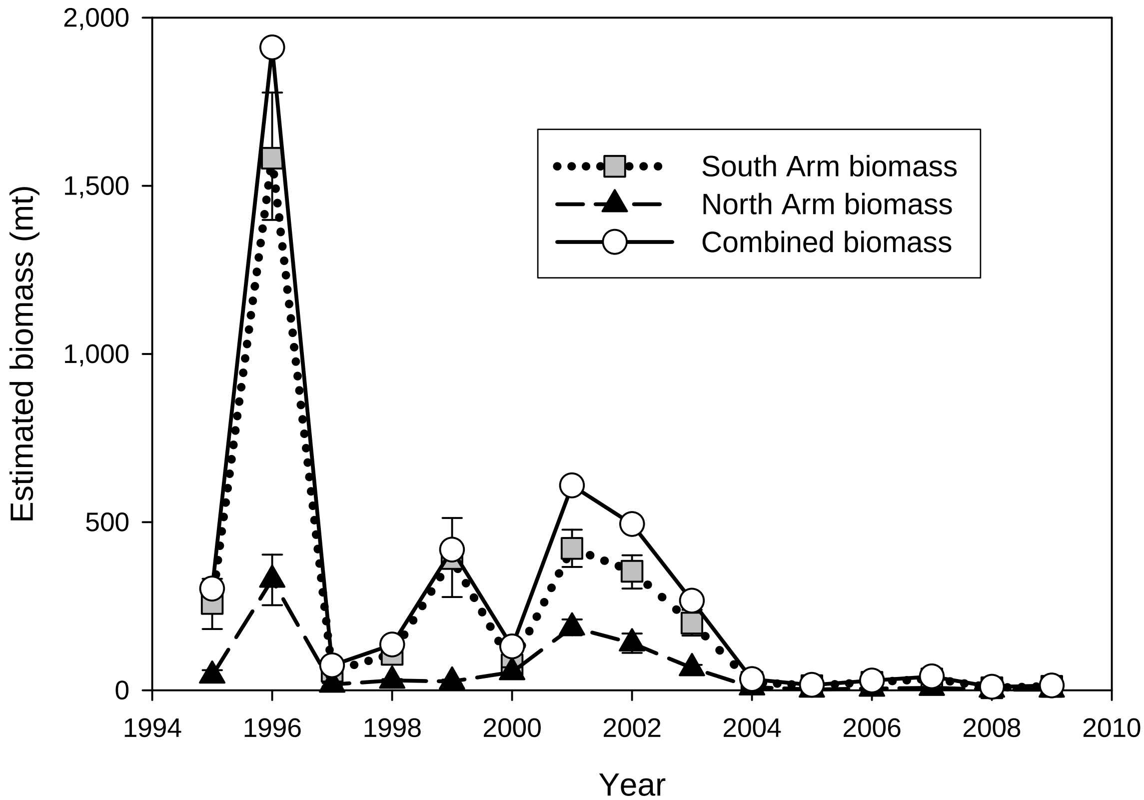

Figure 28. Fraser River eulachon spawning stock biomass from 1995 to 2009 (estimated from egg and larval surveys). Data online at http://www.pac.dfo-mpo.gc.ca/sci/herring/herspawn/pages/river1_e.htm.

to estimate spawning stock biomass has passed rigorous scientific review in Canada (Hay et al. 2002, 2003, 2005, McCarter and Hay 2003, Therriault and McCarter 2005). This methodology is similar to methods used since the early 1970s by many fisheries agencies (WDFW, DFO, CDFG, and Alaska Department of Fish and Game) to calculate Pacific herring spawning stock abundance based on estimates of intertidal and subtidal egg deposition and relative fecundity. The BRT therefore was confident that observed trends in the Fraser River spawning stock abundance data represented a true picture of the status of Fraser River eulachon.

According to Therriault and McCarter (2005), the Fraser River test fishery data did not correspond well with the spawning stock estimates that were based on the egg and larval survey and this may have resulted from variation in the catchability of adults. Eulachon abundance can be inflated when they form dense schools, which can lead to an overestimate of abundance. On the other hand, eulachon may avoid the test fishery gear, leading to an underestimate of the run size. Due to these and other problems with the test fishery methodology (Therriault and McCarter 2005), the BRT did not put a lot of confidence in these data.

The BRT did not formally analyze commercial, recreational, or subsistence fishery landings between 1881 and the present in the Fraser River, as it is believed that for much of this period the commercial fishery landings were largely driven by market demand (Hay et al. 2002,

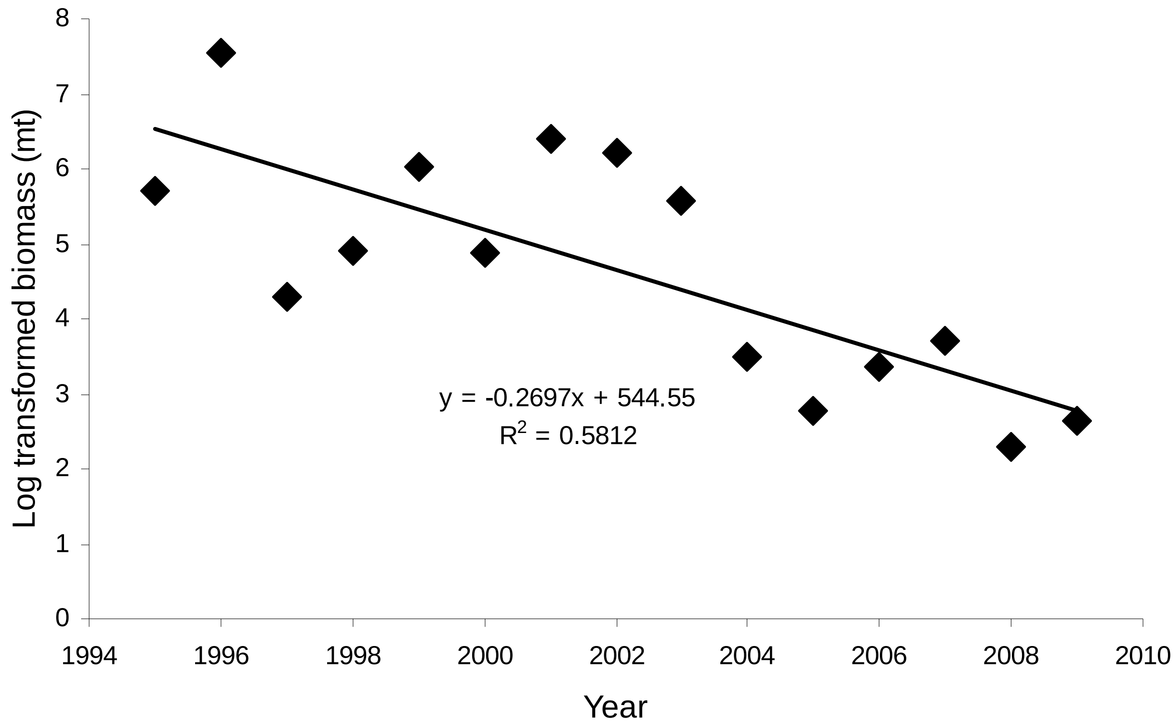

Figure 29. Trend of Fraser River eulachon spawner abundance (mt) from 1995 to 2009. Trend calculated from data in Figure 28.

Moody 2008). However, these data do indicate that eulachon were generally present at harvestable abundance levels in the Fraser River during this time period.

**Knight Inlet**

Hay and McCarter (2000) reported that an annual run of eulachon return on a regular basis to the Klinaklini River at the head of Knight Inlet on the British Columbia coast (Table A-1, Figure 3). Irregular eulachon runs in the Johnstone Strait Region include the Kakweiken River, Homathko River (Bute Inlet), and Stafford and Apple rivers (Loughborough Inlet). Peak spawn timing in the area occurs about the middle of April (Hay and McCarter 2000, Hay 2002, Moody 2008).

There is only a single year's estimate of spawning stock biomass for the Klinaklini River (1995) (Table 11). Records of a commercial fishery are available for 1943–1945 and 1947. First Nations fisheries landings on the Klinaklini River are available for 1947, 1949–1950, 1952, 1959–1973, and 1977 (Table 9); however, after 1977 there is very limited documentation of run sizes of eulachon on the Klinaklini River and these are all anecdotal in nature. These anecdotal qualitative run size comments are listed in Table 12 and indicate an improvement in recent run size estimates.

Prior to 1943 when fisheries-dependent catch records begin, our information for run size of the Klinaklini River is either anecdotal or comes from ethnographic studies. Numerous ethnographic studies describe a large First Nations eulachon fishery on the Klinaklini River that

attracted up to 2,000 Kwakiutl First Nation members in the late nineteenth century (Macnair 1971), some from as far as 250 miles away by canoe (Codere 1990).

There were commercial eulachon fisheries in Knight Inlet in the 1940s that primarily supplied food for the fur farm industry. Combined commercial and First Nations subsistence fisheries landed between 18 and 90 mt annually from 1943 and 1977 in Knight Inlet (Moody 2008), although landings reported by Hay and McCarter (2000) and reported in Table 9 were somewhat higher. At times, eulachon landings from Kingcome and Knight Inlet may have been reported as Knight Inlet landings, which may explain some of this discrepancy (Moody 2008). Berry and Jacob (1998, as cited in Moody 2008) "estimated spawning biomass at approximately 40 mt in the Klinaklini River in 1995" with a larval-based assessment (Hay and McCarter 2000). This value was "thought to be approximately 15% of the historic run size" (Berry and Jacob 1998, as cited in Moody 2008). Based on anecdotal information, Moody (2008) stated that eulachon returns to the Klinaklini River were said to be low "during the 2004 and 2005 seasons … but in 2007, the Klinaklini returns improved and, overall, it appeared to be a very good run" (Table 12).

The BRT was concerned that there are few scientifically obtained abundance data available for eulachon in Knight Inlet, about the absence of a contemporary monitoring program for eulachon, and about the anecdotal nature of the available information. However, the BRT concluded that available catch records, the extensive ethnographic literature, and anecdotal information indicates that Klinaklini River eulachon were probably present in larger annual runs in the past and that current run sizes of eulachon appear inconsistent with the historic level of grease production extensively documented in the ethnographic literature (summaries in Macnair 1971, Codere 1990). However, anecdotal information indicates that recent returns of eulachon to the Klinaklini River have improved from a low point in 2004–2005, so the status of this population is not entirely clear.

**Kingcome Inlet**

Hay and McCarter (2000) reported that an annual run of eulachon return on a regular basis to the Kingcome River at the head of Kingcome Inlet on the British Columbia central coast (Table A-1, Figure 3). Peak spawn timing in the area occurs about the middle of April (Moody 2008). Berry and Jacob (1998, p. 4) reported that "there were at least four waves of spawning with peaks on April 2, April 15, April 21, and May 2, 1997, with the largest occurring around April 15" in the Kingcome River. Berry and Jacob (1998) also reported that there was a spawn in the Kingcome River prior to March 16 and again in early June as indicated by the presence of eggs in the water column.

There is only a single year's estimate of spawning stock biomass for the Kingcome River (1997) (Table 11). First Nations fisheries landings on the Kingcome River are available for 1950, 1957, 1960, 1961, 1963, and 1966 (Moody 2008, her Figure 2.20); however, after 1977 there is very limited documentation of run sizes of eulachon on the Kingcome River and these are all anecdotal in nature. These qualitative run-size comments are listed in Table 12 and indicate a decline in recent run-size estimates.

When Kingcome Inlet First Nation fisheries landings have been reported separately from Knight Inlet, the estimates have averaged around an annual catch of 9 mt (Moody 2008). Moody (2008) reported that the eulachon run in the Kingcome River in 1971 was very small and light catches were reported in 1972. Berry and Jacob (1998) stated that a minimum estimated 14.35 mt of eulachon spawned in the Kingcome River from March 16 to June 3, 1997. Based on anecdotal information, Moody (2008) reported that "In 2001 the Kingcome run improved and was considered good in 2002, with approximately 330 gallons of grease produced." The eulachon run to the Kingcome River was considered to be poor in 2003 and 2004 and of average size in 2005 (Moody 2008). However, eulachon were reportedly absent from the Kingcome River in 2006 "and only small returns were seen in 2007" (Table 12) (Moody 2008).

The BRT was concerned that there are few scientifically obtained abundance data available for eulachon in Kingcome Inlet, about the absence of a contemporary monitoring program for eulachon, and about the anecdotal nature of the evidence. However, the BRT believed that available catch records and anecdotal information indicates that Kingcome River eulachon were probably present in larger annual runs in the past.

**Rivers Inlet**

Hay and McCarter (2000) reported that an annual run of eulachon return on a regular basis to the Wannock, Chuckwalla, and Kilbella rivers in Rivers Inlet on the central coast of British Columbia (Table A-1, Figure 3). The spawning stock biomass of eulachon in Rivers Inlet was estimated using scientific survey methods in 2005 and 2006. First Nations fisheries landings on the Wannock River are available for 1967, 1968, and 1971; however, after 1971 there is very limited documentation of run sizes of eulachon in Rivers Inlet and (with the exception of the information available for 2005 and 2006) these are anecdotal in nature. These anecdotal qualitative run-size comments are listed in Table 12 and indicate a decline in recent run-size estimates.

First Nation fishery landings data for the Wannock River were limited to the years 1967, 1968, and 1971 when catches were 1.81, 2.27, and 4.54 mt, respectively (Moody 2008). Moody (2008) stated that eulachon in "the Wannock River had been gradually declining since the 1970s" and that no eulachon have been caught in First Nations fisheries in the Rivers Inlet area since 1997, when about 150 kg of eulachon were landed from the Kilbella and Chuckwalla rivers (Berry and Jacob 1998). Berry and Jacob (1998, p. 3–4) further reported that "Virtually no eulachon eggs or larvae were found in any of the 376 samples from the Wannock River in 1997" and "this observation is consistent with in-field observations of eulachon entering the river mouth only to exit and possibly go to the nearby Chukwalla or Kilbella rivers to spawn." In 2005 an estimated 2,700 adults returned to the Wannock River, based on the capture of only 11 adults during spawner abundance surveys (Moody 2008) (Table 11). An additional three adult eulachon were taken on the Kilbella River in 2005 (Moody 2008). Moody (2008) stated that this adult spawner survey was repeated in 2006 and although "no adults [were] captured … an estimate of 23,000 adult spawners was calculated" (Table 11 and Table 12).

The BRT was concerned that there are few scientifically obtained abundance data available for eulachon in Rivers Inlet, about the absence of a contemporary monitoring program for eulachon, and about the anecdotal nature of the evidence. The BRT was also concerned that the incomplete record of eulachon catch and spawn biomass in Rivers Inlet does not establish whether eulachon returned on an annual basis to this system in the past. However, the BRT believed that available recent estimates of spawning stock abundance, catch records, ethnographic literature (Hilton 1990), and anecdotal information indicates that Rivers Inlet eulachon were present in larger annual runs in the past. The BRT also believed that the recent spawning stock estimates of 2,700 to 23,000 individual spawners is cause for concern, as these numbers indicate that this subpopulation may be at risk from small population concerns, such as Allee effects and random genetic and demographic effects.

**Dean Channel**

Hay and McCarter (2000) reported that an annual run of eulachon return on a regular basis to the Bella Coola, Dean, and Kimsquit rivers in Dean Channel (Table A-1, Figure 3). Kennedy and Bouchard (1990, p. 325) summarized ethnographic studies on the Nuxalk (Bella Coola) First Nation and stated that "because of their abundance and their value as a trade item, eulachons (particularly when rendered into highly valued grease) were second only to salmon in importance to the Bella Coola." Moody (2008) indicated that historically, peak run timing of eulachon in the Bella Coola River occurred in late March or early April (Table A-9). Moody (2007) also reported that recent run timing of eulachon to the Bella Coola River occurs earlier in the season than it did historically.

Spawning stock biomass data for the Bella Coola River were available for 2001–2004 (Table 11). Records of the Nuxalk First Nation eulachon fishery on the Bella Coola River are available for 1945 and 1946, 1948–1989, 1995, and 1998 (Moody 2008, her Figure 3.13). Moody (2008) also provided estimated First Nations eulachon catch based on a model of eulachon grease production from 1980 to 1998. Anecdotal qualitative run-size comments are listed in Table 12.

Moody (2007) reports relative abundance estimates, based on egg and larval surveys similar to those used on the Fraser River, for the Bella Coola River in 2001 (0.039 mt), 2002 (0.045–0.050 mt), 2003 (0.016 mt), and 2004 (0.0072 mt) (Table 11). Nuxalk First Nation subsistence fishery landings of eulachon from the Bella Coola River show an average catch of 18 mt between 1948 and 1984 (Table 9, Figure 30), with a low of 0.3 mt in 1960 and a high of nearly 70 mt in 1954, based on data available in Hay (2002). These data suggest that recent (2001–2004) spawner biomass in the Bella Coola River is approximately two orders of magnitude less than the average First Nations eulachon landings were between 1948 and 1984. According to Moody (2007), it has been 9 years since the last First Nations fishery occurred on the Bella Coola River.

Anecdotal information indicated that only a very few eulachon are currently found in other rivers in Dean Channel such as the Kimsquit River and the Taleomy, Assek, and Noeick rivers in South Bentnick Arm off Dean Channel (Moody 2008). Moody (2007, 2008) also stated that "it appears that 1996 was the last large run of eulachon to the Bella Coola River" and noticeable runs have not returned to the Dean Channel/Bella Coola area since 1999 (Table 12).

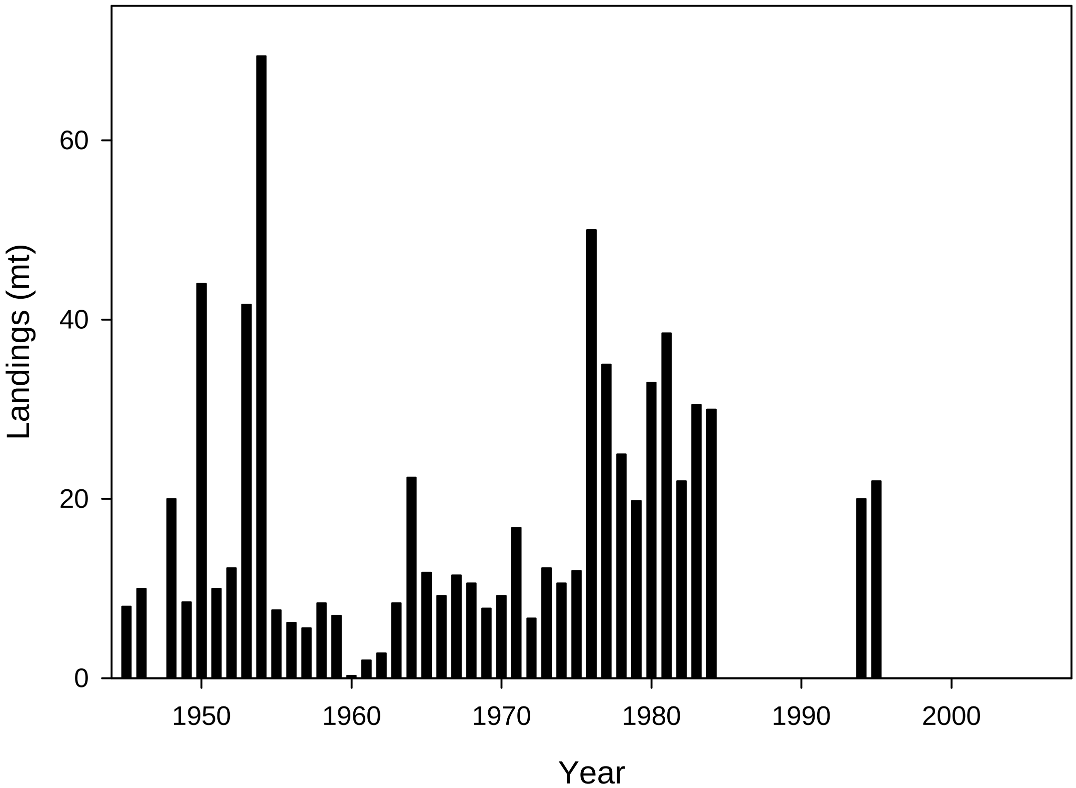

Figure 30. Estimated eulachon First Nations fishery landings on the Bella Coola River (data from Hay 2002). Landings of unknown size occurred from 1985 to 1993 and from 1996 to 1998 (Hay 2002). No fishery has occurred on the Bella Coola River since 1999.

The BRT believed that available spawning stock biomass data collected since 2001, catch records, extensive ethnographic literature, and anecdotal information indicate that Bella Coola River and Dean Channel eulachon in general were present in much larger annual runs in the past. The present run sizes of eulachon appear inconsistent with the historic level of grease production that is extensively documented in the ethnographic literature on the Nuxalk First Nations Peoples (Kennedy and Bouchard 1990, Moody 2008). The BRT was concerned that this information and available data indicate that eulachon in Dean Channel may be at risk from small population concerns, such as Allee effects and random genetic and demographic effects.

**Gardner Canal**

Hay and McCarter (2000) reported that an annual run of eulachon return on a regular basis to the Kemano, Kowesas, and Kitlope rivers in Gardner Canal (Table A-1, Figure 3). Eulachon spawn in late March and early April on the Kemano River, which is unusual in that it is a clear, nonturbid system in a region that is dominated by glacially turbid rivers (Moody 2008).

First Nations fisheries landings on the Kemano River are available for 1969–1973 and 1988–2007. CPUE data in this fishery from 1988–2007 (reported as metric tons caught per set) were presented in graphical form in Moody (2008, her Figure 2.16). A summary of ethnographic studies of the Haisla First Nation indicates that “eulachon were especially important with runs in the … Kemano and Kitlope rivers … in such numbers that they were an important export” (Hamori-Torok 1990, p. 306). Anecdotal qualitative run-size comments on Kemano River eulachon are listed in Table 12 and indicate a decline in recent run-size estimates.

First Nation fisheries landings on the Kemano River ranged from 18.1 to 81.7 mt from 1969 to 1973 (average of 44.3 mt) (Moody 2008, her Figure 2.16). Rio Tinto Alcan Inc. operates a hydroelectric generation facility on the Kemano River and, as part of an environmental management plan, has funded monitoring of eulachon since 1988 (Lewis et al. 2002). From 1988 to 1998, landings ranged from 20.6 to 93.0 mt (average of 57 mt) (Lewis et al. 2002, Moody 2008) (Table 9). However, according to Moody (2008), no run occurred in 1999.

First Nations landings in the Kemano River were low from 2000 to 2002, but improved to between 60 and 80 mt in 2003 and 2004 (Alcan 2005, Moody 2008, her Figure 2.16); however, anecdotal information indicated that eulachon returns were not detected in the Kemano River in 2005 and 2006 (Table 12) (Alcan 2006, 2007, EcoMetrix 2006, as cited in Moody 2008). Based on anecdotal information, Moody (2008) reported that “eulachon were seen in the Kemano estuary in 2007. However, they did not ascend the river.” CPUE data showed similar trends to First Nation fishery landings, with a sharp drop from about 2.5 mt per set in 1998 to less than 0.5 mt per set from 1999 to 2002, a rebound to between 0.5 and 1 mt per set in 2003–2004, and no fish caught in 2005–2007 (Lewis et al. 2002, Moody 2008, her Figure 2.16).

It was the BRT’s best professional judgment that available CPUE data collected since 1988, First Nations catch records, extensive ethnographic literature, and anecdotal information indicate that Kemano River, and Gardner Canal eulachon in general, were present in larger annual runs in the past and that present run sizes of eulachon appear inconsistent with the historic level of grease production that is well documented for this region in the ethnographic literature (Hamori-Torok 1990).

In addition, the BRT believed that the inability to detect eulachon in the Kemano River since 2004 using the same monitoring methods that have been in place since 1988 (Lewis et al. 2002, Moody 2008, her Figure 2.16) and anecdotal information from Rio Tinto Alcan biological surveys that eulachon have failed to return to the Kemano River in 2005–2007 (Alcan 2005, 2006, 2007) is cause for concern, as this information indicates that this subpopulation may be at risk from small population concerns, such as Allee effects and random genetic and demographic effects.

### Douglas Channel

Hay and McCarter (2000) reported that an annual run of eulachon return on a regular basis to the Kitimat and Kildala rivers in Douglas Channel (Table A-1, Figure 3). Spawning in the Kitimat River reportedly peaks in mid to late March (Moody 2008).

The spawning stock biomass of eulachon in the Kitimat River was estimated using scientific survey methods in 1993 (Table 11). First Nations fisheries landings on the Kitimat

River are available for 1969 to 1972. CPUE in this fishery, reported as number of fish caught in a 24-hour period, and estimated spawner abundance are available for 1994–1996 and 1998–2007. A summary of ethnographic studies of the Haisla First Nation indicates that “eulachon were especially important with runs in the Kitimat [and] Kildala … rivers in such numbers that they were an important export” (Hamori-Torok 1990, p. 308). Anecdotal qualitative run-size comments on Kitimat River eulachon are listed in Table 12 and indicate a decline in recent run-size estimates.

Between 1969 and 1972, Kitimat River First Nations fisheries landings of eulachon ranged from 27.2 to 81.6 mt (Moody 2008, her Figure 2.14). The Kitimat River First Nations eulachon fishery reportedly came to an end in 1972 as pollution by industrial (pulp mill) and municipal effluent discharges made the eulachon unpalatable (Pederson et al. 1995, Moody 2008). Pederson et al. (1995) estimated a total spawning biomass in the Kitimat River of 22.6 mt or about 514,000 individual eulachon in 1993. According to Moody (2008, p. 34), CPUE of eulachon on the Kitimat River, as presented in EcoMetrix (2006), declined from 50–60 fish per 24-hour gill net set in 1994–1996 to less than 2 eulachon per gill net set since 1998. According to EcoMetrix (2006, as cited in Moody 2008), abundance of eulachon from 1994 to 1996 ranged between 527,000 and 440,000 individual spawners and from 1998 to 2005 ranged between 13,600 and less than 1,000 (Table 11). Based on anecdotal information, Moody (2008, p. 34) stated that “the last strong run returned to the Kitimat River in 1991 and runs from 1992 to 1996 were estimated at half the size of 1991” (Table 12).

The BRT believed that the available spawning stock biomass data available for 1993, CPUE data since 1994, First Nations landing records, extensive ethnographic literature, and anecdotal information indicate that Kitimat River and Douglas Channel eulachon in general were present in larger annual runs in the past and that present run-size estimates of eulachon appear inconsistent with the historic level of grease production extensively documented in the ethnographic literature (Hamori-Torok 1990). The BRT believed that the decline in estimated spawning stock on the Kitimat River from an annual run size of more than 500,000 eulachon in the mid-1990s to levels of less than 1,000 individual eulachon in 2005 (EcoMetrix 2006, Moody 2008) is cause for concern, as these numbers indicate that this subpopulation may be at risk from small population concerns, such as Allee effects and random genetic and demographic effects.

### Skeena River

Hay and McCarter (2000) and Moody (2008) reported that an annual run of eulachon return on a regular basis to the Skeena River and its tributaries (particularly the Ecstall and Khyex rivers) (Table A-1, Figure 3). The Skeena River run was reportedly small, of short duration, and difficult to harvest because of the large size of the mainstem Skeena River (Stoffels 2001, Moody 2008). Based on anecdotal information, eulachon historically returned to the Skeena River around the first week of March, but in the past decade returns have occasionally returned as early as mid-February (Moody 2008).

The spawning stock biomass of eulachon in the Skeena River was estimated using scientific survey methods in 1997 (Table 11). Combined commercial and First Nations fisheries landings on the Skeena River are available for 1900–1916, 1919, 1924, 1926, 1927, 1929–1932, 1935, and 1941 (Table 9). Qualitative run-size comments on Kitimat River eulachon are listed in Table 12 and indicate a decline in recent run-size estimates.

Lewis (1997) estimated the total spawning stock abundance of the Skeena River eulachon at only 3.0 mt in 1997. A small commercial eulachon fishery operated between 1924 and 1946 (landings ranged from 15.4 mt in 1924 to 0.9 mt in 1935) (Moody 2008). However, total landings records were as high as 100 mt at one time and averaged 27.5 mt from 1900 to 1941 (Table 9). It is likely that local market demands have driven subsistence and past commercial fisheries statistics on the Skeena River and the BRT did not believe that these data were a good index of abundance. Moody (2008) reported anecdotal information indicating that very few Skeena River eulachon were observed between 1997 and 1999, a good run occurred in 2005, and virtually no eulachon were observed in 2006 (Table 12).

The BRT was concerned that there are few scientifically obtained abundance data available for eulachon in the Skeena River, about the absence of a contemporary monitoring program for eulachon, and about the anecdotal nature of the evidence. However, the BRT believed that available catch records and anecdotal information indicate that Skeena River eulachon were present in larger annual runs in the past that at one time supported a large fishery. Although the current status of this subpopulation is unknown, the BRT believed that anecdotal information indicates declines in abundance have occurred.

## Assessment of Demographic Risk and the Risk Matrix Approach

In previous NMFS status reviews, BRTs have used a risk matrix as a method to organize and summarize the professional judgment of a panel of knowledgeable scientists. This approach is described in detail by Wainright and Kope (1999) and has been used for more than 10 years in Pacific salmonid status reviews (e.g., Good et al. 2005, Hard et al. 2007), as well as in reviews of Pacific hake, walleye pollock, Pacific cod (Gustafson et al. 2000), Puget Sound rockfishes (Stout et al. 2001b), Pacific herring (Stout et al. 2001a, Gustafson et al. 2006), and black abalone (*Haliotis cracherodi*) (VanBlaricom et al. 2009). In this risk matrix approach, the collective condition of individual populations is summarized at the DPS level according to four demographic risk criteria: abundance, growth rate/productivity, spatial structure/connectivity, and diversity (Table 13). These viability criteria, outlined in McElhany et al. (2000), reflect concepts that are well founded in conservation biology and generally applicable to a wide variety of species. These criteria describe demographic risks that individually and collectively provide strong indicators of extinction risk. The summary of demographic risks and other pertinent information obtained by this approach is then considered by the BRT in determining the species' overall level of extinction risk.

After reviewing all relevant biological information for the species, each BRT member assigns a risk score (see below) to each of the four demographic criteria. The scores are tallied (means, modes, and range of scores), reviewed, and the range of perspectives discussed by the BRT before making its overall risk determination (see Table 13 for a summary of demographic risk scores). Although this process helps to integrate and summarize a large amount of diverse information, there is no simple way to translate the risk matrix scores directly into a determination of overall extinction risk. For example, a DPS with a single extant subpopulation

Table 13. Template for the risk matrix used in BRT deliberations. The matrix is divided into five sections that correspond to the four viable salmonid population parameters (McElhany et al. 2000) plus a recent events category.

| **Risk category** | **Mean (± SD) and modal score** |
|---|---|
| Abundance[a]<br>Comments: | 4.3 (±0.48)<br>4 |
| Growth rate/productivity[a]<br>Comments: | 3.0 (±1.05)<br>2 |
| Spatial structure and connectivity[a]<br>Comments: | 3.7 (±0.67)<br>4 |
| Diversity[a]<br>Comments: | 2.6 (±0.52)<br>3 |
| Recent events[b] | |

[a]Rate overall risk to the DPS on 5-point scale (1–very low risk, 2–low risk, 3–moderate risk, 4–high risk, 5–very high risk).
[b]Rate recent events from double plus (++) strong benefit to double minus (– –) strong detriment.

might be at a high level of extinction risk because of high risk to spatial structure/connectivity, even if it exhibited low risk for the other demographic criteria. Another species might be at risk of extinction because of moderate risks to several demographic criteria.

For scoring population viability criteria, risks for each demographic criterion are ranked on a scale of 1 (very low risk) to 5 (very high risk):

1. *Very low risk*. Unlikely that this factor contributes significantly to risk of extinction, either by itself or in combination with other factors.

2. *Low risk*. Unlikely that this factor contributes significantly to risk of extinction by itself, but some concern that it may, in combination with other factors.

3. *Moderate risk*. This factor contributes significantly to long-term risk of extinction, but does not in itself constitute a danger of extinction in the near future.

4. *High risk*. This factor contributes significantly to long-term risk of extinction and is likely to contribute to short-term risk of extinction in the foreseeable future.

5. *Very high risk*. This factor by itself indicates danger of extinction in the near future.

Recent events: The recent events category considers events that have predictable consequences for DPS status in the foreseeable future but have occurred too recently to be reflected in the demographic data. Examples include a climatic regime shift or El Niño that may be anticipated to result in increased or decreased predation in subsequent years. This category is scored as follows:

| | |
|---|---|
| ++ | expect a strong improvement in status of the DPS, |
| + | expect some improvement in status, |
| 0 | neutral effect on status, |
| – | expect some decline in status, and |
| – – | expect strong decline in status. |

# Threats Analysis

According to Section 4 of the ESA, the Secretary of Commerce or the Interior shall determine whether a species is threatened or endangered as a result of any (or a combination) of the following factors: 1) destruction or modification of habitat; 2) overutilization for commercial, recreational, scientific, or educational purposes; 3) disease or predation; 4) inadequacy of existing regulatory mechanisms; or 5) other natural or human factors. Collectively, these are often referred to as factors for decline. Herein we examine four of these five factors for their historical, current, or potential impact on eulachon. The consideration of the inadequacy of existing regulatory mechanisms (section 4(a)(1)(D)) will be conducted by the regional office or offices in concert with the evaluation of efforts being made to protect the species. Current and potential threats, along with current species distribution and abundance, help determine the species' present vulnerability to extinction. We include information regarding historic threats to assist in interpretation of population trends. The relationship between historic threats and population trends also provides insights that may help project future population changes in response to current and potential threats.

## Destruction or Modification of Habitat

### Dams and water diversions

Dams and water diversions can change downstream flow intensity and flow timing, reduce transport of fine sediments, and cut off the source of larger sediments like sand and gravel for downstream habitats. Reduced peak flows as a result of upstream dams can also lead to less scouring of the streambed, less erosion, and less deposition of sediments. The streambed downstream of dams may become progressively coarser and become dominated by cobbles and large gravels as smaller gravels and sand are transported downstream without being replaced by transport from upstream sources.

**Klamath River**—There are six hydroelectric dams on the Klamath River (Link River, Keno, J.C. Boyle, Copco 1, Copco 2, and Iron Gate) (NRC 2008). The impact of these dams, and others on the tributary Trinity River (Lewiston and Trinity dams), as well as associated irrigation withdrawals in the upper Klamath River basin, have shifted the spring peak flow of the lower Klamath River from its historical peak in April to its current peak in March, one full month earlier (NRC 2004).

**Columbia River**—Operation of 28 mainstem and about 300 tributary dams and water withdrawals for irrigation have significantly altered the natural hydrologic pattern of the Columbia River (Sherwood et al. 1990, Bottom et al. 2005). According to Bottom et al. (2005, p. xxix):

> the magnitude of maximum spring freshet flow [in the Columbia River] has decreased more than 40% from the predevelopment period (1859–1899) to the present. Flow regulation is responsible for approximately 75% of this loss, irrigation withdrawal for approximately 20%, and climate change for approximately 5% … The timing of maximum spring freshet flow also has changed, primarily because of hydropower and irrigation development upriver, resulting in an approximate two-week shift earlier in the year (mean predevelopment date of 12 June compared to modern mean date of 29 May).

Bottom et al. (2005, p. xx) also stated that:

> Riverine sediment transport to the estuary, an important process affecting the quantity and quality of estuarine habitat for salmon [and other fishes], is correlated with peak river flows … [It] is estimated that the … change in annual average sediment transport (at Vancouver, Washington) for 1945–1999 flows has been about 50–60% of the nineteenth century (1858–1899) virgin sediment transport. The reduction in sands and gravels is higher (>70% of predevelopment) than for silts and clays.

Bonneville Dam on the mainstem Columbia at RKM 235 also impedes migration of eulachon to historical spawning habitat above the dam in the Hood River and possibly the Klickitat River (Smith and Saalfeld 1955, WDFW and ODFW 2008). Eulachon reportedly are unable to ascend fish ladders designed for Pacific salmon (LCFRB 2004a).

**Columbia River tributaries**—In the mid 2000s, Sandy River Basin Partners (2005, p. 2-30) stated that:

> Natural discharge patterns in the Sandy River Basin are primarily altered by 1) storage and diversion of water on the Sandy River (Marmot Dam at RM 30 [RKM 48.3]) and Little Sandy River (Little Sandy Diversion Dam at RM 1.7 [RKM 2.7]), 2) storage and diversion of water from the Bull Run River since 1891 to supply the City of Portland's municipal water needs (the Headworks Dam at RM

> 6 [RKM 9.6]), and 3) diversion of water from the Sandy Hatchery weir on Cedar Creek at RM 0.05 (RKM 0.8), as well as withdrawal of water from Alder Creek to partially supply the City of Sandy's municipal requirements.

Subsequently, Marmot Dam was removed in 2007 and the Little Sandy Dam was taken down in 2008, which should restore much of the river's natural hydrology and result in significant sediment transport into the lower Sandy River where eulachon have spawned in the past.

There are two major dams on the mainstem Cowlitz River: Mayfield Dam at RKM 83.7 forms Mayfield Lake and Mossyrock Dam at RKM 104.6 forms Riffe Lake (Wade 2000b). These dams and other run-of-river dams in the hydropower system largely control flow in the mainstem Cowlitz River. Following the eruption of Mount St. Helens in 1980, the USACE constructed an SRS on the North Fork Toutle "to prevent the continuation of severe downstream sedimentation of stream channels, which created flood conveyance, transportation, and habitat degradation concerns" (LCFRB 2004a, p. E-374). The SRS was constructed in 1989 about 49 km above the confluence of the Toutle and Cowlitz rivers, is approximately 50 m in height, and extends 600 m across the valley of the North Fork Toutle River. The SRS continues to be a source of fine sediment to the lower Cowlitz River (LCFRB 2004a). Anderson (2009, p. 5) stated that:

> The SRS [on the Toutle River], constructed by the USACE, has become ineffective at trapping sediments. Lower Cowlitz River eulachon spawning habitat is considered degraded while the Toutle River is assumed absent of spawning habitat due to this fine sediment inundation. … WDFW considers past and continued fine sediment deposition in the Toutle and Cowlitz rivers as a moderate to high risk for eulachon.

There are three major dams on the mainstem Lewis River, also known as the North Fork Lewis River: Merwin Dam (aka Ariel Dam) at RKM 31.4, built in 1931, forms Lake Merwin; Yale Dam at RKM 55, built in 1953, forms Yale Lake; and Swift Dam at RKM 77.1, built in 1958, forms Swift Creek Reservoir (Wade 2000a). The Lower Columbia Fish Recovery Board (LCFRB 2004a, p. G-35) stated that:

> Hydropower regulation has altered the hydrograph of the lower mainstem [of the Lewis River].… Predam data reveals peaks due to fall/winter rains, winter rain-on-snow, and spring snowmelt. Postdam data shows less overall flow variation, with a general increase in winter flows due to power needs. Postdam data shows a decrease in spring snowmelt flows due to reservoir filling in preparation for dry summer conditions.… The risk of extreme winter peaks has also been reduced, with the trade-off being the reduction of potentially beneficial large magnitude channel-forming flows. … The long-term effects on channel morphology and sediment supply have not been thoroughly investigated.

**British Columbia**—In the mid-1980s there were an estimated 802 licensed dams in the Fraser River basin, mostly for irrigation purposes in the dryer areas above Hope (Birtwell et al. 1988). The impact on eulachon of water withdrawals associated with reservoirs in the Fraser

River has not been studied. The other eulachon river in British Columbia where hydrology has been significantly altered by water diversions is the Kemano River. A hydroelectric plant began operating on the Kemano River in 1954 (Lewis et al. 2002, p. 1), that is powered by:

> water from the Nechako Reservoir [in the Fraser River basin] [that] passes through a 16-km-long diversion tunnel, past the turbines at the Kemano Powerhouse, and into the Kemano River, dropping a total of 850 m. ... The powerhouse outflow combines with the natural flow of the Kemano River and tributaries and flows 16 km to saltwater at Kemano Bay on Gardner Canal.

Lewis et al. (2002, p. 22) further stated that:

> Flow at the Kemano/Wahoo confluence is composed of Kemano Powerhouse discharge and the natural flow from the Kemano River and tributaries. On average, the Kemano powerhouse contributes 57% of the flow at the Kemano/Wahoo confluence. Within the period of eulachon spawning, when natural flows are near the seasonal minimum, discharge from the powerhouse accounts for 80% of the flow at the Kemano/Wahoo confluence. The relative contribution of powerhouse discharge declines to 64% during eulachon incubation and later, during larval migration, to 38% as natural discharges increase.

According to DFO and Transport Canada (2008):

> Kleana Power Corporation proposes to develop a run-of-river hydroelectric power project on the Klinaklini River. … The project consists of: head pond, diversion weir and intake, 18 km penstock/tunnel, powerhouse, tailrace, waste rock disposal, upgrading of the existing logging roads and new road extension where necessary, upgrade to the existing barge landing facility, construction camp, concrete batch plant, and a 180 km twinned aerial transmission line from the powerhouse to Campbell River.

**Sediment dredging**

Potential dredging impacts on eulachon consist of direct effects of entrainment of adults and eggs and potential for smothering of eggs with sediment (Howell and Uusitalo 2000, Howell et al. 2001). Indirect effects may consist of altering the freshwater spawning habitat and estuarine nursery habitat. Larson and Moehl (1990) documented direct entrainment of small amounts of eulachon by hopper dredge at the mouth of the Columbia River during May-October 1985–1988. Johnston (1981, p. 427) reviewed dredging activities in estuarine environments and listed “increased turbidity; altered tidal exchange, mixing, and circulation; reduced nutrient outflow from marshes and swamps; increased saltwater intrusion; and creation of an environment highly susceptible to recurrent low dissolved oxygen levels” as negative impacts. In addition, dredging can resuspend harmful contaminants contained in sediments where they may be more available to estuarine biota in the water column. Lasalle (1990, p. 1) also reviewed the potential physical effects of dredging and listed mobilization of sediment-associated chemical compounds and increased turbidity, as well as the potential “reduction in dissolved oxygen (resulting from the oxidation of anoxic sediment compounds)” as generally expected alterations.

Hay and McCarter (2000) indicated that dredging during the eulachon spawning season in the Fraser River continued until the late 1990s. Tutty and Morrison (1976) estimated about 0.9 mt of adult eulachon were directly entrained during hopper dredging activities between March 15 and June 4, 1976, on the lower Fraser River. Hay and McCarter (2000, p. 38) stated that "the direct loss of about 1 tonne of eulachons may have been small relative to potential deleterious impacts on survival of eulachons eggs—either from the direct effect of entrainment of spawned eggs, or the silt-induced smothering of eggs deposition [sic] in waters downstream of the dredging operations." Hay and McCarter (2000) suggested dredging should be confined to periods outside of the spawning season to minimize impacts on eulachon and that the effects of sediment removal on eulachon spawning habitats should be a topic of research.

FREMP (2007) estimated that from 0.76 to 3.22 million cubic meters of sediment were dredged annually from the lower Fraser River during the years 1997–2007 to prevent grounding of commercial shipping. Increases in vessel size have required deepening of the shipping channel in recent years (FREMP 2007). As mentioned in Pickard and Marmorek (2007), suction dredging is currently restricted to months when eulachon are not spawning in the Fraser and Kitimat rivers. According to FREMP (2006, p. 40), "hydraulic suction dredging and large-scale clamshell dredging undertaken in the Fraser River estuary is restricted so that there is no dredging conducted from March 1 to June 15 of any given year."

It has been suggested that eulachon spawning distribution in the Fraser River has changed in response to dredging and channelization and that dredging, even outside of the spawning period, affects eulachon by destabilization of substrates (Pickard and Marmorek 2007). Pickard and Marmorek (2007, p. 8) reported in their summary of findings of a DFO workshop to determine research priorities for eulachon that "there is consensus that dredging is not the cause of the coastwide decline in eulachon, but there is disagreement about the importance of dredging impacts on eulachon resilience in rivers where it occurs."

The Cowlitz Indian Tribe (2007, p. 15–16) observed that:

> the Cowlitz River and in particular the Toutle River has been greatly impacted by the eruption of Mount St. Helens in 1980 and the resulting SRS built by the U.S. Army Corps of Engineers. Releases of fine sediment from behind the SRS during the spring, when normally the river is clear, have been negatively correlated with Cowlitz River eulachon returns 3 to 4 years later (Lou Reebs, personal communication).

USACE (2007) stated that:

> as much as 414 million cubic yards (mcy) of material will erode from the Mount St. Helens sediment avalanche through year 2035. In addition, it was estimated that over the period from 2000 to 2035 as much as 27 mcy of this material would be deposited in the lower Cowlitz River and will need to be removed in order to maintain flood protection levels in Kelso, Longview, Castle Rock, and Lexington. … This trend is a result of increased sedimentation from the Toutle River watershed from sediments being passed through the SRS in greater amounts. The ability of the SRS to trap sand has decreased since 1998 when the sediment reservoir behind the dam filled in. All flow now passes through the spillway as

> designed, carrying sediment downstream. … Significant sand deposition … continues to occur at the mouth of the Cowlitz River, which has severely reduced the capacity of the river channel to transport sand. … Channel capacity and the authorized levels of flood protection for Kelso, Longview, Lexington, and Castle Rock have been reduced below authorized levels due to sediment deposition in the lower Cowlitz River. … In addition to the initial dredging effort, annual follow-on dredging from the transition area to Cowlitz RM 2.5 [RKM 4.0] to maintain the dredged channel depths and bottom widths will be needed to maintain flood protection levels for the next 5 years. The Corps is also investigating long-term dredging and nondredging alternatives that would maintain the authorized levels of flood protection for the communities on the lower Cowlitz River through the year 2035.

Furthermore, USACE's environmental assessment of interim dredging activities on the Cowlitz River (USACE 2007, p. 33) indicated that:

> The proposed … dredging action may affect spawning adults, outmigrating juveniles, and larvae [of eulachon] in the water column by entrainment. Eggs may be affected by removing substrate needed to allow egg adhesion for incubation and by covering of incubating eggs by increasing suspended sediment.

Sherwood et al. (1990) provided a detailed analysis of historical dredging activities in the Columbia River estuary through the 1980s. They estimated that about 300 million cubic meters of largely sand-sized material were removed from the estuary and river channels between 1909, when substantial dredging started, and 1982. Currently, USACE routinely dredges the mainstem Columbia River shipping channel. The Washington and Oregon Eulachon Management Plan (WDFW and ODFW 2001, p. 25) stated that this "Dredging should not be conducted in winter and early spring to avoid entrainment of eulachon adults or larvae." Romano et al. (2002) suggested that the dynamic nature of sand sediments in areas proposed for channel deepening in the Columbia River were unlikely to support eulachon egg incubation and that direct effects of dredging in these areas on eulachon would be minimal. However, "[eulachon] eggs incubating in near-shore areas in the proximity of dredging activities might be affected if these activities alter flow patterns or increase sedimentation" (Romano et al. 2002, p. 8).

In response to an earlier draft of the present status review document, Anderson (2009, p. 4–5) stated that:

> Risks dependent on timing, location, and life history stage in relation to dredging and in-water dredge material disposal pose a low to moderate threat for adult eulachon and a high risk for incubating eggs. … WDFW considers dredging effects on adult eulachon as a low risk in the mainstem Columbia River and a low to moderate risk in the tributaries. … The risk to larval eulachon from mainstem Columbia River dredging activities is low and in the tributaries is moderate. … Dredging activities can affect egg survival through direct entrainment and from suffocation through burial. The risk to eulachon eggs from dredging and in-water dredge material disposal in eulachon spawning habitat is high.

### Shoreline construction

**Columbia River**—Estuarine habitat in the Columbia River has been modified through "shoreline armoring and construction of structures over water, channel dredging and removal of large woody debris, channelization by pile dikes, and other structures" (Bottom et al. 2005, p. 18). Thomas (1983) estimated that estuarine acreage at the time of his study was only about 76% of the acreage of the estuary in 1870. This reduction was largely the result of dike and levee construction. Approximately 43% of tidal marshes and 77% of tidal swamps in the Columbia River estuary were estimated to have been lost since 1870 (Thomas 1983). Sherwood et al. (1990, p. 299) also reviewed historical changes in the Columbia River estuary and found that "large changes in the morphology of the estuary have been caused by navigational improvements (jetties, dredged channels, and pile dikes) and by the diking and filling of much of the wetland area." Sherwood et al. (1990) suggested that the greatest cause of change in the morphology of the Columbia River estuary was due to construction of permeable pile dikes and jetties, particularly jetties at the mouth of the river. LCFRB (2004a, p. A-157) reported that:

> Artificial channel confinement has altered river discharge and hydrology, as well as disconnected the [Columbia] river from much of its floodplain. … Additionally, channel manipulations for transportation or development have also had substantial influence on river discharge and hydrologic processes in the river.

Bottom et al. (2005, p. xxii) provided a chronology of changes in the Columbia River estuary and stated that:

> The productive capacity of the estuary has likely declined over the past century through the combined effects of diking and filling of shallow-water habitats…. Loss of approximately 65% of the tidal marshes and swamps that existed in the estuary prior to 1870, combined with the loss of 12% of deepwater area, has contributed to a 12–20% reduction in the estuary's tidal prism.

**Columbia River tributaries**—The LCFRB (2004a, p. E-89) observed that "the mainstem Cowlitz below Mayfield Dam has been heavily altered due to adjacent land uses including agriculture, rural residential development, transportation corridors, urbanization, and industry." The LCFRB (2004a, p. E-30) also reported that "the lower 20 miles of the Cowlitz has experienced severe loss of floodplain connectivity due to dikes, riprap, or deposited dredge spoils originating from the Mount St. Helens eruption" (see also Wade 2000b). Major population centers in the lower Cowlitz River basin with their associated industrial and residential development include the towns of Castle Rock, Longview, and Kelso (LCFRB 2004a).

The only urban area in the Kalama River basin is the City of Kalama, located near the river's mouth where dikes have been constructed in the historical floodplain to protect nearby roads and industrial developments (Wade 2000a, LCFRB 2004a). Future development is likely to be concentrated along the lower mainstem Kalama River, where increasing residential development has also occurred in recent years (LCFRB 2004a).

Much of the lower mainstem Lewis River is also "disconnected from its floodplain by dikes and levees" (LCFRB 2004a, p. G-55) and "the largest urban population center, the City of Woodland, lies near the mouth of the river" (Wade 2000a, p. 23). According to (LCFRB 2004a, p. G-87), "the mainstem Lewis below Merwin Dam has been heavily altered due to adjacent land uses including agriculture, residential development, transportation corridors, and industry."

**British Columbia**—Pickard and Marmorek (2007) reported that results of a DFO workshop to determine research priorities for eulachon indicated that shoreline construction in the form of roads, bridges, dikes, piers, wharfs, and so forth may have an impact on eulachon in the Skeena, Kitimat, Kemano, Fraser, and Columbia rivers. According to Pickard and Marmorek (2007, p. 14):

> There is evidence of change in the habitat in developed rivers such as the Fraser and Kitimat. These changes include the loss of side channels, loss of habitat complexity/diversity, and increase in velocity. These habitat changes are thought to affect eulachon, however the magnitude of the effect is not clear.

Pickard and Marmorek (2007) also suggested that an increase in river velocities likely would result in eggs and larvae being rapidly washed downstream, where they may encounter high salinities at an early age. The fate of eggs and larvae that may be prematurely washed out to sea is unknown.

The largest city in British Columbia, Vancouver, together with all of its associated industrial and urban development, abuts the Fraser River estuary (Birtwell et al. 1988). Moody (2008) indicated that an extensive system of dikes was constructed in the lower Fraser River following the 1948 flood. According to Plate (2009, p. 3 and p. iii), recent plans to construct "a new 10-lane Port Mann Bridge [over the Fraser River] represents a major addition to shoreline and in-river construction on the lower Fraser River" and is of concern because "eulachon spawn directly beneath the [current] Port Mann Bridge pillars and in the close upstream vicinity of the bridge, and as expected eulachon use all channels under the bridge for migration to upstream areas."

### Climate change impacts on freshwater habitat

Analyses of temperature trends for the U.S. Pacific Northwest (Mote et al. 1999); the maritime portions of Oregon, Washington, and British Columbia (Mote 2003a); and the Puget Sound–Georgia Basin region (Mote 2003b) have shown that air temperature increased 0.8°C, 0.9°C, and 1.5°C in these respective regions during the twentieth century. Warming in each of these areas was substantially greater than the global average of 0.76 ± 0.19°C (IPCC 2007). During the next century, warming in the Pacific Northwest is predicted to range from 0.1°C to 0.6°C per decade with a mean estimate of 0.3°C per decade, compared to an approximate 0.1°C per decade warming that occurred during the twentieth century (Mote et al. 2005b). Although fluctuations in climate related indices like the PDO and El Niño Southern Oscillation (ENSO) may explain about a third of this temperature rise, "the widespread and fairly monotonic increases in temperature exceed what can be explained by Pacific climate variability and are consistent with the global pattern of anthropogenic temperature increases" (Mote et al. 2005a, p. 47). Results from 10 different climate model simulations that assume two different greenhouse gas emission scenarios predict a 1ºC to 6ºC increase in air temperature for the Pacific Northwest by 2100 (ISAB 2007).

These higher temperatures have led to declines in snowpack, measured as springtime snow water equivalent, in much of the North American west, with the Oregon (Mote et al. 2005a) and Washington (Mote 2006) Cascade Mountains having the largest losses in snow water equivalent. Projected milder wintertime temperatures in much of the North American west suggest that "losses in snowpack observed to date will continue and even accelerate" (Mote et al. 2005a, p. 48). Additional hydrological changes that have occurred in the North American west over the past 50–70 years include more precipitation falling as rain rather than snow (Knowles et al. 2006) and an earlier onset of snowmelt (Groisman et al. 2004, Knowles et al. 2006), resulting in "increased fractions of annual flow occurring earlier in the water year by 1–4 weeks" relative to conditions during the 1950s to 1970s (Stewart et al. 2005, p. 1,136). Trends toward earlier flows "are strongest for midelevation gauges in the interior Northwest, western Canada, and coastal Alaska" (Stewart et al. 2005, p. 1,152).

It is expected that snowmelt dominated systems at low to moderate elevations (Regonda et al. 2005, Knowles et al. 2006) and near-coastal mountains in the Pacific Northwest and California (Hamlet et al. 2005, p. 4,560) will be particularly impacted by declines in the fraction of precipitation falling as snow and thus may experience the greatest changes in river hydrology. Some systems are expected to change from a pattern of steady snow accumulation to a pattern of repeated snow accumulation and loss during the winter season. The Independent Scientific Advisory Board (ISAB 2007, p. iii) summarized projected changes associated with climate change in the Columbia Basin and stated that "Warmer temperatures will result in more precipitation falling as rain rather than snow; snow pack will diminish, and stream flow timing will be altered; and peak river flows will likely increase."

Pickard and Marmorek (2007) summarized similar findings, reported by participants at a DFO workshop to determine research priorities for eulachon, relative to climate-driven changes in freshwater hydrology that are occurring in coastal British Columbia. This report presented evidence that "snowpack accumulations have been declining in many watersheds (e.g., Kitimat, Fraser)" (Pickard and Marmorek 2007, p. 20). Spring freshets throughout British Columbia are also reported to be occurring earlier in the year and more precipitation at lower elevations is reported to be coming as rain than in snow (Pickard and Marmorek 2007, p. 20). Glaciers in British Columbia are also reported to be melting at a faster rate, although "overall runoff from B.C. glaciers is declining due to their reduced size" (Pickard and Marmorek 2007, p. 20).

Foreman et al. (2001) and Morrison et al. (2002) examined historical temperatures and flows in the Fraser River over the past 100 years. Foreman et al. (2001) found that the date at which one-half of the Fraser River yearly discharge is reached occurred at a rate of 0.09 days earlier each year between 1913 and 2000, and that average summer temperatures at Hell's Gate on the Fraser River increased at a rate of 0.022°C per year (0.2°C per decade) from 1953 to 1998. Morrison et al. (2002) developed a flow model based on these trends and predicted that by 2070–2090 spring freshets in the Fraser River would occur on average 24 days earlier in the year and mean summer water temperatures would likely increase by 1.9°C. DFO (2008d) also predicted that peak flows will come earlier in the year and peak flows will be lower over the coming century in the Fraser River.

Meier et al. (2003) and Barry (2006) summarized data on the worldwide status of glaciers, which shows that pervasive glacial retreat has occurred over the past 100 years and suggests that glacial wastage has accelerated in the last several decades. Meier et al. (2003, p. 133) stated that "the retreats of the last century exceed any seen in the last several millennia and are out of the range of normal climate variability for this time period." ISAB (2007, p. 12), in reference to the Pacific Northwest stated that:

> Most glaciers in the region reached their recent maximum extent in the mid-1800s and since that time have been in rapid retreat. Recent studies indicate that the retreat of the past approximately 150 years has now brought many Northwest glaciers back to levels last seen approximately 6,000 years ago.

Since the majority of eulachon rivers are fed by extensive snowmelt or glacial runoff, elevated temperatures, changes in snow pack, and changes in the timing and intensity of stream flows will likely have impacts on eulachon. In most rivers, eulachon typically spawn well before the spring freshet, near the seasonal flow minimum, and this strategy typically results in egg hatch coinciding with peak spring river discharge. The expected alteration in stream flow timing may cause eulachon to spawn earlier or be flushed out of spawning rivers at an earlier date. Early emigration, together with the anticipated delay in the onset of coastal upwelling (see Climate Change Impacts on Ocean Conditions subsection below), may result in a mismatch between entry of larval eulachon into the ocean and coastal upwelling, which could have a negative impact on marine survival of eulachon during this critical transition period.

There are already indications, perhaps in response to warming conditions or altered stream flow timing, that adult eulachon are returning earlier in the season to several rivers within the southern DPS (Moody 2008). Based on accounts in Portland, Oregon, newspapers between 1867 and 1923, the mean date of initial appearance of eulachon in the Columbia River during that time was February 12 (Figure 6, Appendix B). Documented initial landings in the Columbia River commercial eulachon fishery for the years 1949 to 2008 were more than a month earlier, averaging around January 8, based on data supplied by WDFW.[13] Similarly, Lewis et al. (2002, p. 68) noticed a trend for the eulachon run in the Kemano River, British Columbia, to begin and end earlier over the 11-year period from 1988 to 1998. Pickard and Marmorek (2007, p. 20) also reported that "run timing has been getting earlier since 1988–2003 in [the] Kemano [River]."

### Climate change impacts on ocean conditions

Evidence has accumulated over the last decade to demonstrate that there are natural decadal-scale oscillations in North Pacific climatic and oceanic conditions (Mantua et al. 1997, Zhang et al. 1997). One indicator of the ocean-atmosphere variation for the North Pacific is the PDO index whose opposite regimes, characterized by a positive and negative PDO, typically last for 20–30 years (Mantua and Hare 2002) (Figure 15). Negative PDO values are associated with relatively cool ocean temperatures off the Pacific Northwest, and positive values are associated

[13] B. James, Statewide Eulachon Landings database, WDFW, Vancouver, WA. Pers. commun., 20 June 2008.

with warmer, less productive conditions. Warmer, less productive conditions off the Pacific Northwest are also associated with the ENSO, which is unrelated to the PDO and occurs on average every 2 to 7 years and may last from 6 to 18 months.

Changes in regional patterns of the PDO and ENSO have been associated with variation in the abundance of Pacific salmon, forage fish, and species such as Pacific hake in the ocean off the Pacific Northwest (McFarlane et al. 2000, ISAB 2007). ISAB (2007, p. 57–58) suggested that conditions that occur during a positive PDO or an El Niño period may represent possible analogs for future impacts of global warming in the North Pacific and Pacific Northwest. However, as the Intergovernmental Panel on Climate Change (IPCC) stated in its fourth assessment report (IPCC 2007, p. 399), "Long-term trends [in temperature] are rather difficult to discern in the upper Pacific Ocean because of the strong interannual and decadal variability (ENSO and the PDO) and the relatively short length of the observational records."

According to ISAB (2007, p. v):

> Scientific evidence strongly suggests that global climate change is already altering marine ecosystems from the tropics to polar seas. Physical changes associated with warming include increases in ocean temperature, increased stratification of the water column, and changes in the intensity and timing of coastal upwelling. These changes will alter primary and secondary productivity … [and] the structure of marine communities.

**Warmer ocean temperatures**—Levitus et al. (2000, 2005) documented warming of the world's oceans that corresponds to a mean temperature increase of 0.037°C from 1955 to 1998 (Levitus et al. 2005, p. 1). Most of this warming has occurred in the upper 700 m of the ocean over the past 50 years (Levitus et al. 2005). Relatively smaller temperature increases in the world ocean over the past 50 years, compared to the mean worldwide terrestrial air temperature increase of 0.76 ± 0.19°C (IPCC 2007) over the past 100 years, illustrates the ocean's enormous heat capacity compared to the atmosphere (Levitus et al. 2005). According to the IPCC (2007, p. 387):

> The oceans are warming. Over the period 1961 to 2003, global ocean temperature has risen by 0.10°C from the surface to a depth of 700 m. … Relative to 1961 to 2003, the period 1993 to 2003 has high rates of warming but since 2003 there has been some cooling.

The ISAB (2007, p. 65) reported that "In the subarctic Northeast Pacific, sea surface temperatures show a warming trend and salinities a decreasing trend, over the last half century." Sea surface temperatures compiled from lighthouse records in the Canadian portion of the Strait of Georgia show an increase from 1915 to 2004 of 1.0°C (Beamish et al. 2008). However, long-term temperature increase in the ocean off the Pacific Northwest is not occurring in a linear fashion. Crawford et al. (2007, p. 176) reported that the long-term temperature records along Line P, which extends out more than 1,400 km from the North American west coast into the mid Gulf of Alaska, show an increase in temperature by 0.9°C from 1958 to 2005 between depths of 10 and 50 m. But Line P temperature records showed no significant increase prior to 1972 or after 1981 and most of the long-term temperature trend was likely driven by the PDO increase associated with the 1977 regime shift (Crawford et al. 2007, IPCC 2007). Water temperatures off British Columbia were reportedly warmer in 2004 and 2005 than the previous 50 years (DFO 2006b); however, in 2008 water temperatures "off the Pacific coast of Canada were the coldest in 50 years of observations, and the cooling extended far into the Pacific Ocean and south along the American coast" (DFO 2009e, p. 4).

**Changes in intensity and timing of upwelling**—Primary productivity in the northern California Current ecosystem is fueled by wind-driven upwelling of cold, nutrient-rich, deep waters to the surface. Along the coasts of British Columbia, Washington, and Oregon, ocean upwelling is dependent on strong coastal northerly or equator-ward winds which drive warm surface waters offshore and induce upwelling of the deep waters (Bakun 1990, Ware and Thomson 1991, ISAB 2007). Upwelling-favorable winds are more frequent in the spring and summer, but do not occur uniformly even at those times. Ocean upwelling off California is much more consistent, less seasonal, and stronger on average than in areas farther north.

Coastal, upwelling-favorable winds are generated by the "pressure gradient between a thermal low-pressure cell that develops over the heated land mass and the higher barometric pressure over the cooler ocean" (Bakun 1990, p. 198). Bakun (1990) hypothesized that climate warming will intensify these thermal land-sea differences, since land areas are predicted to warm twice as fast as the oceans, and should lead to more intense coastal upwelling in the California Current Province. These land-sea pressure gradients may be further enhanced, leading to even more intense upwelling, if warming leads to less terrestrial vegetation and thus even higher land-sea thermal differences (Diffenbaugh et al. 2004). More intense upwelling should lead to increased primary productivity in the California Current, but the peak upwelling season might occur up to one month later, and primarily from June to September in the northern portion of the California Current (Snyder et al. 2003, Barth et al. 2007, ISAB 2007). Barth et al. (2007, p. 3719) stated that "Delayed early season upwelling and stronger late season upwelling are consistent with predictions of the influence of global warming on coastal upwelling regions." In addition, warming conditions are likely to increase the density of surface waters, resulting in strong water column stratification, which may impede wind-driven upwelling and reduce the availability of nutrients at the ocean surface (ISAB 2007).

**Ocean acidification**—Global increases in atmospheric $CO_2$ have caused an increase in the amount of $CO_2$ absorbed by the oceans. According to the IPCC (2007, p. 387):

> Ocean biogeochemistry is changing. The total inorganic carbon content of the oceans has increased by 118 ± 19 GtC [gigatons carbon] between the end of the preindustrial period (about 1750) and 1994 and continues to increase. … The increase in total inorganic carbon caused a decrease in the depth at which calcium carbonate dissolves, and also caused a decrease in surface ocean pH by an average of 0.1 units since 1750. Direct observations of pH at available time series stations for the last 20 years also show trends of decreasing pH at a rate of 0.02 pH units per decade.

Decreased pH of ocean waters "decreases the availability of carbonate ions and lowers the saturation state of major shell-forming carbonates in marine animals" and is expected to severely impact the abundance and distribution of calcareous organisms such as corals, shelled mollusks, foraminifera, coccolithophores, and pelagic pteropods (ISAB 2007, p. 71). These changes will have unknown consequences for pelagic communities.

**Expected impact on eulachon**—The ISAB functions to provide independent scientific advice to NMFS, the Columbia River Indian Tribes, and the Northwest Power and Conservation Council. In its document Climate Change Impacts on Columbia River Basin Fish and Wildlife, the ISAB (2007, p. 72) stated that:

> Global climate change in the Pacific Northwest is predicted to result in changes in coastal ecosystems … that may be similar or potentially even more severe than those experienced during past periods of strong El Niño events and warm phases of the PDO, with warmer upper ocean temperatures, increased stratification and decreased productivity along the coast. However, a lack of certainty in future wind and weather patterns yields large uncertainties for future changes. …if upwelling winds remain unchanged from those of the past century, coastal upwelling may become less effective at pumping cold, nutrient-rich [water] to the upper ocean because of increased stability in the upper ocean caused by surface warming. Or, as some modeling studies and hypotheses suggest, upwelling winds may become more intense, and perhaps the timing for the upwelling season will change because of timing shifts in upwelling wind patterns. With warmer ocean temperatures we can expect shifts in the size and species composition of zooplankton to smaller lipid-replete zooplankton instead of large, lipid-rich, cool-water species. Because of food chain effects and warm ocean waters, forage fishes will decline and warm-water predators will increase.

All the above predicted changes will likely influence the growth, productivity, survival, and migration of eulachon. Pacific hake undergo seasonal migrations from their winter spawning grounds off southern California to their northern feeding grounds off the west coast of Vancouver Island in summer (Ware and McFarlane 1995, Benson et al. 2002). Large adult Pacific hake are known to prey on eulachon, and the dominant prey of both small Pacific hake and eulachon are euphuasiids (Rexstad and Pikitch 1986, Buckley and Livingston 1997). Beamish et al. (2008, p. 34) stated that "The projected long-term increase in temperatures may result in more offshore hake moving into the Canadian zone, and in the spawning and rearing area off California moving north." Thus projected ocean warming is likely to result in an altered distribution of both predators on eulachon and competitors for food resources.

Initial eulachon survival during the critical transition period between larval and juvenile stages is likely linked to the intensity and timing of upwelling in the northern California Current Province. However, the potential shift of peak upwelling to one month later than normal may result in a temporal trophic match-mismatch between eulachon larval entry into the ocean and presence of preferred prey organisms whose productivity is dependent on the early initiation of upwelling conditions. These conditions would likely have significant negative impacts on marine survival rates of eulachon and recent recruitment failure of eulachon may be traced to mortality during this critical period. Larval and juvenile eulachon are planktivorous and are adapted to feed on a northern or boreal suite of copepods during the critical larval/juvenile transition.

There are two main suites or assemblages of copepod species over the continental shelf off the west coast of North America: a boreal shelf assemblage (e.g., *Calanus marshallae*, *Pseudocalanus mimus*, and *Acartia longiremis*) that normally occurs from central Oregon to the Bering Sea and a southern assemblage (e.g., *Paracalanus parvus*, *Mesocalanus tenuicornis*, *Clausocalanus* spp., and *Ctenocalanus vanus*) that is most abundant along the California coast (Mackas et al. 2001, 2007). Changes in the relative abundance and distribution of these copepod assemblages covary with oceanographic conditions (Roemmich and McGowan 1995, Mackas et al. 2001, 2007, Peterson and Keister 2003, Zamon and Welch 2005, Hooff and Peterson 2006). When warm conditions prevail, as during an El Niño year or when the PDO is positive, the distribution of zooplankton communities can shift to the north and the southern assemblage of copepods can become dominant off southern Vancouver Island (Mackas et al. 2007). For example, abundance of boreal shelf copepods was much lower than normal and southern species dominated off southern Vancouver Island during the warm years between 1992 and 1998 (Mackas et al. 2007). Thus warmer ocean conditions may be expected to contribute to a mismatch between eulachon life history and preferred prey species.

Ocean conditions off the Pacific Northwest in 2005 were similar to what may be expected if climate change predictions for the next 100 years are accurate. According to Barth et al. (2007, p. 3,719), there was a "1-month delay in the 2005 spring transition to upwelling-favorable wind stress in the northern California Current," and during May to July, upwelling-favorable winds were at their lowest levels in 20 years and "nearshore surface waters averaged 2°C warmer than normal." Eulachon returns to spawning rivers in the southern DPS were poor during this period of unfavorable ocean conditions from 2004 to 2008 (JCRMS 2008) and may portend how eulachon will respond to warming ocean conditions.

### Water quality

**General contaminants**—The high lipid content of eulachon suggests they are susceptible to absorption of lipophilic organic contaminants (Higgins et al. 1987, Pickard and Marmorek 2007). Contaminants considered of most concern include: 1) synthetic chlorinated organic chemicals, such as hexachlorobenzene, DDTs, and the polychlorinated biphenyls (PCBs); 2) polycyclic aromatic hydrocarbons (PAHs) from petroleum and creosoted pilings; 3) dioxins and a host of other organic compounds; 4) metals such as mercury, arsenic, and lead; and 5) endocrine-disrupting compounds and new toxics like PBDE (polybrominated diphenyl ether, flame retardants).

No rigorous toxicological studies of the effects of environmental contaminants on eulachon were found. In the Washington Department of Fisheries Annual Report for 1953, Schoettler (1953, p. 54) stated that:

> The effects of the industrial waste products discharged directly into the Columbia River near the mouth of the Cowlitz are under study by the Fisheries Department in cooperation with the State Pollution Commission. In 1951 shipments of artificially fertilized smelt eggs were taken to the Deception Pass Marine laboratory. After hatching, the fry were subjected to various intensities of waste sulfite liquor. Results indicate that the liquors were harmful to young smelt. … Of equal importance were preliminary pollution studies on adult smelt. Effluents

> from three industrial plants at Longview were used. The smelt were placed in a partitioned trough which held pure river water on one side and river water mixed with certain dilutions of effluent on the other. The number of fish emerging from either side of the trough were carefully enumerated. Under these circumstances smelt showed an aversion to the effluents in dilutions approximating 1 part to 800.

The Environmental Protection Agency (EPA 2002) examined contaminants in fish, including whole eulachon, from the Columbia River in 1996–1998. In general EPA (2002, p. 9-204) stated that whole body analysis revealed that:

> While eulachon … had a high lipid content, they had some of the lowest levels of organic chemicals of all the species tested. Aroclors [a mixture of PCBs] and chlordane were not detected in the eulachon. Eulachon had the highest average concentration of arsenic and lead.

Contamination levels in three combined whole body samples of eulachon in the Columbia River collected at RKM 63–66 ranged 860–930 μg/kg arsenic, 9–10 μg/kg cadmium, 920–990 μg/kg copper, 370–680 μg/kg lead, less than 35 μg/kg mercury, 270–300 μg/kg selenium, 10–11 μg/kg p,p'-DDE, less than 4 μg/kg p,p'-DDT, less than 37 μg/kg Aroclor 1254, less than 37 μg/kg Aroclor 1260, less than 0.00005–0.0001 μg/kg 2,3,7,8-TCDD [a chlorinated dioxin], and 0.00058–0.00078 μg/kg 2,3,7,8-TCDF [a chlorinated furan] (EPA 2002). In addition, EPA (2002, p. E-4) stated that:

> DDE [a metabolite of DDT], the most commonly found pesticide in fish tissue from our study … [was found at] 11 ppb [parts per billion] in whole body eulachon. … Aroclors [a PCB mixture] [were] … nondetectable in eulachon … [and] concentrations of arsenic … [were] 890 ppb in whole body eulachon. Mercury … [was at] nondetectable levels in … whole body eulachon.

Rogers et al. (1990, p. 713) examined tissues and whole eulachon from the Fraser River for organochlorine contaminants and found that:

> [eulachon] tissue samples contained chlorophenols from wood preservation operations and chloroguaiacols from pulp bleaching. Whole fish also contained DDE and DDD [metabolites of DDT], while PCBs were present in some fish gonads in 1986, but not in 1988. With the exception of whole body concentrations of 2,3,4,6-tetrachlorophenol (TeCP), concentrations of pentachlorophenol (PCP), 3,4,5- trichloroguaiacol (3,4,5-TCG), tetrachloroguaiacol (TtiCG), DDE, and DDD in whole bodies, livers and gonads revealed an increasing trend with distance of the eulachon capture site upstream from the Fraser River mouth.

Chan et al. (1996, p. 32) examined eulachon collected from the Nass, Kitimat, and Bella Coola rivers and from Kingcome and Knight inlets for levels of persistent organic pollutants including dichlorodiphenyltrichloroethane, hexachlorobenzene, hexachlorohexanes, dieldrin, chlordane, mirex, and PCBs and found that "levels of chlorinated pesticides and PCB increased from the north to the south, with the lowest from Nass River and highest from Knight Inlet." However, contaminant levels in eulachon "were at least an order of magnitude lower than the maximum residual limit established by Health Canada or the action level established by the U.S. Food and Drug Administration" (Chan et al. 1996, p. 40). Since eulachon do not feed during their freshwater spawning run, "the uptake of toxic chemicals must occur directly from the environment" (Rogers et al. 1990, p. 725).

There are innumerable publications analyzing chemical contaminants and their sources in the lower Columbia River basin and only a select number of large-scale reviews are mentioned herein. Rosetta and Borys (1996) estimated that approximately 48% of the volume of contaminant discharges to the lower Columbia River came from industrial sources (5% from chemical and allied products, 3% from primary metal, and 39% from paper and other product manufacturers) and 52% from sewage treatment plants. Fifty-seven facilities in the lower Columbia River were identified as having the potential to release chlorinated dioxins and furans and "55 environmental cleanup sites in the State of Oregon, and 13 sites in the State of Washington [were found to] contain PCB contamination in either groundwater, sediment, or soil which may have the potential to impact the lower Columbia River" (Rosetta and Borys 1996, p. E-7).

Further breakdown of contaminant sources for the lower Columbia River are presented in Tetra Tech (1996). Hinck et al. (2004, 2006) examined contaminant levels throughout the Columbia River Basin, primarily in three resident nonanadromous target species: common carp (*Cyprinus carpio*), bass (*Micropterus* sp.), and largescale sucker (*Catostomus macrocheilus*). Fish were exposed to a variety of chemical and elemental contaminants throughout the Columbia River (Hinck et al. 2004). Temporal trend analyses indicated that PCBs were decreasing in concentration in sites with historical data; however, concentrations of the organochlorine contaminants PCBs and total p,p′-DDE were higher in the lower and middle Columbia River than in the upper Columbia River (Hinck et al. 2004, 2006).

Hall (1976, p. 45) reviewed water quality and sources of pollution in the lower Fraser River and stated that:

> There appear to be two main water quality problems in the lower Fraser, both apparently attributable to the urban-industrial complex of metropolitan Vancouver, namely pathogens and trace metals. … Potential problems are apparent regarding toxic substances such as trace metals. Concentrations are not high enough to be acutely toxic to fish but the sporadic occurrence of higher concentrations of trace metals such as lead, mercury, and zinc in the lower reaches of the river and accumulations in sediments give some cause for concern, especially since these substances are not biodegradable and bioamplification through food chain concentration or direct absorption by the organism cannot be ignored in the sensitive estuarine areas of the lower Fraser.

Types and sources of contaminants in the lower Fraser River consist of insecticides and herbicides used in agricultural production; wood preservatives associated with the lumber industry (e.g., chromium, copper, arsenic, chlorinated phenols, dioxins, polynuclear aromatic hydrocarbons, phenolics, and creosote); leachates from landfills; a wide range of contaminants in stormwater discharge; industrial effluents associated with metal, cement, forest products, and food industries; and municipal effluents (Birtwell et al. 1988).

Although the central and north coast regions of British Columbia possess relatively pristine environments compared to areas to the south, even this area has marine environmental quality concerns. Haggerty et al. (2003) identified a number of contaminant sources in British Columbia's central coast, which extends from northern Vancouver Island to just south of the Queen Charlotte Islands, including: salmon aquaculture, oil pollution, wastewater, pollution from cruise ships, shipping and boating, forestry and forest products, mining, and atmospheric and oceanic transport of chemical contaminants.

Similarly, Johannessen et al. (2007a) identified the 10 main contaminant sources in the north coast regions of British Columbia, which includes eulachon spawning rivers from the Klinaklini to the Nass rivers, to be: vessel traffic, ports, forestry, pulp and paper mills, mining and smelting, aquaculture, Coast Guard and military sites, global pollutants, offshore oil and gas, and ocean dumping. In a larger context, incorporating both the central and north coasts of British Columbia (aka Pacific North Coast Integrated Management Area [PNCIMA]), Johannessen et al. (2007b) listed the main sources of chemical contaminants as: aquaculture, vessel traffic, ports/harbors/marinas, forestry, pulp and paper, mining and smelting, ocean dumping, Coast Guard and military sites, oil and gas, and global pollutants. Detailed analyses of these contaminant sources are found in the relevant publications (Haggerty et al. 2003, Johannessen et al. 2007a, 2007b) and only a selected few major contaminant sources are mentioned below.

Johannessen et al. (2007b) indicates that 78 finfish and 24 shellfish farms operate in the PNCIMA. Many of these are located in the Queen Charlotte Strait near Knight and Kingcome inlets and pose a source of organic waste materials and of "pesticides and other persistent pollutants in fish used in the production of feed" (Johannessen et al. 2007b, p. ix). An average of more than 400,000 vessels of all types transit the PNCIMA annually. About 56% of these vessels are passenger ferries and cruise ships that transport about 1.5 million passengers yearly through the PNCIMA (Johannessen et al. 2007b). According to Johannessen et al. (2007b, p. 12), "Contaminant issues associated with marine traffic include the discharge of sewage, grey water, oily bilge water, shipboard solid wastes, and release of antifouling compounds from ablative coatings."

Prince Rupert and Kitimat, the two main industrial ports in the PNCIMA, are expanding and increasing their capacity for large industrial shipping. The industrial port of Kitimat currently serves the Alcan aluminum smelter, the Eurocan paper mill, and the Methanex methanol plant (Johannessen et al. 2007b). A new Kitimat liquefied natural gas terminal is to begin construction in 2010, and there are plans for a new Kitimat Marine Terminal and pipeline to transport petroleum from near Edmonton, Alberta, to Kitimat and condensate from Kitimat to near Edmonton, together with numerous other industrial terminal projects (Port of Kitimat 2009). Johannessen et al. (2007b, p. ix) stated that:

> Four [pulp] mills exist in the area [PNCIMA], though two of them have operated intermittently. All Canadian pulp mills underwent significant effluent treatment upgrades in the 1990s such that discharge of solids, discharge of oxygen demand, and chlorinated compounds such as dioxins and furans are now significantly reduced.

Johannessen et al. (2007b, p. 25–26) indicated that within the PNCIMA, "12 [mine] sites are a risk to produce acid rock drainage and heavy metal leachate" and that the only active smelter in the PNCIMA is the aluminum smelter at Kitimat, where "several studies have detected elevated PAH concentrations in both marine biota and sediments in the Kitimat Arm area." Johnson et al. (2009) detected elevated concentrations of PAHs in sediments of Kitimat Arm, that are similar to PAHs originating from the Alcan smelter, and in salmon and flatfish collected in Kitimat arm. However, Johnson et al. (2009, p. xv) concluded that:

> The process changes introduced by Alcan appear to be effective at reducing inputs of PAHs into the environment and biota of Kitimat Arm, as PAH concentrations in sediments and fish and fish disease prevalences have remained stable or declined over the past 5 years of sampling.

Kime (1995, p. 67–68) reviewed the literature on the effects of contaminants on fish reproduction prior to fertilization, showed that these effects can occur throughout the reproductive system, and stated that:

> They may cause lesions, haemorrhage, or malformations in the gonads, pituitary, liver, and the brain. Production and secretion of hormones of the hypothalamus, pituitary, and gonads is usually inhibited and their metabolism by the liver can be altered. … Gametes have been shown to be particularly sensitive to pollutants, both in their development, particularly the production and growth of oocytes involving vitellogenin synthesis, and in their fertility. Sperm motility, in particular, has special potential as a rapid and sensitive indicator of pollutant activity.

Analyses of these reproductive biomarkers (quantifiable parameters of an organism's biological state) go beyond the traditional toxicological test of establishing the dose of a contaminant causing death in 50% of the test organisms ($LD_{50}$) and are an example of the problems researchers have in assessing the effects of chronic low-level exposure of contaminants or mixtures of contaminants on fish and fish populations (Eggen et al. 2004, Carvan et al. 2008). As pointed out by Carvan et al. (2008, p. 1,023), most of the problems facing modern ecotoxicology are much more subtle and require development of a suite of biomarkers and the use of controlled laboratory experiments on sentinel fish species, such as zebrafish (*Danio rerio*) (much as laboratory rats are used to assess risk of toxicant exposure to higher mammals), to assess risk to closely related fish species.

**Temperature**—Smith and Saalfeld (1955) reported that eulachon are present in the Columbia River when water temperatures are between 2°C and 10°C and delay migration into spawning tributaries until temperatures are above about 4.4°C (WDFW and ODFW 2001). When river temperatures vary above or below normal, eulachon may fail to spawn in normal areas, delay spawning, or migrate into other tributaries (Smith and Saalfeld 1955, WDFW and ODFW 2001).

Snyder (1970) reported on studies in 1968 and 1969 that examined the temperature tolerance of adult eulachon and eggs taken from the Columbia and Cowlitz rivers and found that eggs were more tolerant to temperature increases than were adults. Increases of 2.8°C and 5.6°C killed 50% and 100% of adult smelt, respectively, within 8 days. Even when exposed to temperatures elevated by 9°C for a single hour, 50% of adult eulachon were dead after 32 hours. When placed in water 3.9°C above river temperatures, females failed to deposit eggs (Snyder 1970). Slightly different results were reported by Blahm and McConnell (1971) on effects of increased temperature on eulachon collected from the Cowlitz River in 1968 and 1969. They reported that the incipient lethal temperature for eulachon acclimated to 5°C was 11°C. All eulachon exposed to 11°C were dead after 8 days exposure. When eulachon had been acclimated to 10°C, a sudden exposure to 18°C for one hour followed by return to 10°C resulted in at least 50% mortality within 50 hours (Blahm and McConnell 1971). All female fish exposed to elevated temperatures failed to deposit eggs within 50 hours, in contrast to female eulachon in control conditions that successfully deposited eggs (Snyder and Blahm 1971).

When evaluating temperature criteria for Washington's water quality standards, Hicks (2000, p. 99) stated that:

> The studies on smelt indicate they have a lower lethal temperature limit than do the salmonids and a lower optimum temperature preferendum. … Given that adult spawners and outgoing juveniles may be in fresh waters as late as March to mid-April, and their temperature requirements may be more strict than most salmonids, the protection of smelt is an important consideration in setting water quality standards. In waters supporting smelt, it is recommended that the 7-day average of the daily maximum temperatures not exceed 12–14°C prior to May 1, with no single daily maximum temperature greater than 16°C.

### Catastrophic events

Larson and Belchik (1998, p. 7) reported that "The eruption of Mount St. Helens severely impacted Cowlitz River spawning success in 1980 and the consequent return of adults in 1984."

Emmett et al. (1990) documented the effects of the dramatic increase in turbidity in the Columbia River on fishes in the estuary following the 18 May 1980 eruption of Mount St. Helens, which resulted in introduction of large quantities of volcanic ash and sediment into the Columbia River estuary. Although hampered by the absence of long-term pre-eruption data, Emmett et al. (1990) showed that densities of benthic invertebrates, particularly amphipods, were significantly reduced and feeding habits and distribution of estuarine fishes were altered following the eruption.

## Overutilization for Commercial, Recreational, Scientific, or Educational Purposes

### Commercial harvest

Landing records of eulachon in commercial fisheries in the Fraser and Columbia rivers were discussed in the above Summary of Regional Demographic Data subsection. Eulachon have been commercially harvested in the Columbia River since the late 1860s and commercial landing records begin in 1888 (Table 7, Figure 22). Smith and Saalfeld (1955), the Washington and Oregon Eulachon Management Plan (WDFW and ODFW 2001), and Bargmann et al. (2005) describe gear types and fishery regulations pertaining to the modern era of the Columbia River commercial eulachon fishery. As described in the Summary of Regional Demographic Data subsection, the Columbia River eulachon commercial fishery has been managed according to the Joint State Eulachon Management Plan since 2001, which provides for three levels of fishing intensity based on an in-season estimate of parental run strength and preseason estimates of juvenile production and ocean productivity (WDFW and ODFW 2001, Bargmann et al. 2005).

More recently, JCRMS (2009, p. 26–27) stated that:

> For January 1–March 31, 2009, the mainstem Columbia River commercial fishery was open from 7 a.m. to 2 p.m. on Mondays and Thursdays. … The Cowlitz River was open from 6 a.m. to 10 p.m. on Saturdays. The Sandy River was open year-round, 7 days a week, 24 hours a day, per permanent regulations. ... Pounds landed in the mainstem Columbia River commercial fisheries [amounted to] 5,600 pounds. No commercial landings were made in Oregon tributaries (i.e., Sandy River) during 2009. Pounds landed in the Cowlitz River commercial fishery [amounted to] 12,100 pounds. … All other Washington tributaries were closed to commercial fishing during 2009.

DFO (2008c) provides a brief history of the Fraser River commercial eulachon fishery, which began in the 1870s and, besides the Nass River fishery which ended in the 1940s, has been the only commercial eulachon fishery operating in British Columbia. DFO (2008c) reported that:

> From 1903 to 1912, the Fraser River eulachon fishery was the fifth largest commercial fishery in BC. … Historically, anyone with a Category C licence or a limited entry vessel-based category of licence was eligible to fish eulachon. … Up to 1995, the fishery was passively managed with an open time from March 15 to May 31 for commercial drift gill nets with a one day per week closure. In 1995 … the fishery was restricted to three days per week in an attempt to provide a “spawning window” which would allow some fish to swim unimpeded by nets to their spawning areas. … The commercial eulachon fishery was closed in 1997 due to the inability to control effort and participation and to ensure conservation objectives were met. … The commercial eulachon fishery sells to the fresh fish market for food. Some of the catch is sold as bait for recreational sturgeon fishing. Based on fish slip records for the period 1980 to 1995, the number of active vessels ranged between 8 and 45.

The Fraser River commercial fishery for eulachon has essentially been closed since 1997, only opening briefly in 2002 and 2004, when 5.76 and 0.44 mt were landed, respectively (Table 9, Figure 27) (DFO 2006a).

**Recreational harvest**

Fry (1979, p. 90) reported that in California, in the past, there were “relatively minor [eulachon] sport fisheries near river mouths, the Klamath fishery being the largest. Dip nets are used.” Numerous anecdotal digital newspaper sources were found that indicate substantial recreational fisheries existed in the Klamath River and in other northern California rivers, as well as in the Umpqua River during the 1960s to the 1980s (see Appendix B).

A large recreational dipnet fishery that occurs almost exclusively in Columbia River tributaries, and for which catch records are unavailable, has existed in concert with commercial fisheries (Bargmann et al. 2005). JCRMS (2008) stated that:

> Prior to 1997, the recreational fishery in Washington tributaries was open 7 days per week the entire year. ... Smelt dippers in Washington were allowed 20 pounds [9.1 kg] per person each day, but beginning in late 1998 the limit has sometimes been 10 pounds [4.5 kg] per person. In Oregon the daily limit remains 25 pounds [11.4 kg] per person with the season open throughout the year. The recreational dip net fishery is very popular, drawing thousands of participants. Smelt are used for human consumption and are also in great demand for sturgeon bait. Annual recreational catch estimates are not available; however, limited past creel census information suggests that the recreational catch may equal the commercial landings in some years when smelt are abundant for a long period of time.

USACE (1952, p. 2,873) reported that:

> During the smelt run literally thousands of people line the banks of the streams, utilizing all sorts of gear to make a catch of this delectable fish. Data are lacking to show the magnitude of this catch, but during the 1948 smelt run to the Sandy River, 32,422 noncommercial licenses were issued to persons engaged in dipping this fish.

In reference to the 2009 recreational fishery season, JCRMS (2009, p. 27) stated that:

> The mainstem Columbia River was open to both Washington and Oregon recreational fishers 7 days per week on a 24-hour basis, with a bag limit of 25 pounds per person under Level One restrictions. The Washington tributary season was restricted to the Cowlitz River from 6 a.m. to 10 p.m. on Saturdays with a bag limit of 10 pounds per person. All Oregon tributaries were open to recreational dipping 7 days per week the entire year as per permanent regulations. Recreational fishing was poor due to low abundance.

Currently, recreational fishing for eulachon with dip nets, gill nets, minnow nets, or cast nets is prohibited in all freshwater systems of British Columbia (DFO Web site at http://www.pac.dfo-mpo.gc.ca/fm-gp/rec/opportunities-possibilites/fin-nageoire-eng.htm. In saltwater, recreational fishing for eulachon is prohibited due to conservation concerns in Areas 6 to 10 (central coast of British Columbia) and 28 and 29 (near the mouth of the Fraser River). In Areas 1 to 5 (north coast of British Columbia) and 11 to 27 (Queen Charlotte Strait, Strait of Georgia, and west coast Vancouver Island), a year round daily limit of 20 kg of eulachon can be recreationally harvested with dip net or gill net, although this harvest is likely minor since eulachon are only accessible to the recreational fishery when they return to spawn in the spring and are close enough to the surface and shore to be caught (DFO 2009f).

## Tribal and First Nations fisheries

The importance of the eulachon run to local Indian tribes in the lower Columbia River was documented as early as the Lewis and Clark Expedition (Burroughs 1961, WDFW and ODFW 2001). JCRMS (2009, p. 26) stated that currently:

> Tribal harvest is essentially nonexistent. … However, the Yakama Nation has taken a few pounds of smelt from the Cowlitz River annually, for ceremonial and subsistence purposes.

Available landing records of eulachon in First Nations subsistence fisheries in British Columbia south of the Nass River were discussed in the above Summary of Regional Demographic Data subsection. Rivers where some data were available included the Fraser, Klinaklini, Kingcome, Wannock, Bella Coola, Kemano, and Kitimat. DFO (2008c) stated that:

> Aboriginal communal licences specify the locations and method permitted for use by First Nations for food, social, and ceremonial harvests. Eulachons are harvested when they return to freshwater to spawn. … Fishing methods will vary by First Nations and river system, but may include beach seine, gill net, conical nets, and dip nets. … Limited information is available on the extent of First Nations' harvest of eulachons for food, social, and ceremonial purposes.

Pickard and Marmorek (2007, p. 40) reported in their summary of findings of a DFO workshop to determine research priorities for eulachon that "it seems unlikely that overfishing is the cause of the recent sharp declines in eulachon abundance; however, it is important to understand how harvesting severely depressed populations may affect the recovery of populations."

# Predation and Disease

## Predation

WDFW and ODFW (2001, p. 5) stated that "impressive numbers of predators and scavengers accompany large runs of smelt from the time they first enter the Columbia through completion of spawning." Beach et al. (1981, 1985) and Jeffries (1984) observed that harbor seals, California sea lions, and Steller sea lions (*Eumetopias jubatus*) move into the Columbia River to feed on eulachon runs in the winter. Jeffries (1984, p. 20) observed that "harbor seals were frequently reported in the area where the Cowlitz River enters the Columbia" and "these population increases … were apparently due to the migration of eulachon into spawning tributaries." Many harbor seals migrate from Grays Harbor and Willapa Bay to the Columbia River in the winter (Beach et al. 1985). Between 1,000 and 1,500 harbor seals have been observed using haul out sites as far as 45 miles upriver on the Columbia River at this time of year and "are frequently seen as far upriver as Longview, Washington (RM 55 [RKM 88.5]), apparently following eulachon runs into this area" (Beach et al. 1981, p. 73). NMFS (1997, p. 29) stated that the highest counts of seals in the river coincide with the winter spawning of eulachon.

Based on the presence of otoliths in harbor seal scat collected from the Columbia River during 1981–1982, Jeffries (1984) reported that eulachon were eaten by 50%, 87%, 44%, and 12% of the harbor seals present in January, February, March, and April, respectively. Brown et al. (1989) determined that 98% of the prey eaten by harbor seals in the Columbia River during the winters of 1986 to 1988 were eulachon, and that 100% of harbor seal stomachs examined contained eulachon (Brown et al. 1989, NMFS 1997). Brown et al. (1989) also estimated that the more than 2,000 harbor seals present during mid winter 1987 in the Columbia River consumed from 2.5 to 10.2 million eulachon or from 105 to 428 mt (assuming an average weight of 42 g per eulachon), which is equal to 12% to 50% of the Columbia River commercial fishery landings of eulachon for that year.

Although accounting for only 0.4% of the diet, Olesiuk (1993) estimated that the 12,000–15,000 harbor seals present in the Strait of Georgia during 1988 consumed an average of approximately 40 mt of eulachon. Harbor seals were known to concentrate and feed on eulachon in the Klinaklini River estuary at the head of Knight Inlet during the eulachon spawning migration in March (Spalding 1964). Eulachon also congregate in the Skeena River off Point Lambert during the eulachon spawning migration in that river (Fisher 1947) and likely follow the eulachon up the tributary Ecstall River (Fisher 1952). Both Imler and Sarber (1947) and Pitcher (1980) indicate that eulachon were the dominant prey of harbor seals from late May to mid-July during eulachon spawning migrations on the Copper River Delta in Alaska. Based on stomach content analyses, harbor seals also prey on eulachon in Prince William Sound (Pitcher 1980, Lowry et al. 2001), lower Cook Inlet, and off Kodiak Island (Pitcher 1980). Nearly 5% of 269 harbor seal stomachs examined in all areas of the Gulf of Alaska by Pitcher (1980) contained eulachon remains.

Eulachon are also a primary prey species of California sea lions in the Columbia River in January to June (Beach et al. 1985, Brown et al. 1995, NMFS 1997), and California sea lions have been observed near Longview at the time of the eulachon run (Beach et al. 1981). Jeffries (1984, p. 17) observed that peak numbers of California sea lions (200–250) in the Columbia River occurred during the months of February and March and they were believed to "move upriver following and feeding on the annual eulachon smelt runs." Maximum numbers of Steller sea lions (80–100) in the Columbia River also occurred during this time of year when they "have been observed feeding upriver on eulachon" (Jeffries 1984, p. 19). Seals and sea lions have also been observed above New Westminster in the Fraser River during the eulachon spawning migration (Hay and McCarter 2000).

Bigg (1988) noted that about 60 individual Steller sea lions congregated each year between 1978 and 1982 near the mouth of the Fraser River at Sand Heads in mid-March to early May to feed on eulachon that spawn in the Fraser at that time. Steller sea lions were similarly reported by fishery officers to enter numerous inlets on the mainland coast of British Columbia to feed on returning eulachon during February to April (Bigg 1988). Although Pitcher (1981) reported that eulachon were not a part of the diet of Steller sea lions in the Gulf of Alaska, numerous other studies (Womble 2003, Sigler et al. 2004, Womble and Sigler 2006, Womble et al. 2005, 2009) have emphasized the seasonal importance of eulachon to Steller sea lions in Southeast Alaska. Steller sea lions are attracted in large numbers to spawning eulachon runs in April and May in various locations in northern Southeast Alaska, especially the Yakutat forelands and Lynn Canal (Sigler et al. 2004, Womble et al. 2005, 2009). Eulachon provide a predictable energy-rich prey item for Steller sea lions during the spring gestation and pupping season (Womble 2003, Sigler et al. 2004). Sigler et al. (2004) estimated that about 10% of the population of Southeast Alaska Steller sea lions were in Berners Bay on Lynn Canal during the 2002 eulachon run and that many other Steller sea lions were likely aggregated in the vicinity of one of the 32 other documented eulachon spawning runs in Southeast Alaska. Large aggregations of Steller sea lions have also been found in the vicinity of the mouth of the Alsek River and Taku, Lutak, and Taiya inlets during eulachon runs (Womble 2003).

Northern fur seals consume eulachon in the California Current (Antonelis and Fiscus 1980) and particularly offshore of Oregon and Washington (Antonelis and Perez 1984). Peak numbers of northern fur seals appear off Oregon and Washington in April (Antonelis and Perez 1984). Based on fur seal diet analyses, Antonelis and Perez (1984) calculated that fur seals consumed a yearly average of 600 mt of eulachon in this offshore region between 1958 and 1974. By comparison, the Columbia River commercial fishery landed an average yearly catch of 650 mt of eulachon over this same time period (Table 9). Spalding (1964) reported that about 100 yearling fur seals congregated at the head of Knight Inlet in March 1961 and that four of these fur seals had been feeding exclusively on eulachon in the Klinaklini River estuary, while another 60 fur seals in the middle of the inlet were feeding on squid. Clemens et al. (1936, p. 6) reported on an analysis of stomach contents of 593 northern fur seals sampled from late March to late June off the west coast of Vancouver Island and stated that:

> Eulachon proved to be the third most important organism in the food of the fur seals [after herring and salmon]. It was found to occur in some 20% of the full stomachs but as a rule in rather small quantities. It comprised about 3% of the total food.

Moore et al. (2000) reported that feeding behavior of beluga whales appears to coincide with the timing and pattern of eulachon runs in Cook Inlet, Alaska. Belugas congregate near the Susitna River Delta at the time of early summer eulachon runs and eulachon have been identified in beluga stomachs (Moore et al. 2000).

Marston et al. (2002) documented 34 separate bird species feeding on eulachon returning to spawn in rivers draining into Berners Bay, Alaska, amounting to more than 46,000 avian predators in 1996 and more than 36,500 in 1997. Thousands of gulls and some of the hundreds of eagles were observed feeding heavily on eulachon during the upriver migration, while shorebirds, waterfowl, corvids, and many eagles fed on spawned-out, dying fish (Marston et al. 2002). WDFW and ODFW (2001, p. 5) stated that "gull counts in the mid-1980s along the lower Cowlitz River during the peak of eulachon abundance exceeded 10,000 birds of 8 species" and that during the 1980s "peak counts of bald eagles in conjunction with eulachon upstream migration and spawning were as high as 50 in areas of the lower mainstem Columbia, along the Cowlitz, and along the Lewis" (Table A-10).

According to Fry (1979, p. 15) "Green sturgeon take advantage of spawning eulachon in the Klamath River, but (like eagles and gulls) probably do more scavenging than actual preying." Analysis of stomach contents revealed that eulachon eggs were a seasonally important prey item for juvenile white sturgeon in May and June 1988 in the Columbia River below Bonneville Dam at RKM 153 (2–12 % of the diet) and RKM 211 (25–50% of the diet) (McCabe et al. 1993).

Eulachon occurred in 100% of 229 spiny dogfish stomachs containing food taken in the Fraser River in May 1953, and in 23% and 92% of stomachs analyzed outside the river's mouth in May 1950 and 1953, respectively (Chatwin and Forrester 1953). According to Chatwin and Forrester (1953, p. 38), "The dogfish which support the fishery in the Fraser River in mid-May are clearly dependent upon the appearance of the eulachon." Analyses of more than 14,000 spiny dogfish stomachs in British Columbia waters over a 30-year period ending in 1977 revealed that eulachon represented approximately 5.5% of the annual dogfish diet, and represented a greater percentage of food types consumed for young (13.4%) and immature (10.2%) dogfish than for adults (1.6%) (Jones and Geen 1977).

Eulachon occurred at low frequency (<1%) in 416 Pacific cod stomachs examined in British Columbia (Hart 1949). Eulachon are also eaten by large Pacific hake, which become increasingly piscivirous as they age, with euphausiids being the dominant prey of small Pacific hake (Rexstad and Pikitch 1986, Buckley and Livingston 1997). Livingston (1983, p. 630) determined that eulachon off Oregon in the spring of 1980 "comprised 22% by weight of the diet of 450–549 mm Pacific whiting [hake] and 79.6% by weight of the diet of 550+ mm fish." The offshore Pacific hake stock migrates northward from winter spawning grounds to feed off the coast of the Pacific Northwest in the summer. This stock represents 61% of the offshore pelagic biomass in the California Current system (Ware and McFarlane 1995), and recent evidence (Benson et al. 2002, Cooke et al. 2006, Phillips et al. 2007) indicates that the feeding migration of Pacific hake may be extending further north within the northern California Current system. Although only about 5% of Pacific hake stomachs examined by Outram and Haegele (1972) off the west coast of Vancouver Island in 1970 contained eulachon, the large biomass of Pacific hake in this region in summer may have a significant impact on eulachon biomass in the area (Hay and McCarter 2000).

Yang and Nelson (2000, p. 159–160) stated that "eulachon [in the Gulf of Alaska in 1990, 1993, and 1996] were consumed by the main piscivorous species (arrowtooth flounder, Pacific halibut, sablefish, Pacific cod, and pollock) but … comprised no more than 5% of the stomach content weight of each of the predator species in every year." These predator species consumed eulachon whose mean standard length ranged from 100 to 150 mm (Yang and Nelson 2000). In 1990 and 2001, eulachon comprised about 5.5% and 2.5% by weight, respectively, of the total sablefish stomach contents examined in the Gulf of Alaska (Yang 1993, Yang et al. 2006). In the Gulf of Alaska, "sablefish less than 55 cm FL only consumed smaller eulachon (<100 mm SL), whereas larger sablefish (>55 cm FL) also consumed some larger eulachon (about 150 mm SL)" (Yang 1993, p. 97). Eulachon were prey items in about 4% of 753 arrowtooth flounder stomachs examined (70% of stomachs contained no food) off the west coast of Vancouver Island in 1968 and 1969 (Kabata and Forrester 1974). Similarly, eulachon were found in about 5% of 341 arrowtooth flounder stomachs examined (about 49% of stomachs were empty) in the summer of 1989 off the coast north of Cape Blanco, Oregon (Buckley et al. 1999).

Barraclough (1967) reported on the stomach contents of surface trawl–caught fish in the Strait of Georgia near the mouth of the Fraser River during 6–8 June 1966, when eulachon larvae

(4.5–16 mm FL) and postlarvae/juveniles (24–49 mm FL) were in the water column. Species and the range of fork lengths of fish consuming eulachon larvae included Pacific herring (33–182 mm FL), surf smelt (70–133 mm FL), Pacific sand lance (35–73 mm FL), and Chinook (67–148 mm FL), sockeye (88–140 mm FL), and chum (37.5 mm FL) salmon. Numbers of eulachon larvae consumed by individual fish ranged from 3–14 for Pacific herring, 1–4 for surf smelt, 1–8 for Pacific sand lance, 9–137 for Chinook, 4–12 for sockeye, and 100 for chum salmon (Barraclough 1967). Similarly, Robinson et al. (1968b) reported on the stomach contents of surface trawl–caught fish in the Strait of Georgia near the mouth of the Fraser River during 5–9 June 1967, when large numbers of eulachon larvae (5–12 mm FL) were in the water column. Species and the range of fork lengths of fish consuming eulachon larvae included Pacific herring (37–258 mm FL), surf smelt (75 mm FL), Pacific sand lance (44–106 mm FL), kelp greenling (63–67 mm FL), threespine stickleback (68 mm FL), steelhead (150 mm FL), and Chinook (100 mm FL), sockeye (98 mm FL), and chum (63–86 mm FL) salmon. Numbers of eulachon larvae consumed by individual fish ranged 1–300 for Pacific herring, 1 for surf smelt, 3–16 for Pacific sand lance, 1–19 for kelp greenling, 12 for threespine stickleback, 1 for steelhead, and 4 for Chinook, 3 for sockeye, and 2–60 for chum salmon (Robinson et al. 1968b).

Barraclough and Fulton (1967) reported on larval/postlarval eulachon (16–26 mm FL) in the stomach contents of surface trawl–caught fish in the Strait of Georgia near the mouth of the Fraser River during 4–8 July 1966. Species and the range of fork lengths of fish consuming eulachon larvae and postlarvae included coho (160 mm FL), sockeye (117 mm FL), chum (95–112 mm FL), and pink (88–135 mm FL) salmon. Numbers of eulachon larvae and postlarvae consumed by individual fish ranged 7 for coho, 13 for sockeye, 2–20 for chum, and 2–118 for pink salmon (Barraclough and Fulton 1967). Moffitt et al. (2002, p. 4) indicated that coho salmon parr and adult Dolly Varden feed on eulachon eggs and larvae in rivers in Southeast Alaska and "returning adult sockeye salmon in the Copper River delta have been found with adult eulachon in their stomachs." Similarly, adult spring-run Chinook salmon have been found with upwards of a dozen eulachon in their stomachs on the Cowlitz River during the spring spawning migration of the two species (Rich 1921). These instances of returning adult salmon feeding on eulachon are highly unusual as "it is well known that the habit of adult salmon, entering streams for the purpose of spawning, is to cease feeding at least as soon as the freshwater is entered" (Rich 1921, p. 7).

Ecosystem impacts of the recent and ongoing expansion of large numbers of jumbo (aka Humboldt) squid (*Dosidicus gigas*) into waters off Oregon, Washington, and British Columbia are uncertain (Zeidberg and Robison 2007, Holmes et al. 2008). An analysis of the contents of 503 jumbo squid stomachs collected in the northern California Current, including 40 collected off Oregon and Washington, failed to record the presence of eulachon or other osmerid smelts in the jumbo squid diet (Field et al. 2007). Jumbo squid, however, were shown to prey heavily on Pacific hake in the size range of 15–45 cm and adult Pacific hake are known predators on eulachon. The absence of eulachon in the diet of jumbo squid analyzed by Field et al. (2007) may be due to a combination of low eulachon abundance in the study area and a lack of significant overlap in the two species' depth range; eulachon are commonly found between 20 and 150 m deep (Hay and McCarter 2000) and are seldom encountered below 200 m and jumbo squid in the Field et al. (2007) study were mostly collected below this depth. Further diet studies of jumbo squid collected off Oregon in 2009 are ongoing; however, a further 400 squid stomachs examined since the publication of Field et al. (2007) has yet to yield eulachon or any osmerids in the diet of jumbo squid.[14] Rapid digestion of small pelagic fish may also limit the ability to detect eulachon in jumbo squid stomachs.

### Disease

Very little information was found relative to impacts of diseases on eulachon. Hedrick et al. (2003) isolated viral hemorrhagic septicemia virus (VHSV) for the first time from adult eulachon collected in March 2001 in Oregon's Sandy River. Six of 15 pooled samples, each consisting of 5 fish, tested positive for VHSV. The overall impact of this virus on eulachon is difficult to assess. This virus has been isolated from a wide range of marine fish hosts and given the right conditions may "cause significant disease associated with morbidity and mortality in populations of marine fish" (Hedrick et al. 2003, p. 212).

## Other Natural or Man-made Factors

### Competition

Euphausiids (principally *Thysanoessa spiniferia* and *Euphausia pacifica*) are a primary prey item of eulachon in the open ocean and are also eaten by many other competing species. Tanasichuk et al. (1991) showed that euphausiids were the most important prey for both spiny dogfish and Pacific hake off the lower west coast of Vancouver Island. Livingston (1983) determined that euphausiids constituted 72% and 90% of the diet by weight of Pacific hake examined off Oregon and Washington, respectively, in 1967, and 97% of the diet by weight of Pacific hake 350–449 mm long off Oregon in 1980. Similarly, Outram and Haegele (1972) indicated that euphausiids were the most numerous prey item of Pacific hake off the British Columbia coast in 1970, occurring in 94% of Pacific hake stomachs analyzed. Rexstad and Pikitch (1986, p. 955) stated that "euphausiids constitute the primary source of food for Pacific hake in the North Pacific." The offshore Pacific hake stock migrates northward from winter spawning grounds to feed off the coast of the Pacific Northwest in the summer. This stock represents the largest component of the offshore pelagic fish biomass in the California Current system (Ware and McFarlane 1995). Recent evidence (Benson et al. 2002, Cooke et al. 2006, Phillips et al. 2007) indicates that Pacific hake spawning may be shifting further north within the northern California Current system. This places more young of the year Pacific hake in that ecosystem (Phillips et al. 2007) in direct competition with eulachon for their preferred prey, euphausiids.

Several studies (Suchman and Brodeur 2005, Ruzicka et al. 2007, Brodeur et al. 2008, Suchman et al. 2008) have suggested that seasonal predation by large jellyfish can have a substantial impact on zooplankton populations in the California Current and these jellyfish may represent significant competitors with pelagic fishes for zooplankton resources. Brodeur et al. (2008, p. 649) examined spatial and dietary overlap of large jellyfish with a number of pelagic fishes in the California Current and stated that:

---

[14] J. Field, Southwest Fisheries Science Center, Santa Cruz, CA. Pers. commun., 15 October 2009.

isotope and diet analyses suggest that jellyfish occupy a trophic level similar to that of small pelagic fishes such as herring, sardines, and northern anchovy. Thus jellyfish have the potential, given their substantial biomass, of competing with these species.

Although eulachon were not specifically examined in this study, a large percentage of the diets of the two large jellyfish examined (*Chrysaora fuscescens* and *Aurelia labiata*) consisted of copepods and various euphausiid life history forms from eggs to adults (Brodeur et al. 2008) that are also significant components of the eulachon diet.

**Euphausiid fisheries**

A commercial fishery for euphausiids (also known as krill) occurs in the British Columbia portion of the Strait of Georgia (DFO 2007b). According to DFO (2007b, p. 6), euphausiid biomass in British Columbia waters "is dominated by five [species]: *Euphausia pacifica*, *Thysanoessa spinifera*, *T. inspinata*, *T. longipes* and *T. raschii*," and *E. pacifica* accounts for 70–100% of the biomass in the Strait of Georgia. The Integrated Fisheries Management Plan for euphausiids limits annual total allowable catch (TAC) of euphausiids in the Strait of Georgia to 500 mt (DFO 2007b). DFO (2007b, p. 3 of its Appendix A) stated that this level of harvest is considered to "be conservative and sustainable" within the Strait of Georgia. Eulachon originating from rivers draining into the Strait of Georgia likely leave the strait for waters over the continental shelf prior to reaching a size where they would begin consuming euphausiids, and thus the impact of this euphausiid fishery on eulachon is expected to be minor.

Although no directed commercial fishery for euphausiids has occurred in U.S. waters off the West Coast, recognition of the importance of krill in the diet of many species influenced the Pacific Fisheries Management Council to propose a ban on commercial harvest of all species of krill (euphausiids) in the Exclusive Economic Zone off the U.S. West Coast, which includes California, Oregon, and Washington (PFMC and NMFS 2008). This krill harvest ban was formally implemented as Amendment 12 to the Coastal Pelagic Species Fishery Management Plan in July 2009 (NMFS 2009).

**Eulachon bycatch**

Eulachon occur as bycatch in shrimp trawl fisheries off the coasts of Washington, Oregon, California, and British Columbia (Hay et al. 1999a, 1999b, Olsen et al. 2000, NWFSC 2008, Hannah and Jones 2009). Offshore trawl fisheries for ocean shrimp (*Pandalus jordani*) occur from the west coast of Vancouver Island to the U.S. West Coast off Cape Mendocino, California (Hannah and Jones 2003) (Figure 31). *Pandalus jordani* is known as the ocean pink shrimp or smooth pink shrimp in Washington, pink shrimp in Oregon, and Pacific ocean shrimp in California. Herein we use the common name ocean shrimp in reference to *P. jordani* as suggested by the American Fisheries Society (McLaughlin et al. 2005). Similar trawl fisheries operate in British Columbia, which mainly target ocean shrimp (aka smooth pink shrimp in Canada), northern pink shrimp (*P. borealis eous*), and sidestripe shrimp (*Pandalopsis dispar*) (Hay et al. 1999a, 1999b, Olsen et al. 2000, Hannah and Jones 2007, NWFSC 2008, DFO 2009c). Information on ocean shrimp fisheries can be found for Washington online at

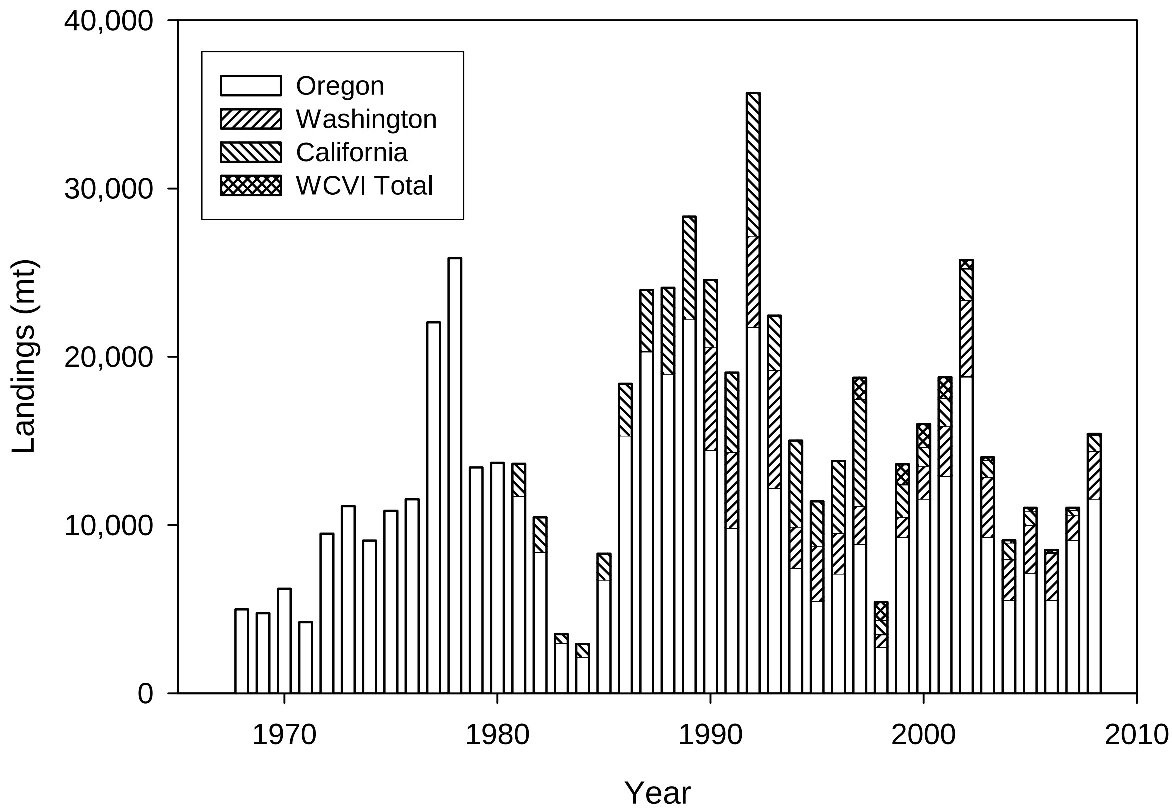

Figure 31. Commercial landings in ocean shrimp trawl fisheries off the U.S. West Coast and in British Columbia, Canada, off the west coast of Vancouver Island. Data for Washington from tables online at http://wdfw.wa.gov/fish/shelfish/shrimp/comm/index.html, for Oregon from Rien[15] and Hannah and Jones (2009), for California from tables online at http://swr.nmfs.noaa.gov/fmd/bill/landings.htm, and for the west coast of Vancouver Island from DFO (2009a).

http://wdfw.wa.gov/fish/shelfish/shrimp/comm/index.html, for Oregon online at http://www.dfw.state.or.us/MRP/shellfish/commercial/shrimp_landings.asp#about, for California in Frimodig et al. (2007), and for British Columbia online at http://www.pac.dfo-mpo.gc.ca/ops/fm/shellfish/shrimp/Default_e.htm.

Prior to the mandated use of bycatch reduction devices (BRDs) in the ocean shrimp fishery, 32–61% of the total catch in the ocean shrimp fishery consisted of nonshrimp biomass, made up mostly of Pacific hake, various species of smelt, yellowtail rockfish, sablefish, and lingcod (*Ophiodon elongatus*) (Hannah and Jones 2007). Reducing bycatch in this fishery has long been an active field of research (Hannah et al. 1996, 2003, Hannah and Jones 2007, 2009, Frimodig 2008) and great progress has been made in reducing bycatch, particularly of larger-bodied fishes. As of 2005, following required implementation of BRDs, the total bycatch by weight had been reduced to about 7.5% of the total catch and osmerid smelt bycatch was reduced to an estimated average of 0.73% of the total catch across all BRD types (Hannah and Jones 2007).

[15] T. Rein, ODFW, Clackamas, OR. Pers. commun., 24 June 2008.

Beginning in 2000 in British Columbia and 2003 in Washington, Oregon, and California, mandated use of of BRDs in offshore shrimp trawl fisheries has substantially reduced bycatch of fin fish in these fisheries (Hannah and Jones 2007, Frimodig 2008). The nearly 97% use of rigid-grate BRDs and increasing use of grates with bar spacing of one inch or less in the Oregon shrimp trawl fishery (Hannah and Jones 2009), and the required use of rigid-grate BRDs with a grid space no greater than 44.5 mm (1.75 inches) and the recommendation to use a 25 mm (1 inch) space between the grid bars when targeting pink shrimp in the British Columbia shrimp trawl fisheries (DFO 2009c) are likely to reduce bycatch rates of small-bodied fishes even further.
