In addition, Reclamation has salvaged fish from canals throughout the Klamath Project each fall since 1991 following dewatering using electofishing techniques (Reclamation, 2008). Reclamation has noted that if electrofishing is found to injure juvenile suckers, they would pursue other techniques to salvage fish (Reclamation, 2008). Sucker mortalities (Lost River suckers, shortnose suckers, and Klamath largescale suckers) do occur during salvage operations, whether due to electrofishing stress or to low levels of dissolved oxygen (for example, Peck, 2000 and 2001). But the protocol to be used during this Project would use a variety of netting (e.g. beach seining, dip netting) before using electrofishing methods to reduce this potential impact (see Conservation Methods below for details).

Acoustic Shock

There will be no blasting or use of mounted hydraulic impact hammer to cross the Lost River. Use of back-hoes for dry open-cut construction will not produce sound levels to cause harm to Lost River suckers, as discussed for coho in Section 3.2.3.2.

**Indirect Effects**

Turbidity

Potential impacts to fisheries by dry open-cutting were discussed above in section 4.5.1.3 Coho (SONCC ESU). As noted in that discussion, dry open-cutting (fluming, dam-and-pump, or some combination of the two) generates small amounts of turbidity compared to wet open-cut procedures. However, adult suckers appear to prefer deep, turbid water but are often forced to utilize shallow, clear water if forced to during degraded water quality conditions in the summer (National Research Council, 2004). The amounts of turbidity generated by dry open-cut construction are not expected to adversely affect Lost River suckers if they are within the Lost River, several hundred feet downstream from the construction site.

Riparian Vegetation

Because HDD would be used to cross the Klamath River, only 0.75 acre within the Klamath River riparian zone (extending 117 feet or one site-potential tree height from each river bank) would be affected. No forested riparian vegetation would be affected. Construction across the Lost River would disturb approximately 2.72 acres within the riparian zone (extending 119 feet from each river bank). Similar to the Klamath River, no forest riparian vegetation would be affected or removed and all effects would be to agricultural land.

Water Temperature

No riparian vegetation would be removed that otherwise would provide shade. Consequently, water temperature would not be affected by construction. Lost River suckers are susceptible to water temperatures $\geq 85^{o}$F (Bellerud and Saiki, 1995). Summertime water temperatures in Upper

Klamath Lake often reach 86$^{o}$F which coincide with or are caused by baseflows of major rivers and small streams (Bortleson and Fretwell 1993).

Frac-Out

The HDD installation method is considered an effective technique for avoiding in-stream impacts by eliminating the need for in-stream excavation (Reid and Anderson, 1998; Reid et al., 2004). Even with this technique, there is a potential for impact as a result of the HDD process. Drilling requires use of a drilling mud for lubrication of the bit and removal of cuttings. A non-toxic, biodegradable bentonite clay mixture makes up drilling mud. Because the drilling mud is under pressure during drilling, if the bit encounters substrate fractures or channels, it is possible for bentonite to escape from the hole (termed a "frac-out"). Bentonite can escape to the surface through fractures in the drilled substrate. Bentonite is non-toxic to aquatic organisms but as with any fine particulate material, it can interfere with oxygen exchange by gills and the degree of interference generally increases with water temperature (see review and discussion of bentonite effects on aquatic organisms under Coho, Oregon Coast ESU, above).

Potential frac-outs are more common near the HDD drill entry and exit locations; however, impacts to waterbodies are minimized by locating the drill entry and exit points away from the waterbody. The probability of a frac-out may increase when the drill bit is working nearest the surface, but is dependent on numerous factors including substrate characteristics, head pressure of the drilling mud, topography, elevation, and subsurface hydrology. Pacific Connector has designed the Klamath River HDD such that areas of greatest risk from frac-out are on uplands and not adjacent to the waterbodies where much greater depth would be achieved and frac-out potential is reduced.

According to GeoEngineer's Feasibility Analysis for pipeline construction using HDD across the Klamath River (see appendix E) the design length of the Klamath River HDD crossing is approximately 2,300 feet. The proposed entry point is located in an open agricultural field on the east side of the Klamath River. The exit point is located in an open area on the west side of the river. The preliminary design provides approximately 60 feet of cover below the bottom of the river. There may be a moderate risk of hydraulic fracture and inadvertent returns near the entry and exit points and also along the eastern portion of the alignment due to the silts observed along the proposed alignment. Additional evaluation of the hydraulic fracture and inadvertent return potential will be completed for the final design.

Hydraulic fracture typically occurs when the drill path passes through relatively weak cohesive soils with low shear strength or very loose granular soils. Loose and silty sands and soft to medium stiff silts and clays typically have a higher hydraulic fracture potential. Medium dense to dense sands and gravels and very stiff to hard silts and clays have a low to moderate hydraulic fracture potential. Unfractured rock, because of its high shear strength, typically has a low potential for hydraulic fracture. HDD installations with greater depth or in formations with higher shear strength may reduce the potential for hydraulic fracturing (see appendix E).

In the event an inadvertent return occurs into the river, drilling fluid will enter the waterway causing short term, temporary water quality impacts downstream of the project area including sedimentation and turbidity. Sediments discharged into aquatic systems have the potential, depending on the concentrations, to wear down fish gills and impair fish vision making it difficult to feed and also making the fish more susceptible to predation. However, these effects typically occur after relatively long-term exposure to concentrated sedimentation. If drilling fluid accumulates in the substrate, it can adversely impact the quality and quantity of aquatic habitat available for aquatic species including salmonid spawning habitat and benthic macroinvertebrate rearing habitat. Drilling fluid that accumulates in the substrate may cover up food sources and smother fish eggs and other aquatic life in the riverbed. However, significant impacts to substrate from inadvertent returns are not likely in large river systems because of the anticipated high volumes and velocities within large rivers.

The rheologic properties of drilling fluid allow it to remain suspended within the water column for prolonged periods of time and would likely settle out in very slow moving water downstream of the release. The distance of expected transport would likely prevent significant concentrations of the fluid from accumulating in one area of the Klamath River. In the event drilling fluid is inadvertently released into the river, the behavioral avoidance response of Lost River sucker is presumed to be triggered within the immediate vicinity of the release and the fish are expected to return and utilize the affected area shortly after the inadvertent release has been halted. If significant concentrations are found during monitoring as a result of a release, the following possible corrective measures would be taken:

1. Increase the drilling fluid viscosity in an attempt at sealing the point at which fluid is leaving the drilled hole. The drilling operation may be suspended for a short period (i.e. overnight) to allow the fractured zone to become sealed with the higher viscosity drilling fluid.
2. If increasing the drilling fluid viscosity is ineffective, lost circulation materials (LCM) may be introduced into the hole by incorporating them in the drilling fluid and pumping the material down-hole. The drilling operation may again be suspended for a short period (i.e. overnight) to allow the fractured zone to become sealed with the lost circulation materials.
3. Depending on the location of the fractured zone, a steel casing may be installed that is of sufficient size to receive the largest expected down-hole tools for the crossing. This casing installation provides a temporary conduit for drilling fluids to flow while opening the remaining section of the hole to a diameter acceptable for receiving the proposed pipe sections. To alleviate future concerns with the steel casing after the HDD installation is completed, the casing is generally extracted from the hole prior to or just after completing the HDD installation. However, there have been instances when attempts at extracting the steel casing were unsuccessful.
4. In the event drilling fluid flow is not regained through the annulus of the drilled hole and a steel casing installation is not utilized, the HDD contractor may elect to install a grout mixture into the drilled hole in an attempt to seal the fractured zone. The down-hole drilling assembly is generally extracted and existing hole is re-drilled to the point at which it had previously been drilled prior to having encountered the loss of drilling fluid. 5. In addition, a grouting program may be implemented from the surface in the event that the installation of grout into the drilled hole is unsuccessful. This approach is only practical in areas where drilling rigs with vertical drilling capabilities can access the HDD alignment. If a surface grouting program is utilized, the HDD drilling assembly is extracted from down-hole. Multiple holes are then drilled vertically on either side and along the HDD alignment to allow for grout slurry to be pumped into the fracture zone where the drilling fluid had previously been lost from the drilled hole. This process can take several days to complete in order to insert the grout in a grid pattern that covers the full fractured zone, during which time the HDD operation is suspended. Upon completion

of the surface grouting program, the HDD operation will resume and the pilot hole will be reestablished through the grouted formation.

In some instances, it may be determined that the existing hole encountered a zone of unsatisfactory soil material and the hole may have to be abandoned. If the hole is abandoned, it will be filled with cuttings and drilling fluid.

**Cumulative Effects**

FWS and NMFS describe cumulative effects (50 CFR § 402.02) as the result of future actions by state or private entities, not involving federal actions, but reasonably certain to occur in the action area considered in this biological assessment. Future federal actions that are unrelated to the proposed action are not considered here because they require separate consultation pursuant to section 7 of the ESA.

Within the action area, 100 percent of all lands are non-federal within the John C. Boyle Reservoir-Klamath River watershed, 99 percent are non-federal lands within the Lake Ewauna-Klamath River watershed, and 94 percent are non-federal lands within the Mills Creek-Lost River fifth-field watershed. Degradation of water quality due to livestock grazing, agriculture, and timber harvest has resulted in severe pollution in Upper Klamath Lake. That in turn has lead to algal blooms with increased mortality of suckers when oxygen depletions occur due to eutrophication particularly during summers when high temperatures combined with nutrient loading from pumping diked wetlands and runoff from farms. Past actions that have lead to increased mortality have been due to private enterprise on private lands. Cumulative impact to Lost River suckers and shortnose suckers would include those same or similar actions which are reasonably foreseeable during the next 4 years. Cumulative impact from non-federal actions on non-federal lands would actually occur before implementation of the proposed action, not after its implementation which is more often the case. Therefore, the proposed Project could potentially contribute to cumulative effects for this species.

**Critical Habitat**

Designated critical habitat for the Lost River sucker is present within the Project area. The PCGP pipeline would cross the Klamath River at RM 249 which is within critical habitat Unit 1, Klamath County (FWS, 2012h). Unit 1 includes Upper Klamath Lake and Agency Lake, together with some wetland habitat; portions of the Williamson and Sprague Rivers; Link River; Lake Ewauna; and the Klamath River from the outlet of Lake Ewauna downstream to Keno Dam. Primary constituent elements could be affected during the HDD across the Klamath River if a frac-out occurred with release of bentonite into the water column; the same effects to critical habitat that were described as Indirect Effects, above, would occur.

Only 0.75 acre assumed to be within the Klamath River 100-year floodplain would be affected by construction and nearly all of that area is in an existing industrial facility.

#### 4.5.5.4 Conservation Measures

Conservation measures have been proposed by Pacific Connector to minimize construction and operation impact to waterbodies and riparian zones. Those measures have been compiled in table 2C in appendix N and apply to Lost River suckers.

Pacific Connector has also proposed measures and to rectify, repair, and rehabilitate and otherwise reduce impact to waterbodies and riparian zones once construction of the Pacific Connector pipeline is complete. Those measures have been compiled in table 3C in appendix N.

Fish Salvage

Lost River suckers can potentially occur within the construction right-of-way on the Lost River at the time of construction. Since the Lost River would be crossed using dry open-cut technology, fish salvage procedures (see section 4.5.1.4 in coho SONCC ESU) may occur while fish, including Lost River suckers, are within isolated construction sites. Since suckers in general appear to be vulnerable to electroshocking, Pacific Connector's fish salvage plan in the Lost River may have to avoid use of electroshock, relying instead on seining and dip netting as described in section 4.5.1.4.

A Fish Salvage Plan has been provided in appendix T. The plan has been developed to minimize adverse effects to listed salmonids (SONCC coho, Oregon Coast coho), non-listed salmonids (Chinook salmon, steelhead, cutthroat trout) and listed catostomids (Lost River sucker, shortnose sucker). The portions of the plan relevant to salvaging salmonids were adapted from the protocol developed by Washington State Department of Transportation (2011b). The protocol specifies procedures to 1) isolate the work area, 2) removing fish and dewatering the work area, 3) handling, holding and releasing fish, and 4) documenting fish that have been captured, handled, held and released and notification to NMFS and FWS. The same protocol would generally be followed during salvage of Klamath Basin suckers. However, salvage operations within the crossing where these suckers may be present would include the latest Handling Guidelines for Klamath Basin Suckers (Reclamation, 2008). These guidelines may be updated frequently. Some of the main factors in handling are the requirement of having a 0.5 percent saline solution of un-chlorinated well water to place any captured listed sucker in should it be collected during fish salvage operations. Aeration would also be supplied and the container a sucker is placed into would have been coated with a commercially available slime coat. Fish would be retained in this solution until released upstream of the capture site unless otherwise indicated through agreement with FWS.

Instream Gravel

Pipeline trenches across the Lost River and other perennial waterbodies within the Upper Klamath River Sub-basin and Lost River Sub-basin would be backfilled with material removed from the trench with the upper 1-foot of the trench backfilled with clean gravel or native cobbles of a size appropriate for resident fish, including suckers. The bottom and banks would be returned to preconstruction contours; banks would be stabilized; and temporary sediment barriers would be installed before returning flow to the waterbody channel.

Streambank Restoration

Pacific Connector's Erosion Control and Revegetation Plan (ECRP – see appendix F) describes the measures that will be used to stabilize streambanks crossed by the pipeline. Pacific Connector would not use riprap to stabilize streambanks. The alignment of the pipeline has been designed at waterbody crossings to be as perpendicular to the axis of the waterbody channel, as engineering and routing constraints allow, minimizing streambank disturbance and avoiding parallel stream alignments or multiple stream crossings. Immediately after installation of a waterbody crossing, the contours of the streambed, shoreline, and streambanks will be restored to preconstruction configurations (i.e., contour/elevations) to restore the physical integrity/condition of these features and to minimize the loss of stream complexity.

Pacific Connector has completed a scour analysis for the project that will be used to ensure that appropriate pipeline burial depths and cover design parameters beneath channel streambeds and adjacent floodplains are utilized, so that the effects on natural stream processes will be avoided or minimized. The project's scour analysis, which was completed by GeoEngineers, was included in Pacific Connector's June 2013 FERC Certificate application.

Pacific Connector will install erosion control fabric (such as jute or excelsior) on streambanks at the time of recontouring. The fabric will be anchored using staples or other appropriate devices. The erosion control fabric to be used on streambanks will be designed for the proposed use and will be approved by Pacific Connector's Environmental Inspectors (EIs).

Consistent with FERC's Wetland and Waterbody Procedures (Section V.C.3.), during streambank restoration/recontouring, the streambanks will be returned to their preconstruction contours or to a stable configuration. The Lost River is included in the application of the conservation measure. Streambank revegetation measures, including supplemental riparian planting procedures are also outlined in Section 10.0 of the ECRP. Riparian zones associated with the Klamath River and Lost River are on land owned by the State of Oregon. Riparian Zones for all other waterbodies crossed that are within range of the Lost River sucker are on private lands. The shrubs and trees planted at each site will be determined at the time of planting based on the moisture regimes and site-specific conditions at each planting location and landowner requirements.

#### 4.5.5.5 Determination of Effects

**Species Effects**

The Project **may affect** Lost River suckers because:

- Lost River suckers occur within the Upper Klamath Sub-basin and Lost Sub-basin which would be affected during construction of the proposed action.

While several project actions are not likely to cause adverse effects, those resulting effects from Project components that are **likely to adversely affect** Lost River suckers include:

- The remote possibility that Lost River suckers could occur within the Lost River when it would be crossed by the Pacific Connector pipeline.
- There may be a moderate risk of hydraulic fracture and inadvertent returns near the entry and exit points and also along the eastern portion of the alignment due to the silts observed along the proposed alignment across the Klamath River
- Adults and juveniles subject to fish salvage within the isolated construction site at the Lost River could be injured or killed if electroshocking is used and stressed if seining is used. Incidental take of a Lost River sucker is possible.

**Critical Habitat Effects**

The Project **may affect** designated critical habitat for the Lost River sucker because:

- There may be a moderate risk of hydraulic fracture and inadvertent returns near the entry and exit points and also along the eastern portion of the alignment due to the silts observed along the proposed alignment across the Klamath River.

### 4.5.6 Shortnose Sucker

#### 4.5.6.1 Species Account and Critical Habitat

**Status**

The shortnose sucker was listed as a federally endangered species on July 18, 1988 (FWS 1988). The shortnose sucker was listed as endangered because of the loss of habitat and access to historical range, resulting in a declining population. A 5-year review was released in July 2007 that recommended down listing the shortnose sucker from endangered to threatened status (FWS 2007h). However, no formal proposal to down list the species to threatened status has been made.

**Threats**

Lost River suckers and shortnose suckers were considered together in the final rule listing both as endangered species. Numerous factors in both species' decline were cited by FWS (1988) including historical over-fishing, dams limiting upstream movements and access to spawning habitats, introduction of non-native species that compete (fathead minnows) and prey on suckers (yellow perch, bullheads, largemouth bass, and various lepomid sunfish), and degradation of water quality due to livestock grazing, agriculture, and timber harvest. Pollution in Upper Klamath Lake has lead to algal blooms with increased mortality of suckers when oxygen depletions occur due to eutrophication. Status assessments conducted in 2001 and 2002 (FWS, 2002c) concluded that the Lost River sucker was threatened by the following: 1) drastically reduced adult populations and reduction in range; 2) extensive habitat loss, degradation, and fragmentation; 3) small or isolated adult populations as a result of dams; 4) poor water quality; 5) lack of sufficient recruitment; 6) entrainment into irrigation and hydropower diversions; 7) hybridization with the other native Klamath sucker species; 8) potential competition with introduced exotic fishes; and 9) lack of regulatory protection.

FWS (2007h) published a more recent status review of Lost River suckers in 2007. Recent habitat loss (wetlands in the upper Klamath Basin) has been minor and numerous habitat restoration projects have resulted in some positive population response by Lost River suckers. Nevertheless, poor water quality in Upper Klamath Lake and the Lost River continues, particularly during summers when high temperatures combined with nutrient loading from pumping diked wetlands and runoff from farms, roads, and other sources as well as from lake sediments create hypereutrophic conditions which lead to depletions of dissolved oxygen and fish die-offs (FWS, 2007h). Populations declined prior to listing due to habitat loss of approximately 75 percent of historic range, restricted access to spawning habitat, overharvest, and increased rates of mortality resulting from entrainment in water management structures and severely impaired water quality. Populations in Upper Klamath Lake have chronically low recruitment, reduced survivorship of adult fish, and reduced age-class diversity. Length-frequency analysis suggests that the last substantial recruitment to the spawning population occurred during the late 1990s (FWS, 2012g).

**Species Recovery**

Actions described in the recovery plan that would aid in the delisting of the shortnose sucker include improving habitat conditions through rehabilitating riparian areas and improving land management practices in the Klamath Basin watershed, developing and achieving water quality and quantity goals, and improving fish passage, spawning habitat, and other habitat conditions.

A recovery plan for Lost River sucker and short-nose sucker was finalized on March 17, 1993 (FWS 1993b). Since then there has been substantial amounts of additional information, prompting recent revision of the recovery plan (FWS, 2012g). The recovery program goal is to stop the population decline and enhance Lost River sucker and shortnose sucker populations so that ESA protection is no longer necessary.

At the time of listing, population declines were related to loss or degradation of spawning, rearing, and adult habitats. Only about 25 percent of the original habitat remains. Reductions in habitat quality compound the effects of reduced habitat quantity and availability on Lost River sucker and shortnose sucker abundance. In addition to habitat, factors currently limiting species recovery include high mortality of larvae and juveniles due to reduced rearing habitat, entrainment in water management structures, poor water quality, and adverse effects (predation, competition) from non-native, introduced fish species. Adult populations are limited by extremely limited recruitment to the population as well as high levels of stress and mortality associated with severely impaired water quality. As a whole the species are potentially limited by the lack of habitat connectivity (FWS, 2012e).

Demographic-based objectives include increasing larval production, individual survival and recruitment to spawning populations, and ultimately increasing abundance in spawning populations. The objectives of restoring spawning and nursery habitat, expanding reproduction, reducing the negative impacts from water quality on all life stages, clarifying the effects of other species on all life stages, reducing entrainment, and establishing auxiliary populations comprise the threats-based objectives. The recovery strategy is intended to produce and document healthy, self-sustaining populations by reduction of mortality, restoration of habitat, including spawning, larval and juvenile habitats, and increasing connectivity between spawning and rearing habitats. It also involves ameliorating adverse effects of degraded water quality, disease, and non-native fish. The plan provides areas of emphasis and guidelines to direct recovery actions (FWS, 2012e).

There are two recovery units for shortnose suckers, the Upper Klamath Lake Unit and Lost River Basin Unit (FWS, 2012g). Upper Klamath Lake Unit includes all Lost River suckers within lake, tributaries to Upper Klamath Lake, and reservoirs within the Klamath River including Keno Reservoir and populations below Keno Reservoir. The Lost River Basin Recovery Unit includes Clear Lake Reservoir and tributaries including Willow Creek and Boles Creek, (FWS, 2012e). The Lost River is not included in designated critical habitat.

**Life History, Habitat Requirements, and Distribution**

Shortnose suckers are native to the Upper Klamath River Basin and Lost River Basin but have adapted to lake habitats and spawn in larger tributary rivers associated with lakes (Moyle, 2002), generally from February through early May. Larval stages persist from May through July (Reclamation, 2007). Although Lost River suckers may live to 43 years old, shortnose suckers are shorter-lived, surviving to 25 years old but females attain sexual maturity at 4 years old while Lost River sucker females are sexually mature at 6 to 9 years old (Reclamation, 2007). Shortnose sucker females may produce 72,000 eggs per spawning season, generally fewer than Lost River suckers.

River spawning habitat occurs in riffles or runs with gravel or cobble substrate, with moderate flows, and in water 4 to 51 inches deep. Shortnose suckers have historically spawned in lakes, particularly at springs occurring along the shorelines (FWS 2007h). Currently, shortnose suckers are found in Upper Klamath Lake and its tributaries, Klamath River downstream to Iron Gate Reservoir, Clear Lake Reservoir and its tributaries, Gerber Reservoir and its tributaries, the Lost River, and Tule Lake. In the Upper Klamath Lake watershed, shortnose sucker spawning runs are primarily limited to the Sprague and Williamson Rivers, although spawning runs may also be present in the Wood River and in Crooked Creek. Shortnose sucker spawning has also been recorded in the Clear Lake watershed (FWS, 1988) and Gerber Reservoir watershed (FWS, 1994a). Adult and juvenile shortnose suckers prefer turbid, highly productive but shallow lakes that are cool in the summer, with adequate dissolved oxygen, and water that is moderately alkaline (FWS, 2007h).

As discussed for Lost River suckers, a small population of several hundred adult shortnose suckers exists in Tule Lake. Shortnose suckers have resident populations in both lake and some riverine habitats, including Lost River, Willow Creek, and other tributaries of Clear Lake and Gerber Reservoir (Reclamation, 2007). Shortnose suckers have been documented spawning below Anderson-Rose Dam, in Big Springs near Bonanza and at the terminal end of the West Canal as it spills into the Lost River. Suitable spawning habitats with riffle areas and rocky substrates include the spillway area below Malone Dam, immediately upstream of Keller Bridge, immediately below Big Springs in the Lost River, below Harpold Dam, and adjacent to Station 48 (Reclamation, 2007). Seasonal movements of shortnose suckers are similar to those described above for Lost River suckers.

**Population Status**

At the time of the Final Rule, estimates of the shortnose sucker population could not be made. Nevertheless, there was very little recruitment to the population and that, plus mortality from fish die-offs and fishing, indicated a declining trend (FWS, 2007h). Continued efforts to estimate shortnose sucker populations have been based on several approaches which indicate a declining population with nearly no measurable recruitment in Upper Klamath Lake and limited survival of adults past the age of sexual maturity. Shortnose suckers attain sexual maturity when 4 to 6 years old and survival after entering the spawning population was estimated at only 3.6 years indicating insufficient time for reproduction to sustain the population (FWS, 2007h).

For several years there was no indication that shortnose suckers continued to inhabit Tule Lake but in 1991 both sucker species were observed spawning below Anderson-Rose Dam, and sampling at Tule Lake in the early 1990s determined that small populations of the two species were present (Reclamation, 2007). Estimates of shortnose sucker annual survival rates in Upper Klamath Lake between 1995 and 2004 indicate that the population is likely to be decreasing, although the survival estimates appear to be imprecise (Reclamation, 2007).

For several years there was no indication that Lost River or shortnosed suckers continued to inhabit Tule Lake but in 1991 both species were observed spawning below Anderson-Rose Dam, and sampling at Tule Lake in the early 1990s determined that small populations of both species were present (Reclamation, 2007). Shortnose sucker spring-spawning abundance in 2007 is estimated to be 42 percent and 48 percent of 2001 abundances for males and females respectively, although the exact abundances are unknown and the spawner abundance relative to an earlier are estimates of population change rather than population size (FWS, 2012g). Tagging studies conducted on Lost River and shortnose suckers in Gerber Reservoir and Clear Lake (both impoundments are connected to the Lost River below Gerber Dam and Clear Lake Dam, respectively) indicate that numbers of large adult suckers of both species have declined since

2000. Declines in large adult shortnose suckers have been particularly pronounced in Clear Lake, possibly due to poor recruitment from younger age classes prior to 2000 (Barry et al., 2009).

### Critical Habitat

Critical habitat for the Lost River sucker and shortnose sucker was proposed by FWS in 1994 which included the majority of known populations of Lost River suckers (FWS, 1994a): Critical habitat for Lost River and shortnose suckers was re-proposed in 2011 and designated in 2012 (FWS, 2012h). In the PCGP Project area, designated critical habitat for Lost River and shortnose sucker (Unit 1 in Klamath County) includes the Link River, Lake Ewauna, and the Klamath River downstream to Keno. Unit 2 in Klamath and Lake Counties, Oregon and Modoc County California includes Clear Lake Reservoir and tributaries and Gerber Reservoir and tribuaries but does not include the Tule Lake and its tributary, the Lost River. For reasons described above (blockage by Anderson Rose Diversion Dam), neither provides spawning habitats or supports viable self-sustaining populations of Lost River or shortnose suckers (FWS, 2012h).

Primary constituent elements of critical habitat include (FWS, 2012f):

1. Water. Areas with sufficient water quantity and depth within lakes, reservoirs, streams, marshes, springs, groundwater sources, and refugia habitats with minimal physical, biological, or chemical impediments to connectivity. Water must have varied depths to accommodate each life stage: Shallow water (up to 3.28 ft (1.0 m)) for larval life stage, and deeper water (up to 14.8 ft (4.5 m)) for older life stages. The water quality characteristics should include water temperatures of less than 82.4 °F (28.0 °C); pH less than 9.75; dissolved oxygen levels greater than 4.0 mg/L; low levels of microcystin; and un-ionized ammonia (less than 0.5 mg/L). Elements also include natural flow regimes that provide flows during the appropriate time of year or, if flows are controlled, minimal flow departure from a natural hydrograph.
2. Spawning and rearing habitat. Streams and shoreline springs with gravel and cobble substrate at depths typically less than 4.3 ft (1.3 m) with adequate stream velocity to allow spawning to occur. Areas containing emergent vegetation adjacent to open water, provides habitat for rearing and facilitates growth and survival of suckers, as well as protection from predation and protection from currents and turbulence.
3. Food. Areas that contain an abundant forage base, including a broad array of chironomidae, crustacea, and other aquatic macroinvertebrates.

## 4.5.6.2 Environmental Baseline

### Analysis Area

The riverine analysis area includes two components: 1) the water column and substrate of all waterbodies crossed by the Pacific Connector pipeline from the point of crossing to the extent downstream where water quality is adversely affected by turbidity generated during construction and sediment generated by runoff from the construction right-of-way; and 2) waterbodies' associated riparian zones affected in the short-term during construction and in the long-term by operation. For shortnose suckers, the riverine analysis area is limited to fresh waterbodies within the Upper Klamath Sub-basin (HUC 18010206 – figure 4.5-33A) and Lost Sub-basin (HUC 18010204 figure 4.5-33B).

**Species Presence**

Currently, shortnose suckers are found in Upper Klamath Lake and its tributaries, Klamath River downstream to Iron Gate Reservoir, Clear Lake Reservoir and its tributaries, Gerber Reservoir and its tributaries, the Lost River, and Tule Lake. Shortnose sucker spawning has also been recorded in the Clear Lake watershed (FWS, 1988) and Gerber Reservoir watershed (FWS, 1994). In the Upper Klamath Sub-basin (HUC 18010206) they are found in the Klamath River as far downstream as Copco Reservoir and possibly Iron Gate Reservoir. In the Lost Sub-basin, they are found in the Lost River mainstem below Anderson Rose Diversion Dam, above Malone Dam, and in Clear Lake Reservoir (Moyle, 2002).

In the project vicinity, shortnose suckers spawn in the Lost River and are present in John C. Boyle Reservoir, downstream from the pipeline crossing at RM 225 (National Research Council, 2004). In addition to collections of Lost River suckers in J.C. Boyle Reservoir, ORBIC (2012) cites records of spawning in the Link River. They have been documented from Lake Ewauna and in the Lost River Diversion Canal. Currently, Lost River suckers migrate a short distance from Tule Lake to spawn in the Lost River below Anderson-Rose Diversion Dam (RM 17.4) south of Merrill and approximately 7.6 river miles from the pipeline crossing of the Lost River (ORBIC, 2012). Suckers also spawn in the Lost River below Malone Dam, downstream from Clear Lake. A population inhabits the Tule Lake sumps at the terminus of the Lost River (FWS, 2007f). That population is isolated from upstream spawning habitats in the Lost River by the Anderson-Rose Dam and the population is not self-sustaining (FWS, 2007h).

Within the Project area, the shortnose sucker has been documented within the Klamath River from Klamath Falls to Keno Reservoir, located 4.3 and 15.1 miles upstream of the Pacific Connector pipeline Project area and riverine analysis area, consecutively. The PCGP pipeline would cross the Klamath River at RM 249. The sucker is also known from Tule Lake Sump and Clear Lake in northern California, which are connected by the Lost River. Tule Lake sumps are at the lower terminus of the Lost River and the population in Tule Lake is isolated from upstream spawning areas by multiple dams including blockage by the Anderson-Rose Dam.

**Habitat**

Dams continue to limit passage and sucker migration, impose isolation of subpopulations, and decrease available spawning habitats which have has raised the possibility of facilitating hybridization between several sucker species (Reclamation, 2007). Dams may also cause stream channel changes, alter water quality, and provide habitat for exotic fish that prey on suckers or compete with them for food and habitat (Reclamation, 2007). Although there are seven major dams in the Klamath Basin that may affect the migration patterns of listed suckers, only the Link River Dam has been recently equipped with a fish ladder that was designed specifically for sucker passage (Reclamation, 2007). Fish ladders are present at J.C. Boyle and Keno dams and, although suckers have been observed to use the ladders, they were not designed for sucker passage and generally are inadequate for sucker passage (Reclamation, 2007).

The Link River Dam regulates water flows downstream to Lake Euwana, Keno Reservoir, and the Klamath River. The river gates on the dam do not protect fish from becoming entrained and numerous juvenile suckers are drawn through the dam gates. Shortnose suckers that survive passing through the hydroelectric facilities either die due to poor summer water quality conditions or pass downstream into the Klamath Reservoirs. At that point, fish cannot return and are believed to be lost from the breeding population (FWS, 2007h). The Pacific Connector pipeline would cross the Klamath River using HDD.

Adverse water quality is the most critical threat to the shortnose sucker (FWS, 2007h). Klamath River and Klamath Lake have been designated as water quality impaired, including for nutrient loads which are enhanced by drainage of irrigation water from agricultural lands adjacent to Klamath Lake. Construction of dikes and drainage systems converted wetlands to agricultural use. Soils high in organic content were subject to mineralization processes which released nutrients into the aquatic system, especially phosphorous and nitrogen (Rykbost and Charlton, 2001).

High levels of phosphorous in Klamath Lake have lead to extreme eutrophication events that promote algal blooms dominated by the blue-green algae *Aphanizomenon flos-aquae* that reach or nearly reach theoretical biological maxima (National Research Council, 2004). As a consequence, portions of Upper Klamath Lake develop conditions of oxygen depletion or are anoxic, and accumulate high concentrations of ammonia which has resulted in mass mortality of fish, including adult suckers (National Research Council, 2004). Shortnose suckers are likely to experience high mortality if exposed to one or more of the following: pH $\geq$ 9.8, ammonia (unionized) concentration $\geq$ 0.34 mg/L, water temperatures $\geq 29.4^{o}$C ($\geq 85^{o}$F), and dissolved oxygen concentration $\leq$ 2.3 mg/L (Bellerud and Saiki, 1995).

No assessments have been conducted for either of the two $5^{th}$ field watersheds that will be crossed by the PCGP Project in the Lost Sub-basin: Lake Ewauna-Klamath River (HUC 1801020412) and Mills Creek-Lost River (HUC 1801020409). Likewise, no stream reaches have been sampled under ODFW's Aquatic Inventories Project in the watersheds. Nevertheless, modifications and degradation of aquatic habitats have been documented by FWS (1993 and 2012), U.S. Geological Survey - USGS (Dileanis et al., 1996), U.S. Bureau of Reclamation (Reclamation, 2007), and the National Research Council (2004), among others.

Dams limit passage and fish migration, impose isolation of subpopulations, and decrease available spawning habitats (Reclamation, 2007). Klamath River and Klamath Lake have been designated as water quality impaired, including for nutrient loads which are enhanced by drainage of irrigation water from agricultural lands adjacent to Klamath Lake. Construction of dikes and drainage systems converted wetlands to agricultural use. Soils high in organic content were subject to mineralization processes which released nutrients into the aquatic system, especially phosphorous and nitrogen (Rykbost and Charlton, 2001). Sediment accumulation rates in Upper Klamath Lake indicate substantial annual increases since the late 1880s due to deforestation, drainage of wetlands, agriculture, livestock production and irrigation (Reclamation, 2007).

High levels of phosphorous in Klamath Lake have lead to extreme eutrophication events that promote algal blooms dominated by the blue-green algae, *Aphanizomenon flos-aquae* that reach or nearly reach theoretical biological maxima (National Research Council, 2004). As a consequence, portions of Upper Klamath Lake develop conditions of oxygen depletion or are anoxic and accumulate high concentrations of ammonia which has resulted in mass mortality of fish (National Research Council, 2004).

There are no recent long-term water discharge data for waterbodies in the Lost River watershed. The A Canal connects the Link River to the Lost River via the B Canal. According to USGS

Gage 11507200, there is no flow in the A Canal between November and March (see figure 4.5-34, above), consistent with periods of water diversions from the Klamath River, discussed above.

### Critical Habitat

Designated critical habitat for the Lost River sucker is present within the Project area. The PCGP pipeline would cross the Klamath River at RM 249 which is within critical habitat Unit 1, Klamath County (FWS, 2012h). Unit 1 includes Upper Klamath Lake and Agency Lake, together with some wetland habitat; portions of the Williamson and Sprague Rivers; Link River; Lake Ewauna; and the Klamath River from the outlet of Lake Ewauna downstream to Keno Dam. Primary constituent elements include (FWS, 2012h, abbreviated from above):

1. Water. Areas with sufficient water quantity and depth within lakes, reservoirs, streams, marshes, springs, groundwater sources, and refugia habitats with minimal physical, biological, or chemical impediments to connectivity.
2. Spawning and rearing habitat. Streams and shoreline springs with gravel and cobble substrate at depths typically less than 1.3 m (4.3 feet) with adequate stream velocity to allow spawning to occur. Areas identified in PCE1 containing emergent vegetation adjacent to open water, provides habitat for rearing and for growth and survival of suckers.
3. Food. Areas that contain an abundant forage base, including a broad array of chironomidae, crustacea, and other aquatic macroinvertebrates.

Critical habitat Unit 2 includes Clear Lake Reservoir and its principal tributary, Willow Creek. Unit 2 does not coincide with the Project area.

### 4.5.6.3 Effects by the Proposed Action

### Direct Effects

Timing

Pacific Connector anticipates beginning construction in the Klamath Basin area (MPs 188 to 228) in fourth quarter 2015 or early 2016. The Klamath River (MP 199.38) and the Lost River (MP 212.05) are the only perennial waterbodies crossed by the PCGP Project on Construction Spread 5. The ODFW (2008) allows instream construction in the Klamath River (above Keno) from July 1 to January 31 and in the Lost River (below Bonanza) from July 1 to March 31. Pacific Connector would cross the Klamath River using HDD crossing methods between July and October. Upland rig-up and preparation are the only HDD activities that would occur outside the recommended ODFW instream construction window. The Lost River would be crossed by dry-open crossing methods during the ODFW-recommended crossing window (July 1 to March 31). One other intermittent drainage that would be crossed at MP 188.9 also has an ODFW-recommended crossing window between July 1 and January 31, but this minor headwater waterbody is expected to be dry at the time of construction.

There are 13 waterbodies between MPs 216.10 and 225.07 that have an ODFW-recommended construction window from July 1 to March 31. These 13 waterbodies are intermittent drainages which would be crossed using dry open-cut crossing methods if flowing at the time of construction. Although seven of the intermittent drainage are presumed to provide habitat for Lost River sucker or shortnose sucker, the PCGP Project's crossing locations are not expected to provide suitable habitat conditions for these species and all of the minor intermittent waterbodies are expected to be dry at the time of construction (see figure 3.2-3).

Fish Salvage

Suckers as a group (family Catostomidae) appear to be susceptible to many of the same deleterious effects from electroshocking that were described above for salmonids (Snyder, 2004). Although records of the effects by electroshock to shortnose suckers have not been compiled, responses by river carpsucker, longnose sucker, white suckers and razorback sucker among others indicate that they are particularly susceptible to spinal injuries and hemorrhages by electrofishing (Snyder, 2004).

Reclamation has salvaged fish from canals throughout the Klamath project each fall since 1991 following dewatering using electrofishing techniques (Reclamation, 2008). Sucker mortalities (shortnose suckers, Lost River suckers and Klamath largescale suckers) do occur during salvage operations, whether due to electrofishing stress or to low levels of dissolved oxygen (for example, Peck, 2000 and 2001). But the protocol to be used during this Project would use a variety of netting (e.g. beach seining, dip netting) before using electrofishing methods to reduce this potential impact (see Conservation Methods below for details).

Acoustic Shock

There will be no blasting or use of mounted hydraulic impact hammer to cross the Lost River. Use of back-hoes for dry open-cut construction will not produce sound levels to cause harm to shortnose suckers.

**Indirect Effects**

Turbidity

Potential impacts to fisheries by dry open-cutting were discussed above in section 4.4.1.3 Coho (SONCC ESU). As noted in that discussion, dry open-cutting (fluming, dam-and-pump, or some combination of the two) generates small amounts of turbidity compared to wet open-cut procedures. However, adult suckers appear to prefer deep, turbid water but are often forced to utilize shallow, clear water if forced to during degraded water quality conditions in the summer (National Research Council, 2004). The amounts of turbidity generated by dry open-cut construction are not expected to adversely affect shortnose suckers if they are within the Lost River, several hundred feet downstream from the construction site.

Riparian Vegetation

Because HDD would be used to cross the Klamath River, only 0.75 acre within the Klamath River riparian zone (extending 117 feet or one site-potential tree height from each river bank) would be affected. No forested riparian vegetation would be affected. Construction across the Lost River would disturb approximately 2.72 acres within the riparian zone (extending 119 feet from each river bank). Similar to the Klamath River, no forest riparian vegetation would be affected or removed and all effects would be to agricultural land.

Water Temperature

No riparian vegetation would be removed that otherwise would provide shade. Consequently, water temperature would not be affected by construction. Shortnose suckers are susceptible to water temperatures $\geq 85^{o}$F (Bellerud and Saiki, 1995) but prefer water temperatures $60^{o}$F to $77^{o}$F (FWS, 2007l). Summertime water temperatures in Upper Klamath Lake often reach $86^{o}$F which coincide with or are caused by baseflows of major rivers and small streams (Bortleson and Fretwell, 1993).

Frac-Out

The HDD installation method is considered an effective technique for avoiding in-stream impacts by eliminating the need for in-stream excavation (Reid and Anderson, 1998; Reid et al., 2004). Even with this technique, there is a potential for impact as a result of the HDD process. Drilling requires use of a drilling mud for lubrication of the bit and removal of cuttings. A non-toxic, biodegradable bentonite clay mixture makes up drilling mud. Because the drilling mud is under pressure during drilling, if the bit encounters substrate fractures or channels, it is possible for bentonite to escape from the hole (termed a "frac-out"). Bentonite can escape to the surface through fractures in the drilled substrate. Bentonite is non-toxic to aquatic organisms but as with any fine particulate material, it can interfere with oxygen exchange by gills and the degree of interference generally increases with water temperature (see review and discussion of bentonite effects on aquatic organisms under Coho, Oregon Coast ESU, above).

Potential frac-outs are more common near the HDD drill entry and exit locations; however, impacts to waterbodies are minimized by locating the drill entry and exit points away from the waterbody. As discussed for Lost River suckers, above, GeoEngineer's Feasibility Analysis for pipeline construction using HDD across the Klamath River (see appendix E) the design length of the Klamath River HDD crossing is approximately 2,300 feet. The proposed entry point is located in an open agricultural field on the east side of the Klamath River. The exit point is located in an open area on the west side of the river. The preliminary design provides approximately 60 feet of cover below the bottom of the river. There may be a moderate risk of hydraulic fracture and inadvertent returns near the entry and exit points and also along the eastern portion of the alignment due to the silts observed along the proposed alignment. Additional evaluation of the hydraulic fracture and inadvertent return potential will be completed for the final design.

If drilling fluid accumulates in the substrate, it can adversely impact the quality and quantity of aquatic habitat available for aquatic species including salmonid spawning habitat and benthic macroinvertebrate rearing habitat. Drilling fluid that accumulates in the substrate may cover up food sources and smother fish eggs and other aquatic life in the riverbed. However, significant impacts to substrate from inadvertent returns are not likely in large river systems because of the anticipated high volumes and velocities within large rivers. As discussed above for Lost River suckers, if drilling fluid is inadvertently released into the Klamath River and significant concentrations are found during monitoring as a result of a release, the following possible corrective measures would be taken:

1. Increase the drilling fluid viscosity in an attempt at sealing the point at which fluid is leaving the drilled hole. The drilling operation may be suspended for a short period (i.e. overnight) to allow the fractured zone to become sealed with the higher viscosity drilling fluid.
2. If increasing the drilling fluid viscosity is ineffective, lost circulation materials (LCM) may be introduced into the hole by incorporating them in the drilling fluid and pumping the material down-hole. The drilling operation may again be suspended for a short period (i.e. overnight) to allow the fractured zone to become sealed with the lost circulation materials.
3. Depending on the location of the fractured zone, a steel casing may be installed that is of sufficient size to receive the largest expected down-hole tools for the crossing. This

casing installation provides a temporary conduit for drilling fluids to flow while opening the remaining section of the hole to a diameter acceptable for receiving the proposed pipe sections. To alleviate future concerns with the steel casing after the HDD installation is completed, the casing is generally extracted from the hole prior to or just after completing the HDD installation. However, there have been instances when attempts at extracting the steel casing were unsuccessful.

4. In the event drilling fluid flow is not regained through the annulus of the drilled hole and a steel casing installation is not utilized, the HDD contractor may elect to install a grout mixture into the drilled hole in an attempt to seal the fractured zone. The down-hole drilling assembly is generally extracted and existing hole is re-drilled to the point at which it had previously been drilled prior to having encountered the loss of drilling fluid. 5. In addition, a grouting program may be implemented from the surface in the event that the installation of grout into the drilled hole is unsuccessful. This approach is only practical in areas where drilling rigs with vertical drilling capabilities can access the HDD alignment. If a surface grouting program is utilized, the HDD drilling assembly is extracted from down-hole. Multiple holes are then drilled vertically on either side and along the HDD alignment to allow for grout slurry to be pumped into the fracture zone where the drilling fluid had previously been lost from the drilled hole. This process can take several days to complete in order to insert the grout in a grid pattern that covers the full fractured zone, during which time the HDD operation is suspended. Upon completion of the surface grouting program, the HDD operation will resume and the pilot hole will be reestablished through the grouted formation.

In some instances, it may be determined that the existing hole encountered a zone of unsatisfactory soil material and the hole may have to be abandoned. If the hole is abandoned, it will be filled with cuttings and drilling fluid.

**Cumulative Effects**

FWS and NMFS describe cumulative effects (50 CFR § 402.02) as the result of future actions by state or private entities, not involving federal actions, but reasonably certain to occur in the action area considered in this biological assessment. Future federal actions that are unrelated to the proposed action are not considered here because they require separate consultation pursuant to section 7 of the ESA.

Within the action area, 100 percent of all lands are non-federal within the John C. Boyle Reservoir-Klamath River watershed, 99 percent are non-federal lands within the Lake Ewauna-Klamath River watershed, and 94 percent are non-federal lands within the Mills Creek-Lost River fifth-field watershed. Degradation of water quality due to livestock grazing, agriculture, and timber harvest has resulted in severe pollution in Upper Klamath Lake. That in turn has lead to algal blooms with increased mortality of suckers when oxygen depletions occur due to eutrophication particularly during summers when high temperatures combined with nutrient loading from pumping diked wetlands and runoff from farms. Past actions that have lead to increased mortality have been due to private enterprise on private lands. Cumulative impact to Lost River suckers and shortnose suckers would include those same or similar actions which are reasonably foreseeable during the next 4 years. Cumulative impact from non-federal actions on non-federal lands would actually occur before implementation of the proposed action, not after its implementation which is more often the case. Therefore, the proposed Project could potentially contribute to cumulative effects for this species.

**Critical Habitat**

Designated critical habitat for the shortnose sucker is present within the Project area. The PCGP pipeline would cross the Klamath River at RM 249 which is within critical habitat Unit 1, Klamath County (FWS, 2012h). Unit 1 includes Upper Klamath Lake and Agency Lake, together with some wetland habitat; portions of the Williamson and Sprague Rivers; Link River; Lake Ewauna; and the Klamath River from the outlet of Lake Ewauna downstream to Keno Dam. Primary constituent elements could be affected during the HDD across the Klamath River if a frac-out occurred with release of bentonite into the water column; the same effects to critical habitat that were described as Indirect Effects, above, would occur.

Only 0.75 acre assumed to be within the Klamath River 100-year floodplain would be affected by construction and nearly all of that area is in an existing industrial facility.

#### 4.5.6.4 Conservation Measures

Conservation measures have been proposed by Pacific Connector to minimize construction and operation impact to waterbodies and riparian zones. Those measures have been compiled in table 2C in appendix N,and apply to shortnose suckers.

Pacific Connector has also proposed measures and to rectify, repair, and rehabilitate and otherwise reduce impact to waterbodies and riparian zones once construction of the Pacific Connector pipeline is complete. Those measures have been compiled in table 3C in appendix N.

**Fish Salvage**

Shortnose suckers can potentially occur within the construction right-of-way on the Lost River at the time of construction. A Fish Salvage Plan has been provided in appendix T. The plan has been developed to minimize adverse effects to listed salmonids (SONCC coho, Oregon Coast coho), non-listed salmonids (Chinook salmon, steelhead, cutthroat trout) and listed catostomids (Lost River sucker, shortnose sucker). The portions of the plan relevant to salvaging salmonids were adapted from the protocol developed by by Washington State Department of Transportation (2011b). The protocol specifies procedures to 1) isolate the work area, 2) removing fish and dewatering the work area, 3) handling, holding and releasing fish, and 4) documenting fish that have been captured, handled, held and released and notification to NMFS and FWS. The same protocol generally would be followed during salvage of Klamath Basin suckers. However salvage operations within the crossing where these sucker may be present would include the latest Handling Guidelines for Klamath Basin Suckers (Reclamation, 2008). These guidelines may be updated frequently. Some of the main factors in handling are the requirement of having a 0.5 percent saline solution of un-chlorinated well water to place any captured listed sucker in should it be collected during fish salvage operations. Aeration would also be supplied and the container a sucker is placed into would have been coated with a commercially available slime coat. Fish would be retained in this solution until released upstream of the capture site unless otherwise indicated through agreement with FWS.

<u>Instream Gravel</u>

Pipeline trenches across the Lost River and other perennial waterbodies within the Upper Klamath River Sub-basin and Lost River Sub-basin would be backfilled with material removed from the trench with the upper 1-foot of the trench backfilled with clean gravel or native cobbles of a size appropriate for resident fish, including suckers. The bottom and banks would be returned to preconstruction contours; banks would be stabilized; and temporary sediment barriers would be installed before returning flow to the waterbody channel.

Streambank Restoration

Pacific Connector's Erosion Control and Revegetation Plan (ECRP – see appendix F) describes the measures that will be used to stabilize streambanks crossed by the pipeline. Pacific Connector would not use riprap to stabilize streambanks. The alignment of the pipeline has been designed at waterbody crossings to be as perpendicular to the axis of the waterbody channel, as engineering and routing constraints allow, minimizing streambank disturbance and avoiding parallel stream alignments or multiple stream crossings. Immediately after installation of a waterbody crossing, the contours of the streambed, shoreline, and streambanks will be restored to preconstruction configurations (i.e., contour/elevations) to restore the physical integrity/condition of these features and to minimize the loss of stream complexity.

Pacific Connector has completed a scour analysis for the project that will be used to ensure that appropriate pipeline burial depths and cover design parameters beneath channel streambeds and adjacent floodplains are utilized, so that the effects on natural stream processes will be avoided or minimized. The project's scour analysis, which was completed by GeoEngineers, was included in Pacific Connector's June 2013 FERC Certificate application.

Pacific Connector will install erosion control fabric (such as jute or excelsior) on streambanks at the time of recontouring. The fabric will be anchored using staples or other appropriate devices. The erosion control fabric to be used on streambanks will be designed for the proposed use and will be approved by Pacific Connector's Environmental Inspectors (EIs).

Consistent with FERC's Wetland and Waterbody Procedures (Section V.C.3.), during streambank restoration/recontouring, the streambanks will be returned to their preconstruction contours or to a stable configuration. The Lost River is included in the application of the conservation measure. Streambank revegetation measures, including supplemental riparian planting procedures are also outlined in Section 10.0 of the ECRP. Riparian zones associated with the Klamath River and Lost River are on land owned by the State of Oregon. Riparian Zones for all other waterbodies crossed that are within range of the Lost River sucker are on private lands. The shrubs and trees planted at each site will be determined at the time of planting based on the moisture regimes and site-specific conditions at each planting location and landowner requirements.

#### 4.5.6.5 Determination of Effects

**Species Effects**

The Project **may affect** shortnose suckers because:

- Shortnose suckers occur within the Upper Klamath River Sub-basin and Lost River Sub-basin which would be affected during construction of the proposed action.

While several project actions are not likely to cause adverse effects, those resulting effects from Project components that are **likely to adversely affect** shortnose suckers include:

- There is a possibility that shortnose suckers could occur within the Lost River when it would be crossed by the Pacific Connector pipeline.

- There may be a moderate risk of hydraulic fracture and inadvertent returns near the entry and exit points and also along the eastern portion of the alignment due to the silts observed along the proposed alignment across the Klamath River
- Adults and juveniles subject to fish salvage within the isolated construction site at the Lost River could be injured or killed if electroshocking is used and stressed if seining is used. Incidental take of a shortnose sucker is possible.

**Critical Habitat Effects**

The Project **may affect** designated critical habitat for the shortnose sucker because:

- There may be a moderate risk of hydraulic fracture and inadvertent returns near the entry and exit points and also along the eastern portion of the alignment due to the silts observed along the proposed alignment across the Klamath River.

## 4.6 INVERTEBRATES

### 4.6.1 Vernal Pool Fairy Shrimp

#### 4.6.1.1 Species Account and Critical Habitat

**Status**

On September 19, 1994, the final rule to list the vernal pool fairy shrimp as threatened was published in the Federal Register (FWS 1994b).

**Threats**

The FWS identified significant threats to vernal pool fairy shrimp including destruction, modification, or curtailment of the species' habitat or range within California. The final rule made no distinction for specific vernal pool fairy shrimp habitats in the Agate Desert/Jackson County area in Southern Oregon because the species was not discovered there until 1998. The vegetation and land use in the Oregon habitat range, however, are similar to those of northern California's inland valleys (FWS 2005d). The FWS determined that the shrimp was imperiled throughout its then-known range by rapid urbanization, agricultural conversion, ORV use, and man-made changes in hydrologic patterns. In many cases, vernal pool complexes inhabited by the shrimp occurred on private land in areas of proposed or ongoing road, utility, residential, and commercial developments. Additionally, the FWS was concerned that landowners were likely to knowingly destroy the vernal pool habitat (FWS 1994b).

Other factors noted as threats to vernal pool fairy shrimp in the final rule include stochastic events, which have disproportionate effects on small isolated populations and may result in extirpations of some. Pools and pool complexes supporting fairy vernal pool shrimp are usually small, and unforeseen natural and man-caused catastrophic events threaten the elimination of some sites (FWS 1994b).

In a 5-year review of the vernal pool fairy shrimp, FWS determined threats to the species have not decreased since the time of listing in 1994 (FWS, 2007j). The loss and modification of vernal pool habitat due to urban development and infrastructure construction continue to be primary threats to the shrimp. The Medford region, where the species is found in Southern Oregon near the Pacific Connector pipeline area, grew by 29.5 percent between 1990 and 2000 (FWS, 2007j), although population growth slowed somewhat to 18.6 perecent between 2000 and

2010 (Oregon.gov, 2012). Other ongoing threats include agricultural conversion, altered hydrology, cessation of grazing or overgrazing, stochastic extinction, hybridization, contaminants, drought and climate change, and other human-cause impacts (FWS 2007i). In their *Recovery Plan for Vernal Pool Ecosystems of California and Southern Oregon* (FWS 2005d), FWS listed commercial and industrial development, agricultural conversion, utility projects, and recreational use as direct threats on vernal pool habitats in Oregon (FWS, 2005d).

**Species Recovery**

A final recovery plan was completed in 2012 (FWS, 2012i) for vernal pool species within the Rogue River and Illinois Valleys that are federally listed or have federal species of concern designation. This plan includes more Oregon-specific direction for recovery of the vernal pool fairy shrimp than *The Recovery Plan for Vernal Pool Ecosystems of California and Southern Oregon* (FWS 2005d) provided. The recovery plan addresses large-flowered woolly meadowfoam, Cook's lomatium, and vernal pool fairy shrimp as well as six plant species of concern, and the hairy water flea.

The recovery goal specific to the vernal pool fairy shrimp is:

- Contribute to the recovery of the vernal pool fairy shrimp as stated in the Recovery Plan for Vernal Pool Ecosystems of California and Southern Oregon (FWS 2005d).

The recovery objectives included in the recovery plan are:

- Stabilize and protect populations so further decline in species status and range are prevented.
- Minimize or eliminate the threats that caused the species to be listed and any newly identified threats.
- Conduct research necessary to refine downlisting and recovery criteria.
- Promote natural ecosystem processes and functions by protecting and conserving intact vernal pool-mounded prairie complexes and seasonally wet meadows within the recovery planning area.

The recovery plan includes the following delisting criteria for vernal pool fairy shrimp in the Klamath Mountina Region:

- At least 80 percent (9 of 11) of the occurrences within the Klamath Mountain Region (Rogue Valley) have been protected.
- At least 85 percent of suitable vernal pool habitat within the Klamath Mountain Vernal Pool Region has been protected.
- Habitat management and monitoring plans that facilitate maintenance of vernal pool ecosystem function and population viability have been developed and implemented for all protected habitat.
- Cyst banking actions have been completed for the vernal pool fairy shrimp.
- Status surveys, 5-year status reviews, and population monitoring show vernal pool fairy shrimp populations within the Klamath Mountain Vernal Pool Region are viable (self-sustaining) and have been maintained (stable, increasing, or showing only minor declines from high population levels) for a 10-year monitoring period.

The recommended recovery and long-term conservation actions are:

1. Protect vernal pool, wet meadow, and sloped mixed-conifer forest habitats.
2. Manage, restore, and monitor vernal pool and wet meadow habitat.
3. Conduct rangewide population status surveys.
4. Conduct research essential to the conservation and recovery of the species.
5. Enhance public awareness and participation in the recovery of the species.
6. Develop a post-delisting monitoring plan.

**Life History, Habitat Requirements, and Distribution**

This freshwater crustacean inhabits vernal pools, or seasonal wetlands that fill with water during fall and winter rains, in California and southwestern Oregon. They are known to occupy a variety of vernal pool habitats, from small, clear, sandstone rock pools to large, turbid, alkaline, grassland valley floor pools. Vernal pools in which the shrimp has been collected have water temperatures ranging from 40° to 73°F, with low to moderate amounts of salinity or total dissolved solids (FWS 2005d). Individuals hatch from cysts during winter storms and require water temperatures of 50°F or lower to hatch. The time to maturity and reproduction is dependent on temperature, ranging between 18 and 147 days, with a mean of 39.7 days. The shrimp can die when water temperatures rise to about 75°F. Flooding and wildlife movement within vernal pool complexes allow the shrimp to disperse between individual pools, indicating that vernal pool fairy shrimp populations are defined by entire pool complexes, rather than individual pools (FWS, 2007i).

Vernal pool fairy shrimp are found in 27 counties across the Central Valley and Coast ranges of California, and the inland valleys of southern California and southern Oregon (FWS 2003c). The shrimp was relatively recently discovered (1998) in Oregon at two distinct vernal pool habitats: on alluvial fan terraces associated with Agate-Winlo soils on the Agate Desert, and in the Table Rocks area on Randcore-Shoat soils underlain by lava bedrock (FWS 2005d). In Oregon, the vernal pool fairy shrimp is associated with the same vernal pool habitats as the large-flowered woolly meadowfoam and Cook’s lomatium plant species (discussed below). The Agate Desert comprises the northern extent of the vernal pool fairy shrimp’s range (2005d).

**Population Status**

The vernal pool fairy shrimp occurs in seaonally wet (autumn or winter) pools in the Agate Desert, White City, and Table Rocks areas in the Rogue Valley of Jackson County, Oregon, as well as various localities in the Central Valley and Coast Ranges of California (FWS, 2012i). The historical distribution is not known, especially in Oregon where it was recently discovered in 1998. Therefore, distribution can only be inferred from the loss of vernal pool habitat, which calculates to an approximate 75 percent decline in the vernal pool fairy shrimp population in the Agate Desert in Jackson County, Oregon (FWS 2005d). Additionally, over 40 percent of the vernal pool habitats remaining in Oregon have been degraded. Vernal pool fairy shrimps have been documented in 50 percent of the pools sampled in the Agate Desert Preserve, which is the highest percentage compared with other locales where the species is found (i.e., California and Denman Wildlife Management Area) (FWS 2005d).

**Critical Habitat**

Within the Rogue Valley, 7,574 acres have been designated as critical habitat for the vernal pool fairy shrimp within the following quadrangles in Jackson County: Shady Cove, Eagle Point, Boswell Mountain, Brownsboro, and Sams Valley (FWS 2003c). When determining areas of critical habitat for the vernal pool fairy shrimp, FWS focused on the principal biological or physical Primary Constituent Elements (PCEs) that are essential to the conservation of the species (FWS 2003c). Specifically, FWS (2003c) determined that two essential PCEs would apply to all critical habitat designated for vernal pool fairy shrimp. They are:

1) Vernal pools, swales, and other ephemeral wetland features of needed size and depth that become inundated during winter rains and hold water for the time necessary for life cycle completion, including but not limited to, Northern Hardpan, Northern Claypan, Northern Volcanic Mud Flow, and Northern Basalt Flow vernal pools; and,
2) The geographic, topographic, and edaphic features that support systems of hydrologically interconnected pools, swales, and other ephemeral wetlands and depressions within a matrix of surrounding uplands that together form what are known as vernal pool complexes (FWS, 2003c).

#### 4.6.1.2 Environmental Baseline

**Analysis Area**

In a general sense, a similar analysis area to the botanical analysis area that is described below for plant species (see Applegate's milk-vetch, section 4.2.1.2) applies to vernal pool fairy shrimp. That is, effects by the Project to vernal pool fairy shrimp could extend 200 feet from the perimeter of five proposed pipeyard storage areas that are located within the Vernal Pool Complex – Agate Desert, Jackson County, Oregon and shown in figure 4.6-1.

**Species Presence**

Six pipe storage yards are proposed within the Eagle Point and Sams Valley quadrangles where ten designated critical habitat units are within 3 miles of the proposed yards. Two proposed yards are adjacent to two critical habitat units (CHU's), identified as VERFS 3A and 3B (FWS 2006g). Surveys have documented vernal pool fairy shrimp in CHUs in Oregon, as well as adjacent to the project area in VERFS 3A and 3B (ORBIC, 2012); the most recent observations were in 2004 and 2005 where 15 to 25 percent of the vernal pools sampled were occupied by fairy shrimp (ORBIC, 2012).

No specific surveys have been conducted for the vernal pool fairy shrimp along the proposed construction right-of-way in the project area. Surveys in potentially suitable vernal pool habitat would be conducted two seasons prior to Project construction, following the interim FWS survey protocol (FWS, 1996b) in expected habitat and by a certified surveyor (see section 4.6.1.4, below). However, potential suitable vernal pool habitat was identified and surveyed at or adjacent to three pipe storage yards for large-flowered woolly meadowfoam and Cook's lomatium, where survey access permission was granted (SBS, 2008a): Rogue Aggregates, Medford Industrial Park, and habitat adjacent to Burrill Lumber (totaling 257.5 acres; table 4.6.1-1). Vernal pool fairy shrimp may be expected in the same habitat, where suitable vernal pool habitat was identified.

**Summary of Proposed Pipe Storage Yards Considered for Use in Jackson County**

| PipeStorage Yard | Size (Acres) | General Description | Wetland and Waterbody Features (taken from RR2) | T&E Botanical Survey (SBS, 2007) |
|---|---|---|---|---|
| Burrill Lumber | 64.11 | Old lumber mill/log yard | Small shallow depressions support hydrophytic species from seasonal ponding. Ponding likely due to past soils soil compaction from previous site landuse. A drainage ditch crosses through the yard from north to south. | Species Surveyed: None – no vernal pool habitat.<br>Surveys Required: None – no vernal pool habitat.<br>No suitable habitat for species associated with vernal pools. Only suitable vernal pool habitat occurs in 65-acre taxlot adjacent to this storage yard that was surveyed for Cook's lomatium and large-flowered woolly meadowfoam. |
| Burrill Real Estate – Medford Industrial Park | 92.05 | Existing industrial park | Narrow wetland ditched drainages along southern, western, and eastern edges and two bisecting the site. Seasonal wetland mosaic in western portion of yard. The drainage features would be matted to cross and the wetlands would be avoided by project activities. | Species Surveyed: Cook's lomatium, Large-flowered woolly meadowfoam.<br>Surveys Required: Vernal pool fairy shrimp<br>Seventeen small, low quality vernal pools mostly in the eastern portion of this site. Remaining portion is used as industrial storage where habitat is disturbed and modified with areas of seasonal saturation. Three ditches associated with vernal pool habitat.<br>This yard was not considered suitable habitat for large-flowered woolly meadowfoam due to high level of surface disturbance/soil compaction, but was considered habitat for Cook's lomatium since that species can handle more disturbance. |
| Avenue F and 11th Street | 26.16 | Industrial business and vacant leveled lot | No wetlands or streams. | Species Surveyed: none – landowner denial.<br>Surveys Required: Cook's lomatium, large-flowered woolly meadowfoam.<br>Potential habitat identified on SW and SE margins of yard, although initial review indicates modified, disturbed unsuitable habitat; area actively used by industry and shows no sign of seasonal saturation.<br>Although this yard was not considered suitable habitat for large-flowered woolly meadowfoam or vernal pool fairy shrimp, surveys for large-flowered woolly meadowfoam will be conducted concurrently with Cook's lomatium when permission is granted. |
| Oregon Opportunities | 5.18 | Undeveloped/vacant lot in industrial park | Seasonal emergent wetland is present along railroad tracks on north end of site. Temporary construction mats or geotextile fabric and gravel padding would be used as a temporary access pad to railroad tracks if offloading pipe is necessary. | Species Surveyed: none – landowner denial.<br>Surveys Required: Cook's lomatium, large-flowered woolly meadowfoam.<br>Potential habitat on north and south end identified for surveys. Initial review indicates unsuitable habitat used as industrial storage with no indication of seasonal saturation.<br>Although this yard was not considered suitable habitat for large-flowered woolly meadowfoam or vernal pool fairy shrimp, surveys for large-flowered woolly meadowfoam will be conducted concurrently with Cook's lomatium when permission is granted. |
| Rogue Aggregates | 111.02 | Active aggregate quarry and processing facility and undeveloped land | No wetlands present. Several small ephemeral streams cross the site; the function of these drainages would not be affected by project activities. North end of site within floodplain. | Species Surveyed: Cook's lomatium, Large-flowered woolly meadowfoam<br>Surveys Required: none – no vernal pool habitat suitable for vernal pool fairy shrimp.<br>No suitable vernal pool habitat for the listed species. Mixture of pasture, mixed hardwoods, a gravel pit, and two ephemeral streams. |

**Habitat Surveyed**

As noted above, Siskiyou BioSurvey conducted botanical surveys within 257.5 acres on three proposed pipe yard storage yards near or in the analysis area (Rogue Aggregates, Medford Industrial Park, and habitat adjacent to Burrill Lumber). Of the 257.5 acres surveyed within the three pipe storage yards, 95.4 acres were found to be suitable vernal pool habitat for Cook's lomatium within Medford Industrial Park. No habitat was considered suitable for large-flowered woolly meadowfoam within the pipe storage yards or within the 200-foot survey buffer. Rogue Aggregates, a proposed pipe storage yard totaling 111.0 acres was surveyed, but no potential vernal pool or seasonal wetland habitat was identified. The site includes a mixture of pasture, mixed hardwoods, a gravel pit, and two ephemeral streams. Also, no suitable habitat for species associated with vernal pools was identified within Burrill Lumber pipe storage yard. Only 17 small, low quality vernal pools and two ditches in Medford Industrial Park were identified as potential suitable habitat for vernal pool fairy shrimp.

Two other areas no longer considered for potential pipe storage yard use were surveyed for large-flowered woolly meadowfoam and Cook's lomatium, and considered potential suitable habitat for vernal pool fairy shrimp. These yards included: one 65-acre taxlot (Maplot #361W17600) adjacent to the proposed 64.1-acre Burrill Lumber Yard that contained five acres of high quality and one acre of low quality vernal pool habitat over 900 feet from proposed Burrill Lumber Yard, and 24 acres of suitable vernal pool habitat located on the Avenue C and 7th Street/Elite Cabinet & Doors Yard that includes disturbed seasonally saturated or seasonal wetland habitat that has been filled and graded in the past (SBS, 2008a).

Two additional pipe storage yards totaling 31.3 acres were not surveyed – Avenue F and 11th Street and Oregon Opportunities (permission for access was denied), of which 4.9 acres of habitat within those pipe storage yards may have potential vernal pool habitat based on aerial photo interpretation and a "drive-by assessment". Avenue F and 11th Street is a 26-acre taxlot that appears to be modified, disturbed habitat that is actively used as industrial land, and shows no sign of seasonal saturation except for possible vernal pool habitat on the southwest and southeast margins of the yard. Oregon Opportunities includes five acres that appear to also have been previously disturbed; the site is unsuitable habitat and is currently used as an industrial storage area with no indication of seasonal saturation. Possible low quality vernal pool habitat exists on the north and south margins of the yard, although there is no sign of seasonal saturation. The proposed pipe storage yards are both highly modified and were not expected to support suitable habitat for vernal pool fairy shrimp.

Nine vernal pools (approximately 0.2 acre) within and adjacent to the proposed right-of-way that are on private lands (MPs 145.34 and 145.40) may also provide suitable habitat for the vernal pool fairy shrimp, although this area is outside of the known range for vernal pool fairy shrimp, but within the correct soils type for the Agate Desert vernal pool habitat. Surveys in potentially suitable vernal pool habitat would be conducted two seasons prior to Project construction, following the interim FWS survey protocol (FWS, 1996b) in expected habitat and by a certified surveyor (see section 4.6.1.4, below).

According to the recovery plan (FWS, 2012i), approximately 3,650 acres of vernal pool fairy shrimp habitat is considered for inclusion within the Agate Desert Wetland Conservation Plan. Approximately 568 acres (16 percent) are in the development category, 1,325 acres (36 percent) are in the protection category, and 1,757 acres (48 percent) are in the incentive for conservation category. The 568 acres slated for development would likely be permanently lost and the fate of the 1,757 acres in the incentive category may depend on funding of conservation incentive programs. None of the 7,500 acres of vernal pool fairy shrimp critical habitat is included in the development category. Approximately 1,200 acres of fairy shrimp critical habitat are included in the protection category with another 1,000 acres included in the incentive category (FWS, 2012i).

**Critical Habitat**

Two proposed pipe storage yards, Burrill Lumber and Burrill Real Estate – Medford Industrial Park, are located in industrial yards that are adjacent to two vernal pool fairy shrimp critical habitat units, VERFS 3A and 3B, in the Shady Cove quadrangle in Jackson County.

- Burrill Lumber (adjacent to VERFS 3A): Burrill Lumber proposed pipe storage yard is an old lumber mill and log yard with existing industrial structures on the south-western portion of the proposed 64 acre yard. This yard is separated from critical habitat unit VERFS 3A by an existing road (Agate Road). In the portion of the yard not recently used for industrial purposes, small shallow depressions are present that support hydrophytic species during seasonal ponding. Ponding is likely due to past soil compaction from previous site land uses and is not considered suitable habitat for federally listed vernal pool species associated with the vernal pool complexes in designated critical habitat units adjacent to this 64 acre lot including, vernal pool fairy shrimp, Cook's lomatium, and large-flowered woolly meadowfoam (SBS, 2008a). A drainage ditch crosses through the yard from north to south. Botanical surveys conducted in 2007 for Cook's lomatium and large-flowered woolly meadowfoam did not locate either species within this storage yard (SBS, 2008a).
- Burrill Real Estate – Medford Industrial Park (adjacent to VERFS 3B): Medford Industrial proposed pipe storage yard (92 acres) is a previously disturbed and modified industrial park located between an existing, paved road (Avenue G) and designated critical habitat unit VERFS 3B. Narrow wetland ditched drainages occur along the southern, western, and eastern edges of the industrial park and two wetland ditches bisect the site. A mosaic of 17 small, low quality seasonal wetlands are located in the eastern portion of the proposed yard, as well as three ditches with potential connections to vernal pool habitat. The remaining portion of the yard is used for industrial storage. Botanical surveys conducted in 2008 for Cook's lomatium and large-flowered woolly meadowfoam did not locate either species within this storage yard (SBS, 2008a).

Pacific Connector intends to avoid using areas within pipe storage yards that may have vernal pool fairy shrimp. If vernal pool fairy shrimp (or other ESA botanical species associated with vernal pools) is identified in previously surveyed or unsurveyed proposed pipe storage yards when access is granted through the FERC Certificate process, Pacific Connector would avoid using that section of the yard.

### 4.6.1.3 Effects by the Proposed Action

**Direct and Indirect Effects**

Because of the rarity of vernal pool fairy shrimp, any direct or indirect impact resulting in species take or habitat loss would be a significant hindrance to its recovery. Direct effects include possible disturbance to pools from driving or storing equipment or pipes near or on pools or wetlands. Those actions could directly destroy or disturb vernal pool fairy shrimp cysts (during the dry season) or live shrimp (during the wet season). The proposed action in pipe storage yards near vernal pool habitats would occur on lands where past heavy industrial uses have occurred. Pacific Connector would avoid using the portion of the pipe storage yard that has suitable or potentially suitable habitat for vernal pool fairy shrimp, similar to actions taken within the 65-acre taxlot adjacent to Burrill Lumber Yard (with 5 acres of high quality suitable vernal pool habitat), and pipe storage yard Avenue C and 7th Street (24 acres of lower quality vernal pool habitat). As a result, no direct effects to vernal pool fairy shrimp or their potential habitat within pipe storage yards are expected.

Indirect effects to vernal pool fairy shrimp and their habitat could occur with increased road use to access the pipe storage yards that are adjacent or in the vicinity of suitable or potentially suitable habitat. Increased road use and the associated dust created might impact vernal pool habitat as dust settles, affecting vegetation and vernal pool physical or chemical properties (pH, water quality, turbidity, sedimentation, temperature). Project use of pipe storage yards (i.e., potential soil compaction by heavy equipment) adjacent to, or in the vicinity of suitable or potentially suitable habitat, may indirectly affect hydrology upon which vernal pools and associated vegetation are dependent. Indirect effects to hydrology could be expected within 527 feet of suitable or potentially suitable vernal pool habitat since at least 20 acres of habitat is considered essential for intact hydrology (see primary constituent element discussion for large-flowered woolly meadowfoam and Cook's lomatium – FWS, 2010b) and 527 feet is the radius of a circle with an area of 20 acres. Also, road use adjacent to or in the vicinity of suitable or potentially suitable vernal pool fairy shrimp habitat may increase the introduction of non-native, weedy species that could compete with native plant species associated with the vernal pool fairy shrimp.

No indirect effects are expected from use of Burrill Lumber pipe storage yard or roads accessing that yard to the five acres of high quality vernal pool habitat located on the northeast corner of the 65-acre taxlot (Maplot #361W17600) since it is located over 900 feet from the perimeter of the proposed Burrill Lumber Yard with a small drainage between the habitat and the industrial area.

Surveys for vernal pool fairy shrimp have not been conducted at 17 seasonal wetlands and saturated areas identified within Medford Industrial Park pipe storage yard as potential habitat, nor within potential habitat identified in nine vernal pools within and adjacent to the proposed right-of-way (MPs 145.34 and 145.40). While the pools at Medford Industrial Park are currently low quality vernal pool fairy shrimp habitat, the species is capable of occupying artificial seasonal wetland habitats (Vollmar, 2002). Also, vernal pools identified along the right-of-way are outside the range of vernal pool fairy shrimp, but may be capable of supporting vernal pool fairy shrimp because the soils are appropriate. Therefore, without surveys to confirm non-occupancy, direct effects from pipe storage yard activities or construction of the pipeline to vernal pool fairy shrimp and their habitat are possible. The two remaining unsurveyed pipe storage yards (Avenue F and 11th Street and Oregon Opportunities) both appear to have no potential vernal pool or seasonal wetland habitat; therefore, no direct or indirect effects are expected at these sites.

**Critical Habitat**

Vernal pool fairy shrimp are dependent on seasonal fluctuations, absence or presence of water during specific times of the year, duration of inundation, and the rate of drying of their habitats to support seed germination, cyst hatching, growth, maturation, reproduction, and dispersal, and the appropriate periods of dry-down for seed and cyst dormancy necessary for their survival (FWS, 2003c). The FWS (2003c) identified two primary constituent elements that were considered when designating critical habitat that considers soil moisture and aquatic environment required, as well as upland areas that may be associated with maintaining the aquatic and drying phases of the vernal pool or complexes. Vernal pools on the Agate Desert Preserve in the vicinity of proposed pipe storage yards in Jackson County, Oregon, generally consist of remnant parcels of disturbed or degraded vernal pool habitat and are threatened by indirect effects of adjacent land use, including alteration of hydrology (FWS, 2007i). Williamson et al. (2005 cited in FWS, 2007m) indicate that surface or subsurface changes to water flow could have deleterious effects on vernal pool ecosystem function protected areas within or adjacent to altered watersheds. Rains et al. (2006 cited in FWS, 2007i) also indicate that small changes in local land use may have considerable impacts on vernal pools and their hydrology. Hydrology can also be altered by non-native grasses that occur commonly in vernal pool complexes.

Two proposed pipe storage yards (Burrill Lumber and Medford Industrial Park) are located adjacent to two vernal pool fairy shrimp critical habitat units – VERFS 3A and VERFS 3B, consecutively. Although critical habitat lies adjacent to the proposed pipe storage yards, no direct impacts from the proposed action are anticipated since equipment and pipe storage would not occur near or on pools or wetlands located in the critical habitat units, nor would traffic to and from the pipe storage yards drive near or on pools within the designated critical habitat units. Possible indirect effects to the critical habitat units may occur as a result of increased road use to access the pipe storage yards that are adjacent to the critical habitat units (Avenues C, F, G, and Antelope and Agate Roads) and use of Medford Industrial Park pipe storage yard that is directly adjacent to critical habitat unit VERFS 3B. Increased road use and the associated dust created, might impact vernal pool habitat as dust settles, affecting associated vegetation and vernal pool physical or chemical properties (pH, water quality, turbidity, sedimentation, and temperature). Use of the Medford Industrial Park yard that includes ground disturbance such as leveling may alter hydrology in vernal pools in critical habitat unit VERS 3B, possibly affecting the frequency or amount of water in adjacent vernal pools, or altering the upland hydrology for which vernal pools and associated vegetation are dependent.

Indirect effects to hydrology could be expected within 527 feet of suitable or potentially suitable vernal pool habitat within VERFS 3B (527 feet is the radius of a 20-acre circle) since at least 20 acres of habitat surrounding a vernal pool site is considered essential for intact hydrology (see proposed primary constituent element discussion for large-flowered woolly meadowfoam and Cook's lomatium – FWS, 2010a). Additionally, use of the roads adjacent to the critical habitat units and the pipe storage yards, themselves, may increase the introduction of non-native, weedy species and contribute to ground/soil compactions which could affect local hydrological connectivity.

Applying conservation measures identified below (section 4.6.1.4) and use/alteration/restoration of pipe storage yards should minimize effects to the timing, duration, magnitude, or quality of hydrological connections to an off-site vernal pool and/or federally-listed vernal-pool obligate species.

#### 4.6.1.4 Conservation Measures

Pacific Connector has eliminated the 26.4-acre Avenue C and 7th Street-Elite Cabinet & Door Pipe Storage Yard, which contained potential vernal pool habitat, from further consideration for Project use to avoid potential effects to vernal pool habitat. Pacific Connector also would not use the 65-acre taxlot (Maplot #361W17600) which was surveyed adjacent to the Burrill Lumber Yard and contains five acres of high quality and one acre of low quality vernal pool habitat.

Once Pacific Connector has determined if Medford Industrial Park would be used for storage of pipe for the Pacific Connector pipeline, surveys for this species would be conducted per FWS interim survey protocol (FWS, 1996b) in expected habitat by a certified surveyor (applying either two full wet season surveys completed within a 5-year period or two consecutive seasons of one full wet season survey and one dry season survey, or visa versa) two seasons prior to Project use. Surveys would also be conducted for vernal pool fairy shrimp within the nine vernal pools identified within and adjacent to the construction right-of-way (MPs 145.34-145.40) two seasons prior to construction. Surveys would not commence until permission is provided by the FWS. Surveys have not been conducted yet to minimize "take" of the species, which could potentially occur if the shrimp are present (per protocol – survey and collect specimens). If this species is noted during survey efforts, Pacific Connector would implement proper sedimentation control barriers (FWS, 2005d) to minimize potential impacts to vernal pool fairy shrimp and associated vernal pools would be avoided. Pacific Connector would also ensure that use of the yards or construction of the pipeline would not affect surface drainage or current hydrologic conditions to adjacent areas if survey results confirm the presence of vernal pool fairy shrimp or if a yard is adjacent to potential suitable habitat or designated critical habitat.

#### 4.6.1.5 Determination of Effects

**Listed Species**

The Project **may affect** vernal pool fairy shrimp because:

- Potential suitable habitat for vernal pool fairy shrimp could be within one site considered for pipe storage (Medford Industrial Park). However, the species has not been surveyed at this site.

The Project is **likely to adversely affect** vernal pool fairy shrimp because:

- Use of the Medford Industrial Park Yard, even if found to not support vernal pool fairy shrimp, is expected to indirectly affect fairy shrimp if they are 527 feet away, possibly in designated critical habitat, since intact hydrologic connections between the yard and vernal pools could potentially be impacted by surface disturbances and/or soil compaction by heavy machinery.

**Critical Habitat**

A **may affect** determination is warranted for vernal pool fairy shrimp critical habitat because:

- The project occurs adjacent to designated vernal pool fairy shrimp critical habitat.
- The project may result in habitat impacts within adjacent designated critical habitat.

A **likely to adversely affect** determination is warranted for vernal pool fairy shrimp critical habitat because:

- The proposed action could potentially adversely modify geographic, topographic, and edaphic features that support systems of hydrologically interconnected pools, swales, and other ephemeral wetlands and depressions within a matrix of surround uplands (PCE 2) through surface disturbances and/or soil compaction by heavy machinery within the Medford industrial Park Yard at least 527 feet away from designated critical habitat unit VERFS 3B.

## 4.7 PLANTS

### 4.7.1 Applegate's Milk-vetch

#### 4.7.1.1 Species Account and Critical Habitat

**Status**

Applegate's milk-vetch was listed as endangered on July 28, 1993 (FWS, 1993c). It was believed to be extinct until its rediscovery in 1983 and at the time of listing was only known from two extant sites.

**Threats**

In the five year review of Applegate's milk-vetch, FWS identified continued destruction, modification or curtailment of its habitat or range, and loss of habitat through competition with non-native weeds as the principal threats to the species survival (FWS, 2009c). Extensive agricultural use had extirpated at least one Applegate's milk-vetch population in Klamath Country, Oregon. Road construction near Klamath Falls eliminated both plants and habitat. At the time of the listing, potential commercial and road development on private land threatened to destroy "probably the only viable population left" of the plant (FWS, 1993c: 40549). In Oregon's Klamath Wildlife Management Area, overgrazing by rabbits and fire and flood management schemes endangered an already waning Applegate's milk-vetch population (FWS, 1993c).

According to FWS Applegate's milk-vetch Recovery Plan (1998b), habitat loss and modification due to development and hydrologic manipulation continue to threaten Applegate's milk-vetch. Portions of the Ewauna Flat population have been destroyed by urban development on private land and more are at risk because they occupy properties zoned industrial. Construction of ditches and dikes in the Klamath Basin alter the hydrologic character of Applegate's milk-vetch habitat. These changes could result in lethally dry conditions, or may indirectly impact the species by introducing drought-tolerant and exotic plants (FWS, 1998b).

Several other factors were identified in the decision to list the Applegate's milk-vetch. Overutilization for commercial, recreational, and scientific purposes was seen as a potential threat at the time of listing because the rare plants are easily accessible by road. FWS identified predation from rabbits and cattle as obstacles to the plant's survival (FWS, 1993c). Additionally, because of the small number of populations, limited gene pool, and small number of plants in general, the FWS determined that potential for extinction from stochastic events (fires or floods) is a threat to the species (FWS, 1993c).

**Species Recovery**

The recovery plan was drafted with the ultimate goal to increase the stability of Applegate's milk-vetch so that it can be down-listed. The two main objectives of the recovery plan (FWS, 1998b) are to:

- Increase the species' representation from the current three areas to at least six areas with a minimum of two populations occurring at each of the recovery areas; and
- Develop management strategies that provide for long-term stability.

In order to achieve the two objectives, the recovery plan recommends the following actions:

- Conserve natural and introduced Applegate's milk-vetch populations.
- Develop long-term, off-site seed storage.
- Conduct research on population sustainability, population establishment and augmentation techniques, efficacy of habitat management strategies, and the plant's edaphic and hydrologic requirements.
- Develop and implement an outreach program.

The 5-year review of Applegate's milk-vetch (FWS, 2009c) reports that since the recovery plan was published, three new occurrences of Applegate's milk-vetch have been found. The review states that recovery critereia should be modified to include oppurtunities to achieve self-sustaining populations at the newly discovered sites. Specifically, the 5-year review suggests that Applegate's milk-vetch will be considered for downlisting to threatened status when (FWS, 2009c):

> "At least two natural and/or introduced self-sustaining populations are preserved in each of the three recovery areas (Ewauna Flat, Miller Island, and Worden), for a total of six or more populations in habitat permanently secured and managed for the benefit of the species. A minimum of 4,500 reproductive plants is needed for a recovery area to meet the downlisting threshold. Self-sustaining populations are defined as containing a minimum of 1,500 reproductive plants, plus sufficient individuals in younger age classes to suggest population stability or growth".

As of 2007, Applegate's milk-vetch population establishment techniques had not been successful and additional transplantation methods were being investigated (Gisler, 2002; ORBIC, 2007). FWS recommends further research on the impacts of weed competition on Applegate's milk-vetch, pollination and self-fertilization processes, and herbivory and predation processes (FWS, 1998b).

**Life History, Habitat Requirements, and Distribution**

Soils in typical Applegate's milk-vetch habitats are characterized as being gray in color, slightly alkaline, with a shallow water table and groundwater with a relatively high salinity due to periodic flooding and evaporation (TNC, 1999). Applegate's milk-vetch grows only in flat-lying, seasonally moist, alkaline soils with underlying clay hardpans. The underlying clay hardpans provide seasonal soil moisture, saturation and retention, forming a hydrological regime which may be a requirement for dry summer months when flowering and seeding occur (FWS 1998b). Alkaline soils may support mycorrhizal fungi and rhizobium bacteria beneficial to the survival and growth of the milk-vetch (FWS, 1998b). As with other plants growing under extreme conditions of alkalinity, heavy metals, and/or salinity, Applegate's milk-vetch may benefit from alkaline soils to help reduce competition from other species (FWS, 1998b).

The vegetative community in which Applegate's milk-vetch sites occurs is classified as interior alkali grassland (TNC, 1999). The species' habitat was historically characterized by sparse, native bunch grasses and patches of bare soil, allowing for some seed dispersal by wind. Today, dense coverage of the habitat by introduced grasses and weeds means seed dispersal is highly localized, with most seedling establishment found adjacent to mature plants (FWS, 1998b). Flowering usually begins in early June and ends in August. Reproduction takes place exclusively by seeds, which are shed soon after flowering. Pollination is thought to be mediated by butterflies (*Lycaedes argyrognomon* and *Plebejus Melissa*) and polylectic bees (Yamamoto, 1985), although the plant is also capable of seed production through self-fertilization.

Since the publication of the recovery plan in 1998, there have been numerous cooperative efforts made by Oregon Department of Agriculture, ORBIC, TNC, the FWS, and private landowners to conduct inventories forApplegate's milk-vetch throughout most of its historical range. The plant is endemic to Klamath County, Oregon (FWS, 1998b), is adapted to a narrow range of environmental conditions, and is known only in the Lower Klamath Basin (the plain containing Lower Klamath Lake), near the City of Klamath Falls in southern Oregon. Three new sites discovered since publication of the recovery plan include the Collins tract, the Klamath Falls Airport, and the Washburn Way-Railroad track (FWS, 2009c).

**Population Status**

At the time of the recovery plan in 1998, there were three known extant populations in Klamath County, numbering about 12,000 plants (FWS 1998b). As of 2008, the last published data available, the number of individuals was estimated to be 33,800 plants on six known sites (FWS 2009). Table 4.7.1-1 provides a summary of Applegate's population status at the time of federal listing in 1993, the draft recovery plan in 1998, and status as of 2008 (FWS, 2009c).

Local populations (table 4.7.1-1) range from nine plants in the Worden site to thousands of plants in two current extant sites (Klamath Airport and Collins Tract sites). Multi-year trend data has been collected at the Nature Conservancy Preserve site near Ewauna Lake. These data document a dramatic downward decline in the subpopulation from 30,000 to 2,000 plants during the five years 2003 to 2008 (FWS, 2008i in SBS, 2008a).

**Table 4.7.1-1**

**Summary of Applegate's Milk-vetch Population Status by Site at the Time of Federal Listing (1993), Publication of the Recovery Plan (1998), and as of 2008**

| Site Name | Ownership | Number of Plants at Time of Listing (1993) | Number of Plants at Time of Recovery Plan (1998) | 2007 Survey | 2008 Survey | Current Status |
|---|---|---|---|---|---|---|
| Ewauana Flat Preserve | The Nature Conservancy | Up to 30,000 plants | Approximately 11,500 plants | Partial Survey (see 2008) | Approximately 2,197 plants (2007/2008 surveys) | Declining |
| Miller Island | State of Oregon | 30 to 80 plants | Fewer than 500 plants | 38 plants | 112 plants | Unknown |
| Keno | Private | Historical (extirpated) | Historical (extirpated) | Historical (extirpated) | Historical (extirpated) | Extirpated |
| Worden | Private | Undiscovered | 3 plants | Extirpated | 9 plants | Unknown |
| Collins Tract | Private | Undiscovered | Undiscovered | Thousands of plants (area not counted) | 10,143 plants | Unknown |
| Klamath Falls Airport | City of Klamath Falls | Undiscovered | Undiscovered | Approximately 1,000 plants (area not completely surveyed) | 21,049 plants | Unknown |
| Washburn Way-Railroad | Private | Undiscovered | Undiscovered | Approximately 100 plants | 307 plants | Unknown |
| Klamath Falls | Private | Believed to have been extirpated | 13 plants found in 1994 | Extirpated site (developed) | Extirpated | Extirpated |

### Critical Habitat

Critical habitat has not been designated for Applegate's milk-vetch.

## 4.7.1.2 Environmental Baseline

### Analysis Area

A botanical analysis area applies to the extent of Project-related effects on listed plant species within a general 400-foot-wide corridor, 200 feet on each side of the proposed Pacific Connector pipeline centerline. That area corresponds to areas that were surveyed for sensitive and listed plant species during surveys conducted between 2007 and 2013. The survey areas were expanded beyond the 400-foot width to include TEWAs, UCSAs associated with the construction right-of-way, rock source and disposal sites, and proposed storage yards on federal or state lands that have potential for listed plant species. Under these criteria, nearly all of the proposed Pacific Connector pipeline route in Douglas and Jackson Counties was designated for survey and is included in the botanical analysis area. In Klamath County, a large area of private land was included for on-the-ground evaluation in order to detect small areas of potential habitat for Applegate's milk-vetch.

**Species Presence**

Herbarium records indicate that a known historical population, now presumed extirpated (ORBIC, 2012), occurred in the vicinity of the proposed pipeline alignment (MP 190.9 to MP 192.3); it was last reported in 1937, approximately 2 miles east of the town of Keno, Oregon (about 10 miles southwest of Klamath Falls; see the Keno Site included in table 4.7.1-1). Efforts to relocate this species in the area have been unsuccessful (ORBIC, 2012; FWS 1998b). Plants have been documented north and south of the proposed pipeline alignment (MP 195.5 to MP 196.7) across the Klamath River from and adjacent to the Lower Klamath National Wildlife Refuge and State Wildlife Area. The last observations were in 2010 with the site ranked as one with excellent estimated viability (ORBIC, 2012). Estimates of more than 10,000 plants at multiple sites in the area were made in 2008 (ORBIC, 2012). The closest mapped population of Applegate's milkvetch to the proposed project construction right-of-way is approximately 60 feet away. All sub-populations in this complex are on private land (including the Collins Tract Site, see Habitat Surveyed, below).

**Habitat Surveyed**

Prior to beginning field surveys in 2007 for the Pacific Connector pipeline, botanists with SBS conducted a habitat review to identify potential habitat and delineate survey areas for Applegate's milk-vetch within the proposed pipeline project area, including existing roads identified for access to the construction right-of-way. Aerial photographs (summer 2005) and knowledge of regional landscape and biological features (soils, geology, topography, elevation, target species habitat, and plant community habitat) were used to determine potential habitat for Applegate's milk-vetch. The same methods have been applied to determine areas of suitable habitat in new locations where the proposed pipeline right-of-way has been relocated.

A total of 687.3 acres have been identified as potential habitat requiring surveys within the current project alignment including a 200-foot buffer (table 4.7.1-2). Of this habitat, 612.1 acres were allowed access to survey (297.2 acres within the project area) of which 131.7 acres (77 acres within the project area) were considered suitable habitat for Applegate's milk-vetch. All potential habitats are located within Klamath County between MPs 190.9 and 214.4.

Approximately 76.2 acres (49.8 acres within the project area) of potentially suitable habitat for Applegate's milkvetch was denied access by the landowner and would need to be surveyed prior to construction for complete surveys of this ecoregion. If the assumption is made that a similar percent of that area is suitable as documented within the rest of the area surveyed, then approximately 17 acres (22 percent of 76.2 acres, or 11 acres within the project area) is probably suitable Applegate's milk-vetch.

**Note:**
[1] The botanical analysis area applies to the extent of pipeline-related effects on listed plant species within a general 400-foot-wide corridor, 200 feet on each side of the proposed Pacific Connector pipeline centerline.

<u>Documented Locations</u>

Three locations with Applegate's milk-vetch plants were documented by SBS during surveys in 2007 and 2008 (see table 4.7.1-3, SBS, 2008). Currently 38.3 acres of Applegate's milk-vetch habitat (with plants present) coincide with the current project alignment and 200 foot buffer: 17.8 acres within the proposed ROW and 20.5 acres outside of the ROW but within the 200-foot buffer.

| 195.35-195.95 | 2008 | 4.1 acres, JWTR LLC |
| 195.49-195.85 | 2008 | 14.1 acres, Collins Tract |
| 196.29 -196.79 | 2007, 2008 | 20.1 acres, Collins Tract |

Note:
[1] Locations and acreages are for discoveries **within** the 200-foot botanical analysis area.

Collins Tract

The Collins Tract site located within and adjacent to the botanical analysis area was first discovered in 1998 (table 4.7.1-1), and field surveys conducted by ORBIC in 2007 discovered two large sub-population, each several acres in size (Roninger, 2008). Expanded survey efforts by FWS and SBS in 2008 discovered several sub-populations clusters in the Collins Tract site, including plants within the FERC-filed construction right-of-way between MP 195.35 and 196.5 (Roninger, 2008; SBS, 2008a). In 2008, the entire Collins Tract was found to contain 10,133 plants on 32.3 acres within a larger 250-acre area (see figure 4.7-1). The 19 individual sub-population clusters ranged from a single plant to thousands of plants. There were seven sub-population clusters that occured within the botanical analysis area. The large sub-populations of Applegate's milk-vetch located at Collins Tract site was in habitat slightly different than other known populations: soil was less alkaline and not associated with the usual vegetative structure (i.e., very little or no rabbitbrush present). Also, weeds present within this area include cheatgrass, mouse barley, and sweet clover (see July 24, 2008 meeting minutes). In 2013, 55.0 acres were surveyed around the Collins Tract (and other areas), but no Applegate's milk-vetch were observed (SBS, 2013).

Although the Collins Tract site was discovered in 1998, the expansion of the sites sub-population was documented in 2007 and by definition in the 1998 Recovery Plan (FWS, 1998b) the site would be considered a self-sustaining population with a minimum of 1,500 reproductive plants with individuals in younger age classes, suggesting population stability and growth. However, additional monitoring of this site is required to verify population sustainability over time.

### Critical Habitat

Critical habitat has not been designated for Applegate's milk-vetch.

### 4.7.1.3 Effects by the Proposed Action

### Direct and Indirect Effects

In June and July 2008, FWS and SBS documented 10,133 plants within the Collins Tract site coinciding with and adjacent to the botanical analysis area. Of those locations, 592 plants were located within various components of the pervious FERC-filed route. Since very few sites of this species exist in Klamath County, and total numbers of individual plants for this species are relatively low, any loss of plants would be significant. The 1998 Recovery Plan identifies the small numbers and limited distribution as a threat because the possibility of extirpation due to random mortality events is increased (FWS, 1998b). Pacific Connector met with several members of the Habitat Quality Subtask Group on July 24, 2008 to discuss impacts to the documented plants and provide recommendations of how to avoid or minimize impact to these plants). In response to recommendations and discussions with agencies, Pacific Connector rerouted the proposed alignment north of its FERC-filed route to wetter soils to avoid individual plants documented during surveys in 2008, as well as more suitable habitat. As a result, use of the currently proposed route would avoid removal of documented plants and no direct impact to individual plants is expected (see figure 4.7-1).

Records of Applegate's milkvetch provided by ORBIC (2012), FWS, and SBS in 2008 north and south of MPs 195.5 and 195.8, and possibly other sites within unsurveyed habitat, may also be indirectly impacted as a result of habitat alteration. Indirect impacts are likely to include: 1) changes in hydrology and soil characteristics, 2) an increase in invasive weeds, 3) alterations of vegetation cover and species composition. Such alterations in suitable habitat would likely cause an increase in weedy grasses and forbs. Competition from invasive weeds may limit the establishment and recovery of Applegate's milk-vetch (FWS, 1998b). Impacts to suitable habitat are expected to negatively affect the recovery of the plant. Very little suitable habitat still exists in the Klamath Basin, and the impacted habitat within the analysis area is therefore expected to represent a significant percentage of the total suitable habitat (SBS, 2008c).

After construction, Pacific Connector would restore the construction right-of-way back to approximate original contours and reseed using a species mix recommended by FWS and appropriate for this area of the pipeline project. Operational impacts would include monitoring and treatment for noxious weeds. No other maintenance impacts are expected within the range of Applegate's milk-vetch because the permanent easement would be maintained in an herbaceous/shrub state, similar to suitable habitat for Applegate's milk-vetch.

**Cumulative Effects**

ESA plant species do not have federal protection in Oregon on private lands except in instances where a federal permit is required or a federal action occurs. Outside of the surveyed area for the Pacific Connector pipeline, it is unknown where Applegate's milk-vetch occurs on private lands throughout the botanical analysis area. Therefore, it is impossible to determine if there are reasonably foreseeable actions which might occur on private lands, which could impact the plant. Given the lack of protections under ESA and Oregon statutes, all federally listed plants on private lands must be considered at risk of adverse effects, wherever they may occur. However, the Pacific Connector pipeline would mitigate for any pipeline impacts to Applegate's milk-vetch.

**Critical Habitat**

No critical habitat would be impacted by the proposed action. Critical habitat has not been designated for Applegate's milk-vetch.

#### 4.7.1.4 Conservation Measures

The only protected Applegate milkvetch populations in the area are those at the Klamath Wildlife Area and Klamath Falls Airport. The proposed pipeline route is within one of the largest private land populations of this species, the Collins Tract, which contains greater than 10,000 plants. The FWS has been exploring conservation agreements with the Collins Company to protect the Collins Tract population. To avoid removing individual plants within the Collins Tract site, Pacific Connector rerouted the original FERC-filed alignment north around other documented sites and in the lower elevations and wetter soils to minimize potential of unforeseen impacts to the plants or its habitat (see draft EIS-revised route). The location of the draft EIS-revised route was recommended by attendees at the July 24, 2008 Habitat Quality Subtask Group meeting. Additionally, TEWAs identified to discharge extra water within the trench were eliminated or moved to avoid impacting smaller plant groups (see figure 4.7-1).

Applegate's milk-vetch is a trailing perennial herb that begins flowering in early June and ends in August. Reproduction takes place exclusively by seeds, which are shed soon after flowering.

Participants of the July 24, 2008 meeting indicated that constructing within this area would be better in the winter than spring or summer to avoid the critical growing, flowering, and seeding cycle of this species. Within the range of Applegate's milk-vetch, Pacific Connector would construct from September 15 in Year 1 through April 30 in Year 2 (see figures 3.2-1 and 3.2-3), which would minimize impact to these critical life cycles.

During winter construction, Pacific Connector would use wetland mats in the travel area between MPs 195.35 to 196.50 where necessary to prevent rutting in saturated areas or to minimize soil compaction and protect existing plants that may be present but not documented. Additionally, Pacific Connector would segregate topsoil from trench spoil to maintain the soil seed bank, as well as maintain microrhyzoids with which the species' root system is associated. After construction, the construction right-of-way would be restored to its original contours and reseeded with an appropriate seed mixture recommended by FWS prior to the following growing season.

To control the potential noxious weed invasion Pacific Connector would implement the procedures outlined in their Noxious Weed Control Plan (section 12.0) provided in the ECRP (see appendix F).

When Pacific Connector acquires access to the construction right-of-way, surveys would be conducted in potential habitat (previously surveyed or unsurveyed) and additional plants located during surveys would be avoided, if feasible. Measures of avoidance may include necking down the construction right-of-way in that area, excluding a portion of an identified temporary extra work space or pipe storage yard, or erecting a protective fence to avoid impact to plants from construction debris. If it is determined that avoidance is not possible, participants of the July 24, 2008 Habitat Quality Subtask Group suggested digging up the plant(s), transplanting, and monitoring; however, Applegate's milk-vetch is difficult to transplant because of the long (approximately five-foot) tap root. Also, no or minimal successful out-planting has been recorded in greenhouses or other locations. Prior to construction, Pacific Connector would collect and bag seeds in June and/or July if plants are identified within the proposed alignment and provide seeds to a suggested repository. If permission is granted by the property owner, Pacific Connector would use the collected seed to plant outside of the permanent right-of-way after construction.

#### 4.7.1.5 Determination of Effects

**Listed Species**

The Project **may affect** Applegate's milk-vetch because:

- Suitable habitat is available within the botanical analysis area.
- Individual plants have been located within the analysis area during survey efforts.

The Project is **likely to adversely affect** Applegate's milk-vetch because:

- Potential suitable habitat occurs along the proposed route and comprehensive surveys have not been conducted in all areas; therefore it is possible that unidentified plants occur within the proposed construction right-of-way and work space.
- Grazing had occurred prior to surveying one area of potential habitat and plants may be located at that site.

- Unidentified plants could occur within unsurveyed habitat, where landowner denied survey permission.

**Critical Habitat**

Critical habitat has not been designated for Applegate's milk-vetch.

### 4.7.2 Gentner's Fritillary

#### 4.7.2.1 Species Account and Critical Habitat

**Status**

Gentner's fritillary was listed as endangered on December 10, 1999 (FWS, 1999b). The reddish-flowered lily's origin may be a recent hybrid but is considered a valid species. It is found in small, scattered locations in Jackson and Josephine counties in Oregon, with one small population recently discovered in northern California (FWS, 2003d).

**Threats**

A key factor in FWS listing Gentner's fritillary was the present or threatened destruction, modification, or curtailment of its habitat and range. FWS identified residential and utility development and agricultural conversion as the causes for these destroyed locations in its relatively isolated population. At that time, 73 percent of the known plants were in a central core area within a seven-mile radius of the Jacksonville Cemetery. FWS noted that habitat loss due to ongoing or future development might occur at 42 percent of the occupied sites (19 plots—all within the central core area) (FWS, 1999b).

Loss of habitat is still a major threat to Gentner's fritillary. In the species' recovery plan (2003d) FWS identified agricultural, urban and residential development, timber harvest, and recreation as ongoing threats to the very narrow geographic range of the plant. The areas most threatened are on private lands. Habitat conversion due to fire suppression continues to be a problem for the endangered species, as well as weed and non-native plant proliferation, and herbicide use. The plant is endangered by the very structure of its remaining populations, which are scattered, isolated, and small in size and number. These small pockets of the plant are at high risk of decline because they lack reserves to ward off stochastic loss, overutilization for commercial and recreational purposes, diseases, climatic shifts, herbivory, localized natural disturbances, and decrease in genetic diversity (FWS, 1999b and 2003d).

**Species Recovery**

A species recovery plan was released by FWS in 2003 (FWS, 2003d). The objective of the recovery plan is to remove threats to the extent that Gentner's fritillary is no longer in danger of extinction and can be downlisted or delisted. To meet the objective, the plan requires the establishment, management, and maintenance of a minimum of eight *Fritillaria* management areas, with at least two distributed within each of four recovery units described in the recovery plan. The recommended recovery actions are listed below:

- Provide private landowners with information on identification and management of habitat to maintain *Fritillaria gentneri*.
- Establish a minimum of eight *Fritillaria* management areas.
- Conduct surveys and research essential to conservation and recovery.
- Develop off-site germplasm banks to maintain reproductive materials.

- Review and revise recovery plan as needed, based on accumulation of new data.

The plan creates four recovery units for Gentner's fritillary to delineate areas that are considered necessary for the viability and recovery of the plant. The recovery strategies for the units include rehabilitation of habitat, restoration of historical sites, and augmentation of existing populations including expansion into nearby suitable habitat (FWS, 2003d). Recovery units are considered individually necessary to the long-term viability of the species. The proposed pipeline coincides with Recovery Unit 3 in northeastern Jackson County.

**Life History, Habitat Requirements, and Distribution**

Gentner's fritillary is often found in grassland habitats within, or on the edge of dry, mixed forest types where overstory can be dominated by Oregon white oak, madrone, Douglas-fir, and ponderosa pine. It occurs at a wide range of elevations, from 1,000 to 5,100 feet, in the rural foothills of the Rogue River Valley of Josephine and Jackson counties (FWS, 2003d and SBS, 2008b). It is usually associated with shrubs that provide protection from the wind and sun.

The perennial reproduces clonally by means of numerous small bulblets that break off larger bulbs and form new plants. Sexual reproduction appears to be a sporadic or episodic event for the plant, although observations suggest hummingbirds and some species of bees may pollinate the plant. Blooming season usually lasts from April through May, and the plant must reach a minimum size before flowering (FWS, 2003d).

The distribution of Gentner's fritillary is characterized by distinct clusters. The species is highly localized, with the populations occurring within a 30-mile radius of Jacksonville Cemetery in Jacksonville, Oregon, with approximately 45 percent of the plants occurring within an 11-mile radius.

**Population Status**

It is often difficult to census populations of Gentner's fritillary because individuals can remain dormant for one or more years underground and not flower. Also, flowering plants can be grazed by deer or cattle before identification and counting can be performed and sometimes it cannot be distinguished from other non-flowering and co-occurring *Fritilleria* species, such as scarlet fritillary or chocolate lily (FWS, 2003d). In 2001, Gentner's fritillary was estimated at 1,696 flowering individuals in Jackson and Josephine counties, and just south of the border in California (FWS, 2003d). A more recent informal count indicates a total number of about at least 3,000 mature, flowering plants in 109 population sites (SBS, 2008b). Most Gentner's fritillary sites include a small number of individual plants, ranging from one to 450 individual plants (mean of 16 plants). The largest number of plants occurs on BLM lands, with 1,653 counted in 2005 during annual monitoring of 56 known sites (SBS, 2008b). Inventories on other monitored sites counted 940 plants on private lands in Jacksonville (SBS, 2008b) and 424 at Pickett Creek (Thorpe et al., 2006 in SBS, 2008b).

**Critical Habitat**

Critical habitat has not been designated for Gentner's fritillary.

#### 4.7.2.2 Environmental Baseline

**Analysis Area**

A botanical analysis area applies to the extent of pipeline-related effects on listed plant species within a general 400-foot-wide corridor, 200 feet on each side of the proposed Pacific Connector pipeline centerline. That area corresponds to areas that were surveyed for sensitive and listed plant species in 2007, 2008 and 2013. See section 4.7.1.2 above for the full botanical analysis area description.

**Species Presence**

The analysis area crosses the species' range approximately from MP 116.96 through 154.22. Twenty-one sites occur within 10 miles of the proposed route (ORBIC, 2012). The proposed pipeline crosses Gentner's fritillary Recovery Unit 3, which is one of four clusters of fritillary sites proposed for conservation management within the 2003 recovery plan. Populations within Recovery Unit 3 are considered to have low vigor (BLM, 2007 in SBS 2008a). One of the most vigorous plant populations in Recovery Unit 3 is closest to the botanical analysis area, located 1.2 miles southeast of MP 134.4 in the Obenchain Mountain area within the BLM Medford District (Friedman, 2006; ORBIC, 2012; SBS, 2008a). However, recent observations at the site reported 19 plants (the observed population in good vigor) in 2005 but just 1 plant in 2009 with the population rated as poor viability (ORBIC, 2012). Pipe storage yards in Jackson County are located more than 3 miles away from several documented populations in Sam's Valley (Friedman, 2006). None of the previously known sites mentioned above are located within the botanical analysis area but are part of the recovery unit located within the analysis area.

**Habitat Surveyed**

Prior to beginning field surveys in 2007 for the Pacific Connector pipeline, botanists with SBS conducted a habitat review to identify potential habitat and delineate survey areas for Gentner's fritillary within the botanical analysis area, including existing roads identified for access to the construction right-of-way. Aerial photographs from summer, 2005 and knowledge of regional landscape and biological features (soils, geology, topography, elevation, target species habitat, and plant community habitat) were used to determine potential habitat for Gentner's fritillary. The same methods were used to determine potential suitable habitat coinciding with new realignments of the project corridor.

A total of 1,738.1 acres have been identified as potential suitable habitat requiring surveys within the current project alignment and associated 200 foot botanical analysis area (see table 4.7.2-1, and detail below under Jackson County Pipeyards). Of this habitat, 1,495.1 acres were permitted survey access (544.6 acres within the project area). A total of 189.7 acres were surveyed on access roads located outside of the current project alignment and outside the 200-foot wide botanical analysis area. The habitat is located within the Rogue Valley Foothills region, Pacific Connector pipeline MP 116.96 through MP 154.22.

Of the 1,495.1 acres of potential habitat allowed for survey access, 1,231.5 acres (449.9 acres within the project area) were considered suitable habitat for Gentner's fritillary. Habitat suitability was qualitatively assessed based on Gentner's fritillary habitat analysis conducted in Oregon by SBS in 2001. Habitat found to be "suitable" in the surveys included areas with some of the characteristics detailed in the Life History, Habitat Requirements, and Distribution section above (SBS, 2008a).

Approximately 243 acres (73.3 acres within the project area) of potentially suitable habitat for this species was denied access by the landowner and would need to be surveyed prior to construction for complete surveys of this eco-region. If the assumption is made that a similar percent of that area is suitable as documented within the rest of the area surveyed, then approximately 200 acres (82 percent of 243 acres, or 60 acres within the project area) is likely to be suitable fritillary habitat.

**Table 4.7.2-1**

**Summary of Potential Suitable Gentner's Fritillary Habitat within the FEIS-Revised Route and the Botanical Analysis Area.**

| Surveyed Area Type and Years Surveyed | Area (acres) Included | | |
|---|---|---|---|
| | FEIS ROW/ Access Roads | 200-foot Botanical Analysis Area [1] (Outside of ROW) | Total |
| **Area Identified for Survey (Potential Habitat)** | 617.9 | 1120.2 | 1738.1 |
| **Area Surveyed to Protocol** | | | |
| 2007 | 64.4 | 116.6 | 181 |
| 2007 and 2008 | 448.4 | 765.5 | 1213.9 |
| 2008 | 16.5 | 40.7 | 57.2 |
| 2010 and 2011 | 8.9 | 16.3 | 25.2 |
| 2013 | 6.4 | 11.4 | 17.8 |
| **Totals** | **544.6** | **950.5** | **1495.1** |
| **Area of Confirmed Potential Habitat** | | | |
| 2007 | 32.8 | 55.8 | 88.6 |
| 2007 and 2008 | 390.4 | 673.3 | 1063.7 |
| 2008 | 11.4 | 24.8 | 36.2 |
| 2010 and 2011 | 8.9 | 16.3 | 25.2 |
| 2013 | 6.4 | 11.4 | 17.8 |
| **Totals** | **449.9** | **781.6** | **1231.5** |
| **Area not Surveyed (access/ early grazing/ reroute / storage yards)** | **73.3** | **169.7** | **243.0** |

**Note:**
[1] The botanical analysis area applies to the extent of pipeline-related effects on listed plant species within a general 400-foot-wide corridor, 200 feet on each side of the proposed Pacific Connector pipeline centerline.

<u>Pacific Connector Gentner's Fritillary Surveys</u>

Two years of surveys are advised to conduct a complete survey for and detect Gentner's fritillary because mature plants do not flower every year and the basal leaves are identical to scarlet fritillary, a species with no special status. Five sites were located during survyes conducted from 2008 to 2013 (table 4.7.2-2).

During the first year of surveys from April 13 to April 30, 2007, surveys were conducted on 181 acres of the current proposed alignment's botanical analysis area (64.4 acres within the project area). No plants were found.

During 2008 (including resurveying the 2007 areas) surveys on 1,213.9 acres (448.4 acres within the current project alignment) between April 26 and May 20, this Gentner's fritillary was located at three sites. One Gentner's fritillary plant was located approximately 0.38 mile north of MP

128.05 near Indian Creek and 50 feet below a four-wheel drive road proposed for access to the construction right-of-way (EAR 128.05 north of the proposed construction right-of-way).

Two additional medium-sized fritillary species (*Fritillaria* sp.) leaves were located nearby at MP 128.1. Unless flowering, however, it is difficult to identify the leave as those of Gentner's fritillary. A second site was approximately one mile west of MP 128.8 which was discovered during surveys of an existing access road (EAR 128.05 south of the proposed construction right-of-way) approximately 100 feet from the access road. This population consists of four individual plants located in a 20 meter area just above the high water line of Indian Creek and no other leaves were located. The third site supported a flowering Gentner's fritillary plant (with no leaves) located near MP 142.10 just within a TEWA (TEWA 142.07-N).

There were additional fritillary species (*Fritillaria* sp.) with leaves located within 150 feet of the flowering site within TEWA 142.07-N and construction right-of-way, as well as two other flowering fritillary species (scarlett fritillary and chocolate lily). It is possible that some of the leaves located within this area could be Gentner's fritillary and therefore a larger area that includes all the leaves encountered in 2008 is considered part of the population area (approximately 0.83 acres) (see figure 4.7-2).

In spring 2011, a single plant was identified outside of the project corridor, but witin the 200-foot botanical analysis area at MP 128.1. In 2013, 23.2 acres were surveyed between MPs 128.8 and 129.4. One plant location was recorded at MP 129, outside of the TEWA, but within the 200-foot botanical analysis area.

The five sites identified within the botanical analysis area are 0.4 to 11.2 miles from each other and therefore are not considered a "population center" by the recovery plan definition (four or more locations occur within 0.3-mile of each other – FWS, 2003d). Also, these sites are about six aerial miles from other known sites and therefore could not be considered part of those population centers. However, it might be considered that these sites are part of a deme within Recovery Unit 3 – "a scattered population of individuals with the potential to exchange genetic material on occasion", because the documented sites are within 9.3 miles of other identified populations, a maximum distance that distribution of plant clusters has been documented (FWS, 2003d).

**Table 4.7.2-2**

**Summary of Gentner's Fritillary Locations**.

| Milepost | Year Located | Site Description |
|---|---|---|
| 128.05 and 128.1 | 2008 | On Indian Creek access road, 50' below road; nearby site recorded non-flowering plants. |
| 128.1 | 2011 | Located 46' from TEWA 128.01-W. Out of ROW but within 200'vegetation buffer. |
| 128.8 | 2008 | Located 100 feet from proposed access road EAR-128.05. |
| 129.1 | 2013 | Out of ROW but within 200'vegetation buffer. |
| 142.1 | 2008 | Flowering plant located within TEWA 142.07-N. |

### Critical Habitat

Critical habitat has not been designated for Gentner's fritillary.

### 4.7.2.3 Effects by the Proposed Action

### Direct and Indirect Effects

Five new Gentner's fritillary locations (eight plants total) were identified within the PCGP Project area during surveys conducted between spring 2008 and 2013. Since only five sites of this species have been located by Pacific Connector within Recovery Unit 3, and total individual plants for this species are relatively low (a reason for federal listing), any loss of plants would be significant.

No direct effects are expected at sites located 50 and 100 feet from a proposed existing access road (MPs 128.05 and 128.10), or at the two sites located within the 200 foot botany zone but outside of the project corridor at MP 128.1 and MP 129.1. The site at MP 128.8 is located 100 feet from an access road. At the other site, SBS documented one flowering Gentner's fritillary plant and several other *Fritillaria* sp. leaves within TEWA 142.07-N and construction right-of-way. Because this site consists of a single plant or perhaps a small cluster of plants, it is more vulnerable to extirpation due to even small-scale losses of habitat or plants (FWS, 2003d). Pacific Connector met with several members of the Habitat Quality Subtask Group on July 24, 2008 to discuss impacts to the documented plant(s) and provide recommendations of how to avoid or minimize impact to these plants (see July 24, 2008 meeting minutes). Participants of this meeting recommended that no direct impacts occur to this site. In response to recommendations and discussions, Pacific Connector has determined that a minor route adjustment of the proposed alignment is feasible to avoid the identified potential Gentner's fritillary sub-population, including the unidentified *Fritilleria* sp. leaves. Also, Pacific Connector removed a portion of TEWA 142.07-N that would directly impact the flowering Gentner's fritillary plant. The revised proposed route avoids removal of the documented plants and *Fritilleria* sp. leaves, and as a result, no direct impact to individual plants documented during surveys is expected (see figure 4.7-2). Pacific Connector anticipates conducting additional surveys of this area to verify species and/or locate additional *Fritilleria* sp.

Since Gentner's fritillary does not flower every year and remains dormant underground for one or more years, it is very possible that not all plants within the suitable habitat in the PCGP Project area were documented during the 2-year survey effort. Therefore, there is a good likelihood that construction activity within identified suitable habitat could remove individual plants, resulting in a direct impact to this species.

Approximately 618 acres (table 4.7.2-1) of suitable or potentially suitable (unsurveyed) habitat between MP 117.0 and 154.2 would be disturbed (removed/modified) by construction of the proposed pipeline resulting in an indirect impact to Gentner's fritillary. Indirect impacts are likely to include: 1) changes in hydrology and soil characteristics, 2) an increase in invasive weeds, 3) alterations of vegetation cover and species composition. Such alterations in suitable habitat would likely cause an increase in weedy grasses and forbs. Competition from invasive weeds may limit the establishment and recovery of Gentner's fritillary (FWS, 2003d); however, the impacted habitat in the analysis area represents a very small percentage of total suitable habitat in the species' range (SBS, 2008b), and so disturbance to the habitat should not impede recovery of the species. To control the potential noxious weed invasion, Pacific Connector would implement the procedures outlined in their Noxious Weed Control Plan (section 12.0) provided in the ECRP (see appendix F).

Operation and maintenance of the proposed pipeline would occur within suitable Gentner's fritillary habitat. Vegetation within the 30-foot operational corridor would be periodically maintained using mowing, cutting, trimming, and herbicides (selectively). Maintenance activities are expected to occur approximately every 3 to 5 years depending on growth rate. However, these activities should not have an adverse affect on Gentner's fritillary because maintenance activities, if necessary, would occur after the critical growing and flowering season. If noxious weed infestation occurs within the permanent easement, selective use of herbicides or mechanical treatments would be used to control weed within proximity to the species. Pacific Connector's protection procedures are outlined in the Noxious Weed Control Plan (Section 12.0 in the ECRP - appendix F).

**Cumulative Effects**

ESA plant species do not have federal protection in Oregon on private lands except in instances where a federal permit is required or a federal action occurs. Outside of the surveyed area for the Pacific Connector pipeline, it is unknown where Gentner's fritillary occurs on private lands throughout the action area. Therefore, it is impossible to determine if there are reasonably foreseeable actions which might occur on private lands, which could impact the plant. Given the lack of protections under ESA and Oregon statutes, all federally listed plants on private lands must be considered at risk of adverse effects, wherever they may occur. However, the Pacific Connector pipeline would mitigate for any Project impacts to Gentner's fritillary.

**Critical Habitat**

No critical habitat would be impacted by the proposed action. Critical habitat has not been designated for Gentner's fritillary.

### 4.7.2.4 Conservation Measures

The objective within each established recovery unit is to have at least 750 flowering plants to downgrade its status to threatened or 1,000 plants to delist the species, monitored biannually for at least 15 years. This recovery unit total may consist of many management areas within each recovery unit, including management areas as small as five flowering plants. Maintaining the subpopulations or population clusters within each recovery unit is important to preserve the genetic diversity within the species, ensure its long-term viability, and reduce the vulnerability of the species to extirpation from random catastrophic events (FWS, 2003d). To avoid all direct impact to the flowering plant documented in 2008 within the FERC-filed route, Pacific Connector has modified TEWA 142.07-N (see figure 4.7-2). To reduce the possibility of eliminating a genetic source of Gentner's fritillary within Recovery Unit 3, Pacific Connector has identified a feasible route to avoid the unidentified *Fritillaria* sp. leaves located within TEWA 142.07. Pacific Connector will conduct additional surveys to verify *Fritilleria* sp., as well as identify any additional flowering plants or *Fritilleria* sp. leaves that should be considered within a route adjustment, prior to consulting with the private landowner regarding a minor route adjustment.

Pacific Connector assumes the potential habitat identified for Gentner's fritillary (surveyed and not surveyed) would be accessible prior to construction of the pipeline. When Pacific Connector acquires access to the construction right-of-way, surveys would be conducted in potential habitat and plants located during surveys would be avoided, if feasible. FWS would be notified of survey results and, if present, the avoidance/conservation measures (including compensatory mitigation) to be taken would be discussed with FWS staff. Measures of avoidance may include necking down the construction right-of-way in that area, excluding a portion of an identified TEWA or pipe storage yard, or erecting a protective fence to avoid impact to plants from construction debris. If it is determined that avoidance is not possible, propagation of collected bulblets followed by offsite cultivation for population augmentation could be a viable conservation measure (SBS, 2008a). This procedure might include (SBS, 2008a):

- identification and tagging plants for propagation during spring flowering (April in lower elevation, May in higher elevations);
- collection of bulblets during dormant season (late summer to fall-August through November);
- cultivation of bulblets off-site; or
- replanting of grown-out bulbs in subsequent years' dormant season.

Transplanting mature, dormant whole bulbs is another possible conservation measure. However, because recent propagation work has focused on augmenting populations, as opposed to moving plants to avoid disturbance, success with transplanting bulbs is not known. Based on that work, it appears reasonable to similarly identify and tag mature plants in the spring, then move and plant the mature bulbs in the fall in suitable habitat nearby. In this scenario, bulbs might need to be stored after the fall bulb harvest and construction disturbance period until the replanting period in the fall of the following year (SBS, 2008a). The associated small bulblets could be grown out to further enhance the recovery site. A conservation easement could be established to compensate for lost habitat and tied to potential transplant projects regardless of whether plants were found in the construction right-of-way or not.

Although the seed of some fritillaries appears to germinate quite easily, germination of seed collected from Gentner's fritillary has rarely been documented. Difficulties in collecting an adequate supply of viable seed, combined with potentially poor germination and seedling survival, currently make propagation from seed a poor method for creating transplants. Attempts to germinate seed at Berry Botanic Garden were not successful, and no reports of germination exist in the available horticultural literature (SBS, 2008b).

Replanting of an area adjacent to the disturbance zone is possible with the propagation techniques discussed above. Replanting adjacent areas of undisturbed areas (with cultivated bulbs or simply moving mature bulbs) requires identification of suitable Gentner's fritillary habitat. Transplanting mature bulbs requires no time for growing out plants, but would require storage of the mature bulbs during construction (i.e. between harvesting in late summer/fall year one, and replanting the following year during late summer/fall). Harvesting of rice-grain bulblets requires additional time to grow out the rice-grain bulblets to sizable plants. Both techniques require harvesting and replanting bulbs in the late summer/fall season, during the dormant season.

For each Gentner's fritillary potential population to be disturbed, the choice of suitable habitat for proposed re-establishment requires consideration of: 1) the proximity of mother plant location to the re-establishment area, 2) the proximity of the established Gentner's fritillary populations within Recovery Unit 3, 3) the proximity and number of individual plants in the closest Gentner's fritillary Management Unit of Recovery Unit 3, 4) the ownership status of the re-establishment location; 5) the quality of the habitat in the proposed reestablishment area, i.e. site characteristics such as level of habitat disturbance, soils, topography, aspect, slope, plant community/vegetation, and weed infestation.

Additionally, about 60 percent of the construction right-of-way that was formerly considered as suitable habitat could be returned to and maintained as suitable habitat through the planting of associated compatible native species, with monitoring for and control of invasive species.

Invasive weed species could affect the existence, establishment, or recovery of Gentner's fritillary. Pacific Connector would monitor and control invasive weed species within the permanent right-of-way; however, some herbicidal treatment of invasive weed species could pose a threat to this species depending on the season of use and type of herbicide used. To minimize impacts to this species, Pacific Connector would either use a dicot-specific herbicide or general herbicide outside of the growing season of Gentner's fritillary. If treatment is necessary within the growing season, Pacific Connector would use triclopyr, a chemical that has little effect on grasses and other monocots including Gentner's fritillary (FWS, 2003d). For more details on the control of potential noxious weed invasions, Pacific Connector's protection procedures are outlined in the Noxious Weed Control Plan in Section 12.0 in the ECRP (see appendix F).

**Mitigation**

Additional mitigation measures for individual Gentner's fritillary plants, if identified within the unsurveyed portions of the proposed route, would be addressed through the Gentner's Fritillary Mitigation Plan (see Appendix O).

In addition, Pacific Connector has agreed to fund a BLM mitigation proposal for *Fritillaria gentneri* to compensate for potential threats to *Fritillaria gentneri* populations located on BLM lands and for potential impacts to non-flowering plants along the pipeline route (see Appendix O – Attachment 1). The BLM mitigation would include augmenting sites at a secure location as a recovery action towards downlisting or delisting the species. The Cobleigh Road *Fritillaria gentneri* ACEC site was proposed as an ACEC for protection and recovery of *Fritillaria gentneri*. This site lies within Recovery Area 3, which includes other populations located along the pipeline route. The ACEC contains more than a dozen documented *Fritillaria gentneri* populations across 1,146 acres. Flowering plant counts in this recovery unit have never reached 750 for downlisting or 1,000 for delisting, but the BLM and Oregon Department of Agriculture are currently using the area for bulb collection and outplanting.

Augmentation would include bulb collection and outplanting. The proposed restoration project would consist of collecting bulblets from existing populations, increasing bulblet numbers to 2,000 through propagation in the greenhouse, planting the bulblets at 4 different locations with 500 bulblets at each site, and monitoring the bulblets for three years. The BLM would add funding to an existing Assistance Agreement with the Oregon Department of Agriculture to conduct the augmentation activities.

### 4.7.2.5 Determination of Effects

**Listed Species**

The Project **may affect** Gentner's fritillary because:

- Suitable habitat is available within the analysis area.
- Individual plants have been located within the analysis area during survey efforts.

The Project is **likely to adversely affect** Gentner's fritillary because:

- Not all potential suitable habitat was surveyed due to landowner access denial.
- Gentner's fritillary does not flower every year, and has been documented to not flower for several years; therefore, it is possible that the two years of surveys conducted for this flower did not locate this species.
- *Fritillaria* sp. leaves were documented within and adjacent to the proposed project and without flowers, it is nearly impossible to determine if those leaves belong to Gentner's fritillary or another *Fritillaria* species.

**Critical Habitat**

Critical habitat has not been designated for Gentner's fritillary.

### 4.7.3 Large-Flowered Woolly Meadowfoam

#### 4.7.3.1 Species Account and Critical Habitat

**Status**

The large-flowered woolly meadowfoam was listed as endangered on November 7, 2002 (FWS 2002d). A recovery plan was developed (FWS, 2012i) for vernal pool species within the Rogue River Valley that are federally listed or have federal species of concern designation, including large-flowered woolly meadowfoam.

**Threats**

A major factor in FWS listing the large-flowered woolly meadowfoam was the present or threatened destruction, modification, or curtailment of its habitat and range. Due to recent rapid population increases in the region, the primary threats to the plant's habitat and range in the Agate Desert (Jackson County, Oregon) are industrial, commercial, and residential development and their residual road and utility construction and maintenance (FWS, 2011e). These important residual impacts include mowing, herbicide use, firebreak construction, and hydrologic alteration (mostly for agriculture).

Grazing can have a mixed effect on large-flowered wooly meadowfoam. The effect of grazing on suitable habitat depends on how the grazing is managed. There are various reports showing how grazing practices can positively or negatively affect native plant species' richness (Marty 2005). Marty's (2005) study indicates that wet season grazing resulted in a decrease of native forb species at vernal pool edge habitat, but year-round grazing actually improved species' richness.

Although disease (fungus), herbivory, and the meadowfoam fly (*Scaptomyza apicalis)* have been identified as potential problems, no data other than casual observations exist to suggest that these factors pose a substantial threat to the species at this point in time (FWS, 2012i).

Because of the enduring population and development pressures on the species' limited habitat and range, it is presumed that the final rule factors in determining its endangered status remain as significant ongoing threats to the species.

**Species Recovery**

The Recovery Plan for Rogue and Illinois Valley Vernal Pool and and Wet Meadow Ecosystems (FWS, 2012i) identifies nine core areas for protection in the Rogue Valley. The recovery plan addresses large-flowered woolly meadowfoam, Cook's lomatium, and vernal pool fairy shrimp, as well as six plant species of concern and the hairy water flea. Approximately 98 percent of known large-flowered woolly meadowfoam populations occur on designated critical habitat for the vernal pool fairy shrimp (FWS, 2006g). The recovery objectives for the large-flowered woolly meadowfoam include:

- Stabilize and protect populations of the the listed species in core areas so further decline in species's status and range are prevented.
- Minimize or eliminate the threats that caused the species to be listed, and any other newly identified threats, in order to be able to delist the species.
- Conduct research necessary to refine downlisting and recovery criteria.
- Ensure long-term conservation.
- Promote natural ecosystem processes and functions by protecting and conserving, in identified core areas, intact vernal pool-mounded prairie complexes and seasonally wet serpentine-derived grassland meadows, sloped mixed-conifer forest openings, and shrub dominated plant communities within the recovery planning area.

Delisting criteria specific to large-flowered woolly meadowfoam:

- At least 17 of 18 occurrences for large-flowered woolly meadowfoam (approximately 95 percent of documented/extant occurrences) should be protected in conservation oriented ownership (i.e., land that is formally secured from habitat loss and degradation by way of conservation easements, formal agreements, conservation banks, or public or conservation group ownership). For occurrences that have become extirpated, reintroduced or introduced populations may be substituted. Introduced or newly discovered populations outside of currently known core areas may be substituted if the FWS deems them equivalent in their contribution to recovery.
- At least 95 percent of suitable vernal pool habitat acreage within each Priority 1 core area for the species and at least 90 percent of suitable vernal pool habitat acreage within each Priority 2 core area for the species has been protected from development. All suitable habitat must include soils and hydrology that support the plant species.
- Conservation oriented management plans for each protected core area are developed to guide protection and conservation following establishment of protected status such as a conservation easement or transfer of ownership to land trusts or government entities. Each management plan should be operational as soon as possible, as funding and staff time allow.
- Additional species occurrences identified through future site assessments, GIS, other analyses, or status surveys, and that are determined essential to recovery, are protected. Status surveys, 5-year status reviews, and population monitoring show achievement of self-sustaining species populations as confirmed through species monitoring and status surveys in each protected occurrence.
- Seeds from each core area of the two species are in storage as insurance against the risk of extirpations and to ensure that genetic lines are preserved. Seed banking is also necessary in order to complete the reintroductions or introductions that can contribute to meeting recovery criteria.

**Life History, Habitat Requirements, and Distribution**

The large-flowered woolly meadowfoam is an annual herb endemic to the Agate Desert area in southern Oregon. It grows on the wetter, inner edges of vernal pools mostly in the Rogue River Valley. Vernal pool-mounded prairie habitats sustain wet soils needed for growth and flowering, and the shallow pools provide for nutlet dispersal during the annual's relatively short life cycle (FWS 2006g). The plant is capable of self-fertilization and self-pollination. Flowering occurs between March and May, with flowers producing nutlets. These nutlets may be dispersed by water, normally only short distances. Thus, it is likely that they do not disperse beyond their pool or swale of origin.

Large-flowered woolly meadowfoam occupies a limited portion of the Rogue Valley. The plant typically occurs in areas mapped with Agate-Winlo soils (FWS, 2012i). There are no significant ecological, genetic, or geographic barriers separating the 21 extant and historical large-flowered woolly meadowfoam occurrences, apart from agricultural and rural development and road systems. All known populations of large-flowered woolly meadowfoam comprise approximately 177 hectares (440 acres), and are grouped into nine core areas that are separated by at least 1 kilometer (0.7 miles). In the Rogue River Valley, large-flowered woolly meadowfoam is found in the same vernal pool habitats as Cook's lomatium and the vernal pool fairy shrimp.

**Population Status**

At the time of listing in 2002, there were 15 known occurrences of large-flowered woolly meadowfoam. At the time of the release of the Draft Recovery Plan in 2006, 22 occurrences were known. Currently, 23 occurrences are known (FWS, 2011e). Portions of 12 occur on public lands, on conservation easements, or on lands managed by The Nature Conservancy (FWS, 2009d) and thus are protected from development. The population of this species fluctuates annually depending on precipitation and temperature, and so fluctuating populations at the various sites of occurrence have a broad range of approximately 100 to 100,000 (FWS 2006g).

**Critical Habitat**

Critical habitat was designated on July 21, 2010, including eight critical habitat units in Jackson County totaling 2,363 hectares (5,840 acres) (FWS, 2010e). The primary constituent elements for large-flowered woolly meadowfoam critical habitat include:

1) Vernal pools or ephemeral wetlands and the adjacent upland margins of these depressions that hold water for a sufficient length of time to sustain large-flowered woolly meadowfoam, growth, and reproduction, between elevations of 1,220 to 1,540 feet, a minimum of 20 acres, and associated with specific dominant native plants (FWS, 2010e).
2) The hydrologically and ecologically functional system of interconnected pools, ephemeral wetlands, or depressions within a matrix of surrounding uplands that together form vernal pool complexes within the greater watershed.
3) Silt, loam, and clay soils that are of alluvial origin, with a 0 to 3 percent slope, primarily classified as Agate– Winlo complex soils, but also including Coker clay, Carney clay, Provig–Agate complex soils, and Winlo very gravelly loam soils.
4) No or negligible presence of competitive, nonnative, invasive plant species.

Eight critical habitat units have been designated for the large-flowered woolly meadowfoam in Jackson County, of which two units are shared by the designated critical habitat for Cook's lomatium (White City and Whetstone Creek, see below). Critical habitat units RV6 and RV8 are within the vicinity of White City, Oregon, where five proposed pipe storage yards for the PCGP Project are located.

#### 4.7.3.2 Environmental Baseline

##### Analysis Area

A botanical analysis area applies to the extent of Project-related effects on listed plant species within a general 400-foot-wide corridor, 200 feet on each side of the proposed Pacific Connector pipeline centerline. That area corresponds to areas that were surveyed for sensitive and listed plant species in 2007 and 2008. The botanical analysis area also applies to known or potential habitats for endemic vernal pool obligate species. Effects by the Project to vernal pool obligates could extend 200 feet from the perimeter of five proposed pipeyard storage areas that are located within the Vernal Pool Complex – Agate Desert, Jackson County, Oregon and shown in figure 4.6-1 under Vernal Pool Fairy Shrimp, above.

##### Species Presence

There are multiple historical records of large-flowered woolly meadowfoam within the Shady Cove-Rogue River watershed – HUC 1710030707 (ORBIC, 2012) through which the proposed pipeline passes for approximately 8.4 miles, from MP 121.77 to MP 130.15. The closest record is a population with poor viability, last observed in 1982 approximately 3.6 miles southwest of the proposed route. Other, more distant populations were extant in the 1980's and 1990's but also rated with poor viability by ORBIC (2012). Populations in the watershed that were found and evaluated within the past fifteen years were rated with excellent viability but those are more than 6 miles from the proposed route.

Five pipe storage yards have been proposed within the range of large-flowered woolly meadowfoam in the Agate Desert in Jackson County. Two of the proposed pipe storage yards (Burrill Lumber and Medford Industrial Park) are adjacent or in close proximity to four critical habitat subunits RV6A, RV6B, RV6C, and RV6D where nine sites of large-flowered woolly meadowfoam have been previously documented (Friedman, 2006). Two other proposed storage yards (Oregon Opportunities and Ave F and 11$^{th}$ St.) are located within 0.5 mile of critical habitat subunits RV6A and RV6B. The known large-flowered woolly meadowfoam sites range from 200 feet to 2,880 feet from the proposed pipe storage yards. The closest known large-flowered woolly meadowfoam sites to Rogue Aggregates pipe storage yard are greater than 1.5 miles away.

Pacific Connector Large-flowered Woolly Meadowfoam Surveys

SBS conducted surveys for large-flowered woolly meadowfoam at three of the five potential pipe storage yards where survey permission was granted: Burrill Lumber, Rogue Aggregates, and Medford Industrial Park (SBS, 2008a). No plants were located within the three proposed pipe storage yards.

Two other areas were surveyed for large-flowered woolly meadowfoam: one 65-acre taxlot (Maplot #361W17600) adjacent to the proposed 64.1-acre Burrill Lumber Yard that contained five acres of high quality (and one acre of low quality vernal pool habitat over 900 feet from proposed Burrill Lumber Yard), and 24 acres of suitable vernal pool habitat located on the Avenue C and 7$^{th}$ Street/Elite Cabinet & Doors Yard that includes disturbed seasonally saturated or seasonal wetland habitat that has been filled and graded in the past (SBS, 2008a). On the 65-

acre taxlot, four small patches (36 plants) of large-flowered woolly meadowfoam were found more than 900 feet northeast of the Burrill Lumber proposed storage yard. Three patches occur on the edges of vernal pools in a quarter-acre area in an undisturbed corner of the property, and one patch is 400 feet to the south, outside of the vernal pool area in a heavily modified swale (SBS, 2008a). The site is located on a portion of the property that has not been heavily modified (SBS, 2007; see figure 4.6-1). The plants located are suspected to be part of a larger large-flowered woolly meadowfoam population located to the east within critical habitat subunit RV6D. Since discovery of the plants, Pacific Connector is not considering the 65 acre taxlot (Maplot #361W17600) for use as a pipe storage yard.

Two other proposed yards, Avenue F and 11th Street and Oregon Opportunities, have not been surveyed due to landowner denial. Initial reviews of habitat via aerial photography and "drive-by" have identified approximately five acres of potential low quality vernal pool habitat on the margins of both of these yards. It is expected that once surveyed, this habitat would be determined not suitable for large-flowered woolly meadowfoam.

### Habitat

None of the the 257.5 acres identified as potentially suitable large-flowered woolly meadowfoam habitat surveyd by SBS in the three pipe storage yards (Burrill Lumber, Medford Industrial Park, and Rogue Aggregates) was considered suitable for large-flowered woolly meadowfoam (table 4.7.3-1).

**Table 4.7.3-1**

**Summary of Potential Habitat and Survey Status for Large-Flowered Woolly Meadowfoam**

| Surveyed Area | Area (acres) Included | | |
|---|---|---|---|
| | FEIS ROW/ Access Roads | 200-foot Botanical Analysis Area [1] (Outside of ROW) | Total |
| **Area of Potential Habitat** (Jackson County Pipe Storage Yards) | 262.4 | 0 | **262.4** |
| **Area of Known Suitable Habitat** (known from surveys) | 0 | 0 | **0** |
| **Areas Surveyed to Protocol** (proposed route) | 257.5 | 0 | **257.5** |
| **Area Not Surveyed** (access denied) | 4.9 | 0 | **4.9** |

**Note:**
[1] The botanical analysis area applies to the extent of pipeline-related effects on listed plant species within a general 400-foot-wide corridor, 200 feet on each side of the proposed Pacific Connector pipeline centerline.

Suitable and occupied large-flowered woolly meadowfoam habitat also exists within proposed critical habitat subunits adjacent or in proximity to the Burrill Lumber and Medford Industrial Park pipe storage yards (see critical habitat discussion, below).

### Critical Habitat

Two of the eight designated critical habitat units for large-flowered woolly meadowfoam are within the vicinity of five proposed pipe storage yards: RV6, which consists of 8 subunits and is approximately 1,829 acres, and RV8 that is approximately 850 acres. Both consist of intact vernal pool-mounded prairie and swale habitats (FWS, 2010b). Four of eight RV6 subunits – RV6A, RV6B, RV6C, and RV6D – are near or adjacent to proposed yards. RV8 is over 1.4 miles from the closest pipe storage yard, and is located between the proposed Rogue Aggregates and the other four pipe storage yards (see figure 4.6-1). Except for subunit RV6D, the other RV6 subunits and RV8 unit coincide with designated critical habitat for vernal pool fairy shrimp: VERFS 3A, 3B, and 3C.

#### 4.7.3.3 Effects by the Proposed Action

**Direct and Indirect Effects**

Possible direct effects to large-flowered woolly meadowfoam include possible disturbance to pools from driving or storing equipment or pipes near or on pools or wetlands with this species. The proposed action in pipe storage yards near vernal pool habitats would occur on lands where past heavy industrial uses, soil grading, and compaction have occurred. Surveys conducted for the proposed project has not identified any plants or suitable habitat for the large-flowered woolly meadowfoam. Also, proposed pipe storage yards that have not been surveyed to-date but have been evaluated by other means (including Avenue F and 11th Street and Oregon Opportunities yards) are not expected to contain suitable habitat for this species. If future surveys identify potential suitable habitat or large-flowered woolly meadowfoam plants within the two unsurveyed pipe storage yards, Pacific Connector would avoid using the portion of the pipe storage yard, similar to actions taken within the 65-acre taxlot adjacent to Burrill Lumber Yard with 5 acres of high quality suitable vernal pool habitat, and pipe storage yard Avenue C and 7th Street that had 24 acres of lower quality vernal pool habitat. No direct effects to large-flowered woolly meadowfoam or their potential habitat within pipe storage yards are expected.

Indirect effects to large-flowered woolly meadowfoam and their habitat could occur with increased road use to access the pipe storage yards that are adjacent or in the vicinity of suitable or potentially suitable habitat. Increased road use and the associated dust created might impact vernal pool habitat as dust settles, affecting vegetation and vernal pool physical or chemical properties (pH, water quality, turbidity, sedimentation, temperature). Project use of pipe storage yards (i.e., potential soil compaction from heavy equipment use) adjacent to, or in the vicinity of suitable or potentially suitable habitat, may indirectly affect hydrology upon which vernal pools and associated vegetation are dependent. Indirect effects to hydrology could be expected within 527 feet (the radius of a 20 acre circle) of suitable or potentially suitable vernal pool habitat since at least 20 acres of habitat is considered essential for intact hydrology (see primary constituent element discussion for large-flowered woolly meadowfoam and Cook's lomatium – FWS, 2010a). Effects could include altering hydrologic processes, such as runoff patterns as a result of soil compaction, as well as increased seeding of non-native invasive plant species (PCEs 1 and 4). However, any potential compaction that may occur at the yard would likely be insignificant because of the previous industrial use, soil grading and compaction, and implementation of the Noxious Weed Control Plan (section 12.0) provided in the ECRP (see appendix F) would reduce spread of noxious species.

Thirty-six large-flowered woolly meadowfoam plants were documented during surveys in 2007 over 900 feet from proposed pipe storage yard Burrill Lumber in the northeast corner of an adjacent 65-acre taxlot (Maplot #361W17600). However, indirect impacts to these plants and their habitat, including hydrology, is not expected to occur from activities associated with the proposed Burrill Lumber Yard because the yard is located over 900 feet from the vernal pool habitat and the large-flowered woolly meadowfoam plants located in the northeast corner of the adjacent taxlot (Maplot #361W17600).

Indirect impacts to suitable and occupied habitat located within the critical habitat units adjacent to or in the proximity of the Burrill Lumber and Medford Industrial Park pipe storage yards is possible, and discussed further in the critical habitat section, below.

**Cumulative Effects**

ESA plant species do not have federal protection in Oregon on private lands except in instances where a federal permit is required or a federal action occurs. Outside of the surveyed area for the Pacific Connector pipeline, it is unknown where large-flowered woolly meadowfoam occurs on private lands throughout the action area. Therefore, it is impossible to determine if there are reasonably foreseeable actions which might occur on private lands, which could impact the plant. Given the lack of protections under ESA and Oregon statutes, all federally listed plants on private lands must be considered at risk of adverse effects, where ever they may occur. However, the Pacific Connector pipeline would mitigate for any Project impacts to large-flowered woolly meadowfoam.

**Critical Habitat**

Large-flowered woolly meadowfoam is dependent on vernal pool or ephemeral wetland complexes, including upland hydrological features, that provide enough water for a sufficient length of time in the winter months to allow meadowfoam to germinate, grow, and reproduce. Vernal pool complexes that this species are dependent on have been threatened by residential, urban, and commercial development, agricultural development, road construction and maintenance, aggregate mining, incompatible grazing practices, off-road vehicle use, vandalism, encroachment by nonnative plants, and herbivory by gophers and voles. Such threats can 1) cause damage to the clay pan layer and allow moisture to drain from the vernal pools or wet meadow habitats that the plants depend upon for reproduction and survival, 2) alter hydrology, or 3) introduce nonnative plants that can outcompete and displace native plant species and may inhibit successful germination of seeds (FWS, 2010e). To protect biological and physical features the meadowfoam depends on, FWS (2010e) has designated eight critical habitat units for this species, of which two units (RV6 and RV8) are within the vicinity of five proposed storage yards in Jackson County, Oregon.

Three of the designated critical habitat subunits, RV6A, RV6B, and RV6C are adjacent to Burrill Lumber and Medford Industrial Park pipe storage yards. Although designated critical habitat lies adjacent to the proposed pipe storage yards, no direct impacts from the proposed action are anticipated since equipment and pipe storage would not occur near or on pools or wetlands located in the critical habitat subunits, nor would traffic to and from the pipe storage yards drive near or on pools within the critical habitat units. Additionally, nine plant sites previously located in areas proposed as critical habitat units RV6B and RV6C are at least 200 feet from the proposed storage yards (Friedman, 2006), so no direct impact to those plant sites are expected. Another subunit, RV6D is located approximately 900 feet north of Burrill Lumber pipe storage yard where survey efforts in 2007 located large-flowered woolly meadowfoam. Previous surveys had also documented plant sites north of this storage yard. Direct effects to critical habitat subunit RV6D are not expected.

Possible indirect effects to the designated critical habitat units in the vicinity of the six pipe storage yards may occur as a result of increased road use to access the pipe storage yards that are adjacent to the critical habitat units (Avenues C, F, G, and Antelope and Agate Roads) and use of Medford Industrial Park pipe storage yard that is directly adjacent to critical habitat subunit RV6B. Increased road use and the associated dust created might impact large-flowered woolly meadowfoam critical habitat as dust settles, affecting associated vegetation and vernal pool physical or chemical properties (pH, water quality, turbidity, sedimentation, and temperature). Primary constituent element 1 specifies that at least 20 acres are essential for intact hydrology. A circle with an area of 20 acres has a radius of 527 feet. Indirect impact to critical habitat units adjacent to pipe storage yards may be expected by actions affecting hydrology at least 527 feet away. Use of the Medford Industrial Park yard that includes ground disturbance such as soil compaction by heavy machinery may alter hydrology in vernal pools in critical habitat unit RV6B, possibly affecting the frequency or amount of water in adjacent vernal pools, or altering the upland hydrology upon which vernal pools and associated vegetation are dependent. Additionally, use of the roads adjacent to the critical habitat units and the pipe storage yards, themselves, may increase the introduction of non-native, weedy species. Primary constituent element 4 specifies that no or negligible presence of competitive nonnative invasive plant species be present for the continued survival and recovery of large-flowered woolly meadowfoam.

Critical habitat unit RV8 is located greater than 1.4 miles from proposed pipe storage yards in Jackson County. The project is not expected to directly or indirectly affect this critical habitat unit.

Applying conservation measures identified below, the use/alteration/restoration of pipe storage yards should not result in modifications in the timing, duration, magnitude, or quality of hydrological connections to an off-site vernal pool and/or federally-listed vernal-pool obligate species. Additionally, measures taken to minimize the introduction and spread of noxious weeds outlined in the ECRP and Project's compensatory mitigation plan would ensure that competition from nonnative species in adjacent critical habitat units remains negligible.

#### 4.7.3.4 Conservation Measures

Pacific Connector would not use the 65-acre taxlot (Maplot #361W17600) which was surveyed adjacent to the Burrill Lumber Yard and contains five acres of high quality and one acre of low quality vernal pool habitat where large-flowered woolly meadowfoam plants were identified during survey efforts.

Once Pacific Connector has determined if Oregon Opportunities and Avenue F and 11th Street pipe storage yards would be used for storage of pipe for the Pacific Connector pipeline and is granted permission to survey those yards through the FERC Certificate process, surveys for large-flowered woolly meadowfoam will be conducted within the 1.9 acres of potential low quality vernal pool habitat. Pacific Connector would not use portions of those proposed pipe storage yards if large-flowered woolly meadowfoam plants or highly suitable habitat is identified, similar to actions taken for the pipe storage yards no longer considered (the 65-acre property adjacent to Burrill Lumber yard).

Pacific Connector would implement proper sedimentation control barriers (FWS 2005d) to minimize potential impacts to identified large-flowered woolly meadowfoam plants and highly suitable habitat. Additional mitigation measures for large-flowered woolly meadowfoam, if identified, are addressed through the Compensatory Mitigation Plan. Such measures could include application of Integrated Weed Management to control existing noxious weeds and prevent new infestations within and adjacent to occupied and potential habitats similar to that recommended for Kincaid's lupine (BLM et al. 2008). Integrated Weed Management in those areas supporting large-flowered woolly meadowfoam could include (BLM et al. 2008, page 13):

- Hand pulling and cutting noxious weeds.
- Mechanical treatments such as mowing prior to seed development.
- Application of an appropriate herbicide treatment for noxious weeds using application methods during the correct phonological periods and using pertinent Best Management Practices to avoid potential effects to large-flowered woolly meadowfoam.
- Cleaning all mechanical equipment and inspecting to insure no noxious weed plant parts are present prior to equipment use within or proximate to large-flowered woolly meadowfoam habitat.
- Flaming with propane burners or hot water treatment of herbaceous noxious weeds.
- Planting desirable grasses, forbs and shrubs to prevent invasion of noxious weeds and invasive non-native species, however the yards would be return to their previous industrial use after temporary use by Pacific Connector.

#### 4.7.3.5 Determination of Effects

**Listed Species**

The Project **may affect** large-flowered woolly meadowfoam because:

- Suitable habitat may be available within the analysis area in 4.9 unsurveyed acres identified as potential low quality vernal pool habitat.

The Project is **likely to adversely affect** large-flowered woolly meadowfoam because

- Use of the Medford Industrial Park Yard, even if it does not support the species, potentially could indirectly affect large-flowered woolly meadowfoam and vernal pools if they are 527 feet away, possibly in proposed critical habitat, since intact hydrologic connections between the yard and vernal pools might be impacted by additional soil compaction by heavy machinery.

**Critical Habitat**

The Project **may affect** designated critical habitat for large-flowered woolly meadowfoam because:

- The project occurs adjacent to large-flowered woolly meadowfoam critical habitat.
- The project may result in habitat impacts within adjacent critical habitat units.

A **likely to adversely affect** determination is warranted for large-flowered woolly meadowfoam critical habitat because:

- The proposed action could potentially adversely modify habitat areas at least 527 feet away that provide sufficient buffer protection from adjacent development and weed sources, continuous nonfragmented habitat and intact hydrology (PCE 1 and 4). Effects from surface disturbances and/or soil compaction by heavy machinery within the

Medford industrial Park Yard would be at least 527 feet away from critical habitat unit RV6B.

### 4.7.4 Cook's Lomatium

#### 4.7.4.1 Species Account and Critical Habitat

**Status**

Cook's lomatium was listed as endangered on November 7, 2002 under the authority of the Endangered Species Act. A recovery plan was developed for vernal pool species within the Rogue River Valley that are federally listed or have federal species of concern designation, including Cook's lomatium.

**Threats**

A major factor in FWS listing Cook's lomatium was the present or threatened destruction, modification, or curtailment of its habitat and range. Due to recent rapid population increases in the region, the primary threats to habitat and range are industrial, commercial, and residential development and their residual road and utility construction and maintenance. These important residual impacts include mowing, herbicide use, firebreak construction, and hydrologic alteration (mostly for agriculture), and some mining. FWS also found that competition from introduced grass species and grazing can reduce or eliminate populations (FWS, 2002d).

Vandalism, in the form of intentional disregard or dismantling of signage or fencing intended to protect certain wetland areas from unauthorized ORV use, and subsequent damage resulting from that use, has resulted in negative effects on the hydrology of the habitat for Cook's lomatium (for example, by altering the surface hydrology, resulting in excess or a lack of hydrology in otherwise suitable habitat).

The effect of grazing on suitable habitat depends on how the grazing is managed. There are various reports showing how grazing practices can positively or negatively affect native plant species' richness (Marty 2005). Marty's (2005) study indicates that wet season grazing resulted in a decrease of native forb species at vernal pool edge habitat, but year-round grazing actually improved species' richness.

Although disease (fungus) and herbivory have been identified as potential problems, no data other than casual observations exist to suggest that these factors pose a substantial threat to the species at this point in time (FWS, 2012a).

Because of the continuing population and development pressures on the limited Cook's lomatium habitat and range, it is presumed that the final rule factors in determining its endangered status remain as significant ongoing threats to the species.

**Species Recovery**

According to the recovery plan, approximately 20 percent of known Cook's lomatium populations occur on designated critical habitat for the vernal pool fairy shrimp. Three core areas occur in the Rogue River Valley Recovery Unit and 13 core areas occur in the Illinois Valley Recovery Unit. The two units are geographically distinct, and it is thought that the populations have genetically adapted to each habitat. At least 95 percent of suitable vernal pool and wet meadow habitat acreage within each Priority 1 core area and 85 percent within one Priority 2 core area in would be required for downlisting (FWS 2006g).

The recovery plan addresses large-flowered woolly meadowfoam, Cook's lomatium, and vernal pool fairy shrimp as well as six plant species of concern and the hairy water flea. Delisting criteria included in the 2012 recovery plan specific to Cook's lomatium include:

- At least 33 of 36 occurrences for Cook's lomatium (approximately 95 percent of documented/extant occurrences) should be protected in conservationoriented ownership (i.e., land that is formally secured from habitat lossand degradation by way of conservation easements, formal agreements, conservation banks, or public or conservation group ownership). For occurrences that have become extirpated, reintroduced or introduced populations may be substituted. Introduced or newly discovered populations outside of currently known core areas may be substituted if the Service deems them equivalent in their contribution to recovery.
- At least 95 percent of suitable vernal pool habitat acreage within each Priority 1 core area for the species and at least 90 percent of suitable vernal pool habitat acreage within each Priority 2 core area for the species has been protected from development. All suitable habitat must include soils and hydrology that support the plant species.
- Conservation oriented management plans for each protected core area are developed to guide protection and conservation following establishment of protected status such as a conservation easement or transfer of ownership to land trusts or government entities. Each management plan should be operational as soon as possible, as funding and staff time allow.
- Additional species occurrences identified through future site assessments, GIS, other analyses, or status surveys, and that are determined essential to recovery, are protected. Status surveys, 5-year status reviews, and population monitoring show achievement of self-sustaining species populations as confirmed through species monitoring and status surveys in each protected occurrence.
- Seeds from each core area of the two species are in storage as insurance against the risk of extirpations and to ensure that genetic lines are preserved. Seed banking is also necessary in order to complete the reintroductions or introductions that can contribute to meeting recovery criteria.

**Life History, Habitat Requirements, and Distribution**

Cook's lomatium is a small perennial in the parsley family. Its range is on seasonally wet soils limited to two areas: 1) along vernal pools in the Agate Desert area of the Rogue River Valley, Jackson County, and 2) in alluvial floodplains within the Illinois River Valley area near Cave Junction, Josephine County. The Jackson County populations occur in vernal pool habitats within a 20,510-acre landform known as the Agate Desert. Located on the floor of the Rogue River basin north of Medford, the Agate Desert is characterized by shallow, Agate-Winlow complex soils, a relative lack of trees, sparse prairie vegetation, and agates commonly found on the soil surface. Fire may maintain suitable habitat because shrubs such as manzanita and scotch broom compete for sun and space in the Illinois Valley and an historical fire regime is thought to have prevented such shrubs from encroaching on Cook's lomatium habitat (FWS, 2006g).

Plants in the Agate Desert are found on the margins and bottoms of vernal pools with standing water from December to April or May. The plant flowers from late March to May and is pollinated entirely by insects. Each flowering stalk produces either primarily male or female flower clusters (FWS 2006g). In the Rogue River Valley, Cook's lomatium is found in the same vernal pool habitats as the large-flowered woolly meadowfoam and the vernal pool fairy shrimp.

The Josephine County populations occur on seasonally wet soils in the Illinois Valley. These populations are found in deep clay loam soils, in open wet meadows and along roadsides adjacent to meadows and oak woodlands. These seasonally wet areas are similar to the vernal pools of the Agate Desert, but lack that region's distinctive mound and swale topography. The Illinois Valley soils are partially derived from serpentine formations that occur on surrounding slopes and hilltops.

**Population Status**

In the Rogue River Valley, which is crossed by the proposed Pacific Connector pipeline area, the Cook's lomatium is estimated at 34,000 plants in 13 populations (FWS 2006g, FWS, 2011, FWS, 2012a).

**Critical Habitat**

Critical habitat for Cook's lomatium was designated on July 21, 2010, including three critical habitat units in Jackson County, totaling 924 hectares (2,282 acres), and 13 critical habitat units in Josephine County, totaling 1,621 hectares (4,007 acres) (FWS, 2010e). The proposed Project occurs within and adjacent to the Agate Desert complex; therefore discussion will focus on this geographic area.

When determining areas for critical habitat for the Cook's lomatium in the Agate Desert, FWS focused on the biological or physical primary constituent elements that are essential to the conservation of the species. The primary constituent elements for Cook's lomatium critical habitat include:

1) Vernal pools or ephemeral wetlands and the adjacent upland margins of these depressions that hold water for a sufficient length of time to sustain Cook's lomatium, growth, and reproduction, between elevations of 1,256 to 1,600 feet, a minimum of 20 acres, and associated with specific dominant native plants (FWS, 2010e).
2) The hydrologically and ecologically functional system of streams, slopes, and wooded systems that surround and maintain seasonally wet alluvial meadows underlain by relatively undisturbed ultramafic soils within the greater watershed.
3) Silt, loam, and clay soils that are of ultramafic and nonultramafic alluvial origin, with a 0 to 40 percent slope, classified as Abegg gravelly loam, Brockman clay loam, Copsey clay. Cornutt–Dubakel complex, Dumps, Eightlar extremely stony clay, Evans loam, Foehlin gravelly loam, Josephine gravelly loam, Kerby loam, Newberg fine sandy loam, Pearsoll–Rock outcrop complex, Pollard loam, Riverwash, Speaker–Josephine gravelly loam, Takilma cobbly loam, or Takilma Variant extremely cobbly loam.
4) No or negligible presence of competitive, nonnative, invasive plant species.

Sixteen critical habitat units have been designated for the Cook's lomatium in Jackson and Josephine Counties, of which two units (White City and Whetstone Creek) are shared by the designated critical habitat for large-flowered woolly meadowfoam (FWS, 2010e - see above). Within the vicinity of White City, Oregon, where five proposed pipe storage yards for the PCGP Project are located, critical habitat units RV6 and RV8 have been designated.

### 4.7.4.2 Environmental Baseline

**Analysis Area**

A botanical analysis area applies to the extent of Project-related effects on listed plant species within a general 400-foot-wide corridor, 200 feet on each side of the proposed Pacific Connector pipeline centerline. The botanical analysis area also includes all TEWAs, rock source and disposal sites, and proposed storage yards that have potential for listed plant species. That area corresponds to areas that were surveyed for sensitive and listed plant species in 2007 and 2008. See Section 4.7.1.2 The botanical analysis area also applies to known or potential habitats for endemic vernal pool obligate species. Effects by the Project to vernal pool obligates could extend 200 feet from the perimeter of five proposed pipeyard storage areas that are located within the Vernal Pool Complex – Agate Desert, Jackson County, Oregon and shown in figure 4.6-1 under Vernal Pool Fairy Shrimp, above.

**Species Presence**

Multiple locations of Cook's lomatium have been documented in the Agate Desert, in and around White City, Jackson County. The closest population to theproposed pipeline right-of-of way is 10.3 miles to the west of MP 145.7 (ORBIC, 2012). However, five proposed pipe storage yards occur within the Agate Desert and near vernal pool habitat. Several patches of Cook's lomatium have been documented in Ken Denman State Game Management Reserve and Agate Desert Preserve, 0.37 mile south of proposed pipe storage yard Oregon Opportunities and 0.26 mile south of the proposed Avenue C and 7$^{th}$ Street yard (Friedman 2006) (see figure 4.6-1). The landscape between the proposed yards and Cook's lomatium locations is now developed with multiple industrial sites on both sides of Avenue C, Antelope Road, and Avenue A, all of which intervene.

**Surveyed Habitat**

Prior to beginning field surveys in 2007 for the Pacific Connector pipeline, botanists with SBS conducted a habitat review to identify potential habitat and delineate survey areas for Cook's lomatium within the botanical analysis area, including existing roads identified for access to the construction right-of-way, and associated impact areas like pipeyards. Aerial photographs (summer 2005) and knowledge of regional landscape and biological features (soils, geology, topography, elevation, target species habitat, and plant community habitat) were used to determine potential habitat for Cook's lomatium. The same methods were used to determine potential suitable habitat coinciding with new realignments of the project corridor.

A total of 228.7 acres have been identified as potential suitable habitat requiring surveys within the proposed pipe storage yards (see table 4.7.4-1) for which access was allowed to survey 226.8 acres. Of the 226.8 acres of potential habitat that was surveyed, 118.0 acres were considered suitable habitat for Cook's lomatium. Habitat found to be "suitable" in the surveys included areas with some of the characteristics detailed in the Life History, Habitat Requirements, and Distribution section above (SBS, 2008a).

**Table 4.7.4-1**

**Summary of Potential Suitable Cook's Lomatium within Pipe Storage Yards**

| **Survey Area Type and Years Surveyed** | **FEIS ROW/ Pipe Yards Area (acres)** |
|---|---|
| **Area Identified for Survey** | 228.7 |
| **Area Surveyed to Protocol** | |
| 2007 | 117.5 |
| 2008 | 92.0 |
| **Visual Survey Only** | 17.3 |
| **Total** | **226.8** |
| **Area of Confirmed Potential Habitat** | |
| 2007 | 23.3 |
| 2008 | 92.0 |
| **Visual Survey Only** | 2.7 |
| **Total** | **118.0** |
| **Area not Surveyed (access denied)** | **1.9** |

<u>Construction Right-of Way.</u>

Surveys were conducted along the proposed pipeline near MP 145.3 where Agate-Winlow soils occur, even though this habitat is outside the range of the species. No Cook's lomatium plants were documented.

<u>Jackson County Pipe Yards</u>

SBS conducted surveys for Cook's lomatium at four of the six potential pipe storage yards where survey permission was granted: Burrill Lumber, Rogue Aggregates, Avenue C and 7th Street/Elite Cabinet & Doors and Medford Industrial Park (SBS, 2008a). No plants were located within the four proposed pipe storage yards, however there were 24 acres of suitable vernal pool habitat located on the Avenue C and 7th Street/Elite Cabinet & Doors Yard, including disturbed seasonally saturated or seasonal wetland habitat that has been filled and graded in the past (SBS, 2008a).

One large lot, a 65-acre taxlot (Maplot #361W17600) adjacent to the proposed 64.1-acre Burrill Lumber Yard, was surveyed for Cook's lomatium and found to contain five acres of high quality (and one acre of low quality vernal pool habitat over 900 feet from the proposed Burrill Lumber Yard). Two other proposed yards, Avenue F and 11th Street yard and Oregon Opportunities yard have not been surveyed due to landowner denial. Initial reviews of habitat via aerial photography and "drive-by" have identified approximately 1.9 acres of potential low quality Cook's lomatium vernal habitat on the margins of the Avenue F and 11th Street yard. No habitat within the potential Oregon Opportunities yard were identified during the visual reconnaissance. At the present, the expectation is that surveys would confirm that the habitat would not be suitable for Cook's lomatiun.

Suitable and occupied Cook's lomatium habitat also exists within proposed critical habitat subunits near or adjacent to proposed pipe storage yards in Jackson County (see critical habitat discussion, below).

**Critical Habitat**

Two of the 16 designated critical habitat units for Cook's lomatium are within the vicinity of six proposed pipe storage yards: RV6, which consists of four subunits identified as habitat for lomatium and is approximately 1,503 acres, and RV8 that is approximately 896 acres, of which both consist of intact vernal pool-mounded prairie and swale habitats (FWS, 2009c). One of four RV6 subunits – RV6A – is near or adjacent to proposed yards, whereas RV8 is located between proposed pipe storage yard Rogue Aggregates and the other five pipe storage yards, over 1.4 miles from the closest pipe storage yard. Designated RV6A subunit and RV8 unit coincide with designated critical habitat for vernal pool fairy shrimp: the southern and western portion of VERFS 3B and VERFS 3C.

#### 4.7.4.3 Effects by the Proposed Action

**Direct and Indirect Effects**

Possible direct effects to Cook's lomatium include possible disturbance to pools from driving on or storing equipment or pipes near or on pools or wetlands associated with this species. In 2007 and 2008, surveys were conducted on 226.8 acres of potentially suitable Cook's lomatium habitat at four pipe storage yards in Jackson County (Burrill Lumber, Medford Industrial Park, Avenue C and 7$^{th}$ Street/Elite Cabinet & Doors, and Rogue Aggregates), and along a portion of the proposed centerline (between MPs 145.3 and 145.5) outside of the known range of the plant but within appropriate Agate-Winlo soils. Approximately 118.0 acres of habitat surveyed was considered suitable habitat for Cook's lomatium within Medford Industrial Park pipe storage yard and the 200-foot survey buffer adjacent to the construction right-of-way between MPs 145.3 and 145.5. Direct impact to suitable habitat identified within Medford Industrial Park is possible. No Cook's lomatium plants were located; therefore, no direct effects to Cook's lomatium plants are expected as a result of the proposed action.

Indirect effects to Cook's lomatium plants and their habitat could occur with increased road use to access the pipe storage yards that are adjacent or in the vicinity of suitable or potentially suitable habitat. Increased road use and the associated dust created might impact vernal pool habitat as dust settles, affecting vegetation and vernal pool physical or chemical properties (pH, water quality, turbidity, sedimentation, temperature). Project use of pipe storage yards (i.e., potential soil compaction by heavy equipment use) adjacent to, or in the vicinity of suitable or potentially suitable habitat, may indirectly affect hydrology upon which vernal pools and associated vegetation are dependent. Indirect effects to hydrology could be expected if such disturbances to ground and/or soils occurred within 527 feet of suitable or potentially suitable vernal pool habitat. The distance of potential effects is based on FWS' (2010e) estimate that at least 20 acres of habitat surrounding a vernal pool site is considered essential for intact hydrology (see primary constituent element discussion for large-flowered woolly meadowfoam and Cook's lomatium – FWS, 2010; 527 feet is the radius of a circle with an area of 20-acre). Such effects could again include altering hydrologic processes, such as runoff patterns as a result of soil compaction, as well as increased seeding of non-native invasive plant species (PCEs 1 and 4). However, any potential compaction that may occur at the proposed yards would likely be insignificant because of the previous industrial use, soil grading and compaction, and implementation of the Noxious Weed Control Plan (section 12.0) provided in the ECRP (see appendix F) would reduce spread of noxious species. .

Surveys for Cook's lomatium have not been conducted on 1.9 acres of potential suitable habitat identified at the Avenue F and 11th Street proposed yard site that had survey access denied. Pacific Connector would avoid portions of those yards if surveys identify suitable Cook's lomatium habitat or plants. Therefore, no direct impact to unsurveyed habitat or unidentified plants is expected. However, indirect impacts may be possible.

Potential impact to 119.9 acres (118.0 acres known, 1.9 acres unsurveyed) of Cook's lomatium suitable habitat from use of the proposed storage yards and pipeline construction is not likely to affect the recovery of the species, because the area only accounts for 0.5 percent of Cook's lomatium sub-range (20,510 acres, total).

Indirect impacts to suitable habitat located within the critical habitat subunit RV6A adjacent to or in proximity of Medford Industrial Park pipe storage yard is possible and discussed further in the critical habitat section, below.

**Cumulative Effects**

ESA plant species do not have federal protection in Oregon on private lands except in instances where a federal permit is required or a federal action occurs. Outside of the surveyed area for the Pacific Connector pipeline, it is unknown where Cook's lomatium occurs on private lands throughout the action area. Therefore, it is impossible to determine if there are reasonably foreseeable actions which might occur on private lands, which could impact the plant. Given the lack of protections under ESA and Oregon statutes, all federally listed plants on private lands must be considered at risk of adverse effects, where ever they may occur. However, the Pacific Connector pipeline would mitigate for any Project impacts to Cook's lomatium.

**Critical Habitat**

Cook's lomatium within the Agate Desert complex is dependent on vernal pool or ephemeral wetland complexes, including upland hydrological features, that provide enough water for a sufficient length of time in the winter months to allow lomatium to germinate, grow, and reproduce. Vernal pool complexes that this species are dependent on have been threatened by residential, urban, and commercial development, agricultural development, road construction and maintenance, aggregate mining, incompatible grazing practices, off-road vehicle use, vandalism, encroachment by nonnative plants, and herbivory by gophers and voles. Such threats can 1) cause damage to the clay pan layer and allow moisture to drain from the vernal pools or wet meadow habitats that the plants depend upon for reproduction and survival, 2) alter hydrology, or 3) introduce nonnative plants that can outcompete and displace native plant species and may inhibit successful germination of seeds (FWS, 2009d). To protect biological and physical features Cook's lomatium depends on, FWS (2010e) has designated 16 critical habitat units for this species in Jackson and Josephine Counties, of which two units (RV6 and RV8) are within the vicinity of five proposed storage yards in Jackson County, Oregon.

A portion of one of the critical habitat subunits, RV6A is adjacent to the western edge of Medford Industrial Park pipe storage yard. Although critical habitat lies adjacent to the proposed pipe storage yard, no direct impacts from the proposed action are anticipated since equipment and pipe storage would not occur near or on pools or wetlands located in the critical habitat subunit, nor would traffic to and from the pipe storage yards drive near or on pools within the critical habitat unit. Several patches of Cook's lomatium have been previously documented in Denman Wildlife Management Area and Agate Desert Preserve in critical habitat subunit RV6A, but are located in the southern portion of the critical habitat subunit at least 0.25 mile south of Oregon Opportunities pipe storage yard (Friedman, 2006), so no direct impact to those plant sites are expected. Possible indirect effects to the critical habitat units in the vicinity of the five pipe storage yards may occur as a result of increased road use to access the pipe storage yards that are adjacent or within the vicinity of the critical habitat units (Avenues C, F, G, and Antelope and Agate Roads). Increased road use and the associated dust created might impact Cook's lomatium critical habitat as dust settles, affecting associated vegetation and vernal pool physical or chemical properties (pH, water quality, turbidity, sedimentation, and temperature). Primary constituent element 1 specifies that at least 20 acres are essential for intact hydrology. A circle with an area of 20 acres will have a radius of 527 feet. Indirect impact to critical habitat units adjacent to pipe storage yards may be expected by actions affecting hydrology at least 527 feet away. Use of the Medford Industrial Park yard that includes ground disturbance such as soil compaction by heavy machinery may alter hydrology in vernal pools in critical habitat unit RV6A, possibly affecting the frequency or amount of water in adjacent vernal pools, or altering the upland hydrology upon which vernal pools and associated vegetation are dependent. Indirect effects to hydrology could be expected if such disturbances to ground and/or soils occurred within 527 feet of suitable or potentially suitable vernal pool habitat. Additionally, use of the roads adjacent to the critical habitat units and the pipe storage yards, themselves, may increase the introduction of non-native, weedy species. Primary constituent element 4 specifies that no or negligible presence of competitive nonnative invasive plant species be present for the continued survival and recovery of Cook's lomatium.

Critical habitat unit RV8 is located greater than 1.5 miles from the pipe storage yards in Jackson County. The project is not expected to directly or indirectly affect this critical habitat unit. Applying conservation measures identified below (section 4.7.5.4) and use/alteration/restoration of pipe storage yards should not result in modifications in the timing, duration, magnitude, or quality of hydrological connections to an off-site vernal pool and/or federally-listed vernal-pool obligate species. Additionally, measures taken to minimize the introduction and spread of noxious weeds outlined in the ECRP and Project's compensatory mitigation plan would ensure that competition from nonnative species in adjacent critical habitat units remains negligible.

#### 4.7.4.4 Conservation Measures

Pacific Connector would not use the 65-acre taxlot (Maplot #361W17600) which was surveyed adjacent to the Burrill Lumber Yard and contains five acres of high quality and one acre of low quality vernal pool habitat.

Once Pacific Connector has determined if Oregon Opportunities and Avenue F and 11th Street pipe storage yards would be used for storage of pipe for the Pacific Connector pipeline and is granted permission to survey those yards through the FERC Certificate process, surveys for Cook's lomatium will be conducted within the 1.9 acres of potential low quality vernal pool habitat. Pacific Connector would not use portions of those proposed pipe storage yards if Cook's lomatium plants or highly suitable habitat is identified, similar to actions taken for the pipe storage yards no longer considered for pipe storage use (the 65-acre property adjacent to Burrill Lumber yard).

Pacific Connector would implement proper sedimentation control barriers (FWS 2005d) to minimize potential impacts to identified Cook's lomatium plants and highly suitable habitat. Additional mitigation measures for Cook's lomatium, if identified, are addressed through the Project's Compensatory Mitigation Plan. Such measures could include application of Integrated Weed Management to control existing noxious weeds and prevent new infestations within and adjacent to occupied and potential habitat similar to that recommended for Kincaid's lupine (BLM et al., 2008). Integrated Weed Management in those areas supporting Cook's lomatium could include (BLM et al., 2008, page 13):

- Hand pulling and cutting noxious weeds.
- Mechanical treatments such as mowing prior to seed development.
- Application of an appropriate herbicide treatment for noxious weeds using application methods during the correct phonological periods and using pertinent Best Management Practices to avoid potential effects to Cook's lomatium.
- Clean all mechanical equipment and inspect to insure no noxious weed plant parts are present prior to equipment use within or proximate to Cook's lomatium habitat.
- Flaming with propane burners or hot water treatment of herbaceous noxious weeds.
- Planting desirable grasses, forbs and shrubs to prevent invasion of noxious weeds and invasive non-native species; however the yards would be return to their previous industrial use after temporary use by Pacific Connector.

#### 4.7.4.5 Determination of Effects

**Listed Species**

The Project **may affect** Cook's lomatium because:

- Potential suitable habitat is available within the analysis area.

The Project is **not likely to adversely affect** Cook's lomatium because:

- Surveyed suitable habitat at proposed pipe storage yards in Jackson County and along the proposed pipeline did not document Cook's lomatium.
- Pacific Connector would avoid using portions of proposed pipe storage yards with high-quality vernal pool habitat.
- Effects to suitable habitat by the proposed action are likely to be insignificant (impact does not reach a level where take occurs) to the point where no meaningful measurement, detection, or evaluation of impact would be possible.
- Sedimentation barriers would be used, as appropriate, to prevent run-off and changes in hydrology.
- Conservation measures have been developed to avoid or minimize impacts to future plants identified during surveys prior to pipeline construction.
- Known sites within the vicinity of the project are further than 0.25 miles from proposed pipe storage yards.

Unsurveyed habitat is low quality vernal pool habitat located over 0.25 miles from known sites with no apparent hydrologic connectivity.

**Critical Habitat**

The Project **may affect** designated critical habitat for Cook's lomatium:

- The project occurs adjacent to Cook's lomatium critical habitat.
- The project may result in habitat impacts within adjacent critical habitat units.

Project components are **not likely to adversely** affect Cook's lomatium critical habitat because:

- The proposed action is not expected to adversely modify habitat areas that provide buffer protection from adjacent development and weed sources, continuous non-fragmented habitat, and intact hydrology (PCE 1 and 4). Effects from surface disturbances and/or soil compaction by heavy machinery within the Medford Industrial park Yard are already present, and would be at least 527 feet away from critical habitat unit RV6A.

### 4.7.5 Kincaid's Lupine

#### 4.7.5.1 Species Account and Critical Habitat

**Status**

Kincaid's lupine was listed as threatened on January 25, 2000 (FWS, 2000b). A recovery outline for the species was released in 2006 (FWS 2006h) a draft recovery plan was published in August 2008 (FWS, 2008e), a five year review was completed in 2010 (FWS, 2010c), and a final recovery plan was published in 2010 (FWS, 2010d).

**Threats**

The three major threats to Kincaid's lupine populations are habitat loss, competition from non-native plants, and elimination of historical disturbance regimes (Wilson et al., 2003, FWS, 2010b). The present or threatened destruction, modification, or curtailment of the Kincaid's lupine habitat and range is a major factor for listing in the final rule. Human alteration of the plant's native prairie in Oregon's Willamette Valley has destroyed over 99 percent of its habitat (FWS 2000c). At the time of listing there were 88 remnants of the native prairie habitat, with Kincaid's lupine occurring at 54 sites. Eighty percent of this remaining prairie habitat is rapidly disappearing because of agricultural practices, development activities, forestry practices, grazing, roadside maintenance, and commercial Christmas tree farming (FWS, 2000c). The remaining Kincaid's lupine populations in prairie habitat are essentially relegated to small, isolated patches of habitat. Habitat loss is likely to continue as private lands are developed.

Most prairie sites require frequent disturbances to hold back the natural succession of trees and shrubs. Before settlement by Euro-Americans, the regular occurrence of fire maintained the open prairie habitats essential to Kincaid's lupine. The loss of a regular disturbance regime, primarily fire, has resulted in the decline of prairie habitats through succession by native trees and shrubs, and has allowed the establishment of numerous non-native grasses and forbs. At the time of federal listing, 83 percent of upland prairie Kincaid's lupine sites were estimated to be succeeding to forest (FWS, 2000c; FWS, 2008e).

In Douglas County, Kincaid's lupine has been found in open woodlands and meadows, often near roads, and associated with Pacific madrone, incense cedar and Douglas-fir with open canopies (FWS, 2008e). Those populations appear to tolerate more shade than populations in the Willamette Valley (BLM et al., 2008). Kincaid's lupine habitat in forested sites is subject to similar alterations from natural succession: fire suppression activities result in increased canopy closure and cover of woody species that contribute to the decline in Kincaid's lupine forested habitat (FWS, 2006i).

The Willamette Valley continues to be an important population center for urban, rural, transportation, commercial and agricultural activities. Ongoing threats to Kincaid's lupine habitat and range presumably mirror the factors listed in FWS's 2000 final rule. These ongoing threats include: further habitat loss or fragmentation due to agriculture, development, and forest practices; herbicide use; disease and predation; invasion of prairie habitats by non-native species; encroachment of trees and shrubs into prairie habitats; elimination of natural disturbance regimes; inbreeding as a result of isolated and fragmented populations (FWS 2008e); and habitat vandalism, which is an uncommon occurrence, but could further reduce habitat function and destroy individual plants (FWS, 2008e, FWS 2010c). Changes in the natural hydrology of a site, such as by ditching or draining a wet prairie, can alter the annual duration of soil saturation, which in turn affects the species composition of the site. Hydrological alterations have been a pervasive factor in the reduction of native species in the Willamette Valley (Finley, 1995; FWS, 2010c).

**Species Recovery**

A final recovery plan for the prairie species of western Oregon, including Kincaid's lupine, was published on January 1, 2010 and includes recovery objectives to delist Kincaid's lupine (FWS, 2010d). Ten recovery zones were established for Kincaid's lupine, of which Douglas County is considered its own recovery zone. Since the clonal or clumping growth pattern of Kincaid's lupine creates a challenge for estimating and monitoring number of plants, the recovery plan provides population targets in terms of foliar cover (measure of the area occupied by the plants).

Within Douglas County where the Project is proposed, the Douglas County Recovery Zone has a recovery goal of a minimum of two populations covering at least 5,000 square meters (1.25 acres) and not be separated by more than 2.0 miles (FWS, 2010f). Additionally, monitoring of these populations should show evidence of reproduction by flowering, seed set, or presence of seedlings, and remain stable or increase in size for a period of at least 15 years. Habitat for Kincaid's lupine populations should be managed to provide high-quality habitat that is protected on lands managed by a government agency or private conservation agreement, and is monitored and controlled from threats to the species (FWS, 2010f). Recovery actions for Kincaid's lupine include:

- Evaluate the status of extant populations.
- Manage population sites to minimize woody plant succession and reduce the threat of competition from nonnative plants, including mowing in late summer (August or September) after the plants have become dormant, and elimination of invasive species with careful and appropriate application of herbicides or mechanical control methods.
- Restore connectivity among populations, establishing subpopulations within 2 miles of each other.
- Augment or reintroduce populations and restore habitat to achieve population targets.
- Monitor populations and trends.
- Monitor prairie quality at all population sites.
- Collect and bank seeds.

**Life History, Habitat Requirements, and Distribution**

Kincaid's lupine is a long-lived perennial herb inhabiting native prairies and foothills (FWS, 2000c). The plant was historically found from Lewis County, Washington in the north, south to the foothills of Douglas County, Oregon; however, most of the known and historical populations are found in Oregon's Willamette Valley (FWS, 2006i).

In Douglas County, Kincaid's lupine appears to tolerate more shaded conditions, where it occurs at sites with canopy cover of 50 to 80 percent. In contrast to the open prairie habitats of the more northerly populations, tree and shrub species dominate the sites in Douglas County including Douglas-fir, California black oak, Pacific madrone, ponderosa pine, incense cedar, hairy manzanita, and poison oak (FWS, 2006i).

Kincaid's lupine does not appear to actually reproduce (i.e., form new, physiologically independent individuals) except by sexual means. Individual clones can be several centuries old (FWS, 2005e; Kaye, 2008) and become quite large with age, producing many flowering stems. Excavations and morphological patterns suggest that plants 33 feet or more apart can be interconnected by below-ground stems and such clones can exceed 66 feet across. Because of vegetative (clonal) growth pattern it is difficult to distinguish individuals; counting individual "plants" and monitoring the size of populations is challenging. Instead, monitoring agencies have used a grid pattern and counted stems or leaves to assess density rather than attempt to count "individuals."

Flowering typically ranges from April through June. Pollinators include small native bumblebees, solitary bees, and occasionally, European honey bees. Insect pollination appears to be critical for successful seed production. Seeds are dispersed from fruits that open explosively upon drying (FWS, 2006i). Kincaid's lupine is also a host plant for the endangered Fender's blue butterfly (FWS, 2008e).

**Population Status**

Prior to Euro-American settlement, Kincaid's lupine was likely well-distributed throughout the prairies of western Oregon and southwestern Washington. Today, fragmentation, degradation, and elimination of natural prairie habitat has resulted in existing populations that are widely separated by expanses of unsuitable habitat (FWS, 2008d). Most of the known extant populations are found in Oregon's Willamette Valley. At the time of listing, approximately 91 percent (51 of 54 sites) of the occupied sites were on private lands and therefore were considered to be at a higher risk of extirpation (FWS, 2008e). Kincaid's lupine is currently known at about 164 sites, comprising about 246 hectares (608 acres) (FWS, 2010b).

**Critical Habitat**

Almost 600 acres of critical habitat were designated on November 30, 2006 in Benton, Lane, Polk, and Yamhill Counties, Oregon, and Lewis County, Washington (FWS, 2006i). The designation did not include Douglas County where conservation agreements were established to formally document the intent to protect, conserve, and contribute to the recovery by implementing recovery actions for Kincaid's lupine and its habitat (see the subsection below).

The PCEs of critical habitat are: 1) the habitat components that provide early seral upland prairie and oak savanna habitat with a mosaic of low growing grasses, forbs, and spaces to establish seedlings or new vegetative growth, with an absence of dense canopy vegetation providing sunlight for individual and population growth and reproduction; and 2) the presence of insect pollinators with available corridors between lupine patches to allow unrestricted movement of pollinators (FWS, 2006i).

Management activities that could adversely modify critical habitat are those that alter PCEs to an extent that the conservation value for Kincaid's lupine is appreciably reduced (FWS, 2006i).

These activities that may affect critical habitat include, but are not limited to: 1) removal or destruction of prairie habitat supporting Kincaid’s lupine populations by grading, leveling, plowing, mowing, burning, motorized equipment operation, or herbicide spraying; and 2) actions that further isolate or reduce genetic interchange among populations within a unit or between subunits, including road construction and expansion, housing and building development, and infrastructure construction (FWS, 2006i).

Conservation Agreements

Roseburg BLM District, Umpqua National Forest, and FWS completed a programmatic conservation agreement for Kincaid’s lupine in Douglas County, which specifies the following goals (BLM et al., 2006):

1. Maintain stable populations by protecting and restoring habitats.
2. Reduce threats to the species on BLM and USFS lands.
3. Promote larger functioning metapopulations, with increased population size and genetic diversity.
4. Meet the recovery criteria in the Recovery Outline for the species (FWS, 2006i).

A Conservation Agreement was also signed with three private timber companies in Douglas County including Lone Rock Timber Management Company, Roseburg Forest Products and Seneca Jones Timber Company. This Voluntary *Agreement for Kincaid’s Lupine (Lupinus Sulphureus Spp. kincaidii) In Douglas County (2006)* includes reporting guidelines and an agreement for road maintenance and minimizing disturbance along roads. The objective of the Voluntary Agreement is “to promote functioning meta-populations”, including coordinating propagation activities for establishing new sites and extending known populations.

In March 2008, a management plan for Kincaid’s lupine in Douglas County was developed between the Roseburg BLM District, the Umpqua National Forest, and the FWS, addressing the populations and habitat of Kincaid’s lupine on BLM and NFS lands in Douglas County (BLM et al. 2008). Kincaid’s lupine occurs on 14 sites within Douglas County of which nine are on federal lands: eight on BLM land (Roseburg District) and one on the Umpqua National Forest (BLM et al. 2008).

### 4.7.5.2 Environmental Baseline

#### Analysis Area

A botanical analysis area applies to the extent of Project-related effects on listed plant species within a general 400-foot-wide corridor, 200 feet on each side of the proposed Pacific Connector pipeline centerline. The botanical analysis area also includes all TEWAs, rock source and disposal sites, and proposed storage yards either on federal or state lands or that have potential for listed plant species. That area corresponds to areas that were surveyed for sensitive and listed plant species from 2007 through 2013. See section 4.7.1 Applegate’s Milk-vetch above, for the full botanical analysis area description. Portions of the botanical analysis area that coincide with Kinkaid’ lupine are included in figures 4.7-3, 4.7-4, and 4.7-5.

#### Species Presence

Records obtained from ORBIC (2012) indicate Kincaid’s lupine had been previously located at eleven sites within 2.5 miles of the proposed Pacific Connector pipeline. The three closest sites are: 1) 10 clumps located 1.5 miles northeast of MP 56.0 in 1999 - plants were within a 200 square-foot area but with poor estimated viability, 2) 400 to 4,000 plants within four sites occupying approximately 3 acres located 2.2 miles southwest of MP 96.0 in 2003 with excellent estimated viability, and 3), about 100 to 200 plants in one acre located in 1992 approximately 1.5 miles east of MP 98.9 with fair estimated viability. Herbarium records indicate that one extinct population (1979) occurred near the 1992 documented site, approximately 1.7 miles east of MP 98.9 and 0.25 mile from the other 1992 population.

**Surveyed Habitat**

Prior to beginning field surveys in 2007 for the Pacific Connector pipeline, botanists with SBS conducted a habitat review to identify potential habitat and delineate survey areas for Kincaid's lupine within the botanical analysis area, including existing roads identified for access to the construction right-of-way. Aerial photographs (summer 2005) and knowledge of regional landscape and biological features (soils, geology, topography, elevation, target species habitat, and plant community habitat) were used to determine potential habitat for Kincaid's lupine. The same methods were used to determine potential suitable habitat coinciding with new realignments of the project corridor.

A total of 3,009.3 acres have been identified as potential suitable habitat requiring surveys within the current project alignment and 200-foot botanical analysis area (see table 4.7.5-1). Of this habitat, 2,054.8 acres were permitted survey access (1,102.6 acres within the project area). A total of 151.2 acres of access roads located outside of the ROW and 200-foot botanical buffer were identified for surveys. Surveys have been completed on 134.5 acres of access roads, while no survyes have been conducted on the remaining 16.7 acres due to denied access. All habitat is located within Pacific Connector pipeline MP's 46.91 through 104.10, as well as at proposed storage yards. The potential suitable habitat includes both meadow (typically non-native pasture) and forested upland Kincaid's lupine habitats.

Of the 2,054.8 acres of potential habitat with access allowed for surveys, 954.5 acres (729.3 acres within the project area) were considered suitable habitat for Kincaid's lupine. Habitat suitability was qualitatively assessed based on Kincaid's lupine habitat analysis conducted in Oregon by SBS in 2001. Habitat found to be "suitable" in the surveys included areas with some of the characteristics detailed in the Life History, Habitat Requirements, and Distribution section above (SBS, 2008a).

Approximately 954.5 acres of potentially suitable habitat for this species (512.5 acres within the project area) were denied access by the landowner and would need to be surveyed prior to construction for complete surveys of this eco-region. If the assumption is made that a similar percent of that area is suitable, as documented within the rest of the area surveyed, then approximately 678 acres (71 percent of 955 acres, or 364 acres within the project area) are probably suitable Kincaid's lupine habitat.

| 2013 | 165.6 | 275.1 | 440.7 |
| **Totals** | **1,102.6** | **952.2** | **2,054.8** |
| **Area of Confirmed Potential Habitat** | | | |
| 2007 | 605.3 | 440.1 | 1,045.4 |
| 2008 | 5.0 | 3.4 | 8.4 |
| 2010 | 9.2 | 2.9 | 12.1 |
| 2013 | 109.8 | 275.1 | 384.9 |
| **Totals** | **729.3** | **721.5** | 1,450.8 |
| **Area not Surveyed (access denied)** | **512.5** | **442.0** | **954.5** |

**Note:**
[1] The botanical analysis area applies to the extent of pipeline-related effects on listed plant species within a general 400-foot-wide corridor, 200 feet on each side of the proposed Pacific Connector pipeline centerline.

### Documented Occurrences

Surveys located three populations in the proposed analysis area (see table 4.7.5-2): two in western and one in eastern Douglas County (also see figures 4.7-3, 4.7-4, and 4.7-5).

| Table 4.7.5-2<br><br>**Summary of Kincaid's Lupine Locations**. | | |

The first site in western Douglas County is located within the FERC-filed route between MP 57.84 and MP 57.92 on private land. Approximately 179 plants were found at this site within seven sub-populations covering approximately 0.6 acre of area scattered within an approximately 4 acre area in pasture habitat (approximately 15 percent cover). Subpopulations or patches range in size from 1 to 54 plants and are anywhere from 20 feet to 177 feet from each other. Plant counts were made by considering all stems in close proximity as one plant. This site is approximately 2.1 miles from a known site 1.5 miles northeast of MP 56.0, and approximately 1.6 miles southwest of the second site located during surveys in 2007 near MP 59.60 (figure 4.7-3).

A second site was located on private land approximately 300 feet north of MP 59.60 and approximately 225 feet north of TEWA 59.30-N. McNabb Creek Road, an identified existing access road (EAR 59.62) runs nearby the site, approximately 43 and 85 feet to the south and west. This site includes approximately 66 plants within 2 clumps or subpopulations (clonal groups) covering approximately 0.5 acre scattered in a 2-acre area on a flat grazed pasture (approximately 25 percent cover). This site is approximately 2.7 miles southeast of the known site, north of MP 56.0 and 1.6 miles east of the site with 179 plants that was documented in 2007 near MP 57.84 and 57.92 (figure 4.7-4).

A third Kincaid's lupine site was found between MPs 96.5 and 96.9 and on access roads south of MPs 96.7 to 96.9. The population occurs on private timberland two miles south of the South Fork Umpqua River on a ridgeline east of Stouts Creek. The plants are all located on loam soils in a young mid-seral mixed conifer and hardwood forest. Plants were located in canopy gaps and, less regularly, under closed canopy (mostly under ponderosa pine trees) and in openings along four-wheel drive roads. Approximately 1,083 plants were located within 28 subpopulations or patches scattered within a 20-acre area. In all, plants occurred on an approximate total area of 0.6 acre (approximately 29 percent cover). The 28 patches ranged in size from 1 plant to 258 plants in a 0.4 acre area. This documented site is approximately 2.5 miles northeast and 2.7 miles northwest of previously known sites documented in 2003 and 1992, consecutively (figure 4.7-5).

**Critical Habitat**

The proposed action would not affect any of the PCEs identified because no critical habitat for Kincaid's lupine is present within the analysis area.

### 4.7.5.3 Effects by the Proposed Action

**Direct and Indirect Effects**

The report published on the Biology of Kincaid's lupine, (Wilson et al. 2003) indicates that Kincaid's lupine spreads extensively by physiologically-interdependent clones interspersed across large distances in the population, making it challenging to distinguish genetically distinct individual plants. Any estimates of number of individuals impacted by the proposed action are subject to broad margins of error. Because even broadly separated clones share resources through caudices, removal of stems from the population may destroy other connected members of the plant, increasing the number of plants taken. There is no evidence to date that clones can survive when separated from the remainder of the plant. Therefore, removing any individuals from small populations like those documented during survey efforts, would likely decrease their potential survival and ability to colonize available habitats.

An important related concern is that these populations may consist of significantly fewer genetically distinct plants than estimated, due to clonal growth. Kincaid's lupine depends on sexual reproduction to replace individual plants that may succumb to numerous threats, to augment populations and to spread into suitable habitat. Such out-crossing plants require a large number of genetically distinct individuals as well as adequate pollinators to maintain genetic diversity and avoid negative effects of inbreeding depression, which may already be impacting these small remnant populations.

The three new populations of Kincaid's lupine identified during surveys in 2007 on private lands at MPs 57.84 through 57.92, 59.60, and 96.48 through 96.9 along Pacific Connector's FERC-filed route are too small to meet the minimum viable population size specified in the FWS recovery plan (either by estimated number of plants or by density within a coverage area). The newly found populations, however, may be contributing to other known meta-populations and recovery plan objectives, and removal of these plants may contribute negatively toward recovery.

The population at MP 57.9 totals 0.6 acre within a 4-acre area (15 percent cover) and the population at MP 59.6 is approximately 0.5 acre within a 2-acre area (25 percent cover). Total cover at these population locations is high due to the vigor and age of the plants. These sites are approximately 2.1 to 2.7 miles from an extant site with plants of low vigor near Ten Mile, but far from other known sites, so are unlikely to be part of an eventual meta-population for meeting Recovery Plan goals (FWS 2008e). They do, however, contribute significantly to the "additional" population goals. These sites are unique for Douglas County in that they occupy Valley-Floor pasture/meadow habitats similar to Willamette Valley populations but very different from the other Douglas County populations. As a result, plants identified during survey efforts may be preserving high value genetic information and diversity.

The population near MP 95.6 is an important element in the recognized Stouts Creek-Callahan Ridge meta-population. It is approximately 2.5 miles east/northeast of the large known population cluster on BLM and Roseburg Timber lands at Stouts Creek, and approximately 2.7 miles west/northwest from the population on USFS and private land at Callahan Ridge, and approximately 3.7 miles from the population at Callahan Meadows. It occurs in a central location between these populations thus forming an important genetic link and increases the possibility of developing a successful South Umpqua "meta-population" to further achieve recovery goals. The population consists of 28 patches within an area of 20 acres, occurring in transitory and natural openings in 45-year old forest. The total cumulative area of the patches documented is approximately 0.57 acre (2.9 percent total cover), with the largest patch covering 0.09 acre. This population could be considered quite significant in meeting the goals of the South Umpqua meta-population.

Direct Impacts

Pacific Connector met with several members of the Habitat Quality Subtask Group on July 24, 2008 to discuss impacts to documented plants and get recommendations on how to avoid or minimize impacts (see July 24, 2008 meeting minutes). One of the biggest concerns the group had was fragmenting the population because the patches were located close enough (within 33 feet of each other) that they could be interconnected by below-ground stems. Therefore, Pacific Connector rerouted the proposed pipeline route south of six of the seven patches documented (see figure 4.7-3), completely avoiding all aboveground documented Kincaid's lupine patches. Subpopulation 7 (1 plant) located south of the proposed route is 150 to 190 feet from the other documented sites and is most likely not a part or clone of the other plants and should not be affected by dissecting below-ground stems. No direct impacts to the subpopulations located aboveground at this site are expected.

No direct effects are expected at the second site near MP 59.60 documented north of TEWA 59.30-N because the site is at least 200 feet from proposed pipeline components. Direct impact from use of the existing access road is also not expected.

The third site between MPs 96.5 and 96.9 documented 1,064 plants within 28 subpopulations. A total of 138 plants (within 8 patches) were located within the FERC-filed construction right-of-way and 80 plants (within 3 patches) within the FERC-filed TEWAs and UCSAs, representing approximately 20.5 percent of the discovered population at this site. Because the FERC-filed route is located on a narrow ridgeline, there are no feasible routing alternatives to realign the pipeline to completely avoid this documented population. Therefore, to minimize impacts to this population, Pacific Connector has modified the construction right-of-way and TEWA 96.66-W, avoiding impacts to 61 plants within three subpopulations and partially avoiding plants within a fourth subpopulation by narrowing the construction right-of-way (see figure 4.7-5, revised proposed route). Approximately 157 plants are expected to be directly impacted; however, because of the rhizomatous nature of the plant, more plants may be impacted by translocation of a partial plant clone. A number of the identified subpopulations (totaling 58 plants) occur along the identified access roads in this area, including EAR 96.29 and EAR 96.67. Project activities on these existing roads during pipeline construction could include filling pot-holes, blading/grading, and brushing, and may directly impact the documented Kincaid's lupine plants. However, Pacific Connector's EIs would ensure that potential impacts to the lupine plants along the proposed access roads are avoided or minimized during any necessary maintenance activities by flagging and fencing the known populations and monitoring maintenance activities during construction.

It is possible that clones of Kincaid's lupine could become reestablished within the construction right-of-way. Pacific Connector would monitor revegetation success in the areas of the restored Kincaid's lupine populations between MPs 57.84 - 57.92 and MPs 96.5 - 96.9 annually for five years after construction. Monitoring would include inspection between those mileposts for any new growths of Kincaid's lupine. If any are found, no mowing would be conducted. The five-year monitoring period is longer than FERC's three-year monitoring period requirement for sensitive areas such as wetlands (see Section VI. D. 3. of FERC's 2003 Wetland and Waterbody Construction and Mitigation Procedures). Monitoring would be completed by a qualified botanist and would be scheduled in June to coincide with the optimal time for plant identification. Pacific Connector also has an agreement in principle with the Forest Service which includes 125.3 acres of meadow restoration on the Umpqua National Forest within the Elk Creek and Days Creek South Umpqua River watershed that will benefit native species including Kincaid's Lupine and which should compensate for any potential effects caused by maintenance of the 30-foot right-of-way.

Indirect Impacts

Indirect impacts to documented patches of lupine are possible from the proposed pipeline, including impacts from heavy dust created during construction activities, sub-surface disturbance to underground stems, and from invasive plants occurring on pipeline route. Approximately 1,394.2 acres of the 3,009.3 acres identified as potential habitat occur outside of the proposed construction work areas, of which 721.5 acres of the 952.2 acres surveyed were determined suitable for Kincaid's lupine (76 percent suitable) during 2007 and 2008 surveys. Approximately 442 acres were outside the proposed construction work areas but within the botanical analysis area and were not surveyed due to denial of access by land owners. Of that unsurveyed area, 336 acres (76 percent of 442 acres) could contain suitable Kincaid's lupine habitat.

Within the known or estimated suitable habitat within the entire botanical analysis area (721.5 acres), Kincaid's lupine plants were documented at three sites on approximately 1.7 acres (see discussion above), or 0.24 percent of habitat surveyed. Therefore, it can be estimated that approximately 0.8 acre of the 336 acres not surveyed within the 200-foot botanical analysis area may be occupied by Kincaid's lupine. Plants located within the 0.8 acre estimated as occupied could also be indirectly affected by the Project. This estimate of 0.8 acre is different from the estimate of 0.34 acres that would be affected by direct impact, above.

Indirect impacts include habitat alteration of 1,057.5 acres (721.5 known plus 336 acres estimated) known or estimated acres of suitable Kincaid's lupine habitat that occur within the botanical analysis area. Indirect impacts are likely to include: 1) changes in hydrology and soil characteristics, 2) an increase in invasive weeds, and 3) alterations of vegetation cover and species composition. Changes in the natural hydrology of a site, such as by ditching or draining a wet prairie, can alter the annual duration of soil saturation, which in turn affects the species composition of the site. The potential for soil compaction along the construction right-of-way could occur from heavy equipment use and repeated vehicle traffic. Soil compaction can alter soil hydrologic conductivities, decreasing soil infiltration rates and available water contents, and increase runoff rates. Pacific Connector's Erosion Control and Revegetation Plan (see Appendix F - Sections 4.2.3, 10.3 and 10.4) describes the mitigation measures that would be implemented during restoration to alleviate potential soil compaction along the right-of-way to ensure revegetation success and to minimize any potential effects to Kincaid's lupine. Such alteration in Kincaid's lupine meadow habitats would likely cause an increase in weedy grasses and forbs. In Kincaid's lupine forested habitat, a decrease in overstory canopy cover and subsequent shift to early seral vegetation associated with logging is expected. A reduction in canopy cover alone (i.e. without the ground disturbance associated with logging activities) could result in an improvement to forested Kincaid's lupine habitat, especially within the population documented between MPs 96.5 and 96.9 that were generally located within canopy gaps of late regenerating/early mid-seral forest and along transitional roadsides. Kincaid's lupine is very sensitive to habitat loss, competition from nonnative plants, and elimination of historical disturbance regimes (and resulting competition from increased vegetation cover), all of which have contributed to the decline of Kincaid's lupine populations.

**Cumulative Effects**

ESA plant species do not have federal protection in Oregon on private lands except in instances where a federal permit is required or a federal action occurs. Outside of the surveyed area for the Pacific Connector pipeline, it is unknown where Kincaid's lupine occurs on private lands throughout the action area. Therefore, it is impossible to determine if there are reasonably foreseeable actions which might occur on private lands, which could impact the plant. Given the lack of protections under ESA and Oregon statutes, all federally listed plants on private lands must be considered at risk of adverse effects, where ever they may occur. However, the Pacific Connector pipeline would mitigate for any Project impacts to Kincaid's lupine.

**Critical Habitat**

No critical habitat would be affected by the proposed action.

### 4.7.5.4 Conservation Measures

Because the removal of any Kincaid's lupine plants may hinder the recovery, and eventual down-listing of the species, Pacific Connector has taken action to avoid or minimize impacts to the populations of Kincaid's lupine that were located during survey efforts near MPs 57.84 to 57.92, 59.60, and 96.5 to 96.9. These measures included altering the proposed route, removing or minimizing proposed TEWAs, and/or minimizing the construction right-of-way (see figures 4.8-3, 4-8-4, and 4.8-5, revised proposed route). At the site between FERC-filed MPs 57.84 and 57.92, all direct impacts to that population were avoided through a reroute. The FERC-filed route near the site between MPs 96.5 and 96.9 follows a narrow ridge-line and no feasible alternate route was available to completely avoid impacting the documented plants at this site. Therefore, Pacific Connector minimized the construction right-of-way and modified TEWAs to avoid directly impacting some Kincaid's lupine patches. Also at this site, subpopulations identified along the existing access roads (EARs 96.29 and 96.67) would be flagged by a qualified botanist prior to Project activities in the area and Pacific Connector's EIs would clearly fence the road edges adjacent to these subpopulations to minimize potential disturbance from road use and maintenance activities. Traffic identified to use EAR 96.67 would be instructed to stay within the construction right-of-way rather than using portions of the road outside of the construction right-of-way with adjacent Kincaid's lupine patches. Similar measures described above would be applied to other areas of the proposed pipeline where survey access was denied, if other Kincaid's lupine populations are identified during survey efforts once Pacific Connector is granted survey access through the FERC certificate process. For additional detail, see the Draft Mitigation Plan for Kincaid's lupine submitted as part of the draft Compensatory Mitigation Plan in appendix O.

Not all documented plants or patches of Kincaid's lupine would be avoided at the site located between MPs 96.5 and 96.9, or possibly at other populations identified if Pacific Connector is granted survey access permission on all unsurveyed parcels. To off-set this impact, plant salvage and seed collection would be attempted. While salvage and re-planting of existing plants would be attempted, there is no guarantee that it would be successful since recent Kincaid's lupine propagation work has focused on augmenting populations, rather than moving plants to avoid disturbance. To date, efforts to establish new populations of Kincaid's lupine using seeds and transplants have met with mixed success. The earliest recorded efforts to establish plants in the field were made by Ingersoll (Gisler 2004). In this study, only five percent of 150 seedlings sown in April 1992 survived the first year. Direct seeding with pre-scarified seeds proved more successful, with 68 percent survival through the first growing season. Kaye (2008) states that germinating and growing Kincaid's lupine seedlings in nursery environments consistently results in large sized plants, although transplanted seedlings typically require three years in the field to assess success (i.e. to achieve flowering plants). Therefore, transplanting mature but dormant plants may be a possible, more viable option, since Kaye (2008) does not advise transplanting of adult plants immediately, nor during the growing season. To increase success in transplanting, a likely timeline might include: 1) identify and tag adult plants during flowering season (May to June); 2) dig up dormant plants during fall (October to December); 3) pot dormant plants and maintain in nursery environment for at least one year to condition plants; and 4) plant out plants during the fall (October to December). Collected seeds would also be provided to a certified seed repository (possibly the Berry Botanic Garden Seed Bank for Range and Endangered Plants, Portland, Oregon) for long-term storage and for use in establishing transplants (BLM et al. 2008).

If Pacific Connector receives approval from the landowner between MPs 96.5 and 96.9, a qualified botanist would attempt to salvage the Kincaid's lupine plants that cannot be avoided within the construction right-of-way in the fall prior to construction to transplant off-site (e.g., adjacent to the proposed project) in suitable habitat openings. The salvaged plants would be temporarily potted and moved to a nursery to condition for a minimum of one year, as recommended by FWS. The feasibility of salvaging and successfully transplanting the salvaged plants is expected to be difficult because of the lupine's vegetative growth pattern (clonal) that renders it difficult to distinguish individuals. Excavations and morphological patterns suggest that plants 33 feet or more apart can be interconnected by below-ground stems, and that clones can exceed 66 feet across (FWS, 2005e; Kaye, 2008). Therefore, the ability to efficiently and successfully complete plant salvage efforts would be determined during the salvaging efforts by Pacific Connector's environmental staff and the salvaging botanist.

Seed collection of Kincaid's lupine from the populations between MPs 96.5 and 96.9, as well as other populations that could be identified on unsurveyed parcels where Pacific Connector has been granted survey access through the FERC Certificate process, would be completed in the 2 years prior to construction after flowering and when the seeds have developed and matured. Seed collection is proposed for 2 years because of the species' low seed production (Gisler 2004). The collected seed would either be provided to a certified repository (i.e., The Berry Botanic Garden) or would be replanted within or adjacent to the construction right-of-way during restoration efforts on suitable BLM lands where future protection can be managed or on private lands where a conservation easement has been acquired. If planting is to occur on the construction right-of-way, it would occur outside the 30-foot maintained easement. For additional detail, see the Draft Mitigation Plan for Kincaid's lupine in appendix O.

Pacific Connector assumes the identified potential habitat for Kincaid's lupine (surveyed and not surveyed) would be accessible prior to construction of the pipeline. When Pacific Connector acquires access to the construction right-of-way, it would conduct surveys in potential habitat and plants located during surveys would be avoided, if possible. Measures of avoidance may include minor alignment reroutes, necking down the construction right-of-way in that area, excluding a portion of an identified temporary extra work space or pipe storage yard, or erecting a protective fence to avoid impact to plants from construction debris, similar to actions taken at the previously identified Kincaid's lupine sites documented within the project area. If it is determined that avoidance is not possible, replanting an area may be considered, either on-site or off-site to supplement conservation agreements and recovery goals. Augmentation of known populations is possible. Approximately 1,468 acres of suitable Kincaid's lupine habitat occur along the proposed pipeline corridor within the botanical analysis area. Appropriate habitat within those acres would need to be selected and assessed.

Additional suitable habitat may exist outside of the botanical analysis area on private land or federal ownership. Appropriate habitat within any private or federal (i.e. non-analysis area) ownership would need to be identified and assessed. Considerations for appropriate habitat include quality of habitat, soil and hydrology characteristics, level of weed infestation, similar habitat/plant community (meadow habitat or forest habitat), proximity to the Kincaid's lupine seed source area, proximity to historical Kincaid's lupine population sites, the ownership status of the site and the ability to protect the site from disturbance. Additional considerations include the proximity of the selected site to the metapopulations within the Douglas County Recovery Unit, and the number of individuals in those metapopulations.

The population at MP 57.9 is a high-value valley floor habitat and would need to be augmented within suitable nearby valley floor habitat. All potential out-planting sites along the right-of way are on private lands and would require a conservation easement or purchase of the land.

The population at MP 96.5 is in upland forest in transitory openings and natural openings and could possibly be augmented by outplantings on BLM land approximately 0.4 mile to the north (T.30S R.3W S.35 SE1/4 of SE ¼) as well as outplantings within the population to augment sub-populations that occur in natural openings. The latter would require a conservation easement.

Additional mitigation measures for the impacts to individual Kincaid's lupine plants would be addressed through the Compensatory Mitigation Plan (see appendix O). Such measures could include application of Integrated Weed Management (BLM et al., 2008) to control existing noxious weeds and prevent new infestations within and adjacent to occupied and potential habitats. Competition with invasive species (Himalayan blackberry, oxeye daisy, grasses, Scotch boom) have been the biggest threat to maintaining or reestablishing Kincaid's lupine in some locations (Thorpe and Massatti, 2008; Thorpe et al. 2009). Integrated Weed Management in those areas could include (BLM et al. 2008, page 13):

- Hand pulling and cutting noxious weeds.
- Mechanical treatments such as mowing prior to seed development.
- Application of an appropriate herbicide treatment for noxious weeds using application methods during the correct phonological periods and using pertinent Best Management Practices to avoid potential effects to Kincaid's lupine.
- Clean all mechanical equipment and inspect to insure no noxious weed plant parts are present prior to equipment use within Kincaid's lupine habitat.
- Flaming with propane burners or hot water treatment of herbaceous noxious weeds.
- Planting desirable grasses, forbs and shrubs to prevent invasion of noxious weeds and invasive non-native species.

Other measures could include planting native forbs and shrubs adjacent to Kincaid's lupine populations to encourage a variety of pollinating insects. Controlling canopy cover in occupied or potential wood habitats could also stimulate growth of existing clones if shading is judged to be a limiting factor.

**Mitigation**

Mitigation for proposed damage to these populations are detailed in the Compensatory Mitigation Plan (see appendix O) and would include the collection of seeds and attempted salvage and transplanting of plants from the population between MPs 96.5 to 96.9. However, harvesting seeds from any population may negatively impact that population's ability to produce new individuals. Also, these Douglas County populations may host unique genetic resources that could contribute to the genetic viability for a restored population. Seeds from other sources, such as from the Willamette Valley populations could be used, but may lack locally adapted genotypes required for successful establishment and growth in Douglas County. Future propagation efforts for the taxon as a whole would likely depend on availability of seed sources from all extant populations. With so little known about genetics in this taxon, it is important to maintain all extant populations.

#### 4.7.5.5 Determination of Effects

**Listed Species**

The Project **may affect** Kincaid's lupine because:

- Suitable habitat is present within the analysis area.
- Individual plants have been located within the analysis area during survey efforts.

The Project is **likely to adversely affect** Kincaid's lupine because:

- Individual plants would be removed.
- Indirect impacts are expected to documented or suspected plants outside of the construction right-of-way and along proposed access roads.
- Trenching activities associated with the proposed pipeline could impact below-ground stems and the expected impact to extant plants is unknown.
- Potential suitable habitat has not been surveyed due to landowner access denial.

**Critical Habitat**

A **no effect** determination is warranted for Kincaid's lupine because:

- The pipeline does not occur within designated Kincaid's lupine critical habitat.

### 4.7.6 Western Lily

#### 4.7.6.1 Species Account and Critical Habitat

**Status**

The western lily was listed as endangered on August 17, 1994 (FWS, 1994c), and a final recovery plan (FWS, 1998c) was released four years later.

**Threats**

In the final rule to classify the western lily as an endangered species, FWS identified agricultural conversion and use, urban and rural development on public and private lands, and forest encroachment as threats that destroy, modify, or curtail the plant's habitat or range. The western lily occupies a very limited range of habitat near the coasts of Oregon and Northern California. Coincidentally, these areas are desirable regions for private land residential development and the plant's habitat during the time of listing was threatened by intense pressure from this current and future development. FWS noted that overutilization for commercial and recreation uses, disease, predation, grazing, and other natural or manmade factors affecting the plant are threats to the western lily's continued existence (FWS, 1994c).

The ongoing threat of development includes creation of new cranberry bogs, residential development, utility and road construction and maintenance, land clearing and drainage for livestock grazing, fire suppression, agricultural plowing, and logging. Lily populations are directly affected by these developments, but are also impacted by the activities on surrounding lands because of degraded hydrological conditions. FWS considers competitive exclusion by shrubs and trees to be the most significant long-term threat to the western lily (FWS, 1998c).

**Species Recovery**

The recovery plan for western lily identifies six recovery areas. When at least 20 viable populations (a viable population consists of 1,000 flowering plants) distributed among these six areas are protected and managed, the western lily can be downlisted to threatened. In coastal areas within Oregon where the lily occurs, the recovery plan recommends that all conifers and alders within 33 feet of the plants be removed to minimize vegetative succession surrounding the population. Additionally, the recovery plan suggests posting coded signs so that accidental destruction of plants through excavation or herbicide treatments do not occur (FWS, 1998c).

The objective of the recovery plan is to stabilize and protect existing occupied sites as viable populations so that the species can be downlisted or delisted in the future. To achieve the objective, the following steps are recommended (FWS 1998c):

- On-site conservation that manages the habitat in appropriate seral stages (i.e., prevents or reverses encroachment by trees and shrubs).
- Off-site conservation by reintroducing or augmenting populations from seeds.
- Conduct and encourage public outreach.

Six recovery areas have been identified within the range of the western lily. These areas are not defined geographically, but are positioned between known extant sites or historical sites. The proposed pipeline and LNG terminal occurs within Recovery Area 1, within which four extant populations and one "unknown status" population occur.

**Life History, Habitat Requirements, and Distribution**

Western lily is present in 31 small, widely separated populations inhabiting sphagnum bogs, coastal scrub and prairie, and other poorly drained soils along the coast of southern Oregon and northern California. Western lilies have an extremely restricted distribution within 2 miles of the coast from Hauser, Coos County, Oregon to Loleta, Humboldt County, California. The plant occurs in seven widely separated regions along the coast within 4 miles of the Pacific Ocean. Such populations are densely clumped and mostly on isolated wetlands that are fewer than 10 acres (FWS 1994c and 1998c).

Western lily is known to occur from early successional fens and coastal scrub habitat in northwestern California to southwest Oregon (Kal,t 2006). Habitats with which this species is associated include coastal bluff scrub, coastal prairie, and openings in coastal coniferous forest dominated by Sitka spruce, including freshwater marshes and swamps (CNDDB, 2005). In Oregon, western lily emerges in late March or early April and flowers in late June or July (Imper, 2003). The species grows in soils that are described as both well-drained or poorly drained and have a significant layer of organic topsoil. The soil profile also includes an iron or clay-confining layer which serves to perch moisture late in the growing season (Imper, 2003). Species typically associated with western lily include Sitka spruce, Pacific reed grass, willows, false lily-of-the-valley, and evergreen huckleberry (Imper, 2003).

## Population Status

At the time of the species recovery plan (1998), western lily had been extirpated from 18 of an estimated 55 sites. Twenty-eight sites had been surveyed (FWS, 1998c). Since 1998, the number and size of populations has declined, with current populations found on nine extant sites in Oregon and seven in California (Imper, 2008 cited in SBS, 2008b).

## Critical Habitat

Critical habitat has not been designated for western lily.

### 4.7.6.2 Environmental Baseline

## Analysis Area

A botanical analysis area applies to the extent of Project-related effects on listed plant species within a general 400-foot-wide corridor, 200 feet on each side of the proposed Pacific Connector pipeline centerline. That area corresponds to areas that were surveyed for sensitive and listed plant species in 2007 and 2008. A limited area of private lands in Coos County immediately adjacent to Coos Bay was included as potential habitat for western lily. See section 4.7.1.2 above for the full botanical analysis area description. On the JCEP LNG Terminal site the analysis area includes the project footprint and potential habitat for western lily extending north from the footprint to the Trans-Pacific Highway and in potential habitat approximately 300 feet west of the proposed slip and LNG storage tank sites.

## Species Presence

The botanical analysis area crosses the plant's range from approximately MP 0 to MP 11.5 (SBS, 2008b). The closest known western lily occurrence is approximately 5.2 miles northeast of the JCEP LNG Terminal site and South Dunes Powerplant site at Hauser Bog (ORBIC, 2012). The occurrence is on Blacklock soils which are found on marine deposits, are deep, poorly drained with high organic content. In 2009, there were 494 plants observed at the site although the population was rated as poor estimated viability (ORBIC, 2012). At the time of listing in 1994, there were 43 plants reported flowering (although based on an incomplete survey – FWS, 2009d). Western lilies at the Hauser Bog site sustain inundation because they grow on mounds that allow bulbs to remain above high water (FWS, 2009d); high groundwater has been implicated in mortality of western lilies at other sites (FWS, 2009d).

Other extant populations of western lily are present south of the JCEP LNG terminal at Bastendorff Bog Preserve (7.8 miles), Sunset Bay State Park (8.7 miles), and several sites within Shore Acres State Park (9.6 miles) (FWS, 1998c). Western lilies in those populations have been rated with excellent or good estimated viabilities except for the population at Sunset Bay State Park which last observed in 2004 and ranked with poor viability (ORBIC, 2012). The western lily has not been documented within the project botanical analysis area (ORBIC, 2012).

## Surveyed Habitat

<u>Jordan Cove Western Lily Surveys</u>

Western lily surveys were conducted in the vicinity of the JCEP LNG terminal and slip area within habitat identified as suitable for this species during the floristically appropriate season in 2006 and again in 2013 (see SHN, 2013). The 2013 surveys included potential habitats within the analysis area (described above) north of the proposed South Dunes Power Plant site to the Trans Pacific Highway.

Botanical reconnaissance assessments in the vicinity of the LNG terminal and slip were conducted in 2005 and 2006 and included evaluations of aerial photography and on-site surveys that initially covered 42 acres on and adjacent to the Roseburg property, which includes the LNG terminal site. Suitable habitat for western lily was found to be limited due to lack of appropriate substrate. The soil types on-site are dune land, Heceta fine sands, Waldport fine sands, and Walport-Heceta fine sands. All of those soils are derived from Eolian deposits rather than marine terrace deposits. Based on soil types present within the study area and the species' moisture requirements, suitable low to moderate quality habitat within the study area is limited to the freshwater wetlands on site that have a significant organic layer within the soil profile. The soil profile within the wetland habitat at and surrounding Jordan Lake lacks the amount of significant organic accumulations that were observed in a section of the Northcentral Wetland and Henderson Marsh.

All freshwater wetlands within the project footprint were reviewed for potential western lily habitat. Wetland sites where fill has been placed were also searched, as they could contain pockets of native soils. Wetlands created for industrial uses (sludge ponds) or estuarine habitats were not included in the surveys, as they would not contain the habitat necessary for the species. Focused surveys for western lily were conducted at 11 sites adjacent to or coinciding with the Project footprint, including the South Dunes Powerplant site, on July 8, 9, 10, and 11, 2013 (SHN, 2013). Sites included freshwater wetlands as far north as the border the Trans Pacific Parkway. Two sites were in disturbed habitat along Jordan Cove Road and the Trans Pacific Parkway and two sites were on highly degraded habitat located on fill that functions as a drainage for surrounding industrial sites. No western lilies were observed during any surveys conducted on the JCEP LNG Terminal site and South Dunes Powerplant site (SHN, 2013).

<u>Pacific Connector Western Lily Surveys</u>

Prior to beginning field surveys in 2007 for the Pacific Connector pipeline, botanists with SBS conducted a habitat review to identify potential habitat and delineate survey areas for western lily within the botanical analysis area, including existing roads identified for access to the construction right-of-way. Aerial photographs (summer 2005) and knowledge of regional landscape and biological features (soils, geology, topography, elevation, target species habitat, and plant community habitat) were used to determine potential habitat for western lily. The same methods were used to determine potential suitable habitat coinciding with new realignments of the project corridor.

A total of 37.6 acres have been identified as potential suitable habitat requiring surveys within the current project alignment and 200 foot botanical analysis area (see table 4.7.6-1). Of that potential habitat, access was allowed to survey 36.1 acres (including 13.7 acres within the project area). An additional 9.3 acres of potential suitable habitat was surveyed adjacent to the Noah Butte access road, but no suitable habitat was located. All potential suitable habitats are located within Pacific Connector pipeline MP 4.15 through MP 11.42, and are all in Coos County.

Of the 36.1 acres of potential habitat that was surveyed, none were considered suitable habitat for western lily. Approximately 1.5 acres (0.2 acres within the project area) of potentially suitable habitat for this species was denied access by the landowner and would need to be surveyed prior to construction for complete surveys of this eco-region. Given the unsuitable habitat conditions surveyed in adjacent areas, the 1.5 acres remaining to be surveyed (see table 4.7.6-1) are not expected to provide suitable habitat for western lily. No western lilies have been observed during surveys conducted on accessible potential habitat and the chance that western lilies occur on the unsurveyed 1.5 acres (0.2 acres within the project area) is judged to be highly unlikely.

**Table 4.7.6-1**

**Summary of Potential Suitable Western Lily Habitat within the FEIS-Revised Route and Botanical Analysis Area**

| Surveyed Area Type and Years Surveyed | Area (acres) Included: FEIS ROW | Area (acres) Included: 200-foot Botanical Analysis Area [1] (Outside of ROW) | Area (acres) Included: Total |
|---|---|---|---|
| **Area Identified for Survey (Potential Habitat)** | 13.9 | 23.7 | 37.6 |
| **Area Surveyed to Protocol** | | | |
| 2007 | 13.0 | 21.1 | 34.1 |
| 2013 | 0.7 | 1.3 | 2.0 |
| **Totals** | **13.7** | **22.4** | **36.1** |
| **Area of Confirmed Potential Habitat** | | | |
| 2007 | 0.0 | 0.0 | 0.0 |
| 2013 | 0.0 | 0.0 | 0.0 |
| **Totals** | **0.0** | **0.0** | **0.0** |
| **Area not Surveyed (access denied)** | **0.2** | **1.3** | **1.5** |

**Note:**
[1] The botanical analysis area applies to the extent of pipeline-related effects on listed plant species within a general 400-foot-wide corridor, 200 feet on each side of the proposed Pacific Connector pipeline centerline.

### Critical Habitat

No critical habitat has been designated for western lily.

## 4.7.6.3 Effects by the Proposed Action

### Direct and Indirect Effects

No direct effects to western lily are expected as a result of the proposed action because surveys conducted at the JCEP LNG Terminal site, the South Dunes Powerplant site, and along the PCGP pipeline route did not locate any plants. Known western lily sites and plants are at least 5 miles from the botanical analysis area.

Approximately 37.6 acres of potential habitat within the botanical analysis area has been identified as potential western lily habitat, of which 36.1 acres have been surveyed. None of the surveyed habitat was found to have suitable conditions to support western lily. A small portion of potential habitat remains to be surveyed; the chance that western lilies occur on the unsurveyed 1.5 acres (0.2 acres within the project area) is judged to be highly unlikely.

Review of NRCS soil survey data, indicates that the potential suitable habitat areas along the proposed PCGP route does not have the combination of the soil characteristics (i.e., deep, poorly drained marine deposits with high organic content) that support the known western lily populations.  Furthermore, the upland proposed route is within a narrow range of the plant, which has been relatively well-explored botanically, and no plants identified (FWS, 1998c).  Since suitable habitat has not been previously identified within the proposed route and suitable habitat is not expected to be present in the proposed route, the Pacific proposed route is not expected to impact western lily.  However, that will be confirmed once Pacific Connector is granted survey access permission on the unsurveyed parcel and surveys for western lily can be completed.

**Cumulative Effects**

ESA plant species do not have federal protection in Oregon on private lands except in instances where a federal permit is required or a federal action occurs.  Outside of the surveyed area for the Pacific Connector pipeline, it is unknown where western lily occurs on private lands throughout the action area.  Therefore, it is impossible to determine if there are reasonably foreseeable actions which might occur on private lands, which could impact the plant.  Given the lack of protections under ESA and Oregon statutes, all federally listed plants on private lands must be considered at risk of adverse effects, where ever they may occur.  However, the Pacific Connector pipeline would mitigate for any pipeline impacts to western lily.

**Critical Habitat**

Critical habitat has not been designated for western lily.

#### 4.7.6.4 Conservation Measures

If the Project is approved, Pacific Connector would have access to the identified potential habitat for western lily shortly prior to construction of the pipeline.  When Pacific Connector acquires access to the construction right-of-way, surveys would be conducted in previously unsurveyed potential habitat and any plants located during surveys would be avoided, if feasible.  Measures of avoidance may include necking down the construction right-of-way in that area, excluding a portion of an identified temporary extra work space or pipe storage yard, or erecting a protective fence to avoid impact to plants from construction debris.  If a population is documented within the revised proposed route and seed is needed to augment the population, the Berry Botanic Garden has a few collections of western lily seed, including populations within Recovery Area 1 where the proposed pipeline is located (FWS, 1998c).  The FWS would be provided all survey results.

#### 4.7.6.5 Determination of Effects

**Listed Species**

The Project **may affect** western lily because:

- Known populations occur within 10 miles of the botanical analysis area.
- Potential suitable habitat is available within the analysis area.

The Project is **not likely to adversely affect** western lily because:

- Surveys of potential western lily habitat at the JCEP LNG terminal site, at the South Dunes Powerplant site, and along the PCGP proposed pipeline route did not document

western lily nor did the surveys identify suitable western lily habitats within the botanical analysis area.
- Initial reviews of soils at potential suitable habitat sites that have not been surveyed do not appear to be suitable to support western lily plants.
- The closest known population of western lily is located 5.2 miles northeast of the JCEP LNG Terminal site at Hauser Bog.
- Surveys in potentially suitable habitat identified within the FEIS-revised proposed route (1.5 acres) would occur prior to ground disturbing activities; if plants are identified, conservation measures developed to avoid or minimize impacts to future plants would be applied.
- Given current knowledge that the species is absent and suitable habitat would not be affected and there is no reason to expect that future surveys would identify western lily plants, project effects to the species are currently insignificant and discountable.

**Critical Habitat**

Critical habitat has not been designated for western lily.

### 4.7.7 Rough Popcornflower

#### 4.7.7.1 Species Account and Critical Habitat

**Status**

The rough popcornflower was listed as endangered on January 25, 2000 (FWS, 2000d).

**Threats**

At the time of listing in the FWS final rule, the rough popcornflower was threatened by the destruction, modification, or curtailment of its wetland habitat and range. The species was then limited to 17 small, isolated habitat patches. Areas supporting the rough popcornflower were threatened by hydrological alterations (including ditching and wetland fill), livestock grazing, agricultural land conversion, non-native vegetation invasion, forest succession and canopy cover, residential and commercial development.

Predation and other natural or manmade factors are also threats identified in the endangered status listing. These factors include herbicide and pesticide use, chemical spills and runoff from roads, roadside maintenance, habitat vandalism, and grazing. Overgrazing likely contributed to declining numbers throughout its historical range. Livestock grazing in spring and summer months can cause the most damage. When flowers and seed heads are grazed, the reproductive output for the year is destroyed. However, FWS notes in the final rule that grazing in the fall, during the plant's dormant stage; can be a benefit by reducing the growth of weedy competitors (FWS 2000d). The small, isolated populations also make the species vulnerable to disease outbreaks, weak genetic viability, adverse pollinator activity, and random environmental events.

Since the publication of the final rule for rough popcornflower, the potential for further development in the plant's habitat remains the most urgent threat. Habitat destruction and fragmentation from residential, commercial, and agricultural development continues as the Sutherlin, Oregon area expands. Competitive exclusion by other wetland vegetation is another major threat to the plant. Other ongoing threats include, forest succession, overgrazing by livestock, chemical spills and fire along roadsides, herbicide use, wetland infill, and the intentional destruction of suitable habitat and plants (FWS, 2003e).

**Species Recovery**

A recovery plan was developed in 2003 (FWS, 2003e). To ensure that the rough popcornflower was conserved throughout its range in the North Umpqua system, three recovery units were created. Part of the recovery plan also involves a goal of nine reserves, each containing a minimum of 5,000 plants, distributed across the three recovery units of Calapooya Creek, Sutherlin Creek, and Yoncalla Creek (FWS, 2003e). However, all the units identified occur north of the proposed Pacific Connector pipeline and the Project is not expected to affect these units.

The objective of the recovery plan is to reduce threats and increase population viability until the rough popcornflower can be downlisted. The recommended steps are as follows:

- Conserve and manage a minimum of nine reserves within three recovery units.
- Practice ex-situ conservation.
- Research factors that threaten the recovery of the species.
- Provide outreach services for owners of reserve populations and the general public.

**Life History, Habitat Requirements, and Distribution**

The rough popcornflower is currently found in seasonal wet meadows or wet prairies in poorly drained clay or silty clay loam soils at elevations ranging from 100 to 900 feet. Deep, poorly drained soils provide a high-to-surface-level water table from November to May, when rough popcornflowers' seedlings germinate and overwinter as submerged rosettes. In these areas, the rough popcornflower is often observed in the deeper sections of shallow meadow pools that lack significant shade, and are associated with typical marshland sedge and grasses (FWS, 2003e).

Rough popcornflower generally blooms from June through July. Rough popcornflower grows in scattered groups and reproduces largely by insect-aided cross-pollination and partially by self-pollination (FWS, 2008f). The herbaceous plant occurs in the vicinity of Sutherlin and Yoncalla, mostly on private lands in the Umpqua River drainage (FWS, 2003e).

**Population Status**

There are 15 known naturally-occurring extant sites of the Rough popcornflower within its limited range, as found in the Oregon Natural Heritage Program database. In addition to the naturally occurring populations, rough popcornflower transplants have been introduced at two sites on the BLM North Bank Habitat Management Area (FWS, 2003e). Five population patches are considered protected, two of which are on State of Oregon lands managed by The Nature Conservancy as part of the Popcorn Swale Preserve (FWS, 2003e).

**Critical Habitat**

Critical habitat has not been designated for the rough popcornflower.

### 4.7.7.2 Environmental Baseline

**Analysis Area**

A botanical analysis area applies to the extent of Project-related effects on listed plant species within a general 400-foot-wide corridor, 200 feet on each side of the proposed Pacific Connector pipeline centerline. The botanical analysis area also includes all TEWAs, rock source and disposal sites, and proposed storage yards either on federal or state lands or that have potential for listed plant species. That area corresponds to areas that were surveyed for sensitive and listed plant species in 2007 and 2008. See section 4.7.1.2 Applegate's Milk-vetch above, for the full botanical analysis area description.

**Species Presence**

This species has only been documented in northern Douglas County. As of 2010, there were 14 extant occurrences of rough popcornflower distributed from Yoncalla Creek near Rice Hill, south to Sutherlin Creek near Wilbur (FWS, 2010g). The patches along Sutherlin Creek are within the Lower Noth Umpqua River watershed (HUC 171003011) and extend from inside the city of Sutherlin to the south for four miles. The closest rough popcorn occurrence occurrence to the proposed pipeline route is 17.5 miles north of MP 68.

However, there are historical records of rough popcorn flowers near two proposed pipeyards. One record is of a population of 300 to 500 plants when first observed in 1983, but fewer than 50 plants were observed in 1998. The population was proximate to the proposed Sutherlin John Murphy pipe yard, an 85.48 acre site in the city of Sutherlin, Orgon. In 1998 there were very few plants remaining and the site was being drained; the expectation then was that complete extirpation was imminent (ORBIC, 2012). The 1998 record is west of Taylor Road in Sutherlin while the Sutherlin John Murphy Pipe Yard is east of Taylor Road, a major thoroughfare in the city. Although the 1998 record is 120 feet across the road from the John Murphy yard property edge, that portion of the property is covered by the North Douglas Log Ponds. The 1998 record is >1,000 feet from the actual asphalt surfaced yard associated with the former John Murphy Plywood Mill.

Currently the proposed pipeyard is an active laminated beam factory on private land. The proposed yard site would not be used unless the factory closed prior to pipeline construction. If the site is used for pipe storage, only the existing paved portions of the site would be used which amount to 31.3 acres. The North Douglas Log Ponds are still present at the southern portion of the property and wetland habitat may be present, providing suitable conditions similar to suitable habitat in shallow meadow pools that lack significant shade, and associated with typical marshland sedge and grasses. The periphery of the poposed Sutherlin John Murphy pipe yard has not been surveyed for rough popcornflower.

The second record is of an historical population located between railroad tracks that parallel Interstate 5 and Sutherlin Creek. The site was last observed in 1998 with plants present but the population was rated with fair or poor estimated viability (ORBIC, 2012). The rough popcornflower population occurred in a wetland swale on both sides of a private driveway and had been impacted by fall livestock grazing. It was noted that grazing during spring would destroy the population (ORBIC, 2012). There is no information indicating that the population has persisted.

That site is adjacent to an 8.76 acre parcel proposed for use as the Old Highway 99 pipe yard. Approximately 4.9 acres of the proposed yard site are graveled and currently provide storage as an equipment auction business. A small 1.2 acre pond is present south of the gravel yard surface and separates the yard from the historic population of rough popcornflower to the south. As with the Sutherlin Jack Murphy yard, the proposed Old Highway 99 yard site would not be used unless the business closed prior to pipeline construction. If the site is used for pipe storage, only the existing 4.9-acre gravelled portion of the site would be used. The periphery of the poposed Old Highway 99 pipe yard has not been surveyed for rough popcornflower.

**Surveyed Habitat**

Pacific Connector Rough Popcornflower Surveys (2007)

Prior to beginning field surveys in 2007 for the Pacific Connector pipeline, botanists with SBS conducted a habitat review to identify potential habitat and delineate survey areas for rough popcorn flower within the botanical analysis area, including existing roads identified for access to the construction right-of-way. Aerial photographs (summer 2005) and knowledge of regional landscape and biological features (soils, geology, topography, elevation, target species habitat, and plant community habitat) were used to determine potential habitat for rough popcorn flower. The same methods were used to determine potential suitable habitat coinciding with new realignments of the project corridor.

A total of 41.6 acres have been identified as potential suitable habitat requiring surveys within the current project alignment and 200-foot botanical analysis area (see table 4.7.7-1). Of this habitat, access was allowed to survey on 11.7 acres (3.3 acres within the project area). A total of 22.1 acres of unassessed habitat are located on pipeyards. Potential suitable habitat is located within Pacific Connector pipeline MP 51.7 through MP 66.96, all in Douglas County.

Of the 11.7 acres of potential habitat with allowed access to survey, 3.4 acres (1.0 acre within the project area) were considered suitable habitat for rough popcornflower. Habitat found to be "suitable" in the surveys included areas with some of the characteristics detailed in the Life History, Habitat Requirements, and Distribution section above (SBS, 2008a).

Approximately 29.9 acres (24.3 acres within the project area) of potentially suitable habitat for this species was denied access by the landowner and would need to be surveyed prior to construction for complete surveys of this eco-region. If the assumption is made that a similar percent of that area is suitable as documented within the rest of the area surveyed, then approximately 3.0 acres (10 percent of 29.9 acres, or 2.4 acres within the project area) is probably suitable popcorn flower habitat. No rough popcorn flower individuals were located during surveys conducted in 2007.

| Table 4.7.7-1<br><br>Summary of Potential Suitable Rough Popcornflower within the FEIS-Revised Route and Botanical Analysis Area. | | | |
|---|---|---|---|
| | **Area (acres) Included** | | |
| **Surveyed Area Type and Years Surveyed** | **FEIS ROW** | **200-foot Botanical Analysis Area** [1] **(Outside of ROW)** | **Total** |
| **Area Identified for Survey (Potential Habitat)** | 27.6 | 14.0 | 41.6 |
| **Area Surveyed to Protocol** | | | |
| 2007 | 3.3 | 8.3 | 11.6 |
| 2013 | 0.0 | 0.1 | 0.1 |
| **Totals** | **3.3** | **8.4** | **11.7** |
| **Area of Confirmed Potential Habitat** | | | |
| 2007 | 1.0 | 2.3 | 3.3 |
| 2013 | 0.0 | 0.1 | 0.1 |

| **Area not Surveyed (access denied)** | **24.3** | **5.6** | **29.9** |

**Note:**
[1] The botanical analysis area applies to the extent of pipeline-related effects on listed plant species within a general 400-foot-wide corridor, 200 feet on each side of the proposed Pacific Connector pipeline centerline.

### Critical Habitat

Critical habitat has not been designated for this species.

## 4.7.7.3 Effects by the Proposed Action

### Direct and Indirect Effects

Surveys conducted within potential suitable rough popcornflower habitat did not locate any plants; therefore, no direct effects to rough popcornflower plants are expected as a result of the proposed action. Potential wetland habitat for the species may be present at the periphery of two proposed pipe yard but surveys have not been conducted at those sites. Based on the current businesses occupying the proposed Sutherlin John Murphy pipe yard and proposed Old Highway 99 pipe yard sites, neither would be used for pipe storage if the businesses are present at the time of project initiation. In that circirmstance, there would be no project-related effects to rough popcornflower. If either or both proposed pipe yards will be used by the project, surveys along the perimeters of the paved or graveled surfaces that are adjacent to standing water would be conducted.

### Cumulative Effects

ESA plant species do not have federal protection in Oregon on private lands except in instances where a federal permit is required or a federal action occurs. Outside of the surveyed area for the Pacific Connector pipeline, it is unknown where rough popcornflower occurs on private lands throughout the action area. Therefore, it is impossible to determine if there are reasonably foreseeable actions which might occur on private lands, which could impact the plant. Given the lack of protections under ESA and Oregon statutes, all federally listed plants on private lands must be considered at risk of adverse effects, where ever they may occur. However, the Pacific Connector pipeline would mitigate for any Project impacts to rough popcornflower.

**Critical Habitat**

No critical habitat has been designated.

### 4.7.7.4 Conservation Measures

No measures to conserve rough popcornflower have been included in the proposed action.

### 4.7.7.5 Determination of Effects

**Listed Species**

The Project **may affect** rough popcornflower because:

- Historical populations occur in the vicinity of two proposed pipe storage yards.
- Potential suitable habitat might be present within the 200-foot botanical analysis area extending from the perimeter of either yard.

The Project is **not likely to adversely affect** rough popcornflower because:

- It does not appear likely that either yard would be used for the project, based on current occupancies of the properties.
- Suitable wetland habitats within the 200-foot botanical analysis area surrounding either yard may be present, but no historica populations of rough popcornflower have been reported in the analysis areas.
- Surveys in potentially suitable habitat identified within the botanical analysis areas surrounding the two proposed yards would occur prior to ground disturbing activities; if plants are identified, conservation measures developed to avoid or minimize impacts to future plants would be applied.
- Given current use of the two proposed pipe yards, no rough popcornflowers are present within portions that would be used for pipe storage and there is no reason to expect that future surveys would identify rough popcornflowers within the botanical analysis area surrounding the yards. Project effects to the species are currently insignificant and discountable.

**Critical Habitat**

Critical habitat has not been designated for rough popcornflower.

## 5.0 INTERDEPENDENT AND INTERRELATED EFFECTS

The ESA, as amended, described interrelated actions as those that are part of a larger action and depend on the larger action for their justification. Interdependent actions are those that have no independent utility apart from the action under consideration" (50 § CFR 402.02).

For the LNG component, unless analyzed differently by FERC, the South Dunes Power Plant would not be included in the EIS. However, the disturbance area necessary to construct the power plant was included in the environmental analysis in the Jordan Cove Resource Reports provided to FERC. The power plant connects directly to the LNG component but does not affect the configuration and location of the LNG component. The power plant is outside of FERC's jurisdiction as the siting, construction, and operation of this facility is under the jurisdiction of the State of Oregon Energy Facility Siting Council. The power lines that connect the power plant to the LNG component are located within a corridor that is under the FERC's jurisdiction. The power plant is being privately developed by Jordan Cove; it has no federal financing or guarantees. Prior to construction of the power plant, a federal permit will be required for wetlands from previous activities on the site that are affected by the site closure plan that was previously approved by the ODEQ; no federal lands would be involved.

For the Pacific Connector pipeline component, interrelated/interdependent facilities would include local power and telephone service to the compressor station and meter stations. Exisiting local facilities are available at each of the aboveground facility locations. There are no permits required of Pacific Connector for purchase power or telephone service to the Klamath Compressor Station, Clarks Branch Meter Station, or Jordan Cove Meter Station, and there are no additional impacts on environmental resources beyond those already accounted for by Pacific Connector and Jordan Cove in their respective FERC Certificate applications.

The PCGP Project scope currently includes interconnections with three interstate gas transmission pipeline systems. Two of the systems are Gas Transmission Northwest and Ruby Pipeline, which would have interconnects at the proposed Klamath Compressor Station site (MP 228.13), where both these pipeline systems have existing below and aboveground facilities. The PCGP Project would also interconnect with Northwest Pipeline's Grants Pass Lateral at the proposed Clarks Branch Meter Station (MP 71.46). All facilities and actions necessary to effectuate these interconnections are under FERC's jurisdiction.

# 6.0 ESSENTIAL FISH HABITAT

The Sustainable Fisheries Act of 1996 amended the Magnuson-Stevens Act and requires federal agencies, in part, to consult with the NMFS about activities that may adversely affect EFH (NMFS, 1997a). The Magnuson-Stevens Act established guidelines for Regional Fishery Management Councils to identify and describe EFH in Fishery Management Plans (FMPs) to responsibly manage exploited fish and invertebrate species in federal waters. The Pacific Fishery Management Council (PFMC) has developed four FMPs that address EFH for managed species in the Pacific Connector pipeline area, (PFMC, 2004; PFMC, 1998; and PFMC, 1999).

The Magnuson-Stevens Act describes EFH as those waters and substrate necessary to fish for spawning, breeding, feeding or growth to maturity (NMFS, 1997a). The Magnuson-Stevens Act provides these additional definitions:

- "Waters" include aquatic areas and their associated physical, chemical, and biological properties that are used by fish, and may include areas historically used by fish where appropriate.
- "Substrate" includes sediment, hard bottom, structures underlying the waters, and associated biological communities.
- "Necessary" means the habitat required to support a sustainable fishery and the managed species contribution to a healthy ecosystem.
- "Spawning, breeding, feeding, or growth to maturity" covers the full life cycle of a species.

There are four federal fishery management plans and associated essential fish habitats that coincide with the EEZ analysis area, the estuarine analysis area, and several riverine analysis areas that were defined in the introduction to Section 4.0 of the Biological Assessment for this Proposed Action. The four fisheries managed by the PFMC are highly migratory species, coastal pelagic species, groundfish, and Pacific Coast salmon.

## 6.1 HIGHLY MIGRATORY SPECIES

### 6.1.1 Essential Fish Habitat

Highly migratory species occur within the EEZ analysis area (from the coast seaward to 200 nmi) and beyond since they migrate considerable distances across oceans to feed and reproduce. Highly migratory species defined by the Pacific Fishery Management Council include tunas (5 species), sharks (5 species), billfish/swordfish (2 species), and the dorado (also called dolphinfish or mahi-mahi). However, highly migratory species and their various life stages are not uniformly distributed within the EEZ analysis area. Species' life cycles included in table 6.1.1-1 have been separated by their distributions in the EEZ north of 37$^{o}$N latitude (north of Monterey Bay, California) and/or south of 37$^{o}$N. Within the EEZ analysis area, the earliest life stages for most highly migratory species occur south of Monterey Bay (South of 37$^{o}$N latitude in table 6.1.1-1).

**Table 6.1.1-1**
**Highly Migratory Fish Species Managed by the Pacific Fishery Management Council For Which Essential Fish Habitat Has Been Identified and May Occur Within the Proposed Action EEZ Analysis Area**

| Common Name/Scientific Name | Life Cycle and Habitat Associations [1] | Distribution within the EEZ Analysis Area North of 37°N Latitude | | | | | Distribution within the EEZ Analysis Area South of 37°N Latitude | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|
| | | Eggs | Larvae | Neonate-Early Juvenile [2] | Late Juvenile - Sub-adults [2] | Adult | Eggs | Larvae | Neonate-Early Juvenile [2] | Late Juvenile - Sub-adults [2] | Adult |
| Common thresher shark *Alopias vulpinus* | Epipelagic, neritic, and oceanic waters off beaches, in shallow bays, open coast bays and offshore, in near surface waters. Feeds primarily on northern anchovy, Pacific hake, Pacific mackerel, and sardine. | | | | | X | | | X | X | X |
| Pelagic thresher shark *Alopias pelagicus* | Epipelagic and predominantly oceanic waters. Associates with sea surface temperatures of 21°C or warmer. Nothing known of diet. | | | | | | | | | X | X |
| Bigeye thresher shark *Alopias superciliosus* | Coastal and oceanic waters in epi- and mesopelagic zones. Little known of diet; presumably feeds on pelagic fishes and squids. | | | | | X | | | | X | X |
| Blue shark *Prionace glauca* | Epipelagic and oceanic waters. Feeds on northern anchovy, Pacific hake, squid, spiny dogfish, herring, flatfishes. | | | X | X | X | | | X | X | X |
| Shortfin mako shark *Isurus oxyrinchus* | Oceanic and epipelagic waters. Reportedly feed on mackerel, sardine, bonito, anchovy, tuna, other sharks, swordfish, and squid. | | | X | X | X | | | X | X | X |
| Albacore *Thunnus alalunga* | Oceanic, epipelagic waters. Feed opportunistically. Younger fish may aggregate in vicinity of upwelling fronts to feed. | | | X | | X | | | X | | X |
| Bigeye Tuna *Thunnus obesus* | Oceanic, epipelagic, and mesopelagic waters. Nothing known of diet. | | | | | | | | X | | X |
| Northern bluefin tuna *Thunnus thynnus* | Juvenile-oceanic, epipelagic waters. Major part of diet is northern anchovy. | | | X | | | | | X | | |
| Skipjack tuna *Katsuwonus pelamis* | Adult-oceanic, epipelagic waters. Major part of diet are pelagic red crab and northern anchovy. | | | | | X | | | | | X |
| Yellowfin tuna *Thunnus albacares* | Juvenile-oceanic, epipelagic waters. Diet on pelagic red crab and northern anchovy. | | | | | | | | X | | |
| Striped marlin *Tetrapturus audax* | Adult-oceanic, epipelagic waters. Preferred water temperature bounded by 20-25°C. Diet includes Pacific saury, northern anchovy, Pacific sardine, jack mackerel, squid, and pelagic red crab. | | | | | | | | | | X |
| Broadbill swordfish *Xiphias gladius* | Oceanic, epipelagic, and mesopelagic waters. Food species not documented. | | | X | | X | | | X | | X |
| Dorado *Coryphaena hippurus* | Epipelagic and predominantly oceanic waters. Prefers sea temperatures 20°C and higher during warm water incursions. Diet unknown. | | | | | | | | X | | X |

[1] PFMC 2007.
[2] All juvenile life stages are combined for species other than sharks.

### 6.1.2 Analysis of Effects

Analyses of effects to EFH for highly migratory species by the proposed action have been provided in multiple sections in the BA. For Highly Migratory Species EFH, Project effects are expected to be associated with accidental spills and releases at sea by LNG carriers transiting at least 50 nmi offshore within the EEZ from south to north (San Diego to Coos Bay) and from LNG carriers approaching Coos Bay from the west through the 200 nmi-wide EEZ.

Oil spills at sea or offshore might directly harm highly migratory fish species. The quantity of oil and other petroleum products on board an LNG vessel are low (fuels or lubricants associated with the operation of the LNG carrier) relative to oil tankers, so any spill is likely to be small and the chance of any spill remote. A total of about 90 LNG vessel trips would occur annually when spills may occur along the route. As reported by Pacific States/British Columbia annual reports, the number of oil spills reported from fishing and other harbor marine vessels ranged from 9 to 65 per year, fairly infrequent for the large number of marine vessels in that area.

An LNG spill is very unlikely to impact highly migratory fish. If an unignited LNG spill were to occur along the LNG carrier transit route in the areas where this species is located, the LNG would float on the water until it vaporizes would not have an adverse effect on this species, unless individuals come in direct contact with the LNG. Should a fish directly contact the LNG when it is first released, before any warming occurs, could have its flesh frozen as the temperature is very low (-260$^0$C). The chance of this occurring would be extremely remote as it would require a fish to be at or above the water surface at the direct point of LNG spill. Some cooling of the upper water layers closest to the LNG spill would be expected, but would not likely cause the overall water column to cool to the point of affecting the fish species in the water, given the ambient water temperatures in the transit route. If the vapor from an LNG spill were to come in contact with an ignition source, the resulting fire would burn back to the spill source and would affect species on the water or in the area that come in direct contact with the fire. Fish in the water would not be affected as the fire would be above the water in the area of the spill where the vaporized LNG is flammable. LNG density as a gas (mostly methane) is less than air and would rise above the water as it turns to vapor. In either case of lower or higher water temperatures based on the spill scenario, mobile fish species would move out of the area until the water temperatures return to normal.

Additionally the chances of an LNG spill are remote. Considering the double-hulled construction of LNG carriers and the outstanding operating and safety record of LNG carriers, the probability of any incidents that could result in the loss of LNG cargo, are extremely low. LNG carriers have been operating commercially since 1959. Since then there have been more than 38,000 LNG carrier voyages covering more than 60 million miles and transported a total of 1.5 billion cubic meters of LNG. Currently, approximately 196 LNG carriers safely transport more than 287 million cubic meters of LNG annually to ports around the world. There have been approximately 11 reportable incidents between 1979 and 2006 worldwide. Since LNG has not been transported to or from the Pacific Northwest, no data are available. However, due to the double hulls of LNG carriers, none of the incidents that have occurred with LNG carriers have resulted in the loss of LNG cargo or other significant petroleum based spills.

Additional details of effects have been included for mammals (whales in sections 4.2.1.3, 4.2.2.3, 4.2.3.3, 4.2.4.3, 4.2.5.3, 4.2.6.3, and 4.2.7.3), reptiles (sea turtles in sections 4.4.1.3, 4.4.2.3, 4.4.3.3, and 4.4.4.3), and fish (Southern DPS North American green sturgeon in section

4.5.1.3, Southern DPS Pacific eulachon in section 4.5.2.3, and Oregon Coast coho salmon ESU in section 4.5.4.3).

**Conservation Measures**

Measures to minimize effects to listed whales would likewise minimize potential accidental spills and releases at sea which could affect EFH within the EEZ analysis area. Those measures include 1) LNG carriers approaching the Port of Coos Bay would be traveling slowly and escorted by tractor tugs from 50 nmi offshore to the Port; and 2) spills or releases of LNG at sea would not cause the water column to cool to the point of affecting highly migratory fish species in the water.

### 6.1.3 Effects Determination

The proposed action **would not adversely affect** EFH for highly migratory species because accidental spills and releases at sea, if they should occur, are not expected to diminish water quality within the EEZ analysis area.

## 6.2 COASTAL PELAGIC SPECIES

### 6.2.1 Essential Fish Habitat

Coastal pelagic species also occur from the ocean surface to depths of 1,000 m (547 fm) within the EEZ analysis area but distributions of several species tend to be in relatively shallow water closer to shore, including the estuarine analysis area. Coastal pelagic species include four fin fish – northern anchovy, Pacific sardine, Pacific (chub) mackerel, and jack mackerel – and the invertebrate market squid. Coastal pelagic species occur near the ocean surface and are not associated with substrates. EFH for coastal pelagic species also includes portions of the water column where sea surface temperatures range between 50°F (near the United States/Mexico maritime boundary) and 79°F (seasonally and annually variable) (PFMC, 2006).

All life stages for each of the coastal pelagic species are expected to occur within the EEZ analysis area and adults of most species are expected within the estuarine analysis area (table 6.2.1-1). Northern anchovies are the only coastal pelagic species for which all life stages are likely to utilize the estuarine analysis area (table 6.2.1-1). Site F, off the mouth of Coos Bay, also contains at least juvenile and adult stages of both northern anchovy and Pacific mackerel, based primarily on trawl samples at this dredge discharge site (table 6.2.1-1) Within the Coos Bay estuary, northern anchovies are expected to be transient users of eelgrass (Phillips 1984). Eelgrass provides indirect benefits to these species by contributing to productivity in the estuary, and eelgrass drift may provide cover for coastal pelagic species (Nightengale and Simenstad, 2001).

**Table 6.2.1-1**
**Coastal Pelagic Fish Species Managed by the Pacific Fishery Management Council For Which Essential Fish Habitat Has Been Identified and May Occur Within the Proposed Action Estuarine Analysis Area and EEZ Analysis Area**

| Common Name Scientific Name | Life Cycle and Habitat Associations [1] | Distribution within Estuarine Analysis Area | | | | Distribution within EEZ Analysis Area | | | | Site F Presence [2] | |
|---|---|---|---|---|---|---|---|---|---|---|---|
| | | Eggs | Larvae | Juvenile | Adult | Eggs | Larvae | Juvenile | Adult | Juvenile | Adult |
| Pacific sardine Sardinops sagax | Pelagic commercially-harvested schooling fish that inhabits coastal subtropical and temperate waters. Occur in estuaries, but more commonly near shore and offshore. Highly mobile, moving seasonally along the coast. More abundant in Oregon during the summer and warm water years. Spawning occurs year-round (spatially and seasonally dependent on temperature) in loosely aggregated schools in the upper 50 yards of the water column, generally 30-90 miles offshore. Major prey species for commercially valuable and endangered fish species. | | | ? | X | X | X | X | X | | |
| Northern anchovy Engraulis mordax | Often in schools near the surface. Spawning occurs every month, especially in late winter and early spring (February – April). Overwinter in mixed layer temperatures. Nearshore habitats support most of the juvenile population. Eat phytoplankton or zooplankton by either filter-feeding or biting. Considered a valuable source of food for endangered fish and bird species. | X | X | X | X | X | X | X | X | X | X |
| Pacific (chub) mackerel Scomber japonicus | Pelagic for all life stages. Adults commonly found in shallow banks with increased abundance from July to November. Spawning peaks April through July in California. | | | ? | ? | X | X | X | X | ? | ? |
| Jack Mackerel Trachurus symmetricus | Pelagic schooling fish that range widely. Diet on large zooplankton, juvenile squid, and anchovy. They are more available on offshore banks in late spring, summer and early fall than during the remainder of the year. Much of their range lies outside the 200 mile EEZ. | | | | X | X | X | X | X | | |
| Market Squid Loligo opalescens | Prefer oceanic salinities and rarely found in bays, estuaries, or near river mouths. Spawning occurs year-round. They are important as forage foods for many species. | | X | X | X | X | X | X | X | | |

## 6.2.2 Analysis of Effects

Analyses of effects to EFH for coastal pelagic species by the proposed action have been provided in multiple sections in the BA. For EFH within the EEZ analysis area, Project effects are expected to be associated with accidental spills and releases at sea by LNG carriers transiting at least 50 nmi offshore within the EEZ from south to north (from San Diego to Coos Bay) and from LNG carriers approaching Coos Bay from the west through the 200 nmi-wide EEZ. These effects have been discussed under Highly Migratory species in Section 6.2.1 above. Additional details of effects have been included for mammals (whales in sections 4.2.1.3, 4.2.2.3, 4.2.3.3, 4.2.4.3, 4.2.5.3, 4.2.6.3, and 4.2.7.3), reptiles (sea turtles in sections 4.4.1.3, 4.4.2.3, 4.4.3.3, and 4.4.4.3), and fish (Southern DPS North American green sturgeon in section 4.5.1.3, Southern DPS Pacific eulachon in section 4.5.2.3, and Oregon Coast coho salmon ESU in section 4.5.4.3).

Within the estuarine analysis area of Coos Bay, Project effects to coastal pelagic species are expected to be associated with effects to eelgrass habitats; short-term turbidity produced by construction of LNG carrier berth, access channel, and Pacific Connector pipeline; entrainment of larvae, juveniles and adults by hydraulic dredging and ballast and cooling water expulsion; acoustic effects from ship noise, effects of operational lighting and wakes associated with LNG carriers; effects of facilitated predation by shading from over-water structures; introduction of exotic species; and windblown sand from stockpiles. Those effects have been included for Southern DPS green sturgeon in section 4.5.1.3 and Oregon Coast ESU coho salmon in section 4.5.4.3.

Eelgrass Habitat

Construction of the pipeline across the Haynes Inlet of Coos Bay estuary would span 2.5 miles and disturb approximately 0.068 mile of eelgrass or 2.8 percent of that amount, most of which classified as low-density eelgrass beds (see discussion in Section 4.5.4.3, Oregon Coast coho). Construction of the pipeline across the estuary is planned from October 1 through February 15 following ODFW’s recommendation. During most of that period, eelgrass in Coos Bay would be dormant, coinciding with low temperatures and short photoperiods (Fonseca et al., 1998).

Ellis Ecological Services, Inc. (2013) conducted a survey of eelgrass beds within Coos Bay along the pipeline route. Based on the survey of the route in 2013, there was 5.0 acres of eelgrass beds that will be directly affected by the construction right-of-way (including temporary extra work areas - TEWAs). Eelgrass beds were placed into three categories based on density: low, medium, and high. Most of the area affected would be low density, and none were categorized as high-density eelgrass. Approximately 0.1 percent of the total eelgrass beds present in Coos Bay would be directly disturbed from pipeline construction across Haynes Inlet (Ellis Ecological Services, 2013).

Entrainment and Impingement

LNG carriers would re-circulate water while loading LNG at the berth and the amount of cooling water to be re-circulated is a function of the propulsion system for the vessels. Once the LNG fleet has been identified, cooling water flow rates and the amount of water required can be further addressed. It is expected that a high portion of juvenile larval stages of fish and invertebrates entrained or impinged would suffer mortality. Ballast and cooling water intake could be highly variable depending on multiple factors but could range from about 64 to 285 thousand $m^3$ per vessel offloading trip. The details of how entrainment may affect coastal pelagic species is similar to that of Groundfish EFH resources (Section 6.3.2), which is presented in more detail. Juvenile or larval fish would need to be present in the slip area near the LNG carrier’s intake screens and be small enough to fit through the sea chests which are covered with screens composed of 4.5 mm thick bars spaced 24 mm apart and located approximately 32 feet below the water line, or 5.6 feet from the keel of the LNG carrier. The intake velocities for cooling water are low enough that it is not anticipated that any larger organisms (fish, marine mammals, or invertebrates) would be impinged on the intake screen. Generally the total water intake would occur over a 24-hour period during each loading period, about 90 times per year.

The LNG ships will also re-circulate water for engine cooling while loading LNG at the berth. The power requirements for loading LNG in the export mode are less than those for unloading LNG in the import mode because the LNG carrier does not have to use on board LNG pumps to handle LNG cargo; hence both the LNG carrier engine requirement and the required amount of cooling water flow are reduced. For reasons discussed in Section 4.5.1.3, green sturgeon, it is anticipated that the effect associated with the intake of cooling water will be minimal. The intake velocities for the cooling water are low enough that it is not anticipated that any larger organisms (fish, marine mammals and reptiles or amphibians) will be impinged on the intake screen. Overall, the loss of marine fish including coastal pelagic fish and their prey resources, relative to numbers in Coos Bay, would be very small, but lacking specific data is difficult to estimate.

Stranding from Ship Wake and Propeller Wash

Fish stranding can occur when fish become caught in a vessel's wake and are deposited on shore by the wave generated by the vessel wake. Stranding typically results in mortality unless another wave carries the fish back into the water. A series of interlinked factors act together to produce stranding during vessel traffic and may include water surface elevations, with low tides more likely to result in strandings than high tide; beach slope, with strandings more likely on low gradients than high; wake characteristics influenced by vessel size, hull form, depth underwater (draught), and speed; and biological factors, such as numbers of small fish present near the shoreline and whether fish are strong swimmers or not (see discussion in Section 4.5.1.3, green sturgeon). Size of juvenile coho in the estuary are expected to be comparable to sizes of juvenile chinook salmon (<9 cm) which became stranded by ship wakes in the Columbia River (Pearson et al., 2006); juvenile coho may be susceptible to stranding by ship wake.

Ship wakes produced by deep-draft vessels traveling at speeds greater than the estimates for LNG carrier speeds within the Coos Bay estuary have been observed to cause occasional stranding of juvenile salmon (Pearson et al., 2006); however, no strandings were observed as a result of vessels traveling at speeds under 9 knots (10.4 mph). The hull geometry of the LNG carriers is such that bow wakes are minimized, especially at the slower speeds of 4 to 6 knots that would occur during most of the transit route through Coos Bay. Therefore, the LNG carriers would be traveling at speeds less than that observed (Pearson et al., 2006) to cause stranding. In models and research conducted by the JCEP, wave heights produced by LNG carrier traffic would not exceed that of normal conditions in Coos Bay and overall waves would contribute to a small portion of the total waves that occur in the bay. In addition, the LNG carriers would be arriving and leaving at high tide, which is a period when gently sloping beaches are mostly covered and less likely dewatered from waves. Considering that LNG marine traffic would enter and leave at high slack tide, have low vessel speeds, and wave height would be in normal range, it appears unlikely that the Project would contribute to stranding of coastal pelagic species within Coos Bay.

Turbidity Effects –Propeller Wash and Ship Wake

Propeller wash from LNG vessels and tug boat propellers associated with the Project, as well as ship wakes breaking on shore, could cause increased erosion along the shoreline and re-suspend the eroded material within the water column. This may affect the diversity and health of the benthic community regarding food availability and feeding conditions for foraging and migrating fish species (see discussion in Section 4.5.1.3, green sturgeon).

Hydrodynamic effects from pressure field velocities measured along the sensitive shoreline from existing deep-draft vessels exceed the pressure field velocities that may be generated by future LNG carriers. The USCG has mandated that all LNG carriers be escorted by a minimum of two tractor tugs which allows the LNG carrier to transit at a lower speed than the existing vessels which transit without tug assist. Vessel velocity, rather than size, has a much greater impact on the amplitude of the pressure wave which would be less impact on coastal process at the sensitive shoreline by LNG carriers than from the existing deep-draft vessels using the estuary.

The results of the swash transport calculations generated by vessel wake effects (see discussion in Section 4.5.1.3, green sturgeon) show a small increase in wake-generated swash sediment transport at the areas of interest due to LNG carriers. The results show that the increase in swash sediment transport from combined inbound and outbound carrier traffic would not exceed six percent at Pigeon Point, eight percent at Clam Island, and five percent at the Airport sensitive shorelines. The total sediment transport for future inbound and outbound LNG carrier traffic will be less than eight percent of the existing and future wind-wave swash sediment transport. The estimated increase in swash sediment transport due to the LNG carrier traffic is a small fraction of the swash sediment transport due to the natural wind-wave conditions. This increase most likely would not be detected in a general balance of swash sediment transport due to yearly variability of wind-wave conditions and swash sediment transport. Based on these results it is not anticipated that suspended sediment generated by propeller wash and ship wake will be adverse effects to coastal pelagic species within Coos Bay.

Underwater Noise

Underwater noise may affect coastal pelagic species. LNG carriers transiting the EEZ would produce underwater noise. Underwater noise levels are expected to vary by ship type and also by vessel length, gross tonnage, vessel speed, and to some extent, vessel age - older vessels tended to be louder than newer vessels (see discussion in Section 4.2.1.3 for blue whales). Based on the general trend for higher underwater noise generated by larger vessels (McKenna et al., 2013), it is possible for many of the LNG carriers that would utilize the Jordan Cove terminal to generate more noise than the loudest container ship reported by McKenna et al. (2013), reported at >188 dB re: 1 µPa @ 1 meter.

State agencies in Washington, Oregon, and California, along with federal agencies have developed interim noise exposure threshold criteria for pile driving effects on fish (Washington State Department of Transportation, 2011a; Popper et al., 2006). Although ship noise reported by McKenna et al. (2013) is not directly equivalent to pile driving noise (see discussions in Section 4.5.4.3 for Oregon Coast coho), or the interim noise exposure criteria, any LNG carrier noise generated in the EEZ would be below thresholds for adverse effects to fish. Noise from LNG carriers would likely increase the background noise within the EEZ, and which is occurring globally (Slabbekoorn et al., 2010). Fish in the EEZ or Coos Bay Estuary might detect noise from LNG carriers but are not expected to be adversely affected by the projected since vessel traffic due to LNG carries is expected to add to the projected vessel traffic in 2017-2018 by 1.2 percent increase in shipping in coastal Oregon and Washington over the 2017-2018 estimates (see discussion in Section 4.2.1.3 for blue whales). Underwater noise generated by LNG carriers transiting the EEZ and estuary is not expected to adversely affect coastal pelagic species within Coos Bay.

Effects of Operational Lighting

Localized changes in light regime have been shown to affect fish species behavior in a variety of ways (see discussion in Section 4.5.1.3, green sturgeon). Lighting at the LNG Terminal and onshore facilities would likely include a mixture of low-power fluorescent lighting and higher intensity security lighting that would primarily be located on shore, in and adjacent to the slip. When an LNG carrier is not in the berth, the lighting would be reduced to that required for security. It would be focused upon the structures and not be in proximity to the water so as to serve as an attractant or deterrent to fish species. When an LNG carrier is at the berth, it would physically block the lighting on the berth from the slip waters and, due to its proximity to the slip wall, would block the fish from getting too close to the lighting on the berth. Lighting used would be similar to that already in place at other Coos Bay facilities.

Lighting on the tug dock would be low intensity lighting for safety, providing sufficient light for personnel movements on the trestle out to the tug berth and for movement on the berth itself. The reduced lighting levels near the water would reduce or eliminate any behavioral effects to fish in the Project vicinity. Increased lighting from facility operations is not expected to adversely affect coastal pelagic species within Coos Bay.

Water Cooling

The LNG ships will re-circulate water for engine cooling while loading LNG at the berth. The engines will be running to provide power for standard hotelling activities as well as running the ballast water pumps (see discussion discussion in Section 4.5.1.3, green sturgeon). The total gross waste heat discharged into the slip from the cooling water stream will be due primarily from the hotelling operations (including the power required to run the ballast water discharge pumps) as the shore side LNG pumps will be used to transfer the LNG from the LNG storage tanks to the LNG carrier.

Because of the extreme differential of the temperature of the cargo in the LNG carrier (-260$^{o}$F) and that of the surrounding air and water (nominally 45$^{o}$F) there is a constant uptake of heat by the LNG carrier from its surroundings. Analysis and numerical modeling were performed to identify potential impacts of LNG carrier cooling water discharge on water quality in the slip and adjacent area of Coos Bay. The modeling was initially performed with two different numerical models: the 3-D UM3 model and the DKHW model. The models simulate hydrodynamic mixing processes of submerged discharges and predict temperature fields and dispersion of non-conserved substances in ambient water bodies. Cooling water numerical modeling requires input of steady-state flow velocity in the modeling domain. For cooling water modeling, two steady state ambient flow velocities were assumed and used further in the analysis: high velocity = 0.32 ft/sec and typical velocity = 0.16 ft/sec.

The following conservative assumptions were used in the analysis. The assumptions are conservative in that a steam powered ship was used. The steam powered ships tend to be older than the newer more modern dual fuel diesel electric ships that require lower quantities of cooling water.

- LNG carriers are steam-powered with a cargo capacity of 148,000 m$^3$.
- Maximum pump capacity for main condenser cooling is 10,000 m$^3$/hr (44,030 gpm) and maximum pump capacity for LNG carrier's equipment cooling is 3,000 m$^3$/hr

(13,209 gpm). Total capacity being used at a given time is typically in the range of 6,300 $m^3$/hr (27,739 gpm). For the analysis, 6,300 $m^3$/hr (27,739 gpm) was used.

- Diameter of the horizontal discharge port is 1.1 meters (3.6 feet).
- Depth of discharge port below still water is 10.0 meters (32.8 feet).
- Maximum heating of cooling water at time of discharge is 3 ºC (5.4 ºF) above ambient temperature.

Results of the modeling showed that for typical ambient flow conditions at a distance of 50 feet from the discharge point (LNG carrier sea chest), temperatures will not exceed 0.3 ºC (0.54 ºF) above the ambient temperature. This difference will decrease with further distance. Water cooling while loading LNG at the berth by LNG is not expected to adversely affect coastal pelagic species within Coos Bay.

Turbidity Effects – Slip and Access Channel

Construction of the LNG terminal slip will require the excavation and dredging of approximately 4.3 million cubic yards (cy) of material (2.3 million cy excavated and 2.0 million cy dredged) and the construction of the access channel will require the dredging of 1.3 million cy for a total of approximately 5.6 million cy (see discussion in Section 4.5.1.3, green sturgeon). The majority of the dredging for the slip will be conducted in isolation from the waters of Coos Bay. While the future slip area is being excavated and dredged, a berm will be maintained to provide complete separation of the excavation and dredging activities from the bay, resulting in no turbidity being released to the waters of Coos Bay. Dredging of the berm separating the portion of slip from the bay and the access channel will result in temporary siltation and sedimentation impacts similar to those that currently occur during maintenance dredging activities. The dredging activity will occur only during the in-water work window established by ODFW.

On average, the USACE removes approximately 550,000 cy from the bar, 200,000 cy from Channel Mile (CM) 2-12 and 150,000 cy from CM 12-15 each year. In comparison, approximately 500,000 cy will be removed in the water during the removal of the berm and dredging of the access channel. Since the duration of the dredging in the bay will be 4-6 months and only during the in-water work window from October 1 to February 15 (ODFW, 2008), the minimal amount of turbidity created will be relatively short term and localized. Turbidity modeling demonstrated that turbidity levels dropped to near background levels beyond 200 meters (660 feet) of the dredging activity.

Turbidity was modeled for the new construction and maintenance dredging operations based on the anticipated geotechnical and environmental conditions for this project using the United States Army Corps of Engineers (USACE) DREDGE model and two dimensional numerical model Mike21 (see discussion in Section 4.5.1.3, green sturgeon). During the project construction period, the maximum modeled suspended sediment concentrations (primarily sand) produced by the DREDGE model for an open “clamshell” dredge were less than 6,000 mg/L at the dredge location and decreased to less than 50 mg/L at 200 m (approximately 660 feet). For the hydraulic cutterhead dredge the TSS levels were significantly lower with maximum of 500 mg/L in the vicinity of the dredge. The TSS concentrations decreased to a maximum of 14 mg/L at 60 meters (200 ft) away from the dredge vicinity.

During the project maintenance dredging period, the dredged material is expected to be primarily fines (mud, clay, silt). Concentration predicted with the DREDGE model for the open “clamshell” dredge were lower than during the construction stage with the maximum of 830 mg/l in vicinity of the dredge and decreasing to 125 mg/l at 200 m (approximately 660 feet). The results from the Mike21 simulations show that distribution of the generated plume depends on location of the dredge in the channel and basin area. For dredging with an open “clamshell” dredge in the channel the generated sediment plume (concentration higher than 150 mg/l) can move up to 1.2–1.9 miles from the dredging location at highest ebb or flood currents; however, the duration of such entrainment is limited by not more than a two hour period and the time average concentrations do not exceed natural ambient concentrations (10–30 mg/l) outside the dredging area.

During maintenance dredging with an open “clamshell” dredge, the maximum concentrations in the generated plume do not exceed 50 mg/L. Estuarine environments often have moderately elevated suspended sediment concentrations (i.e. >15 mg/L) and they are very productive (Gregory and Northcote, 1993). The amount of sediment produced by open cutting depends on multiple characteristics at the construction site including depth and width of the waterbody (effects mixing of the sediment plume in the water column), current velocity and local turbulence at the site and downstream, concentrations of suspended sediment initially at the site and at some distance downstream, particle diameter, specific weight, and settling velocity of the excavated and backfilled materials (Ritter, 1984; Reid et al., 2004). Based on sediment transport modeling, dispersal of the exposed and disturbed sediments will be very minor in intertidal areas of Haynes Inlet due to the low water velocities and sediment composition in that area. Based on this information it is not anticipated that turbidity generation at the dredging site will be an adverse affect to coastal pelagic species within Coos Bay.

Additionally, discharge of maintenance dredging spoils, at the EPA-approved Site F clean maintenance dredge spoils discharge location off the mouth of Coos Bay, would have Project effects associated with turbidity plume and short-term burial of potential prey resources. The turbidity plume would cause short-term avoidance (e.g., hours) of the discharge area, and briefly reduce primary production. Some short-term loss of benthic invertebrates from burial (weeks/months) would occur but the extent of the area would be extremely small relative to amount of this habitat available. Also, the site is low in diversity of organisms. The site has been approved partly for its minimal effects to recourses from discharge of clean (hazardous substance free) sediment.

**Conservation Measures**

Measures to minimize effects to listed whales would likewise minimize potential accidental spills and releases at sea which could affect EFH within the EEZ analysis area. Those measures include: 1) LNG carriers approaching the Port of Coos Bay would be traveling slowly and escorted by tractor tugs from 50 nmi offshore to the Port, and 2) spills or releases of LNG at sea would not cause the water column to cool to the point of affecting coastal pelagic fish species in the water.

Measures to minimize effects to listed coho salmon and green sturgeon would likewise minimize potential effects to EFH within the estuarine analysis area. Coastal pelagic species are not estuarine resident species and utilize Coos Bay on a seasonal basis, primarily in summer months. Construction is planned within the period from October 1 through February 15 following ODFW’s recommendation and would coincide with a period when fewest coastal pelagic species are expected to be present. Effects to food resources and eelgrass habitats would be minimized by construction from October 1 through February 15 when eelgrass within Coos Bay is dormant.

Turbidity within Coos Bay and Haynes Inlet, produced by construction of the slip, access channel, and Pacific Connector pipeline would be short-term, relatively confined to elongated plumes, and is expected to quickly dissipate to turbidity levels generally associated with winter tides and storm wave action.

### 6.2.3 Effects Determination

The proposed action **may adversely affect** EFH for coastal pelagic species in the short term from loss of eelgrass areas until the mitigation beds and pipeline areas regrowth occurs. Also the disposal of dredge material at Site F would temporarily bury potential food resources for coastal pelagic fish. Additionally, juvenile larval stages of fish could be entrained or impinged and suffer mortality. Accidental spills and releases at sea, if they should occur, and Project construction within the Coos Bay estuary are not expected to diminish water quality or substrates within the EEZ analysis area or the estuarine analysis area.

## 6.3 GROUNDFISH

### 6.3.1 Essential Fish Habitat

There are over 80 species of groundfish, most of which live at or near the ocean bottom, and are managed under the Pacific Coast Groundfish Management Plan (PFMC, 2008). Many groundfish species occur within the EEZ and estuarine analysis areas. The Groundfish Fishery Management Plan includes EFH within the waters and substrates at "depths less than or equal to 3,500 m (1,914 fm) to mean higher high water level (MHHW) or the upriver extent of saltwater intrusion, defined as upstream and landward to where ocean-derived salts measure less than 0.5 ppt during the period of average annual low flow" (PFMC, 2005).

Not every groundfish species is expected to occur within the proposed action estuarine analysis area and/or the EEZ analysis area. Species' distributions, based on mapped habitat suitability probabilities for spatial occurrences by different life stages (Appendix B-4 in PFMC 2006), were used to evaluate likely species' occurrences within either analysis area. The results of that evaluation are summarized in table 6.3.1-1.

Site F, centered 1.6 miles off the mouth of Coos Bay, also is inhabited by groundfish, including an estimated 18 species, with some adult and juvenile stages assumed or known to be present. This includes 5 species of rockfish and 10 of flatfish, including speckled sanddab, which was the most abundant in trawl surveys of the area (Hinton and Emmett, 1994, see table 6.2.1-1).

**Table 6.3.1-1**
**Groundfish Species Managed by the Pacific Fishery Management Council for which Essential Fish Habitat Has Been Identified and May Occur Within the Proposed Action Estuarine Analysis Area and EEZ Analysis Area**

| Common Name Scientific Name | Life Cycle and Habitat Associations [1] | Distribution within Estuarine Analysis Area [2] | | | | Distribution within EEZ Analysis Area [2] | | | | Site F Presence [4] | |
|---|---|---|---|---|---|---|---|---|---|---|---|
| | | Eggs [3] | Larvae [3] | Juvenile [3] | Adult [3] | Eggs [3] | Larvae [3] | Juvenile [3] | Adult [3] | Juvenile | Adult |
| Soupfin shark *Galeorhinus galeus* | Coastal-pelagic species associated with the bottom, inhabiting bays, muddy shallows and offshore up to 225 fathoms (fm). Adult males occur in deeper waters and females usually at less than 30 fm. From dense shoals, migrating north in the summer and south in the winter. Mating occurs in the spring. | | | L | M | | | H | H | | |
| Spiny dogfish *Squalus acanthias* | An inner shelf-mesobenthal species with a depth range of 0 to 677 fm. Common in inland seas and shallow bays. Seasonal migrations occur within preferred temperature range. | | | L | H | | | H | H | | |
| Leopard shark *Triakis semifasciata* | Inhabits enclosed muddy bays, flat sandy areas, mud flats, sandy and muddy bottoms strewn with rock near reefs and kelp beds. Common in littoral waters and around jetties and piers. Pupping and feeding/rearing grounds in estuaries and shallow coast waters. Found at depths up to 50 fm, common at 0 to 2 fm. | | | H | H | | | H | H | | |
| Big skate *Raja binoculata* | Inhabits inner and outer shelf areas, particularly on soft bottom sediments. Either associated with silty sediment, or with sediment consisting of a mixture of mud, sand, gravel, and cobble. Found at depths up to 55 fm. | U | | U | U | H | | H | H | | X |
| California skate *Raja inornata* | Usually occur in habitats with muddy bottoms. Juveniles are associated with soft bottom sediments. Common in inshore waters and shallow bays; sometimes in deep water. | H | | U | H | H | | H | H | | |
| Longnose skate *Raja rhina* | Occurs on the bottom inner and outer shelf areas, usually less than about 175 fathoms deep. Juveniles and adults are associated with soft bottom sediments with combinations of mud and cobble near high relief structures. | L | | L | U | H | | H | H | | |
| Pacific cod *Gadus macrocephalus* | Adults and juveniles prefer mud, sand, and clay. Usually found near bottom, with a wide depth range of 7 to 300 fm. Spawning occurs from the late fall to early spring. Larvae and small juveniles are pelagic, large juveniles and adults are parademersal. | L | U | U | U | H | H | M | L | | X |
| Pacific grenadier (rattail) *Coryphaenoides acrolepis* | Commercial species that inhabits the continental slope. Highest densities occur on the sandy bottoms of abyssal plains. Migrations have not been documented, but larger fish are found in deeper water. Larvae are pelagic | H | H | U | U | H | H | L | H | | |
| Pacific whiting (hake) *Merluccius productus* | Inhabits euhaline waters of the continental shelf. Juveniles reside in shallow coastal waters, bays, and inland seas and move deeper as they get older. Highly migratory. Spawns from December through March, perhaps more than once per season. | U | | U | H | H | | U | H | | |
| Spotted ratfish *Hydrolagus colliei* | Found near the bottom, from close inshore to about 500 fm. Abundant in cold waters at moderate depths. Feed on mollusks, crustaceans and fishes; also echinoderms and worms. Fishers are reputed to fear the jaws of the ratfish more than they do the dorsal spine. | U | | U | U | H | | H | H | | |
| Rougheye rockfish | Usually found on the bottom in deep, offshore waters with soft substrata, frequenting | | | U | U | | | H | L | | |

| Common Name Scientific Name | Life Cycle and Habitat Associations [1] | Distribution within Estuarine Analysis Area [2] | | | | Distribution within EEZ Analysis Area [2] | | | | Site F Presence [4] | |
|---|---|---|---|---|---|---|---|---|---|---|---|
| | | Eggs [3] | Larvae [3] | Juvenile [3] | Adult [3] | Eggs [3] | Larvae [3] | Juvenile [3] | Adult [3] | Juvenile | Adult |
| *Sebastes aleutianus* | boulders and at slopes greater than 20 degrees. Depths range from 14 to 478 fm. | | | | | | | | | | |
| Pacific Ocean Perch *Sebastes alutus* | This commercially important schooling fish is abundant offshore, often found along submarine canyons, depressions, pinnacles, and seamounts. Depth ranges from surface to 451 fm (most occur in 80 to 200 fm). | | U | U | U | | H | H | M | | |
| Kelp rockfish *Sebastes atrovirens* | Inhabiting shallow waters, adults are primarily residential in kelp forests and on the bottom near rocky areas and are considered parademersal. Common at depths of 5 to 7 fm, but found up to 25 fm with a distribution mostly off the coast of California. | | | | U | | | | H | | |
| Brown rockfish *Sebastes auriculatus* | Display strong reef fidelity with a distribution from Gulf of Alaska to Baja California. Bottom dwellers of shallow waters. Juveniles usually live in shallower water than adults. Maintain small home ranges on high-relief rocky reefs and common at less than 55 fm. | — | — | — | — | — | — | — | — | | |
| Aurora rockfish *Sebastes aurora* | Adults and juveniles are found in soft- and hard- bottom habitats on the continental slope/basin. Distribution ranges from Vancouver Island, British Columbia to Cedros Island, Baja California. Depth ranges from 68 to 420 fm. | | U | U | U | | H | H | H | | |
| Redbanded rockfish *Sebastes babcocki* | Thought to associate with both soft substrata and hard-bottom substrata, and in crevices between boulders. This deepwater species has been caught in the 50 to 342 fm range and is found from Amchitka Island, Alaska to San Diego, California. | | | | U | | | | H | | |
| Silvergray rockfish *Sebastes brevispinis* | Inhabits the outer shelf-mesobenthal zone on a variety of rocky-bottom habitats. Found at the surface to 205 fm, from the Bering Sea to Baja California. | | | | U | | | | L | | |
| Shortraker rockfish *Sebastes borealiz* | Deepwater species inhabiting the middle shelf to the mesobenthal slope and common on the bottom from 100 to 478 fm. Distribution from the Aleutian Islands and down to Point Conception, California | | | | U | | | | H | | |
| Gopher rockfish *Sebastes carnatus* | These are shallow-water benthic fish that inhabit rocky reefs, kelp beds, and sandy areas near reefs. Common depth from surface to 9 fm and mostly limited to the California coast. | | U | U | U | | H | H | H | | |
| Copper rockfish *Sebastes caurinus* | Occur in nearshore waters, from the surface to 100 fm. Found on or near natural rocky reefs, boulder fields, artificial reefs, oil platforms and rockpiles; usually directly on the bottom with reefs or kelp bed areas. May move inshore to release their young. | | | | U | | | | H | | |
| Greenspotted rockfish *Sebastes chlorostictus* | Associated with soft-bottom habitats and also with rock outcrops, reefs, caves, and crevices. Range is from Washington to Baja California with depths 27-150 fm | | | U | U | | | H | L | | |
| Black and yellow rockfish *Sebastes chrysomelas* | Inhabits holes and crevices in rocky areas. Found in intertidal areas and depths to 20 fm. | | U | U | U | | H | M | M | | |
| Starry rockfish *Sebastes constellatus* | Usually found on reefs. Viviparous, with planktonic larvae and pelagic juvenlies. Limited distribution along the California coast from north of San Franciscon to Baja. Depth ranges from 13 – 150 fm. | | | U | U | | | U | M | | |
| Darkblotched rockfish *Sebastes crameri* | Adults are associated with muddy areas near cobble or boulders. Found at depths of 14 to 328 fm from the Bering Sea to Catalina Island, California. | | U | U | U | | H | H | H | | |

| | | Eggs [3] | Larvae [3] | Juvenile [3] | Adult [3] | Eggs [3] | Larvae [3] | Juvenile [3] | Adult [3] | Juvenile | Adult |
| Splitnose rockfish *Sebastes diploproa* | Associated with offshore mud habitats near isolated rock cobble and boulder fields. Most common at 50 to 250 fm. Young occur in shallow water, often at the surface under drifting kelp, algae, and seagrass. Emigration from surface waters occurs primarily in May and June. | | H | U | U | | H | H | H | | |
| Greenstriped rockfish *Sebastes elongatus* | Prefers a mixture of mud and rock bottom and found at depths of 14 to 232 fm. Distribution from Alaska to Baja California. | | | U | U | | | H | H | | |
| Widow rockfish *Sebastes entomelas* | All life stages are pelagic, but older juveniles and adults are associated with hard bottoms among rocks. This important commercial fish ranges from near Kodiak Island, Alaska to Todos Santos Bay in Baja California; from surface to 300 fm. | | | U | U | | | H | M | | |
| Pink rockfish *Sebastes eos* | Demersal, inhabiting rocky bottoms in isolated areas from Southern Oregon to Central Baja California. Depth range from 40 to 200 fm. | | | | U | | | | H | | |
| Yellowtail rockfish *Sebastes flavidus* | They are considered a middle shelf-mesobenthal species most common near the bottom. This schooling rockfish has a range from Unalaska Island, Alaska to San Diego, California and is found from the surface down to 300 fm. | | | U | U | | | H | H | | X |
| Chilipepper rockfish *Sebastes goodei* | Most commonly associated with deep, high-relief rocky areas and along cliffs. A commercially important species in California found at the surface to 232 fm. | | | L | U | | | H | H | X | |
| Rosethorn rockfish *Sebastes helvomaculatus* | Adults are mostly found in muddy areas adjacent to boulders, cobble, or rock. Depth range from 40 to 300 fm. Limited distribution from Alaska to Baja California. | | | | U | | | | L | | |
| Squarespot *rockfish* *Sebastes hopkinsi* | They are reef-associated, in areas with cobble and have a depth range of 2 to 120 fm. | | | U | U | | | H | H | | |
| Shortbelly rockfish *Sebastes jordani* | Can be found in large schools, offshore and off smooth bottom areas near the shelf break and sharp drop-offs. Depths of 0 to 191 fm. | | | | U | | | | H | | |
| Cowcod *Sebastes levi* | Adults are primarily found over high-relief rocky areas. Juveniles prefer soft bottom habitats and those consisting of low-relief rocks. Mostly found off California at depths of 11 to 200 fm. | | | U | U | | | H | L-M | | |
| Quillback rockfish *Sebastes maliger* | A common, shallow-water benthic species, from subtidal depths to 150 fm. Young occur along shores and adults usually in deeper waters. | | | U | | | | H | | | |
| Black rockfish *Sebastes melanops* | Adults inhabit midwater and surface areas over-high relief rocky reefs, in and around kelp beds, boulder fields, pinnacles, and artificial reefs. Larvae and young juveniles are pelagic. | | | M | U | | | H | H | | |
| Blackgill rockfish *Sebastes melanostomus* | An aggregate species, usually inhabiting deep rocky-or hard-bottom habitats along steep dropoffs. Larvae inhabit the upper mixed layer of water, juveniles are pelagic (associated with flat bottoms) and migrate shoreward. Spawn from January to June. | | U | U | U | | H | H | H | | |
| Vermilion rockfish *Sebastes miniatus* | Found over rocks, along drop-offs, and over hard bottom. Adults inhabit rocky reefs at depths of 8 to 150 fm. Larvae are pelagic and found near the surface for three to four | | | | U | | | | H | X | |

| | months, and are frequently associated with algae. | | | | | | | | | | |
| Blue rockfish *Sebastes mystinus* | Strong affinity for kelp forests. Adults inhabit midwater and surface areas around high relief rocky areas, within and round the kelp colony, and around artificial reefs. Common depth range of 33 to 167 fm. Larvae and early stage juveniles are pelagic, and older individuals are semi-demersal or demersal. | | L | U | U | | H | H | H | | |
| China rockfish *Sebastes nebulosus* | Occur both inshore and along the open coast from 1 to 75 fm. Most Juveniles are pelagic, but adults are sedentary, associated with rocky reefs or cobble. They are residential and associated the bottom, crevices, and kelp beds. | | | U | U | | | H | H | | |
| Tiger rockfish *Sebastes nigrocinctus* | Found at depths of 5 to 150 fm. Juveniles are pelagic, common near water surface with algae mats and plants. Adults are semi-demersal. Often found in caves, off cliffs, and on floors. Solitary, may be territorial. | | | | U | | | | H | | |
| Speckled rockfish *Sebastes ovalis* | They occur in midwater over rocks and are also found near the bottom on reefs and among boulders. Depths range from 17 to 200 fm. | | | U | U | | | H | H | | |
| Bocaccio *Sebastes paucispinis* | Benthic juveniles and adults are found around vertical relief; over sand-mud bottoms with little relief; and in areas with mixtures of rocks and boulders, rock ridges, and rocks and boulders among mud. Most common at depths of 40 to 175 fm. Larvae and small juveniles are pelagic; large juveniles and adults are semi-demersal. | | L | U | U | | H | H | M | X | |
| Canary rockfish *Sebastes pinniger* | Most abundant above hard bottoms, usually 50 to 110 fm. In its southern range, it is a reef associated species. Larvae and juveniles are pelagic. Young of the year can be found in tide pools, and can be associated with artificial reefs and interfaces between mud and rock. Juveniles descend deeper as they mature. Capable of large latitudinal movements. | | | U | U | | | H | H | | |
| Redstripe rockfish *Sebastes prorigger* | Generally found off the bottom over both high- and low-relief rocky areas. Depths range from 7 to 232 fm (most common at 70 to 150 fm.) | | | | U | | | | H | | |
| Grass rockfish *Sebastes rastrelliger* | Common in nearshore rocky areas, along jetties, and in kelp and eelgrass. Residential species at shallow depths. | | | U | U | | | H | H | | |
| Yellowmouth rockfish *Sebastes reedi* | Found over rough bottoms from the Northern Gulf of Alaska to the south of Crecent City, California, with a depth range from 75 to 200 fm. More common at 100 to 200 fm. | | | U | U | | | H | M | | |
| Rosy rockfish *Sebastes rosaceus* | These fish are solitary bottom-dwellers found over hard, high-relief areas and at low-relief spots among rocks and sand. Depths range from 27 to 150 fm. | | | U | U | | | H | H | | |
| Yelloweye rockfish *Sebastes ruberrimus* | Inhabits rocky reefs and boulder fields from Prince William Sound, Alaska to Ensenada, Baja California. An important commercial species ranging from 8 to 300 fm. | | | U | U | | | H | H | | |
| Flag rockfish *Sebastes rubrivinctus* | These demersal fish inhabit rocky areas and have a depth range of 0 to 302 meters. | | | U | U | | | M | H | | |
| Bank rockfish *Sebastes rufus* | Juveniles are parademersal and prefer mixed mud and rock habitats. Adults can be found on rocky reefs, among boulder fields, cobble, and mixed mud-rock bottoms. Depths range | | | U | U | | | H | L | | |

| | from 17 to 135 fm. | | | | | | | | | | |
| Stripetail rockfish *Sebastes saxicola* | A dominant soft-bottom fish. Pelagic juveniles, with a narrow depth range of 27 to 30 fm, are associated with sandy bottoms. Adult depth ranges from 5 to 299 fm (most common 80-150 fm). | | | U | U | | | H | H | X | |
| Sharpchin rockfish *Sebastes zacentrus* | An outer shelf-mesobenthal species preferring mud and cobble and mud and boulder substrata. Found at depths from 14 to 260 fm. | | U | U | U | | H | H | M | | |
| Shortspine thornyhead *Sebastolobus alascanus* | Juveniles occupy shallower waters than adults, usually over muddy bottoms near rocks. Adults are found on muddy bottoms and bottoms with mud and cobble/boulder mixes. A deepwater species, found at 10 to 833 fm. | | | U | U | | | H | H | | |
| Longspine thornyhead *Sebastolobus altivelis* | Juvenile and adults are demersal and occupy the sediment surface, preferably sand or mud. A deepwater species, found often at 110 to 960 fm. | | | U | U | | | H | H | | |
| Cabezon *Scorpaenichthys marmoratus* | Most abundant in estuaries where all life stages may be present. Found intertidally or in shallow subtidal areas in a variety of habitats, often in the vicinity of kelp beds, jetties, oil platforms, isolated rocky reefs or pinnacles, and shallow tide pools. Mostly utilize rocky bottoms and cobble substrata. | | | | U | | | | H | | |
| Sablefish *Anoplopoma fimbria* | Inner shelf-bathybenthal commercial species. Eggs, larvae, and young juveniles are pelagic. Older-juveniles and adults are benthopelagic on soft bottoms, commonly with mud and sea urchins. Often migratory, wide-ranging depths from 170 fm to 1000 fm. Spawning occurs in the late fall and early winter in waters at depths >167 fm. | L | U | U | U | H | H | H | H | | |
| Lingcod *Ophiodon elongatus* | Occupy the estuarine-mesobenthic zone, from intertidal areas to 266 fm. Mostly inhabit slopes of submerged banks with seaweed, kelp and eelgrass beds. Spawning occurs from December through April, 2-5 fm below mean lower low water over rocky reefs in areas with a swift current. | H | U | U | U | H | H | H | H | X | |
| Finescale codling (mora) *Antimora microlepis* | Inhabits the lower regions of the continental slope between 437 fm and 980 fm. Whether or not the species migrates extensively or uses the North American west coast slopes only as feeding areas is not known. | | | | U | | | | H | | |
| Kelp greenling *Hexagrammos decagrammus* | High affinity for rocky banks near dense algae or kelp beds, or in kelp beds. Larvae and small juveniles are pelagic, adults are demersal (but not usually below 11 fm). Juveniles associated with rocky reefs and microalgae. Newly hatched larvae move out of estuaries or shallow nearshore areas into open water. Spawning occurs in the fall. | | M | | U | | H | | M | | |
| Pacific sanddab *Citharichthys sordidus* | Inhabit s inner continental shelf along the West Coast. Most abundant in 20 to 50 fm. Small juveniles prefer silty sand substrata and adults prefer sand and coarser sediments and low-relief rock bottoms. Spawning occurs late winter through summer. | | | | U | | | | H | X | X |
| Arrowtooth flounder *Atheresthes stomias* | Eggs and larvae are palegic and juveniles and adults are demersal. Juveniles and adults are usually found on sand or sandy gravelly substrata, but occasionally over rock-relief sponge bottoms. Migrate from shallow-water summer feeding grounds on the continental shelf to | H | H | U | U | H | H | H | H | | X |

| | deep-water spawning grounds over the continental shelf. Spawning occurs in the winter. | | | | | | | | | | |
| Petrale Sole *Eopsetta jordani* | Juveniles and adults are demersal. Adults migrate seasonally between deep-water winter spawning areas to shallower, spring feeding grounds. Found on sand and mud bottoms from 10 to 300 fm. Most abundant at 30 to 70 fm from April through October and at 150 to 250 fm during winter. | | | U | U | | | H | H | X | X |
| Rex sole *Glyptocephalus zachirus* | Abundant on sandy, muddy, and gravely bottoms. Also in complexes of mud and boulders. Cold temperate, upper-slope, outer-shelf flatfish with pelagic eggs and larvae. Move inshore in summer and offshore for spawning in winter and early spring. | | | U | U | | | H | H | X | X |
| Flathead sole *Hippoglossoides elassodon* | These sole inhabit soft, silty or muddy bottoms from 0 to 575 fm. (common 55 to 135 fm). They can also be associated with mud mixed with gravel or sand. | | | U | U | | | L | L | X | X |
| Dover sole *Microstomus pacificus* | Innershelf-mesobenthal commercially caught species, mostly in waters <273 fm. Adults and juveniles have high affinity for soft bottoms of fine mud and sand. Commonly associated with mud and sea urchins. Eggs are epipelagic, larvae are epi-mesopelagic, and juveniles and adults are demersal. Spawning occurs in the spring near the bottom of the water. Females and juveniles migrate offshore to deeper waters in the fall. | | | U | U | | | H | H | | |
| English sole *Parophrys vetulus* | Shallow-water, soft-bottom, marine and estuarine environments. Spawning occurs in winter to early spring over soft-bottom mud strata, depths of 27-38 fm. Eggs and larvae are pelagic and adults are demersal | | M | L | L | | H | H | H | X | X |
| Starry flounder *Platichthys stellatus* | Occur in the inner continental shelf and shallow sublittoral communities. Older individuals occur from 75 miles upstream to the outer continental shelf. Juveniles prefer sandy to muddy substrata. Spawning occurs in late winter-early spring in estuaries or sheltered inshore bays with less than 25 fm. | L | | U | L | H | | H | H | X | X |
| Rock sole *Pleuronectes bilineatus* | Juveniles and adults are demersal and found primarily in shallow water bays and over the continental shelf on rocky, pebbly, or sandy bottoms form 0 to 200 fm. Most are caught in 20 to 40 fm. | | | | U | | | | H | X | X |
| Curlfin sole *Pleuronichthys decurrens* | Curlfin are found on soft bottoms from 4 to 291 fm, but usually are found in shallower waters. | | | | L | | | | H | | |
| Sand sole *Psettichthys melanostictus* | High affinity to shallow waters with sandy/muddy substrate. Spawning occurs in winter and spring near shore. Larvae and small juveniles are pelagic and transported to estuaries by tidal current. | | M | U | U | | H | H | H | X | X |

### 6.3.2 Analysis of Effects

Analysis of effects to EFH for groundfish species by the proposed action have been provided in multiple sections in the BA. For EFH within the EEZ analysis area, Project effects are expected to be associated with accidental spills and releases at sea by LNG carriers transiting at least 50 nmi offshore within the EEZ from south to north (from San Diego to Coos Bay), from LNG carriers approaching Coos Bay from the west through the 200 nmi-wide EEZ, and from tugs hauling sand barges between Coos Bay and San Francisco Bay 12 nmi or more offshore. These effects have been discussed under Highly Migratory species in section 6.2.1 above Additional details of effects have been included for mammals (whales in sections 4.2.1.3, 4.2.2.3, 4.2.3.3, 4.2.4.3, 4.2.5.3, 4.2.6.3, and 4.2.7.3), reptiles (sea turtles in sections 4.4.1.3, 4.4.2.3, 4.4.3.3, and 4.4.4.3), and fish (Southern DPS North American green sturgeon in section 4.5.1.3, Southern DPS Pacific eulachon in section 4.5.2.3, and Oregon Coast coho salmon ESU in section 4.5.4.3).

Within the estuarine analysis area of Coos Bay, Project effects to groundfish species are expected to be associated with effects to eelgrass habitats; short-term turbidity produced by construction of the slip, access channel and Pacific Connector pipeline; entrainment of larvae, juveniles and adults by hydraulic dredging and ballast and cooling water withdrawal; acoustic effects due to pile driving; effects of operational lighting and wakes associated with LNG carriers, effects of facilitated predation by shading from over-water structures; introduction of exotic species; and windblown sand from stockpiles sources.

Ballast and cooling water intake by LNG carriers during the 24-hour offloading period could result in organism entrainment or impingement. An approved screening system is currently not planned (see Oregon Coastal Coho salmon). Even with an approved screening plan zooplankton, phytoplankton, planktonic shellfish larvae, and ichthyoplankton (larval fish and fish eggs) would be subject to entrainment in this ballast and cooling water.

Of the EFH species that inhabit Coos Bay, species with planktonic/pelagic eggs and larvae include: English sole, rex sole, sand sole, starry flounder, lingcod, cabezon and possibly boccacio. There is limited information on the densities of ichythoplankton, zooplankton, phytoplankton and planktonic shellfish larvae for Coos Bay, but it can be expected that large numbers of these life stages would be entrained during seasonal periods of high abundance. These planktonic life stages are widely dispersed within the estuary. Miller and Shanks (2005) collected a total of 35 species of ichthyoplankton in Coos Bay, the most abundant species of which were penpoint gunnel, northern anchovy, rosylip sculpin, Pacific sardine, and surf smelt. These five species consistently comprised >70 percent of the total catch. All of these species are small, abundant, forage species. Miller and Shanks (2005) found that at both ocean-dominated and up-estuary sites in Coos Bay, the majority of the catch occurred from October 1 to May 31, although the seasonal difference was less marked within the estuary than it was at the estuary mouth.

There are limited additional data on type, size, and organism distribution in the Coos Bay estuary, especially near the proposed slip. Jordan Cove has therefore developed a study plan and begun conducting studies to determine this information. The studies period would be during the 3 years prior to and during slip construction. These studies began in August 2009 and are nearly completed through the first year of data collection. The studies are intended to determine background species numbers, as well as their timing and distribution around the slip area. This plan and results will be presented to NMFS and FWS, and the approach and findings will be discussed with them. The goal would be to establish numerical estimates of likely entrainment and following this, if necessary, provide compensatory mitigation. Preliminary results of plankton sampling (Shanks et al. 2010) have been sent to FERC. The study results to date address zooplankton including larval fish.

Direct loss of young life stages may have an effect on production of older individuals. EPA (2004) examined the effects of entrainment by California power plants on marine fish and shellfish. The document developed natural mortality information by life stage of common marine and estuarine species or groups of species present in the California coastal region. Many of the species groups are common to the Coos Bay area. This information supplies an additional indication that loss of early life stages because of high natural mortality, would not markedly reduce later life stages. Table 6.3.2-1 shows the relative survival percent from one life stage to the next up to age 2, and overall percent survival from larval to age 1 and 2, based on the EPA (2004) document. For most taxa less than one percent of larvae would be expected to survive to age 1, as the highest rate of mortality occurs in early life stages. Adult or harvestable populations of a fish species are also affected by many factors (e.g., currents, food, temperature, usable habitat) that are generally independent of numbers or survival of early life stages. Overall, the loss of marine fish including groundfish and their prey resources from entrainment, relative to numbers in Coos Bay, would be small based on the information discussed.

**Table 6.3.2-1**
**Selected Survival Values by Life Stage of Pacific Marine Species or Groups of Species that May Be Present in the Project Area used by EPA (2004) for Power Plant's Entrainment and Impingement Studies in California Coastal Waters.**

| Taxa Group/Species [2] | Percent Survival by Life Stages [1] | | | | |
|---|---|---|---|---|---|
| | Larvae to Juvenile | Juvenile to Age 1 | Age 1 to Age 2 | Larvae to Age 1 | Larvae to Age 2 |

| Average | 7.06% | 32.90% | 48.23% | 2.32% | 1.607% |
| Median | 0.90% | 36.79% | 51.17% | 0.45% | 0.07% |

1 Values based on natural mortality rates by life stage
2 Groups include multiple species defined in Appendix B1 of EPA (2004)

Evaluation of entrainment effects at some similar projects concluded substantial effects were unlikely. Environmental assessment studies conducted at the KeySpan LNG in Rhode Island (FERC 2005) and the El Paso Energy Bridge LNG facility in the Gulf of Mexico (Coast Guard 2003) off the coast of Louisiana have addressed the issue of entrainment of ichthyoplankton organisms in ballast water and other consumptive water uses. In both cases, they concluded that the losses of eggs and larvae when converted to adult equivalents were small and largely limited to small forage species. Based on the species composition of ichthyoplankton in Coos Bay (Miller and Shanks, 2005; Shanks et al., 2010), and the small portion of total bay water used, similar conclusions in Coos Bay would be likely, indicating unsubstantial adverse effect to EFH species.

The potential for fish stranding loss from vessel wake for groundfish would be similar to those discussed for coastal pelagic species (see section 6.2.2 and discussion in Section 4.5.1.3 for green sturgeon). While more species and life stages would be present year round in the Coos Bay for groundfish than coastal pelagic species their susceptibility to stranding and loss from vessel wake should not be markedly different than those discussed in the other subsections. Overall effects to groundfish EFH from vessel wakes would therefore be minimal and discountable for similar reasons noted in these two subsections.

Groundfish resources may be affected through direct mortality or short term increased susceptibility to predation from acoustic shock waves caused by impact hammer pile driving. But, as discussed for coastal pelagic species, acoustic effects of pile driving to groundfish EFH would be unsubstantial due to the use of a bubble curtain (reducing affect zone to about 3 m) and limited number of piles being driven (likely only 8, up to 24).

As noted in Section 4.5.1.3, green sturgeon, increased suspended sediment would occur from both dredging for the new facility and pipeline construction crossing of Coos bay. The result would be similar to that noted for coastal pelagic species (see section 6.2.2) and would be some short term adverse effects (primarily avoidance) to EFH of groundfish species during construction of the slip and the installation of the pipeline.

Of particular concern to groundfish is the potential increase for bioavailability of contaminants due to sediment suspension during construction and operation of the proposed action. Findings made in 2004 by the COE from sampling conducted within the Coos Bay Navigation Channel (COE, 2005) indicate that resuspension of sediments associated with the dredging for the access channel should not result in significant increases in the bioavailability of contaminants to fish and fish food organisms within the Project area.

Many groundfish EFH species are known to occur within the Estuary either seasonally or year-round. Project activities are likely to have the greatest impact on flatfish residents of the lower bay, including English sole and starry flounder. Access channel dredging would convert 16.8 acres of shallow water habitat to deepwater habitat. Juvenile English sole and starry flounder are typically found in shallow water near shore in estuarine environments. Therefore, the conversion from shallow water to deep water habitat would represent a reduction in habitat quality and quantity over existing conditions. Dredging is not expected to cause a significant change in sediment grain size. Flatfish species are expected to return to the area after dredging is completed. Most EFH rockfish species in the lower bay prefer rocky reef habitat and do not commonly utilize sand/mud substrates that would be affected by dredging. Juvenile lingcod and adult cabazon and boccacio are known to utilize sandy flats habitat and would suffer some loss of habitat. However, the sandy habitats that would be lost are common within the primary action area. It is anticipated that groundfish species would be able to relocate to nearby suitable habitats.

Indirect effects, as defined for EFH consultations under 50 CFR 600.810, require an assessment of the short-term disturbance of food organisms for groundfish and coastal pelagic species. Substrate disturbances caused by the proposed activities would be primarily limited to the access channel dredge prism, but would also include benthic habitats affected by the turbidity plume within the estuarine analysis area. The groundfish EFH species primarily feed on small fish and benthic invertebrates while the coastal pelagic EFH species forage on phytoplankton and zooplankton. Turbidity increases may cause a small reduction in prey abundance and decrease foraging efficiencies for species that forage in the water column.

The eelgrass proposed for removal by the proposed action may provide foraging and nursery habitat for various groundfish species. The loss of 1 acre of low to moderate density eelgrass during construction of the pipeline across Haynes Inlet would adversely affect EFH for some species. Turbidity effects on eelgrass habitats within the primary action area would be minimal due to scheduling dredging outside the blooming season (when eelgrass is dormant).

Construction of the Pacific Connector pipeline within the Coos Bay estuary may directly affect 5.0 acres of eelgrass beds by the construction right-of-way (including TEWAs). Of the three density categories of eelgrass found in the survey (low, medium and high) no high density was found and the majority was low density (Ellis Ecological Services 2013). Some (not quantified) of the eelgrass has been identified as Japanese or dwarf eelgrass (*Zostera japonica*), an introduced species which may compete with native eelgrass (*Z. marina*). The largest and most contiguous beds of submerged grasses are located in both the lower and upper bay, in the North and South Sloughs, and in Haynes Inlet. Total eelgrass area within Coos Bay was estimated to be about 1,400 acres in 1997 (ODLCD, 1998). While current abundance may differ, overall portion of important eelgrass habitat directly affected is very small. Due to the lack of large eelgrass beds within the estuarine analysis area, turbidity increases are not expected to significantly impact eelgrass populations in the lower bay. However, this region would take time to regrow the following year and may take additional plantings to be successful for full restoration. So, in the short term, some eelgrass habitat would be lost.

Water quality impacts would be short-term and defined by the turbidity plume, which would be subject to prevailing tidal conditions. Based on previous turbidity modeling efforts, the turbidity plume is not expected to exceed the boundaries of the primary action area (Moffatt and Nichol 2006a). No significant turbidity increases are expected in Jordan Cove or Pony Slough, which are important alcove habitats that may be utilized by EFH species. Dredging of the access channel is not expected to cause resuspension of sediment contaminants that could harm EFH species.

Discharge of the maintenance dredging at Site F, about 1.6 miles off the mouth of Coos Bay, would generate a turbidity plume that could affect ground fish within the EEZ analysis area. Site F is about 2,700 acres and ranges from 25 to 150 feet deep. Approximately 37,700 cy is the total maintenance dredging volume expected at year 1 and 34,600 cy is the total maintenance dredging volume expected at year 10. In the first 10 years, an approximate total of 360,000 cy would be removed and in the next 10 years approximately 330,000 cy would be removed for an approximate total of 690,000 cy in comparison to the earlier prediction of 1.75 million cy. This is a substantial reduction in volume which in turn will reduce the demand for disposal space at Site F. The original estimate for the frequency of dredging was every two years. Now, with the additional information from the modeling, the recommended future maintenance dredging requirements are approximately 115,000 cy would need to be dredged every three years for the first 9-12 years (10 years approximately) and after 10 years it would be safe to reduce the volume of dredging to some values in the range of 115,000 to 160,000 cy with a frequency of five years between dredging events.

Turbidity generated from discharge at Site F would be rapidly dissipated and may cause some short-term avoidance of the area by ground fish during discharge. But there is the possibility that fish, if they were present directly under the sediment discharge from the barge or ship, would be unable to dart out of the plume of sediment and become trapped in the sediment during active discharge. Potential adverse effects would occur to smaller subadults if they were present within the area. In addition, some short-term loss of benthic invertebrates from burial (weeks/months) would occur, but the extent of the area would be extremely small relative to amount of this habitat available. Also, the site is low in diversity and abundance of organisms. The site has been approved partly for its minimal effects to recourses from discharge of clean (hazardous substance free) sediment here.

**Conservation Measures**

Measures to minimize effects to listed whales would likewise minimize potential accidental spills and releases at sea which could affect EFH within the EEZ analysis area. Those measures include: 1) LNG carriers approaching the Port of Coos Bay would be traveling slowly and escorted by tractor tugs from 50 nmi offshore to the Port, and 2) spills or releases of LNG at sea would not cause the water column to cool to the point of affecting coastal pelagic fish species in the water.

Measures to minimize effects to listed Oregon Coast coho salmon and green sturgeon would likewise minimize potential effects to EFH within the estuarine analysis area. Groundfish species primarily utilize Coos Bay on a seasonal basis, mostly during summer months. Construction is planned within the period from October 1 through February 15 following ODFW's recommendation and would coincide with a period when fewest groundfish species are expected to be present. Effects to food resources and eelgrass habitats would be minimized by construction from October 1 through February 15 when eelgrass within Coos Bay is dormant.

Turbidity within Coos Bay and Haynes Inlet, produced by construction of the slip, access channel, and Pacific Connector pipeline would be short-term, relatively confined to elongated plumes, and is expected to quickly dissipate to turbidity levels generally associated with winter tides and storm wave action.

### 6.3.3 Effects Determination

The proposed action **may adversely affect** EFH for groundfish species in the short term from loss of eelgrass areas until the mitigation beds and pipeline areas regrowth occurs. Also the disposal of dredge material at Site F would temporarily bury potential food resources for groundfish. Additionally, juvenile larval stages of fish could be entrained or impinged and suffer mortality. Accidental spills and releases at sea, if they should occur, and Project construction within the Coos Bay estuary are not expected to diminish water quality or substrates within the EEZ analysis area or the estuarine analysis area.

## 6.4 PACIFIC SALMON

### 6.4.1 Essential Fish Habitat

EFH for Pacific salmon includes estuaries, nearshore marine water, and waters extending out to the 200 nmi-wide EEZ of the coast of Washington, Oregon, and in California north of Point Conception. It also includes freshwater and substrates associated with streams, lakes, ponds, wetlands and other waterbodies that were historically accessible to salmon. EFH excludes habitats upstream from longstanding impassible barriers (waterfalls) and upstream from impassible barriers (dams) identified by PFMC (1999).

EFH for chinook and coho salmon has been designated within the following watersheds that coincide with the proposed action riverine analysis areas: South Umpqua River (HUC 17100302), Coos River (HUC 17100304), Coquille River (HUC 17100305), and Upper Rogue River (HUC 17100307). Essential fish habitat for chinook salmon and coho salmon is also present in the Upper Klamath River (HUC 18010206) in California and Oregon but construction of multiple dams on the mainstem Klamath River have made upstream areas impassible to anadromous fish (Hamilton et al., 2005). Habitats within the Project Area upstream from the Iron Gate Dam are not currently accessible to coho or Chinook salmon. , but the Oregon Fish and Game Commission in July 2008 authorized the study of reintroduction of anadromous fish into the Klamath River system in Oregon.

Coho salmon within the Upper Rogue River (HUC 17100307) watershed are within the SONCC ESU and their threatened status, environmental baseline, Project effects and determination of effects under ESA (species effects and effects to designated critical habitat) were addressed in Section 4.4.1. Likewise, coho within the South Umpqua River (HUC 17100302), Coos River (HUC 17100304), Coquille River (HUC 17100305) watersheds are within the Oregon Coast ESU, listed as threatened and with designated critical habitat under ESA, were similarly evaluated in section 4.5.1. EFH for coho in both ESUs is present within several proposed action riverine analysis areas, as well as the estuarine and EEZ analysis area (Oregon Coast coho).. Likewise, EFH for Chinook salmon in the Oregon Coast and SONCC ESUs, is present within the same analyses areas as for coho although neither Chinook salmon ESU is listed under ESA.

Specific timings of life history phases for fall-run Chinook salmon within the estuarine and riverine analysis areas are shown in figure 6.4-1. Spawning does not occur within the Coos Bay estuary or the analysis area included for Coos River. Spawning does occur within the Coquille River and tributaries, in the Rogue River mainstem and tributaries, as well as the South Umpqua River mainstem and tributaries.

Whereas adult coho in the SONCC ESU and Oregon Coast ESU begin upstream migrations in September, fall Chinook salmon in some watersheds begin as early as mid-July (Coos River and Coquille River) or early August. Similar to coho, fall Chinook salmon in the South Umpqua River begin upstream migrations in early September. Spawning in the South Umpqua mainstem is as early as mid-September but begins in October within tributaries to the South Umpqua. Spawning in the Rogue River mainstem and tributaries also begins in October (see figure 6.4-1).

Specific timings of life history phases for spring-run Chinook salmon within the riverine analysis areas are shown in figure 6.4-2. No life-phase timing of spring Chinook salmon is reported for the Coos Bay estuary or Coos River. Spawning does occur in the Coquille River and tributaries from September through mid-November. Spawning also occurs within the Rogue River mainstem and tributaries in October and November as well as in the South Umpqua River mainstem from mid-September through January and in its tributaries from October through mid-January (see figure 6.4-2).

### 6.4.2 Analysis of Effects

Within the 200 nmi-wide EEZ, effects by the proposed action to coho salmon and Chinook salmon EFH within the analysis area are expected to be associated with accidental spills and releases at sea by LNG carriers transiting at least 50 nmi offshore within the EEZ from south to north (from San Diego to Coos Bay), from LNG carriers approaching Coos Bay from the west through the 200 nmi-wide EEZ, and from tugs hauling sand barges between Coos Bay and San Francisco Bay 12 nmi or more offshore. These effects have been discussed under Highly Migratory Species in section 6.2.1 above. Additional effects about these spills are noted in the in sections for Oregon Coast coho salmon ESU in Sections 4.5.4.3 and Southern DPS green sturgeon in Section 4.5.1.3. Likewise, effects to coho salmon within the estuarine analysis area (Oregon Coast ESU) were described in Section 4.5.4.3 and are applicable to other coho salmon and similar for Chinook salmon EFH. Various life stages of fall Chinook salmon are expected within the Coos Bay estuary throughout the year (see figure 6.4-1). During the period when within-water construction is planned, October 1 through February 15, adult fall-run Chinook salmon would be holding within Coos Bay and migrating upstream within the Coos River (see figure 6.4-1).

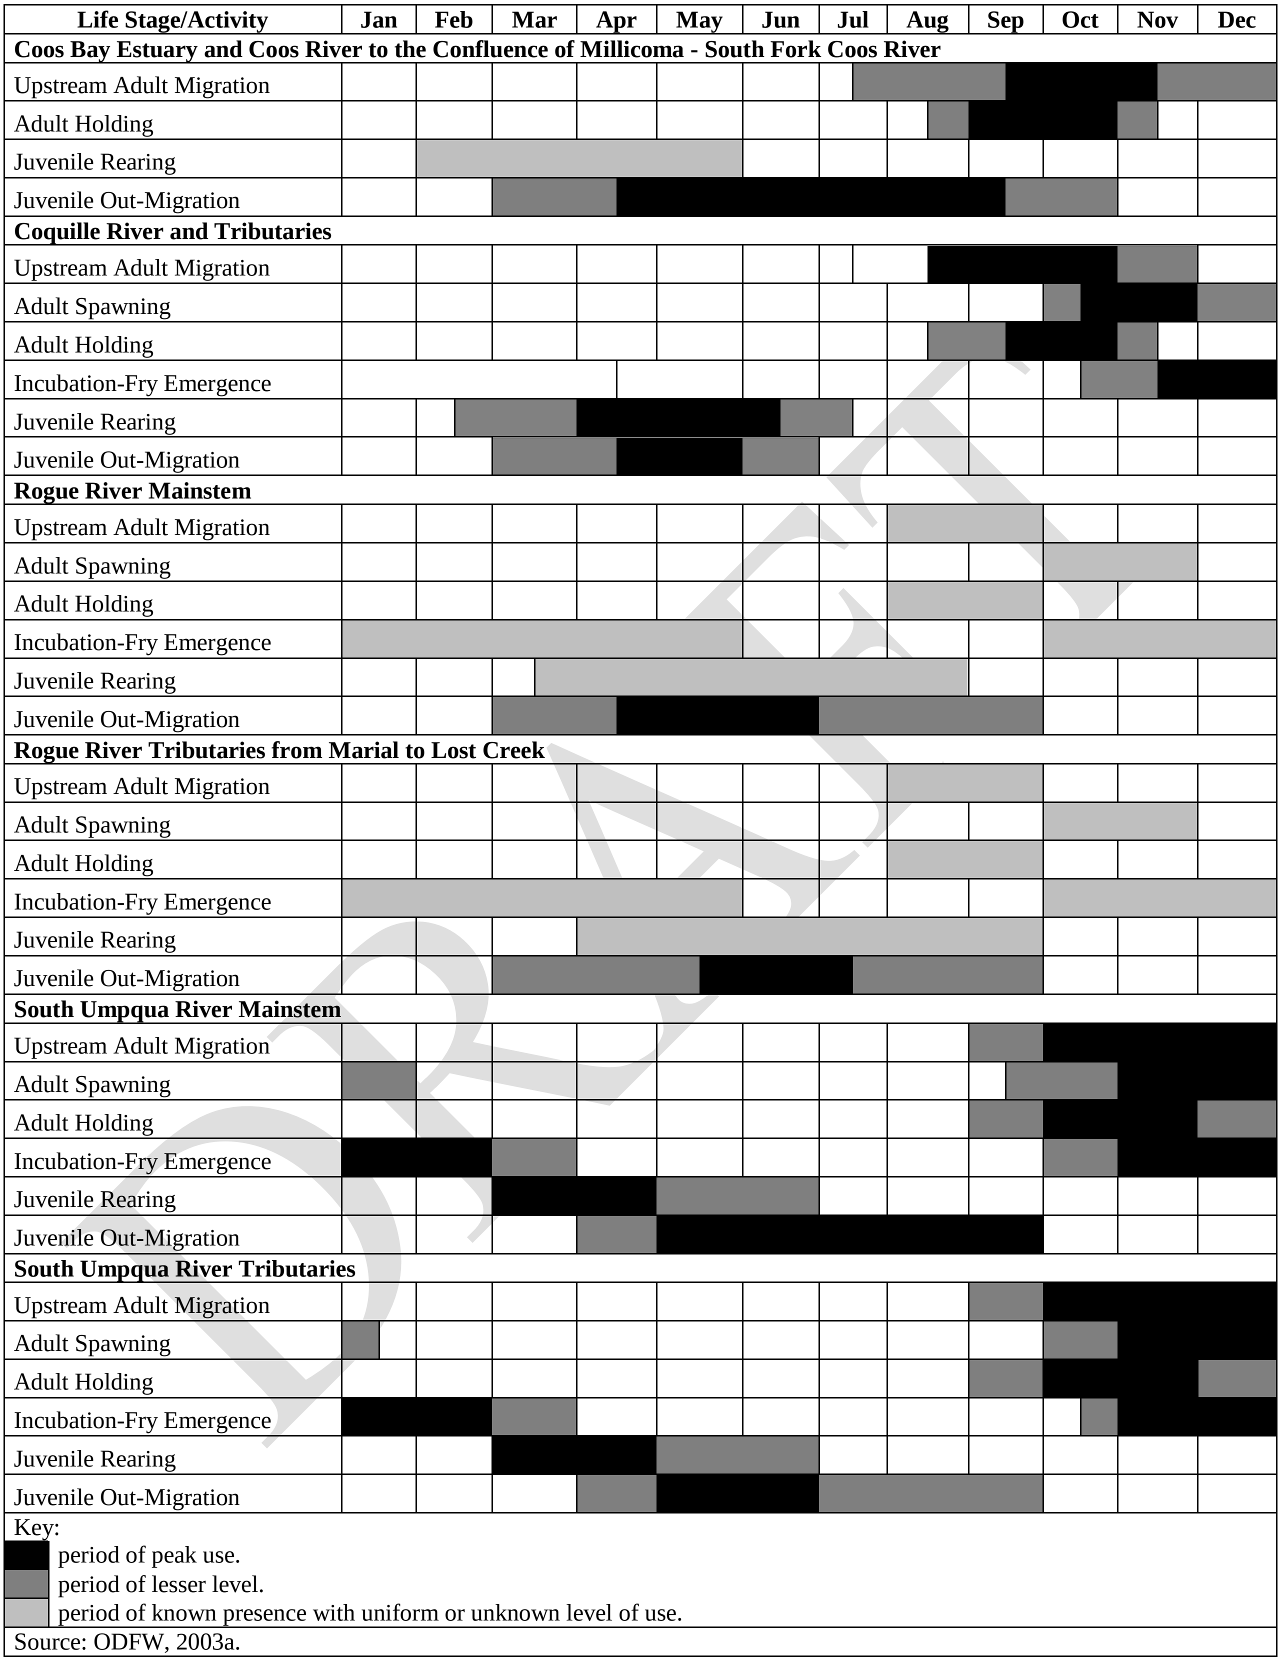

**Figure 6.4-1**
**Approximate Timing of Fall Chinook Salmon Use of Streams and Estuaries in the Pacific Connector Pipeline Area**

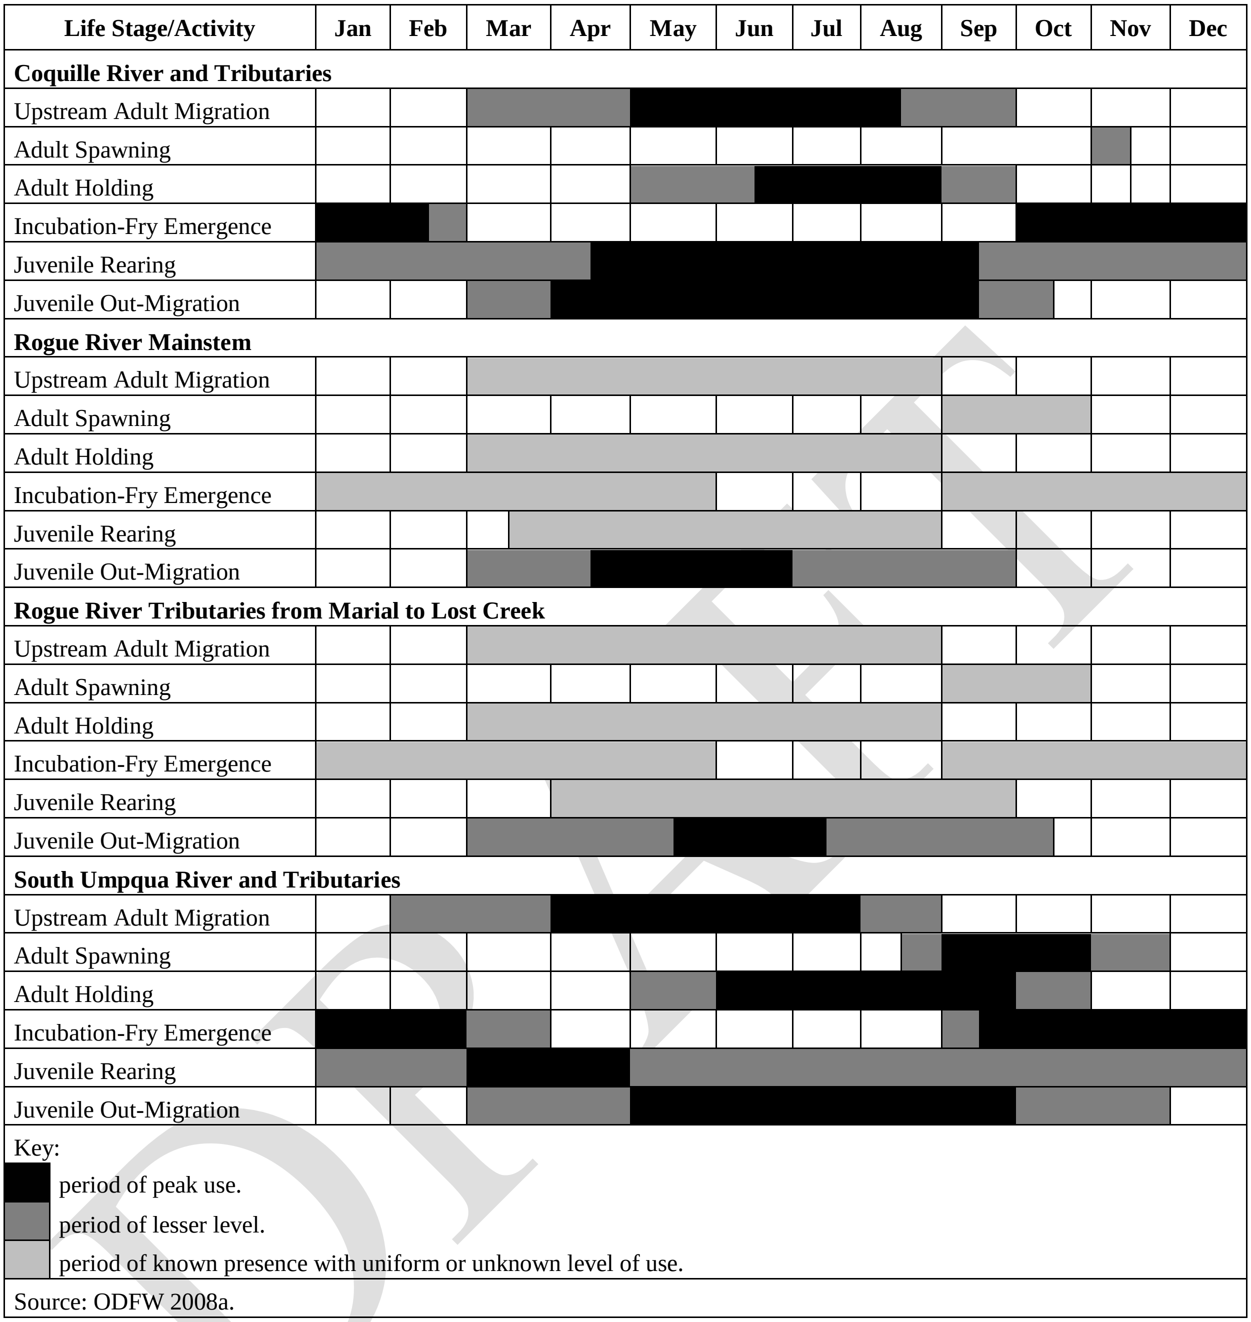

**Figure 6.4-2**
**Approximate Timing of Spring Chinook Salmon Use of Streams in the Pacific Connector Pipeline Area**

Construction within Coos Bay is likely to increase local turbidity over the short-term while adult Chinook salmon are present. Juvenile Chinook salmon may also be present in the estuarine analysis area during construction. However, Chinook salmon smolts appear to be more tolerant to high levels of suspended sediments than juvenile coho salmon coho since $LC_{50}$ values for smolts exposed for 96 hours were found to be 11,000 mg/L (Ross, 1982) compared to $LC_{50}$ of 509 mg/L for coho salmon coho smolts (Stober et al., 1981). However effects still remain for Chinook salmon juveniles from turbidity. Similarly, effects, distance, and effective area of downstream turbidity produced during instream construction, within freshwater EFH, that were described and analyzed above for coho salmon are not expected to specifically apply to fall or spring Chinook salmon.

Construction of the LNG bay and the pipeline route would cause some initial loss of eelgrass habitat, an important food and rearing environment for juvenile coho and Chinook salmon. While mitigation would replace some of the lost habitat from the dredging of the LNG facility it would take time for the replacement area to develop. Also regrowth of eelgrass in the region of the Coos Bay pipeline dredging would take time to reestablish and may require additional plantings causing a short term loss of this habitat.

LNG carriers would re-circulate water while loading LNG at the berth and the amount of cooling water to be re-circulated is a function of the propulsion system for the vessels. Once the LNG fleet has been identified, cooling water flow rates and the amount of water required can be further addressed. It is likely that some organisms small enough to pass through the screens covering the carrier's intake port will be drawn in with the cooling water and will be lost from the population in the slip area; however, it is anticipated that the effect associated with the intake of cooling water will be minimal. Juvenile fish would need to be present in the slip area near the carrier's intake screens and be small enough to fit through the sea chests which are covered with screens composed of 4.5 mm thick bars spaced 24 mm apart and located approximately 32 feet below the water line, or 5.6 feet from the keel of the LNG carrier. The intake velocities for cooling water are low enough that it is not anticipated that any larger organisms (fish, marine mammals, or invertebrates) would be impinged on the intake screen.

Near and offshore marine areas that supply potential food sources for salmon near Coos Bay may be affected by disposal of dredge spoils at Site F, a 2,700-acre clean dredge disposal site centered 1.6 miles off the mouth of Coos Bay (discussed above in Section 6.3.2 for ground fish). Disposal would initially bury benthic and epibenthic non-mobile organisms and cause a short-term turbidity plume both within Coos Bay during dredging and at the discharge locations. While this site has been used by COE for disposal since 1986, the Project would increase the frequency and quantity of disposal at this site. Effects to EFH for Pacific salmon would be similar to those described for Oregon Coast coho salmon (Section 4.5.4.3), for both other coho salmon and juvenile Chinook salmon, including short-term displacement of fish near the tailings plume and short-term loss of deeper water potential benthic food resources.

The potential for fish stranding loss from vessel wake in Coos Bay for coho salmon was assessed in Section 4.5.4.3 and concluded to be discountable because of several factors. Most of those factors also apply to juvenile Chinook salmon in Coos Bay. However age 0 Chinook salmon in the lower Columbia River system have been found to be more susceptible to stranding than juvenile coho salmon in this system (Pearson et al., 2006). It has been observed in net sampling studies in the lower Columbia River that age 0 Chinook salmon appear to be more oriented to the shoreline areas than age 1 Chinook salmon or coho salmon (Johnsen and Sims 1973, Dawley et al. 1986). While age 0 Chinook salmon are more susceptible to stranding, partly because of their apparent distribution, the procedures to be used for vessel traffic in Coos Bay such, as low vessels speed and travel at high tide only, have been found to reduce to insignificant the loss of even age 0 Chinook salmon in the lower Columbia River (Hinton and Emmett, 1994). The outer mile of the channel, where vessel speed would be the highest would appear to be a region of greatest potential stranding from large waves generated by vessels. However area is also a region of naturally higher waves due to its proximity to the ocean (Wagner et al., 1990), so ship wake is likely to be much lower effect than natural conditions relative to frequency and magnitude of shore waves. Also although data for Coos Bay is not specifically available radio tagging studies of juvenile salmonids in the Columbia River suggest that even age 0 Chinook salmon tended to be more commonly offshore when they are approaching the marine environment near the mouth of the Columbia River (Carter et al. 2009). This behavior, if it occurs in Coos Bay, would reduce further the chance of age 0 Chinook salmon from being stranded from vessel wakes. Overall stranding potential is higher for age 0 Chinook salmon in Coos Bay from vessel wake than other salmonids but available information suggests stranding of all juvenile salmonids would not be substantial. Overall effects to Pacific salmon EFH from vessel wakes would therefore be minimal and discountable for reasons noted in above.

Instream construction in all watersheds (Coos, Coquille, South Umpqua, and Upper Rogue) within which there is EFH for fall and/or spring Chinook salmon would coincide with upstream migration, adult spawning, adult holding, incubation and fry emergence, juvenile rearing, and/or juvenile out-migration for one or both runs of Chinook salmon (figures 6.4-1 and 6.4-2).

**Conservation Measures**

Measures to minimize effects to listed coho salmon and green sturgeon would likewise minimize potential effects to EFH within the estuarine analysis area. The Conservation Measures (see appendix N) and the Compensatory Mitigation Plan (see appendix O) described are also applicable to EFH and would satisfy requirements pursuant to Section 305(b)(4)(A) of the MSA. Overall, the proposed conservation measures are expected to increase habitat value within the lower bay and provide long-term benefits to EFH species managed under the MSA but short term habitat effects remain. Conservation measures applied to freshwater EFH would provide long-term benefits, particularly instream and riparian zone installations of LWD.

### 6.4.3 Effects Determination

Effects to freshwater Pacific Coast Salmon EFH by the proposed action **may adversely affect** riverine habitats by impacting substrates and water quality over the short-term and by removal of riparian vegetation which could affect water quality over the long-term. Additionally, the Project may adversely affect the estuarine and nearshore marine sites in the short term from loss of important eelgrass habitat until it reestablishes after dredging and restoration in the bay and benthic food resources in the offshore disposal Site F. Also juvenile salmon may be trapped in the ocean tailings discharge while disposal occurs at Site F. Additionally, juvenile salmon stages could be entrained or impinged and suffer mortality from water withdrawal.

16. ABSTRACT

Protection of Washington State's salmonids requires that transportation officials consider the effect of suspended sediments released into streams during transportation projects. Many state and provincial criteria are based on a threshold of exceedance for background levels of turbidity. However, determining natural background levels of turbidity is a difficult endeavor.

The inconsistent correlation between turbidity measurements and mass of suspended solids, as well as the difficulty in achieving repeatability using turbidimeters contributes to concerns that turbidity may not be a consistent and reliable tool determining the effects of suspended solids on salmonids. Other factors, such as life stage, time of year, size and angularity of sediment, availability of off-channel and tributary habitat, and composition of sediment may be more telling in determining the effect of sediment on salmonids in Northwestern rivers.

For short-term construction projects, operators will need to measure background turbidities on a case by case basis to determine if they are exceeding regulations. However, transportation projects may also produce long-term, chronic effects.

To adequately protect salmonids during their freshwater residence, TSS data on physiological, behavioral, and habitat effects should be viewed in a layer context, incorporating both the spatial geometry of suitable habitat and the temporal changes associated with life history, year class, and climate variability. Spatial and temporal considerations provide the foundation to decipher legacy effects as well as cumulative and synergistic effects on salmonid protection and recovery.

## Summary

Human activities in Northwestern watersheds, including logging, grazing, agriculture, mining, road building, urbanization, and commercial construction contribute to periodic pulses or chronic levels of suspended sediment in streams. Suspended sediment is associated with negative effects on the spawning, growth, and reproduction of salmonids.

Effects on salmonids will differ based on their developmental stage. Suspended sediments may affect salmonids by altering their physiology, behavior, and habitat, all of which may lead to physiological stress and reduced survival rates. A sizable body of data (laboratory and field-based) has been gathered in North America focusing on the relationship between turbidity, total suspended sediments, and salmonid health. The controlled environment of laboratory studies tends to give clearer results than field studies.

Understanding the relationship between turbidity measurements, suspended sediments, and their effects on salmonids at various life stages will assist agencies implementing transportation projects to devise techniques to reduce temporary and chronic erosion and sedimentation associated with these activities. There are three primary ways in which sediment in the water column is measured: turbidity, total suspended solids, and water clarity. While these measures are frequently correlated with one another, the strength of correlation may vary widely between samples from different monitoring sites and between different watersheds. Turbidity is currently in widespread use by resource managers, partially due to the ease of taking turbidity measurements. In addition, current state regulations addressing suspended sediment are usually NTU-based. The disadvantage of turbidity is that it is only an indicator of suspended sediment effects, rather than a direct measure, and may not accurately reflect the effect on salmonids.

Protection of Washington State's salmonids requires that transportation officials consider the effect of suspended sediments released into streams during transportation projects.

Many state and provincial criteria are based on a threshold of exceedance for background levels of turbidity. However, determining natural background levels of turbidity is a difficult endeavor. Turbidity measures may be affected by 1) differing physical processes between watersheds including geologic, hydrologic and hydraulic

conditions; 2) legacy issues (activities historically conducted in the watershed); and 3) problems with instrumentation and repeatability of turbidity measurements. Altered systems may not provide accurate baseline conditions.

The inconsistent correlation between turbidity measurements and mass of suspended solids, as well as the difficulty in achieving repeatability using turbidimeters contributes to concerns that turbidity may not be a consistent and reliable tool determining the effects of suspended solids on salmonids. Other factors, such as life stage, time of year, size and angularity of sediment, availability of off-channel and tributary habitat, and composition of sediment may be more telling in determining the effect of sediment on salmonids in Northwestern rivers.

Although salmonids are found in naturally turbid river systems in the Northwest, this does not necessarily mean that salmonids in general can tolerate increases over time of suspended sediments. An understanding of sediment size, shape, and composition, salmonid species and life history stages, cumulative and synergistic stressor effects, and overall habitat complexity and availability in a watershed is required.

For short-term construction projects, operators will need to measure background turbidities on a case by case basis to determine if they are exceeding regulations. However, transportation projects may also produce long-term, chronic effects. Short-term pulses will presumably have a different effect on salmonids than chronic exposure.

To adequately protect salmonids during their freshwater residence, TSS data on physiological, behavioral, and habitat effects should be viewed in a layer context incorporating both the spatial geometry of suitable habitat and the temporal changes associated with life history, year class, and climate variability. Spatial and temporal considerations provide the foundation to decipher legacy effects as well as cumulative and synergistic effects on salmonid protection and recovery.

# I. Introduction

Human activities in Northwestern watersheds, including logging, grazing, agriculture,

mining, road building, urbanization, and commercial construction have often resulted in periodic pulses or chronic levels of suspended sediment in streams. Suspended sediment is associated with negative effects on the spawning, growth, and reproduction of salmonids (e.g., Noggle 1978, Berg 1982, Lloyd et al. 1987, Reid 1998).

Effects on salmonids will differ based on their developmental stage. Suspended sediments may affect salmonids by altering their physiology, behavior, and habitat, all of which may lead to physiological stress and reduced survival rates. A sizable body of data has been gathered in North America focusing on the relationship between turbidity, total suspended sediments, and salmonid health.

Recent listings of salmonids under the Endangered Species Act (ESA) and the desire to protect and restore declining stocks have increased interest in the relationship between the release of fine sediment and salmonid productivity and survival. The purpose of this report is to provide an analysis of the current state of the science regarding the relationship between turbidity levels and the survival, reproduction, and growth functions of salmonids. We will also examine research that measures the effect of total suspended sediment on the health of salmonids.

Transportation projects often include activities that may negatively affect water quality, via disturbance of instream sediments for bridge and culvert construction or stormwater runoff from transportation construction sites (E. Molash, pers. commun.). Road-related erosion may significantly increase chronic turbidity levels in streams (Reid 1998). Roading may also affect subsurface flows, affecting upwelling in the stream (Sedell et al. 1990). It should be noted that much of the research on the effects of roads on suspended sediment and turbidity has focused on unpaved forest roads.

Understanding the relationship between turbidity measurements, suspended sediments, and their effects on salmonids at various life stages will assist agencies implementing transportation projects to devise techniques to reduce temporary and chronic erosion and sedimentation associated with these activities. Methods such as soil covers, project staging, land clearing windows, and water treatment systems could be implemented to prevent occurrence of critical turbidity levels (E. Molash, pers. commun.).

## II. Definitions

### Measurements

There are three primary ways in which sediment in the water column is measured: turbidity, total suspended solids, and water clarity. Although these three metrics measure different aspects of suspended sediments, they are often incorrectly used in research papers (A. Steel, pers. commun.). While these measures are frequently correlated with one another, the strength of correlation may vary widely between samples from different monitoring sites and between different watersheds (Duchrow and Everhart 1971, A. Steel, pers. commun.). For example, parent material in a basin, weathering rate, texture of sediment and soils produced through weathering and erodibility all have a great influence on the amount, texture, and behavior of fine sediments in streams (Everest et al. 1987).

**Turbidity** is an optical property of water where suspended and dissolved materials such as silt, clay, finely divided organic and inorganic matter, chemicals, plankton, and other microscopic organisms cause light to be scattered rather than transmitted in straight lines. Measurements of turbidity have been developed to quickly estimate the amount of sediment within a sample of water and to describe the effect of suspended solids blocking the transmission of light through a body of water (Lloyd 1987).

Turbidity is usually measured by nephelometry – the relative measurement of light scattering through a restricted range of angles to the incident light beam. Typically, nephelometers detect light scattered by a water sample usually at 90° to the incident beam. Nephelometric turbidity units (NTUs) are used as a rough index of the fine suspended sediment content of the water (Davies-Colley and Smith 2000). In the past, turbidity was measured using Jackson Turbidity Units (JTUs). The Jackson Candle Turbidimeter was limited in that it could not measure turbidities lower than 25 JTU and was dependent on human judgment (Web Site Ref. #3). At high turbidities, JTUs and NTUs are roughly equivalent (Lloyd 1987). Please note that JTUs are only used in this report in tables culled from previous literature reviews.

**Total Suspended Solids (TSS)** represents the actual measure of mineral and organic particles transported in the water column. TSS is an important measure of erosion, and is linked to transport of nutrients, metals, and industrial and agricultural chemicals through river systems. Suspended sediment consists primarily of silt and clay-size particles that may be rapidly transported downstream and locally deposited on floodplains and overbank storage locations or may infiltrate into gravel interstices of the bed (Everest et al. 1987). Note that in older literature, TSS may also be referred to as suspended sediment concentration (SSC). This term will be used in the literature review where appropriate. Fluctuating TSS levels may influence aquatic life from fish to phytoplankton. Fine particles may carry substances that are harmful or toxic to aquatic life.

TSS is determined by measuring the residue in a well-mixed sample of water which will not pass a standard (glass fiber) filter. The residue trapped on the filter is dried (103-105 °C) and reported in units of weight per volume (typically mg/l) (Sorenson et al. 1977).

**Water clarity**, a direct measure of visible distance through water is another important measure related to the presence of sediment in the water column. Visual water clarity describes the distance that an organism can see underwater. Water clarity is affected by suspended and dissolved materials (Davies-Colley and Smith 2000). Correlations between visual water clarity and turbidity (NTU) or TSS may vary dramatically between watersheds.

Changes in water clarity alter the balance between predators and prey and may have a strong effect on individual behaviors (A. Steel, pers. commun.). Historically, water clarity has been measured with a Secchi disk, a black and white disk submerged vertically into the water until it can no longer be seen (Davies-Colley and Smith 2000).

Three water quality tests are related to sedimentation in streams:

| **Turbidity** | **Total Suspended Solids** | **Water Clarity** |
|---|---|---|
| Measure of the refractory characteristics of material in the water. Not always correlated with total suspended solids | Actual measure of the amount of sediment suspended in the water column | Measure of visual distance in the water column |

**Limitations of Using Turbidity as a Measurement**

The widespread use of turbidity as a water quality standard and indicator of suspended solid concentration can, at least in part, be attributed to the ease and cost of using a nephelometric turbidity meter in the field (Davis-Colley and Smith 2000) in comparison to the direct measurement of suspended solids. Duchrow and Everhart (1971) noted that direct measurement of settleable solids is difficult and time consuming.

Turbidity cannot always be correlated with suspended solid concentrations due to the effects of size, shape, and refractive index of particles (Sorenson et al. 1977). Duchrow and Everhart (1971) noted that turbidity measurements are primarily useful if: 1) a major portion of the total turbidity is contributed by settleable solids; 2) a relationship exists between turbidity readings and weight per unit of volume of suspended sediment and; 3) if a reliable meter is available.

Duchrow and Everhart (1971) tested different materials to determine if similar turbidity readings were obtained at the same concentration. At higher turbidity readings, they found a poor correlation between readings and suspended sediment concentrations (SSC) for all materials tested. Duchrow and Everhart (1971) questioned the use of turbidity as a parameter for establishing water quality standards, as too many factors must remain constant before a turbidity measurement can be converted to a corresponding SSC.

The relationship between turbidity and SSC may also change along a downstream gradient from a sediment source. Larger particles, which generally produce less turbidity per unit concentration than smaller particles, gradually settle out, thus shifting the turbidity versus SSC relationship to a higher NTU per unit SSC in reaches progressively farther down stream (Lloyd 1987).

Davies-Colley and Smith (2000) have suggested that water clarity is a more useful measure for determining the effect of suspended solids. These researchers suggest that turbidity is only a relative measurement that has no environmental relevance in itself, unless calibrated to clarity or some other absolute optical quantity or to suspended sediment mass concentration, at each site of interest.

This research implies that turbidity may not be a reliable tool for determining the effects of suspended solids on salmonids. The inconsistent correlation between turbidity measurements and mass of suspended solids, as well as the difficulty in achieving repeatability using turbidimeters contributes to concerns regarding this technique.

**Turbidity Meters**

The consistency of turbidimeters is an issue of concern. Duchrow and Everhart (1971) tested three different turbidimeters and found that there was a highly significant difference between readings on the same sample of suspended sediment. Further examination revealed increasing variance between readings with an increase in turbidity. Highly significant differences were also present between readings obtained on the seven materials for each meter. Recent studies in King County also noted problems with reliability and consistency of turbidimeters (D. Booth, pers. commun.).

**Summary**

Turbidity, TSS and water clarity are three common measures used to determine the effect of suspended sediment on salmonids. Turbidity is currently in widespread use by resource managers, partially due to the ease of taking turbidity measurements. In addition, current state regulations addressing suspended sediment are usually NTU-based. The disadvantage of turbidity is that it is only an indicator of suspended sediment effects, rather than a direct measure, and may not accurately reflect the effect on salmonids.

Other factors, such as life stage, time of year, size and angularity of sediment, availability of off-channel and tributary habitat, and composition of sediment may be more telling in determining the effect of sediment on salmonids in Northwestern rivers. In addition, many watersheds have been affected by land use that alters sediment input and transport, and therefore do not provide accurate baseline conditions. Unaltered systems display wide ranges of turbidity over space and time, and therefore long-term data are needed to understand baseline conditions.

## III. Natural Background Levels of Turbidity in the Pacific Northwest

Determining natural background levels of turbidity is a difficult endeavor. Turbidity measures may be affected by 1) differing physical processes between watersheds; 2) legacy issues (activities historically conducted in the watershed); and 3) problems with instrumentation and repeatability of turbidity measurements (as mentioned in the previous section).

Turbidity can vary between watersheds, based on the geology of each particular basin. For example, systems fed by glacial meltwater often have higher turbidities than other systems (Lloyd et al. 1987). In addition, tributaries and stream segments within the same system may have widely divergent background turbidities. Headwater streams tend to be less turbid then mainstems or estuaries – faster flowing water transports suspended sediment downstream quickly. The patchiness of turbidity, both spatially and temporally, influences how salmonids use a river system in various life stages (Sedell et al. 1990).

In Northwestern watersheds, natural background turbidity varies on a seasonal basis depending on when precipitation and runoff occur (higher in spring in the Fraser River, Servizi and Martens 1987) and depends on the hydrologic regime (lowland Washington streams typically see higher turbidity in fall and winter; **Appendix A)**. Increased rainfall and storm events usually produce an increase in erosion and transport of sediments deposited in streams. Monitoring at specific sites throughout a watershed would allow managers to understand the range of change that occurs at a particular site and across the watershed. Methods of monitoring turbidity vary in quality and convenience and their effectiveness changes with stream size (E. Ritzenthaler, pers. commun.).

The State of Washington's 1999 Water Quality Data Report provides water quality data points for a number of Washington state creeks and rivers, including turbidity measurements (Web Site Ref. #11). Twelve measures were taken between the end of 1998 and September of 1999. Monthly values for turbidity from this report for four sites (two on the Stilliguamish, one on the Skagit, one on the Samish) are in **Appendix A**. Note the fluctuation in turbidity at some of these monitoring stations over a twelve month period. In order to determine "natural background turbidity," continuous measurements would be necessary over time and across space. Historical and current changes to the system affecting sediment input and processes, load, and transport must also be understood. This data set does not provide enough context to determine "natural background turbidity." In addition to state water quality data, a sample of data collected by King County METRO is included in **Appendix A**. Three rivers were sampled in 1988-1999 to determine where turbidity and total suspended solids were of concern.

Without continuous monitoring throughout a basin, turbidity data only provides a series of scattered data points that are not linked to temporal or spatial parameters of the watershed. Without this context, it is difficult to make a determination regarding how turbidity levels are affecting the system. This problem is inherent in the collection of water quality data and development of water quality criteria.

**Summary**

In order to develop "natural" background turbidities, a stratified sample allowing one to differentiate between different physical and biological processes affecting watersheds is necessary. Continuous sampling across these systems may also provide information on how salmonids persist within highly variable systems. The historical legacy of systems is also an important and necessary factor to consider in evaluating this information.

## IV. Effects of Turbidity and Suspended Solids on Salmonids

Sedimentation derived from land use activities is recognized as a primary cause of habitat degradation in the range of west coast chinook, steelhead, cutthroat, and bull trout (USFWS 1998, Web Site Ref. #6). Land-use practices, through alteration of vegetation, hydrology and soil structure can alter the delivery of fine and coarse sediments to streams, thus affecting salmonid habitats. Sediment delivery rates and composition are controled by topography, climate, geology, hydrology, and vegetation (Spence et al. 1996).

The alteration of upslope hydrological and erosional processes with associated changes in instream hydrological, erosional, and depositional processes has resulted in a reduction in channel depth and increased fine and course sediment load. Logging, grazing, irrigation, stream channelization, chemical and nutrient applications, mining, agriculture, road construction, dam development and operation, and urban and rural development have played a role in altering upslope and instream physical and biological processes (Berman 1998).

**Range of Effects on Salmonids**

A range of studies have illustrated the effect of turbidity levels beyond natural background on the physiology and behavior of salmonids (Lloyd 1987, Everest et al. 1987, Newcombe and MacDonald 1991, Gregory and Northcote 1993). Lloyd (1987) suggested that high levels of suspended solids may be fatal to salmonids, while lower levels of suspended solids and turbidity may cause chronic sublethal effects such as loss or reduction of foraging capability, reduced growth, resistance to disease, increased stress, and interference with cues necessary for orientation in homing and migration.

Salmonid populations not normally exposed to high levels of natural turbidity or exposed to anthropogenic sediment sources may be deleteriously affected by levels of turbidity considered to be relatively low (18-70 NTU) (Gregory 1992). Low levels of turbidity appear to correspond to sediment concentrations that may adversely affect coldwater salmonids (Lloyd 1987).

Newcombe and MacDonald (1991) grouped effects of sediment on salmonids into three categories: lethal, sublethal and behavioral.

- ***Lethal effects*** kill individual fish, cause overall population reductions, and damage the capacity of the system to produce future populations. This category includes reductions caused by sublethal or behavioral effects.
- ***Sublethal effects*** relate to tissue injury or alteration of the physiology of an organism. Effects are chronic in nature and while not leading to immediate death, may produce mortalities and population decline over time.
- ***Behavioral effects*** are described by any effect that results in a change of activity usually associated with an organism in an undisturbed environment. These changes may lead to immediate death or population decline or mortality over time.

It is apparent that salmonids have the ability to cope with some level of turbidity at certain life stages (Gregory and Northcote 1993). Evidence of this is illustrated by the presence of juvenile salmonids in turbid estuaries prior to leaving for the ocean and in local streams characterized by high natural levels of glacial silt, and therefore high turbidity and low visibility (Gregory and Northcote 1993).

**Table 1. Effects of turbidity on salmonids**

| Physiological | Behavioral | Habitat |
|---|---|---|
| gill trauma | avoidance | reduction in spawning habitat |
| osmoregulation | territoriality | effect on hyporheic upwelling |
| blood chemistry | foraging and predation | reduction in BI habitat |
| reproduction and growth | homing and migration | damage to redds |

## Cumulative Effects

Ecological setting, landscape and evolutionary processes, and the physiological and behavioral response to sediment regime alteration are each important and contribute to our understanding of species response to turbidity. Therefore, it is important to examine a system as opposed to single effects or sites – without ecosystem based options for salmonids, species flexibility is diminished in responding to variable sediment loading (Berman 1998).

Anthropogenic disturbances often differ from natural disturbances in magnitude, frequency, and duration of events. Cumulatively, anthropogenic disturbances may decrease system heterogeneity, as well as connectivity. This reduces refuge options available to species during disturbance events. Altered levels of turbidity are just one of many conditions that may have a cumulative effect on the health and survival of salmon stocks.

While many laboratory studies have been performed to determine the effect of sediments on salmonids, the cumulative effect on salmonids is difficult to capture. Many of the effects on salmon are synergistic in nature; one effect can lead to a host of other effects that may affect the growth, reproduction, and survival of the fish. The following factors mediate effects of sediment on salmonids.

**Environmental Factors Affecting the Effect of Sediment on Salmonids**

Duration of exposure
Frequency of exposure
Toxicity
Temperature
Life stage of fish
Angularity of particle
Size of particle
Type of particle
Severity/magnitude of pulse
Natural background turbidity of area (e.g. watershed position, legacy)
Time of occurrence
Other stressors and general condition of biota
Availability of and access to refugia

Salmonid response (often measured in terms of physical stress) is dependent on environmental factors such as duration of exposure and temperature (Servizi and Martens 1992). Rogers (1969) suggested that the variability in tolerance to suspended sediment could be explained by sediment particle characteristics, water temperature, species differences and other stressors that might have synergistic effects.

An example of a synergistic effect of sediment can be illustrated by examining the avoidance response of salmonids to turbid water. Life history stages and populations sensitive to sediment loads may be forced to move to other areas of the system to avoid negative effects on survival. These "turbidity refugia" must be available and accessible.

Stream reach or segment emigration is a bioenergetic demand that may affect the growth or reproductive success of the individual.

To illustrate seasonal and population differences, an example from the Western Olympic Peninsula is provided. H. Michael (pers. commun.) suggested that fish respond differentially to TSS in summer and winter. He noted that protective mucous secretions are inadequate during summer months and thereby expose individuals to increased risks. There are also salmonid populations that thrive in glacially turbid streams. However, biological and physical mechanisms related to these systems are unclear. Finally, "turbidity refugia" such as tributaries, sloughs, off-channel habitat, and lakes are important during different parts of the year. Organismic response to variables such as TSS require further understanding and evaluation.

**Reduction in Buffering Capacity**

The overall buffering capacity of a system may be reduced by frequent sediment loading. Salmonids are known to use refugia in a river system to escape negative water quality conditions, such as high temperatures (Berman and Quinn 1991). For example, bull trout seek out side channels in the winter during high flow periods for protection (USFWS 1998). Sediment may also cover intergravel crevices fish use for shelter (Waters 1995). In laboratory experiments, it has been shown that salmonids will move to less turbid waters, if available, after a short-term pulse (Berg and Northcote 1985). Bisson and Bilby (1982) illustrated the displacement of salmonids in water with turbidities greater than 70 NTU. These results suggest that salmonids in a river system might seek out turbidity refugia when subjected to short-term pulses of sediment.

Loss of acceptable habitat and refugia as well as decreased connectivity between habitat reduces the carrying capacity of streams for salmonids. In systems lacking adequate number, distribution, and connectivity of refugia, fish may travel longer distances or to less desirable habitat and may encounter a variety of other conditions including increased bioenergetic demands.

Reid (1998) summed up the cumulative effect created by turbidity upon salmonids in a disturbed system:

> "Salmonid strategies for coping with high turbidity are likely to include use of off-channel, clean-water refugia and temporary holding at clean-water tributary mouths. These coping strategies are partially defeated by the spatial distribution of roads: road runoff discharges into low-order channels that once would have provided clean inflows, and riparian roads restrict access to flood-plain and off-channel refugia. The temporal distribution of the high-turbidity inflows also decreases the effectiveness of coping strategies: turbidities are high even during low-magnitude events when flows may not be sufficient to allow access to refugia. The combined influences of increased turbidity and restricted opportunities for escape from the effect constitute a cumulative effect. Further, traffic-related turbidity is highest during the day, when salmonids feed, and traffic produces high turbidity even during small and moderate storm flows of autumn and spring, when water is warmer than during winter floods. Because salmonid metabolic rates are temperature-dependent, salmonids may be particularly sensitive to these unseasonable bouts of high turbidity."

In consideration of the effect of increased turbidities upon salmonids, the current state of available habitat and refugia must be examined. Can a watershed, given past management practices, provide the protection needed to salmonids at various life stages if additional sediment pulses are released?

It is also important to note in reviewing the following section that much of the research undertaken to examine turbidity effects on salmonids was performed in laboratories, where control turbidities do not necessarily reflect field conditions, such as prey quantities and other potential synergistic effects.

**Research Summary**

The purpose of this section is to review recent research regarding the effect of turbidity and suspended sediments on salmonids. The research is summarized in three sections:

A. **Physiological effects**
B. **Behavioral effects**
C. **Habitat effects**

**Physiological effects** cover stressors to the physical health of salmonids attributed to the presence of high turbidity or high levels of suspended solids. Some indicators of stress to salmonids that have been studied include gill trauma, blood sugar levels, and osmoregulatory function.

**Behavioral effects** cover changes in activity attributed to increased sediment in the water column. Behavioral effects reviewed here include avoidance, changes in foraging ability, responses to predation risk, and reduced territoriality.

**Habitat effects** cover changes to spawning and rearing habitat of salmonids.

### Note on Turbidity and Sediment Studies

Most laboratory studies examine the effect of sediment on salmonids in a controlled environment, where individual variables are tested. Everest et al. (1987) note that there are significant difficulties in extrapolating laboratory findings to the field. Many laboratory survival studies use simplified unnatural gravel mixtures to test incubation and emergence of salmonid fry. Other factors that may affect results include disease organism presence, temperature, and prey availability.

The authors note that factors in streams, such as structural roughness and spawning behavior of females complicate field application of laboratory studies. Studies dealing with effects of sediment from forest management in natural environments have been less conclusive, as increased fine sediment from forest management is almost always accompanied by other environmental effects (Everest et al. 1987).

In general, studies focusing on physiological effects (gill trauma, blood chemistry, osmoregulation, and reproduction and growth) were conducted in a laboratory environment. Research on behavioral effects included both laboratory and field studies. Studies related to avoidance, territoriality, foraging and predation were primarily performed in artificial holding tanks. Field studies, however, were conducted in projects focused on abundance and diversity of prey, primary production, and homing and migration. Research related to the effect of sediment inputs on habitat were primarily performed in the field.

### A. Physiological Effects

Turbidity is associated with a number of physiological effects in Pacific salmon (Berg 1982). Researchers have used several physiological indicators to determine the effect of incremental increases of suspended sediment on salmonids. The outcome of a stress response is dependent on synergistic factors such as duration of exposure, frequency, magnitude, temperature, and other environmental variables (Servizi and Martens 1992). Some physiological indicators used by researchers include gill trauma (Berg 1982; Berg and Northcote 1985), increased levels of blood glucose, plasma glucose, plasma cortisol, and osmoregulatory ability (Redding et al. 1987; Servizi and Martens 1987). The stress response itself may compromise the organism's immune system (increasing disease susceptibility) thereby affecting mortality rates (USFWS 1998).

Among salmonids, some species may be more sensitive to suspended sediment than others, and the sensitivity of the egg and juvenile stages of most species seemingly exceed that of adults (Lloyd 1987). Owing to their extended fresh water residency, juvenile chinook, coho, and steelhead may be more sensitive to increases in suspended sediment (Noggle 1978), as opposed to pinks and chum, which spend very little time in streams after hatching.

***Gill Trauma***

The presence of suspended sediments in the water column has been shown to produce gill trauma in sockeye underyearlings (Servizi and Martens 1987), gill flaring in response to short term sediment pulses (Berg 1982; Berg and Northcote 1985), and increased coughing frequency (Servizi and Martens 1992).

Fish gills are delicate and easily damaged by abrasive silt particles. As sediment begins to accumulate in the filaments, fish excessively open and close their gills to expunge the silt. If irritation continues, mucus is produced to protect the gill surface, which may impede the circulation of water over gills and interfere with fish respiration (Berg 1982).

Laboratory Studies

Servizi and Martens (1987) found that the lethality of Fraser River sediments on underyearling sockeye salmon (*Oncorhynchus nerka*) increased with increasing particle size. Fines (0-740 µm) lodged in gills and caused gill trauma at 3,148 mg/l or 0.2 of the 96 h LC50 value. This value is consistent with normal levels of suspended solids measured at Hell's Gate on the Fraser River. Particle size and shape may also affect the degree of damage to the gills (Servizi and Martens 1992). The LC50 decreased as particle size increased, for particles described as angular to subangular, in their work with

Fraser River sediments. Sockeye exposed to volcanic ash by Newcomb and Flagg (1983) experienced greater mortality at lower concentrations, indicating that the combination of slightly larger, more angular particles in volcanic ash may cause higher mortality.

Cough frequency is a sublethal effect that impairs the respiratory ability of salmonids. Servizi and Martens (1992) examined the effect of sublethal concentrations of Fraser River suspended sediments on underyearling coho salmon. Cough frequency was elevated eightfold over control levels at 240 mg/l (turbidity of 30 NTUs). Berg (1982) examined the effect of a short-term sediment pulse (initially 3 days at 60 NTU, then a reduction on the seventh day to 10 NTU) on coughing frequency of juvenile coho. In two of four tests, coughing rates increased significantly when turbidity was raised to 60 NTU. As turbidity declined to 10 NTU, coughing declined or remained at pretreatment levels. Noggle (1978), upon histological examination, found suspended sediments damaged gill structures. Berg and Northcote (1985) reported increases in gill flaring after a short-term sediment pulse, reaching 60 NTU. Flaring continued as turbidity dropped to 30 and 20 NTU.

***Blood Physiology***

Measures of elevated blood sugars (Servizi and Martens 1992), plasma glucose (Servizi and Martens 1987), and plasma cortisol have all been used as indicators of stress in fishes. Physiological stress in fishes may decrease immunological competence, growth, and reproductive success.

Laboratory Studies

Servizi and Martens (1987) identified increases in plasma glucose in juvenile sockeye salmon exposed to fine sediment. Plasma glucose levels of adult sockeye increased 150 and 39% as a result of exposures to 1,500 and 500 mg/l respectively of fine sediment. Servizi and Martens (1992) noted elevated blood sugar levels in underyearling coho salmon exposed to sublethal concentrations of Fraser River suspended sediments.

Redding et al. (1987) exposed yearling coho salmon and steelhead to high (2,000-3,000 mg/l) or low (400-600 mg/l) concentrations of volcanic ash, topsoil and kaolin clay for 7-8 days. Plasma cortisol levels were elevated in both species after exposure to high levels of topsoil. Yearling steelhead exposed to high or low concentrations for 2 days also showed elevated plasma cortisol levels.

A change in blood physiology is an indicator that a fish is experiencing some level of stress. At the individual fish level, stress may affect physiological systems, reduce growth, increase disease incidence, and reduce ability to tolerate additional stressors. At the population level, the effects of stress may include reduced spawning success, increased larval mortality, reduced recruitment to succeeding life stages and overall population declines. Stress to salmonids can affect the parr-smolt transformation, resulting in impaired migratory behavior, decreased osmoregulatory competence, and reduced early marine survival (Wedemeyer and McLeay 1981).

***Osmoregulation***

Laboratory Studies

The process of smolt transformation is critical to successful transfer of juvenile salmonids from fresh to marine waters. Disruptions of this process lead to osmotic imbalances and produce sublethal effects and eventual mortality (Redding et al. 1987). During the smolt transformation process, there appears to be an increased sensitivity to total suspended solids. Noggle (1978) conducted studies to assess the effects of suspended sediment upon juvenile salmonids in the stream environment. Results indicated seasonal changes in tolerance of salmonids to suspended sediment. Bioassays conducted in summer produced LC50's less than 1,500 mg/l, while autumn bioassays showed LC50's in excess of 30,000 mg/l. Spring/summer bioassays were coincidental to smolt transformation periods. Sockeye smolts suffered a slight impairment in hypoosmoregulatory capacity when exposed 96 h to 14,407 mg/l of fine sediment (Servizi and Martens 1987).

***Reproduction and Growth***

Salmonids require gravels that have low concentrations of fine sediments for successful spawning and incubation (Spence et al. 1996). Chronic turbidity during emergence and rearing of young anadromous salmonids could affect the quantity and quality of fish produced (Sigler et al. 1984). Organic matter entering substrate interstices depletes oxygen and reduces dissolved oxygen concentrations, harming eggs (Spence et al. 1996).

Settleable solids may prevent eggs from receiving necessary oxygen and inhibit removal of waste products within the redd and may create a physical barrier to fry emergence. The greater the proportion of fine sediments in redds, the greater likelihood that fry hatching from normally developed embryos will be entrapped and unable to emerge (Everest et al. 1987). Eggs, larvae, and fingerling fish are generally more susceptible to stress by dissolved or suspended solids than are adult fish. Intrusion of fines may occur initially in the upper 10 cm of the streambed gravels (Beschta and Jackson 1979). The intrusion or infiltration of fines into streambed gravels can thus alter the quality of the bed for spawning by fish or for use by other instream biota (Everest et al. 1987).

Sediments may also alter hyporheic inputs thereby reducing the availability of upwelling areas and potentially decreasing egg to fry survival. Transportation projects may affect these zones both by contribution of sediment and interception of sub-surface flow by road networks (Sedell et al. 1990, Poole and Berman 2001).

Intragravel water flow (Vaux 1962; Cooper 1965) and availability of dissolved oxygen for developing embryos (Cooper 1965; Daykin 1965) is key to egg survival. Low dissolved oxygen can cause direct mortality or delay development of alevins (Shumway et al. 1964; Brannon 1965). Delayed emergence may lead to smaller fry that are less able to compete for environmental resources than their larger cohorts that have undergone normal development and emergence (from Everest et al. 1987). Small size may also affect migration timing and marine survival (Holtby 1988; Holtby et al. 1989).

Researchers have found an inverse relationship between fines (% sediment < 3 mm) and fry survival (Bjornn 1968; Phillips et al. 1975, Everest et al. 1987) with decreases in survival ranging up to 3.4% for each 1% increase in fine sediment < 0.850mm (Cederholm et al. 1981).

Laboratory Studies

Sigler et al. (1984) identified a significant difference in growth rates between steelhead and coho in clear versus turbid water. As little as 25 NTUs of turbidity caused a reduction in fish growth. The implication of this finding is that fish subjected to turbidity in this experiment might experience increased probability of mortality in comparison to those fish experiencing normal growth (Sigler et al. 1984).

Shelton and Pollock (1966) demonstrated that low survival of chinook eggs in an incubation channel occurred when 15 to 30% of voids in the gravel bed were filled with sediment. Crouse et al. (1981) used Substrate Score, a visual technique for evaluating stream substrate quality to determine the effect of sediment on juvenile coho salmon production. The authors found that production of juvenile coho salmon was inversely related to quantities of fine sediment. Significant decreases in fish production occurred in streams with 80% and 100% embeddedness where fine sediments (<2.0 mm) were 26 and 31% by volume of the total substrate.

Sediments less than 0.850 mm diameter were inversely correlated with survival of coho salmon in artificial streams. Coho salmon eggs in landslide affected gravels in the East Fork Miller Creek survived only 40% as well to hatching when compared to the control group and survived only 9% as well to the button-up stage of development (Cederholm and Salo 1979).

**B. Behavioral Effects**

A number of research efforts have focused on the effect of turbidity levels on salmonid behavior. Behaviors examined by researchers include avoidance, territoriality, and foraging.

***Avoidance***

In many cases, salmonids avoid turbid water. In these instances, fish must successfully emigrate to areas of lower TSS. Factors affecting emigration may include availability and connectivity of patches with lower turbidity as well as the developmental stage of the fish (Sedell et al. 1990).

<u>Laboratory Studies</u>

Sigler et al. (1984) conducted tests to determine the point at which juvenile steelhead and coho subjected to continuous clay turbidities would emigrate from an area. Tested turbidities ranged from 57 to 265 NTUs. In tanks with mean turbidities of 167 NTUs or higher, no fish were found. Fish were found in tanks with lower turbidities (57 and 77 NTUs) at numbers near carrying capacity.

Newly emerged fry appear to be more susceptible to even moderate turbidities than are older fish. Turbidities in the 25-50 NTU range (equivalent to 125-175 mg/l of bentonite clay) reduced growth and caused more young coho salmon and steelhead to emigrate from laboratory streams than did clear water (Sigler et al. 1984). Juvenile salmonids tend to avoid streams that are chronically turbid, such as glacial streams or those disturbed by human activities (Lloyd et al. 1987), except when the fish have to traverse them along migration routes.

A mean avoidance of 25% was discovered for juvenile coho exposed to a 7,000 mg/l level of suspended sediment (Servizi and Martens 1992). The authors estimated that the threshold for avoidance by juvenile coho in the vertical plane was 37 NTU.

Berg (1982) found that juvenile coho exposed to a short-term pulse of 60 NTU left the water column and congregated at the bottom of an experimental tank. When the turbidity was reduced to 20 NTU, the fish returned to the water column. Bisson and Bilby (1982) subjected juvenile coho to experimentally elevated concentrations of suspended sediment. In their work, juveniles did not avoid moderate increases in turbidity when background levels were low. Significant avoidance, however, was observed at a level of 70 NTU.

Field Studies

In a study related to deposition of Mt. St. Helens ash in the Columbia River Basin, McCabe et al. (1981) noted a severe decline in the catch of juvenile chinook in upper reaches with highest ash deposition.

In addition to avoidance behavior by juveniles, suspended sediment may affect the reproductive success of returning adults. Physiological, bioenergetic and behavioral alterations stemming from increased suspended sediment loads (such as a delay in return to spawning habitat) may affect egg quality or quantity and subsequent egg development. Previous research on sublethal temperature exposure of adult chinook has illustrated this point (Berman and Quinn 1991). We hypothesize that elevated TSS may lead to similar results.

***Territoriality***

Laboratory Studies

The presence of turbid water appears to disturb normal social behavior and alter the nature of aggressive interactions. It has been suggested that the loss of territoriality and the breakdown of social structure can lead to secondary effects. Juvenile coho rearing in streams affected by frequent short-term sediment pulses with concomitant loss of territoriality may experience a decrease in growth and feeding rates, which may affect overall mortality (Berg 1982).

Juvenile coho exposed to short-term sediment pulses exhibited altered territory structure and altered feeding behavior (Berg and Northcote 1985). Normally, a dominant fish positioned upstream would consume the majority of the prey. During turbid phases, territories broke down, and subordinate fish captured a greater proportion of the prey. This was most evident at 30 and 60 NTU.

Subsequent to a sediment pulse, a breakdown in social organization among juvenile coho in an artificial stream occurred (Berg, 1982). Territoriality appeared to cease during a short-term sediment pulse, possibly due to the inability of the fish to see the positions of their neighbors. Territory was reestablished when turbidity decreased to 20 NTU. Lateral displays, a territorial action performed by salmonids, were limited under the experimental conditions. Experiments conducted by Noggle (1978) within a turbid artificial stream and clear tributary illustrated avoidance by fish of their established territories.

***Foraging and Predation***

Turbidity appears to affect a number of factors related to feeding for salmonids, including feeding rates, reaction distance, prey selection, and prey abundance. Changes in feeding behavior are primarily related to the reduction in visibility that occurs in turbid water. Effects on feeding ability are important as salmonids must meet energy demands to compete with other fishes for resources and to avoid predators. Turbidity may lead to a reduction in foraging rates, which has been linked to a decrease in growth and health of fishes (Gardner 1981).

The literature presents two major themes on the effect of turbidity on foraging. Many studies indicate that as visual feeders, the effectiveness of salmonids in obtaining food is reduced by turbidity at levels as low as 20 NTU (Berg 1982). Other research indicates that some species of salmonids (juvenile coho, steelhead, and chinook) appear to prefer slightly to moderately turbid water for foraging, as reported in studies by Sigler et al. (1984) and Gregory (1988). This behavior may represent a trade-off between predation risk and bioenergetic demand and benefits of increased growth. While ability to forage in turbid water may be reduced, the reduction in predation risk may make it worthwhile to operate in partially turbid areas (Gregory and Northcote 1993).

Suspended particulate material reduces the underwater visual range of fish, which may either act as a protective cover from predators or reduce the ability of these species to detect predators (Gregory and Levings 1996). Reduced visual clarity of waters may greatly affect the behavior of visual predators, notably fishes and piscivorous birds (Davies-Colley and Smith 2000). The reaction of salmonids to these factors is variable, as shown by the results reviewed below.

Laboratory Studies

Berg (1982) showed a decrease in feeding ability by juvenile coho in response to short-term pulses of suspended sediment in a laboratory environment. At 0 NTU, 100% of the prey items offered to the fish were consumed, whereas at 60 NTU, only 35% of introduced prey were consumed. At a turbidity level of 10 NTU, fish were noted to frequently misstrike prey items. A significant delay in the response of fish to introduced prey was noted at turbidities of 20 and 60 NTU. The acquisition of food resources in turbid waters may be reduced due to the effects of turbidity on behavior and vision. As coho are visual feeders relying on drift, reduction in feeding ability may lead to depressed growth rates (Berg 1982). Reid (1998) reported that published data suggest that feeding efficiency of juvenile coho salmon drops by 45% at a turbidity of 100 NTU. Additionally, prey behavior is also altered by TSS.

Berg and Northcote (1985) showed a reduction in reaction distance by juvenile coho to adult brine shrimp after a sediment pulse (60-20 NTU) was introduced. Prey acquisition increased as the pulse dropped from 60 NTU to 20 NTU, but remained below levels occurring prior to the pulse. The authors suggested that feeding affects were primarily the result of loss of vision. Ingestion rates decreased to below 50% at higher turbidities (30 and 60 NTU).

Gregory and Northcote (1993) assessed the effects of turbidity on the foraging behavior of juvenile chinook in the laboratory. The reaction distance of the fish to planktonic adult *Artemia* prey was measured by examining the visual ability of the subjects. The foraging rate by juvenile salmonids for surface, planktonic and benthic prey was measured across a range of turbidity levels (<1, 18, 35, 70, 150, 370, 810 NTU). For all three prey types, foraging was reduced at higher turbidities. Foraging rates for surface and benthic prey were also reduced in clear water, with highest foraging rates attained at 35-150 NTU. The authors suggested that the increased feeding rate in turbid conditions may reflect reduced risk from predators.

Gregory (1992) noted that preference for foraging in moderate turbidity appeared to be size dependent, as smaller individuals exhibited greater foraging rates in clear waters. The author suggested that it may be to the advantage of an individual to grow quickly to sizes where it is less vulnerable to predation, even if it may temporarily expose itself to greater risk by foraging in clear water.

Redding et al. (1987) observed reduced feeding rates among yearling coho and steelhead exposed to 2,000-4,000 mg/l of topsoil, kaolin clay and volcanic ash. Less food was found in the stomachs of yearling fish exposed to high concentrations of suspended topsoil, suggesting suspended solids might inhibit feeding. The authors suggested that inhibition may result from a loss of vision in turbid water or may be an indirect consequence of stress.

Boehlert and Morgan (1985) studied the effects of turbidity on feeding abilities of larval Pacific herring. Maximum feeding incidence and intensity occurred at 500 or 1,000 mg/l. Feeding was reduced at concentrations higher than 1,000 mg/l. The authors hypothesized that suspension of sediment may enhance feeding for the larvae by providing visual contrast of prey items.

Gardner (1981) showed reduced feeding rates for bluegills in turbid waters. Feeding rates in a 3 minute period declined from 14 prey per minute in clear water to 11, 10, and 7 per minute in pools of 60, 120, and 190 NTU. Gardner suggested that high (>50 NTU) levels of turbidity would reduce energy intake (through decreased feeding rates) thus reducing production of fish populations.

Vogel and Beauchamp (1999) quantified the reaction distance of adult lake trout (as predators) to rainbow trout and cutthroat as a function of light (0.17 – 261 1x; 1x is a measurement of light intensity measured with a light meter), prey size (55, 75, and 139 mm) and turbidity (0.09, 3.18, and 7.40 NTU). Reaction distances of adult lake trout to rainbow and cutthroat trout increased with increasing light (25 cm at .17 1x, to 100 cm at 17.8x). Reaction distance decreased as a decaying power function of turbidity. Vogel and Beauchamp (1999) used results to model prey detection capabilities of piscivores at varying depths and times of day in natural environments.

Gregory (1988) examined the foraging behavior of juvenile chinook in elevated turbidity in a series of laboratory experiments. Experiments determined the reaction distance to invertebrate prey, perceived risk to a model predator, and the foraging rate of chinook on benthic Tubifex worms, in turbid conditions ranging from 0 to 800 mg/l. Reaction distance and perceived risk declined inversely with turbidity. Foraging rates on Tubifex worms were highest at intermediate levels (50-200 mg/l) and lowest at 0.0 mg/l (control) and 800 mg/l. The results suggested a tradeoff between perceived risk to predation and the effects of reduced reaction distance.

Gregory (1993) illustrated this consideration with research simulating predation in both clear and turbid environments. In the absence of risk, fish occupied the bottom in clear conditions (<1 NTU). In turbid conditions (NTU = 23), fish were randomly distributed throughout the tank. In the presence of risk (bird and fish models to simulate predators), the juveniles occupied the deep parts of the tank regardless of turbidity. However, responses to simulated predation were less marked and of shorter duration in the turbid conditions. Each simulation elicited a similar response – a distinct rapid movement into deep water.

Gregory and Levings (1996) studied the effect of turbidity and artificial vegetation (as cover types) on the predation mortality of juvenile salmonids in concrete ponds. Adult coastal cutthroat trout were used as predators on juvenile chinook, chum, sockeye, and cutthroat trout. The daily predation rate was determined for each turbidity and vegetation treatment. In the presence of cover, daily predation rates were 10-75% lower. The effects of turbidity were not significant and not additive with the effects of vegetation – turbidity appeared to reduce the effectiveness of vegetation as cover for chinook and sockeye. The authors suggested that the two forms of cover affected predation risks by different mechanisms.

Ginetz and Larkin (1976) examined the predation of rainbow trout on migrant sockeye fry. Feeding rates were higher on fry at lesser turbidities and at lower stream velocities. The authors suggested that this information could be used to improve the timing of hatchery releases of fry.

***Abundance and Diversity of Prey***

The presence of fine sediment in the substrate affects the benthic community, especially those species living and feeding in the riverbottom. Effects on the benthic community may negatively affect salmonids, as they are an important food source for the fish. (Tebo 1955; Rosenberg and Wiens 1978; Cederholm and Salo 1979; Brzezinski and Holton 1983). Decreased prey abundance may affect growth rate, susceptibility to predation, competition, and susceptibility to disease.

As most experimental studies occur in a laboratory, prey abundance is controlled, usually providing more than adequate prey quantity for salmon present. In natural systems, salmonids may not be fed to satiation and stressor effects may therefore be different. It is difficult to ascertain systemic effects on both fish feeding and benthic health from these results.

Newcombe and MacDonald (1991) note that a change in sediment concentration can adversely affect secondary production by affecting algal growth, biomass, and species composition. Sediment can clog feeding structures, reducing efficiency and growth rates of filter feeders. Benthic macroinvertebrates living in the substrate are subject to scouring, which can damage respiratory organs and expose organisms to predation through dislodgement. High sediment levels and high flow rates can scour algae and reduce periphyton biomass.

Turbidity and siltation causes an overall reduction in the number of bottom organisms, which results in changes to community structure, density, and diversity. (Sorenson et al. 1977). Lloyd (1987) suggested that turbidity can account for the decrease in primary production in shallow interior Alaskan streams, and subsequent reductions in abundance of zooplankton and macroinvertebrates.

<u>Field Studies</u>

Tebo (1955) pointed to erosion and sedimentation produced by logging roads as a factor in the decrease of benthic macroinvertebrates in a river system in North Carolina. Two stations were used, above and below a logged watershed to determine effects of sedimentation on bottom fauna. At the lower station there were 7.3 organisms per square foot, in comparison to 25.5 organisms per square foot at the upper station.

Rosenberg and Wiens (1978) examined the responses of macroinvertebrates to sediment addition. Increased sediment led to an increased number of macrobenthos drifting in comparison with invertebrates in the control. Total drift was more than 3 times higher in August (sediment addition of 28.27 kg or 138,000 mg/m$^{-2}$) and more than 2 times higher in September (sediment addition of 35.88 kg or 153,000 mg/m$^{-2}$). No significant difference was found in standing crops of macrobenthos in the substrate in the control or sediment channels after sediment addition. The researchers suggested that future efforts focus on the quantitative response of macrobenthos to settled rather than suspended sediments. It was also suggested that highway and pipeline construction undertaken in watersheds of this region resulting in sediment addition be performed in the summer rather than spring or fall, providing discharge is adequate to transport added sediment.

Brzezinski and Holton (1983) examined the relationship between abundance of benthic taxa and the presence of ash in river sediments. The abundance was dependent on distribution of ash within the sediment column. When ash is the top sediment layer, amphipod abundance was zero. Amphipods were present if there were a distinct ash layer at depth (12,500 individuals/m$^2$) or if ash were mixed with sediment (13,300 individuals/m$^2$). The authors concluded that the ash affects the fauna through some physical effect, possibly related to fine grain size.

Gammon (1970) studied substrate types and their relation to benthic macroinvertebrate numbers. Moss, gravel and rubble were the most occupied substrates. Substrates with silt rated fairly low. Benthic populations residing below and above a limestone quarry which contributed approximately 40 mg/l suspended solids to the stream were examined. Suspended sediments above the quarry ranged from 13-52 mg/l, and from 21 – 250 mg/l below. Drift rates increased linearly with increasing suspended solids up to 160 mg/l. An increase of 40 mg/l suspended solids above normal resulted in a 25% increase in drift. A 90% increase in drift occurred at an increase of 80 mg/l suspended solids above normal.

***Microfauna***

The response of daphnia to suspensions of several types of solids was reviewed by EIFAC (1965). The following results were reported:

Daphnia – harmful levels of solids
Kaolinite - 102 ppm
Montmorillonite - 82 ppm
Charcoal - 82 ppm
Pond sediment – 1458 ppm

Reproduction rate increased for Daphnia at lower rates of suspended sediment.

Sorenson et al. (1977) assumed that as turbidity limits light penetration and hence aquatic algae and plant productivity, the grazing microfauna would also be limited. The abrasive action of suspended solids would also be expected to have an adverse effect on attached protozoans and micrometazoans (Sorenson et al. 1977).

Field Studies

McCabe et al. (1981) examined the effects of the deposition of Mt. St. Helens ash on demersal fish populations in the Columbia River estuary. The study revealed a change in diet habits and prey consumption by juvenile salmonids. Reduced feeding intensity and lower diet diversity reflected a reduction in *Corophium salmonis*, an amphipod frequently exploited by juvenile salmonids. The authors identified a reduced number of a normally highly used amphipod, *Corophium salmonis*.

McCabe and O'Brien (1983) determined that turbidity levels as low as 10 NTUs can cause significant declines in feeding rate, food assimilation, and reproductive potential of *Daphnia pulex*. Suspended sediment concentrations of 50-100 mg/l reduced algal carbon ingested by cladocerans to potential starvation levels. These zooplankton are an important food item for salmonid fishes.

***Primary Production***

Suspended material reduces the amount of light available to illuminate submerged objects and provide energy for plant photosynthesis. A change in light penetration through water may be expected to have far-reaching ramifications for whole aquatic ecosystems because of its influence on photosynthetic fixation of energy by aquatic plants (Davies-Colley and Smith 2000).

Major ecological parameters of suspended solids which affect photosynthesis include reduction in light penetration, abrasive action, and effects of adsorbed toxins. A reduction in light penetration may reduce primary producers, with the exception of those species that are planktonic or living on floating debris. Reduction of light may also alter oxygen relationships in surface waters. A decrease in oxygen production due to excess turbidity might be critical in some large streams (Sorenson et al. 1977). Related effects include decreased production of zooplankton and macroinvertebrates, decreased abundance and production of fish, reduced angler use and success, and decreased efficiency of some fish management techniques (Lloyd 1987).

Field Studies

A 5 NTU increase in turbidity in a clear-water lake may reduce the productive volume of that lake by about 80% and a 25 NTU increase in a clear-water stream 0.5 m deep may reduce plant production by approximately 50% (Lloyd et al. 1987). A 5 NTU increase in turbidity in a clear stream 0.5 m deep may reduce primary production by 13% or more, depending on stream depth.

Summary

The results discussed in this section indicate that TSS and turbidity have the potential to affect salmonids through alteration of prey composition and availability. TSS and turbidity appear to affect prey abundance, diversity, and behavior, in part by reducing habitat available to benthic macroinvertebrates. In addition, feeding efficiency of salmonids may be reduced, as salmon are visual predators and may not easily sight food in turbid waters. Finally, the results indicate that in some cases, a reduced level of predation risk may occur under turbid conditions.

***Homing and Migration***

Migrating salmonids avoid waters with high silt loads, or cease migration when such loads are unavoidable (Cordone and Kelley 1961). It is unknown to what degree the "bouquet" of each stream may be altered by the addition of exotic chemicals, trans-basin diversions, and increased suspended sediment levels (Bjornn and Reiser 1991).

Field Studies

High turbidity may delay migration, but turbidity alone does not seem to affect homing. Whitman et al. (1982) found that salmon preferred natal stream water without ash, but still recognized natal streams despite ash presence and attempted to ascend natal streams. Quinn and Fresh (1984) reported that the rate of straying of chinook to the Cowlitz River Hatchery was low and unaffected by the 1980 Mt. St. Helens eruption, but that many coho salmon in the Toutle River, the river most affected by the eruption, did stray to nearby streams in 1980 and 1981.

Adult chinook males showed an avoidance response to their home water in the presence of a seven-day exposure to ash suspension of 650 mg/l (Whitman et al. 1982). Experimental fish returns did not differ from control returns, indicating that homing performance was not influenced by ash.

Timing of arrival at spawning grounds by chinook that migrate upstream during snowmelt runoff can vary by a month or more, depending on the concentration of suspended solids in rivers along their migration route (Bjornn 1968). In the lower Columbia River, the upstream migration of salmon may be retarded when Secchi disk readings are less than 0.6 m (Cederholm and Salo 1979). Delays in spawning migration and associated energy expenditure may reduce spawning success (Berman and Quinn 1991).

**C. Habitat**

In addition to affecting salmonid physiology and behavior, deposited sediments may affect salmonids by altering the physical structure of the stream environment. Sediments pose a direct threat to salmonid embryos through deposition in interstitial spaces, thereby reducing oxygen rich flows and pathways for waste removal as well as potentially entombing emerging fry. Broader systemic effects of sedimentation in streams include the loss of habitat complexity and abundance, loss of refugia, and alterations to hyporheic flow (Sedell et al. 1990; Poole and Berman 2001).

***Increased Embeddedness***

Intragravel survival of salmonid embryos is dependent on a streambed structure that facilitates the influx of oxygen rich waters and the removal of waste products associated with embryo and alevin development. High levels of fines (less than 0.85 mm in diameter) in or on spawning gravels can reduce intragravel permeability (Cederholm and Salo 1979). The effect of sediment on pre-emergent survival for a particular gravel composition varies, and may depend on the salmonid species as well as hydrologic conditions of the watershed. In addition to indirect mortality, direct mortality may be caused by sediment that physically prevents fry emergence (Cederholm and Salo 1979).

***Reduction in Habitat Complexity and Abundance***

Salmonids require a variety of habitats throughout their lifetime. Sediment inputs may decrease both habitat complexity and availability. Large pools, consisting of a wide range of water depths, velocities, substrates, temperatures, and cover are characteristic of high quality habitat and channel complexity. Many of these pools have been lost in recent times, at least in part to sediment contributed by timber harvesting, roading, and historical grazing practices (USFWS 1998). Reduction in pool volume decreases rearing habitat for juveniles and holding pools for migrating adults.

Elevated sediment loads also increase frequency of channel scour and fill events, and increase channel width through aggradation. The stability of large woody debris, an important habitat component, is also compromised (Spence et al. 1996). The pool to riffle ratio present in a stream is important for provision of refugia and maintenance of hyporheic flows (see below) (Poole and Berman 2001).

***Refugia***

Refugia are created and maintained by watershed processes. Systems altered by anthropogenic activities may not contain the necessary distribution and abundance of refugia to maintain salmonid populations in the face of natural and anthropogenic disturbances. Habitat heterogeneity may provide localized refugia against turbidity extremes for fishes and other organisms. Loss of channel structure and streambed heterogeneity leads to decreases in the abundance of suitable habitat and the distribution, abundance, and connectivity of refugia. As suspended solids progressively change geomorphic channel structure, suitable habitat may become marginal and marginal habitat may become unusable (Poole and Berman 2001).

Loss of refugia as well as decreased connectivity between refugia will reduce carrying capacity of streams for salmonids. Fish may be required to travel longer distances or to less desirable habitat in systems lacking adequate number, distribution, and connectivity of refugia. Fish may suffer a variety of secondary effects from meeting these extra energy demands.

***Alterations to Hyporheic Inputs***

Hyporheic inputs throughout a watershed may contribute upwelling flows that reduce temperatures in areas where streams might normally be too warm for salmonid activity. The presence of hyporheic flows throughout a system contribute to spatial and temporal heterogeneity important to salmonids (Poole and Berman 2001). Upwelling areas are also critical to proper water exchange in salmonid redds. Bull trout have been observed selecting redd sites that correlate to areas of hyporheic exchange (Baxter and Hauer 2000).

Increasing sediment load can clog coarse streambed gravels with fine sediments, thereby decreasing streambed conductivity and reducing the exchange of ground water and surface water across the streambed. Sediment may alter the dynamics of heating, cooling, and temperature buffering. The two-way exchange between the stream channel and the hyporheic zone is perhaps the most important buffer to high stream temperatures (Poole and Berman 2001).

***Note on Bull Trout***

Bull trout are highly susceptible to sediment inputs. They require the lowest turbidity and suspended sediment levels of all salmonids for spawning, incubation, and juvenile rearing (USFWS 1998). Bull trout are strongly associated with cover, including interstitial spaces in gravel. Additionally, they have protracted embryo/alevin development with approximately 220 days required from egg deposition to fry emergence (USFWS 1998). Thus they are highly susceptible to the effects of sediment deposition and bedload movement.

Bull trout show preference for stream bottoms and deep pools of cold water. This strong association with the substrate makes them susceptible to human activities that directly or indirectly change substrate composition. There is also a strong association between juveniles and streambed cobble, and substrates low in fine sediment. Bull trout also require a large network of suitable freshwater habitat with migratory corridors, and deep pools for thermal refugia (USFWS 1998).

***Specific Road and Devegetation Effects***

Field Studies

Burns (1972) linked sedimentation with higher temperatures and low dissolved oxygen in streams. The use of bulldozers on steep slopes caused excessive sedimentation in narrow streams. During heavy rainfall after construction, erosion and road slippage caused turbidities of 3,000 ppm and deposition of as much as 0.6 m of sediment in the stream. Brown and Krygier (1971) found that sediment production doubled after road construction but before logging in one watershed, and tripled after burning and clearcutting in another watershed.

Fifteen years of heavy logging and road construction in the South Fork River in Idaho, followed by flood caused massive sedimentation of habitat. Roads were the largest contributor of sediment to the system. Spawning, rearing, and holding habitats of summer chinook and summer steelhead were inundated with fine granitic sediments, and fine sediment filled pools (Platts and Megahan 1975).

Reid (1998) used flow and turbidity data from Caspar Creek, California, to model the potential influence of the presence and use of roads on cumulative duration curves for stream turbidity. Her results suggested that a proportional increase in fine-sediment production equivalent to that measured in coastal Washington (i.e. a 5.8 fold increase due to road-related erosion) would increase the average annual duration turbidities greater than 100 NTU by a factor of 73 (i.e. from 0.5 day to 36.5 days).

Smedley et al. (1970) found that the percentage of fine sediment <0.83 mm in diameter increased in all study areas for six years during logging, and remained at elevated levels for 3 years after. Fines increased 6-8% as a result of logging. Low survival of pink salmon brood stock from 1966 was attributed to sedimentation of spawning areas (from Everest et al. 1987).

Scrivener and Brownlee (1982) showed an increase in fines between 0.3 and 9.6 mm in diameter within the top 12 cm of riffle gravels 3 years after logging was begun in the Carnation Creek Watershed.

**Previous Literature Reviews: Lloyd (1987) and Newcombe and MacDonald (1991)**

Lloyd (1987) and Newcombe and MacDonald (1991) examined research on turbidity and suspended solids to illustrate the levels of tolerance to these two measures exhibited by salmonids and other fishes at various life stages. **Table 2** provides the results of Lloyd's (1987) research, developed in an effort to determine possible turbidity criteria for Alaska cold water fisheries. **Table 3** summarizes suspended sediment effects on selected salmonids present in the Yakima basin of Washington State. This table was compiled from Newcombe and MacDonald (1991) for the Yakima River Total Maximum

Daily Load (TMDL) Report. **Table 4** includes data derived from 1) research conducted after 1991; and 2) research prior to 1991 not presented by Lloyd (1987) and Newcombe and MacDonald (1991).

Lloyd (1987) examined the use of turbidity as a water quality standard for salmonid habitats in Alaska. Lloyd suggested that evidence of trophic level changes induced by reduction in light penetration, and known direct effects of sediment and turbidity on aquatic life indicates that turbidity constitutes a useful water quality standard for protecting aquatic habitats from sediment pollution.

According to Lloyd (1987), relatively low turbidity or SSC may stress salmonids, alter behavior patterns, or lead to acute mortality. Even low turbidities near 10-25 NTU and suspended sediment concentrations near 35 ppm can have deleterious effects on fish (Berg 1982; Sigler et al. 1984; Berg and Northcote 1985).

Effects of Turbidity and Suspended Sediment on Salmonids (Lloyd 1987)

1) Reduced light penetration in lakes and streams
2) Associated with decreased production and abundance of plant material (primary production)
3) Decreased abundance of fish food organisms (secondary production)
4) Decreased production and abundance of fish

Newcombe and MacDonald (1991) suggested that the use of concentration of suspended solids alone is a poor indicator of physiological and behavioral effects. The authors suggested using both concentration and duration of exposure in a “stress index” to determine relative impacts on salmonids. The authors believe this is a convenient tool for predicting effects for a pollution episode of known intensity. The results of this work can be found in **Appendix B.**

It is important to remember that the listings below are primarily laboratory studies. For example, prey rations, temperature, disease, and intra- and interspecific encounters are controlled. Therefore, it is difficult to clearly illustrate how fish would be affected by high turbidities in the field. In addition to those factors mentioned above, most experiments cited do not account for spatial and temporal factors, such as the distribution, abundance, or availability of suitable habitat, time of year, frequency, duration, and magnitude of events, and cumulative or synergistic effects.

## Table 2. Some reported effects of turbidity and suspended sediment concentrations on salmonids outside Alaska (Lloyd 1987).

| Effect | Species[a] (life stage) | *Location* | Reported turbidity[b] or suspended sediment concentration | Reference |
|---|---|---|---|---|
| Fatal (96-h LC50) | Coho salmon (juveniles) | Washington | 1,200 mg/l | Noggle (1978) |
| Fatal (96-h LC50) | Coho salmon (juveniles) | Washington | 509; 1,217 mg/l | Stober et al. (1981) |
| Fatal (96-h LC50) | Chinook salmon (juveniles) | Washington | 488 mg/l | Stober et al. (1981) |
| Reduced survival (marked) | Chum salmon (eggs) | British Columbia | 97 mg/l | Langer (1980) |
| Reduced survival (marked) | Rainbow trout (eggs) | Great Britain | 110 mg/l | Scullion and Edwards (1980) |
| Reduced survival (marked) | Rainbow trout (eggs) | Oregon | 1,000-2,500 ppm | Campbell (1954) |
| Reduced survival (marked) | Rainbow trout (juveniles) | Great Britain | 270 ppm | Herbert and Merkens (1961) |
| Reduced survival (marked) | Rainbow trout (juveniles) | Great Britain | 200 ppm | Herbert and Richards (1963) |
| Reduced survival (marked) | Rainbow trout (juveniles) | Oregon | 1,000-2,500 ppm | Campbell (1954) |
| Reduced survival (marked) | Rainbow trout (juveniles) | Great Britain | 90 ppm | Herbert and Merkens (1961) |
| Reduced survival (marked) | Coho salmon (juveniles) | Pennsylvania | 6; 12 mg Fe/l (15-27 JTU) | Smith and Sykora (1976) |
| Reduced survival (marked) | Coho salmon (adults) | Washington | 1,400-1,600 mg/l | Stober et al. (1981) |
| Reduced abundance (marked) | Brown trout | Great Britain | 1,000; 6,000 ppm | Herbert et al. (1961) |
| Reduced abundance (marked) | Lake trout | Northwest Territories | <10 FTU | McCart et al. (1980) |
| Reduced growth (marked) | Brook trout (juveniles) | Pennsylvania | 50 mg Fe/l (86 JTU) | Sykora et al. (1972) |
| Reduced growth (slight) | Brook trout (juveniles) | Pennsylvania | 12 mg Fe/l (32 JTU) | Sykora et al. (1972) |
| Reduced growth (slight) | Rainbow trout (juveniles) | Great Britain | 50 ppm | Herbert and Richards (1963) |
| Reduced growth | Coho salmon (juveniles) | Idaho | 25 NTU | Sigler et al. (1984) |
| Reduced growth (marked) | Arctic grayling (juveniles) | Yukon | 1,000 mg/l | McLeay et al. (1984) |
| Reduced growth (slight) | Arctic grayling (juveniles) | Yukon | 100; 300 mg/l | McLeay et al. (1984) |

# V. Assessment of Whether Emulsion Characteristics of Turbidity Have a Significant Differential Effect on Salmonid Survival, Growth, and Reproduction

Salmonids encounter “naturally” turbid conditions in estuaries and glacially-fed streams. Managers are interested in determining whether there is something inherent in “natural” turbidity sources that make them somehow less harmful to fish then anthropogenic sediment inputs. A pertinent question is the relationship between sediment size, shape, and composition and salmonids viability.

It is difficult to determine the effect of sediments of various sizes and shapes based on laboratory experimentation owing to the complexity of natural systems. In addition to the character of the material, a number of other factors must be considered in evaluating salmonid response to suspended sediments. These factors include the life history stage, presence of cumulative stressors, availability of refugia that are well distributed, connected, and accessible, condition of biotic community, frequency and magnitude of exposure to the sediments, and the physical processes associated with hydrology, sediment input, transport, and storage present in a particular watershed. Past land use practices within a watershed are also of import.

Various types of sediment have been used in experiments developed to test the effect of suspended solids on salmonid health. Very few studies, however, provide a comparison of the effect of different sediment types and sizes on salmonids.

Davies-Colley and Smith (2000) noted that the physical and chemical, and therefore optical, character of suspended particles can vary widely between stream systems as well as within the same system. The important attributes of aquatic particles in addition to optical character include settling velocity and particle size, shape, and composition.

Based on current studies, it appears that gill injuries increase as angularity and particle size increase. Servizi and Martens (1987) studied gill injuries among underyearling sockeye exposed to fine and medium coarse sediments. The size and shape of particles appeared to affect the yearlings differentially. The study demonstrated that tolerance decreased as particle size increased, specifically for particles described as "angular to subangular." Underyearling sockeye experienced gill trauma at 3,143 mg/l, levels that have been measured at Hell's Gate on the Fraser River.

Newcomb and Flagg (in Servizi and Martens 1987) reported a 36 h LC50 of Mt. St. Helens ash to be 6,100 mg/l for sockeye smolts, whereas there were no mortalities when smolts were exposed to 14,407 mg/l of Fraser River sediments. These data suggest that sockeye smolts may be more sensitive to slightly larger, largely angular ash particles than subangular to angular particles. The 96 h LC50s of four Fraser River sediments to underyearling sockeye ranged from 1,674 to 17,560 mg/l and were related to particle size (Servizi and Martens 1987).

**Table 5. Classification of suspended solids and their probable major effects on freshwater ecosystems** (from Sorenson et al. 1977).

| | **Biochemical, Chemical, and Physical Effects** | **Biological Effects*** |
|---|---|---|
| Clays, silts, sand | Sedimentation, erosion and abrasion, turbidity (light reduction), habitat change | Respiratory interference, habitat restriction, light limitation |
| Natural organic matter | Sedimentation, DO utilization | Food sources, DO effects |
| Wastewater organic particles | Sedimentation, DO utilization, nutrient source | DO effects, eutrophication |
| Toxicants sorbed to particles | All of the above | Toxicity |

* Biological effects may result directly from pollutants (primary effect), changes due to biochemical, chemical, or physical changes (secondary), or biological interactions (tertiary effects).

**Table 6. Sediment particle size** (modified from Waters 1995).

| **Category** | **Size Range** | **Phi scale** |
|---|---|---|
| Boulder | > 256 mm | -8 |
| Cobble | 64-256 mm | -6,-7 |
| Pebble | 16-64 mm | -4,-5 |
| Gravel | 2-16 mm | -1,-2,-3 |
| Very coarse sand | 1-2 mm | 0 |
| Coarse sand | 0.5-1 mm | 1 |
| Medium sand | 0.25-0.5 mm | 2 |
| Fine sand | 0.125-0.25 mm | 3 |
| Very fine sand | 0.0625-0.125 mm | 4 |
| Silt | 4-62 um | 5,6,7,8 |
| Clay | < 4 um | 9 |

**Summary**

Additional research needs to be undertaken in this area. Laboratory results indicate that size, shape, and composition of sediment particles may have differential effects on salmonids. It is important to understand all of the mechanisms by which suspended sediments affect salmonids in order to reduce effects associated with land use.

## VI. Current State and Provincial Turbidity Standards

This section provides a review of the current turbidity requirements in Alaska, Idaho, Oregon, Washington, and British Columbia. The standards reviewed here require that turbidity be measured against a "background turbidity," established at a point upstream of the affected area. Only two of the five standards reviewed include a limit on the duration of exposure to a certain turbidity level (Idaho and British Columbia).

Best Available Technology (BAT) TSS requirements are commonly used in writing National Pollutant Discharge Elimination System (NPDES) discharge permits in Washington State. For many industrial applications, the BAT standard is 45 mg/l for a long-term average and 90 mg/l for a daily maximum (E. Molash, pers. commun.). To address watershed scale turbidity or total suspended solid issues, the four states have the option of using the Total Maximum Daily Load (TMDL) process to assess the need for overall reductions in turbidity levels and suspended sediments.

The TMDL process was established by section 303(d) of the Clean Water Act. Federal law requires states to identify sources of pollution in waters that fail to meet state water quality standards after all point sources have been permitted, and to develop cleanup plans to address pollutants of concern. A TMDL is a calculation of the maximum amount of a pollutant that a water body can receive and still meet state water quality standards. Percentages of the total maximum daily load are allocated to the various pollutant sources (Web Site Ref. #10). More detailed information on TMDLs in Washington, Oregon, and Idaho can be found in Appendix D.

A number of researchers analyzed existing state regulations for turbidity and total suspended solids to determine if the level of protection afforded to salmonids is adequate. Bisson and Bilby (1982) noted that state regulations at that time did not consider acclimation of stream biota to high turbidity, as regulations permitted only minor increases in suspended sediment when background turbidity was low, but allowed greater absolute increases as background levels rise.

Lloyd (1987) examined the use of turbidity as a water quality standard for salmonid habitats in Alaska. Lloyd's (1987) review indicated that water quality standards allowing increases in coldwater habitats of 25 NTU above ambient turbidity would provide "moderate" protection, while a standard allowing a 5 NTU increase above ambient turbidity would provide “high” protection for salmonids. This determination was based on a number of studies which indicated that turbidities as low as 10-25 NTUs can have deleterious effects on fish (Berg 1982; McCabe and O’Brien 1983; Sigler et al. 1984; Berg and Northcote 1985).

Lloyd (1987) suggested that an acceptable turbidity standard must do two things to protect aquatic habitats: prevent loss of aquatic productivity and cause no lethal or chronic sublethal effects on fish and wildlife. Other researchers have suggested the need for standards other than simple turbidity criteria to control pollution by sediment. The National Academy of Sciences and National Academy of Engineering (1973) recommended that depth of light penetration not be decreased by more than 10% and that suspended sediment concentrations be limited to specific values.

Sorenson et al. (1977) cited concern over the difficulty in setting rigid standards for suspended solids. The concentration of suspended solids in natural waters is influenced by such factors as topography, geology, soil condition, intensity and duration of rainfall, type and amount of vegetation in the drainage basin, and past and current human activity. Flowing waters may have considerable variation in SSC from day-to-day and year-to-year. Since natural variation in suspended solids is so great, the authors suggested that it is not desirable to have fixed rigid standards.

Duchrow and Everhart (1971) and Bisson and Bilby (1982) called for consideration of standards for settleable solids, as they are of primary concern in the protection of aquatic fauna. As sediment type and aquatic fauna vary across and between watersheds, specific standards might have to be applied depending on conditions within and between watersheds.

**Table 7** provides a summary of current turbidity standards for states in the Northwestern United States and British Columbia, Canada. **Table 8** provides standards for the year 1987. This is provided to show changes in regulations between 1987 and 2001. **Appendix C** provides detailed information on turbidity standards for each state and province.

**Table 7. 2001 comparison table of state and provincial turbidity standards.**

| State/Province | Standard | Notes |
|---|---|---|
| **Alaska**<br>(Web Site Ref. #1) | May not exceed 25 NTU above natural conditions. For all lake waters, may not exceed 5 NTU above natural conditions. | Standard for growth and propagation of fish, shellfish, other aquatic life, and wildlife. *End-of-pipe unless a mixing zone has been approved*. |
| **British Columbia**<br>(Web Site Ref. #2) | Maximum Induced Turbidity – NTU or % of background:<br><br>8 NTU in 24 hours when background is less than or equal to 8<br>….<br>Mean of 2 NTU in 30 days when background is less than or equal to 8<br>________________________<br>8 NTU when background is between 8 and 80<br>….<br>10% when background is greater than or equal to 80 | Standard for aquatic life, fresh, marine, estuarine<br><br>BC regulations also include limits on Maximum Induced Suspended Sediments –mg/L or % of background and limits on streambed substrate composition (% fines at spawning sites, geometric mean diameter not less than 12 mm)<br><br>*Edge of mixing zone.* |
| **Idaho**<br>(Web Site Ref. #5) | Turbidity, below any applicable mixing zone set by the Department, shall not exceed background turbidity by more than (50) NTU instantaneously or more than twenty-five (25) NTU for more than ten (10) consecutive days. | Standard for aquatic life use designations.<br><br>*Edge of mixing zone*<br><br>(Exceedance limited to 5 NTU if a point source) |
| **Oregon**<br>(Web Site Ref. #7) | No more than ten percent cumulative increase in natural stream turbidities, as measured relative to a control point immediately upstream of the turbidity causing activities. | Limited duration activities that exceed requirements may be authorized (see Oregon Turbidity Standards Section).<br><br>*End-of-pipe unless a mixing zone has been approved.XX* |
| **Washington**<br>(Web Site Ref. #12) | Turbidity shall not exceed 5 NTU over background turbidity when the background turbidity is 50 NTU or less, or have more than a 10 percent increase in turbidity when the background is > 50 NTU | For Class A Waters; for Class B waters, turbidity shall not exceed a 10 NTU increase over background turbidities of 50 NTU or less, or a 20% increase when background turbidity is greater than 50 NTU<br><br>*Edge of mixing zone* |

**Table 8. Numerical turbidity standards for protection of fish and wildlife habitats in Alaska and other states** (as cited by Lloyd 1987).

| State | Turbidity (NTU or JTU)[a] |
|---|---|
| Alaska | 25 units above natural in streams<br>5 units above natural in lakes |
| California | 20% above natural, not to exceed 10 units above natural |
| Idaho | 5 units above natural |
| Minnesota | 10 units |
| Montana | 10 units (5 above natural)[b] |
| Oregon | 10% above natural |
| Washington | 25 units above natural (5 and 10 above natural)[c] |
| Wyoming | 10 units above natural |

a Nephelometric (NTU) and Jackson (JTU) turbidity units are roughly equivalent (USEPA 1983).
b Montana places the more stringent limit on waters containing salmonid fishes.
c API (1980) reports different values in Washington for "excellent" and "good" classes of water.

## Summary

Each state and province in the northwest attempts to control sediment input to rivers by placing limits on turbidity increases above "natural background levels." Natural background turbidity levels may vary widely between watersheds due to factors such as base geology, legacy conditions, and land-cover and within a system (e.g. headwaters versus estuary). In addition, turbidity may change daily, seasonally, and annually depending on physical and biological changes in the system. This variability makes it difficult to quantify natural background turbidity.

To adequately protect salmonids during their freshwater residence, TSS data on physiological, behavioral, and habitat effects should be viewed in a layer context incorporating both the spatial geometry of suitable habitat and the temporal changes associated with life history, year class, and climate variability. Spatial and temporal considerations provide the foundation to decipher legacy effects as well as cumulative and synergistic effects on salmonid protection and recovery.

## VII. Turbidity Requirements for Hatcheries

In Washington State, hatcheries do not follow specific turbidity requirements regarding water used for hatchery operations. However, hatchery operators often have unstated guidelines to determine when turbidity levels pose a risk to eggs and juvenile salmonids. In many cases, hatchery managers rely on visual measurement rather than numeric guidelines to determine risk to developing salmonids.

Upland hatcheries are subject to regulations regarding the water released from facilities and the byproducts of hatchery operations. Hatcheries must obtain NPDES permits to address discharges from their facilities into streams.

### Controlling Turbidity and Suspended Solids in Hatchery Water

In general, hatcheries in Washington State receive water supplies from nearby creeks and rivers. In a minority of cases, groundwater or springs are used where available (H. Michael, pers. commun.). The advantage of groundwater and spring sources is 1) lower concentrations of suspended solids and 2) reduced pathogen presence from river water. There are additional costs, however, associated with using groundwater and spring sources, such as pumping the water from the source to the facility.

Hatchery operators must monitor the sediment concentration of the water and determine the point at which the condition will be deleterious to fish at various life stages. It is important for hatchery managers to determine when to "clean" eggs that are exposed to suspended sediments. Even when the water supply contains low levels of suspended sediment, operations must be observed carefully. Over a period of 3 or 4 months even a low level of sediment could eventually smother eggs (H. Michael, pers. commun.).

The Soos Creek Hatchery in Auburn does not adhere to specific turbidity criteria during operation. The staff use professional knowledge to identify when the water supply is turbid to the point of endangering the eggs. In these cases, the eggs are temporarily removed from their tanks until turbidity decreases. This emergency measure most often occurs as the result of rainfall and a subsequent storm surge. The hatchery uses water from Soos Creek for raising coho, and spring water for raising steelhead (T. Sorbo, pers. commun.).

At a hatchery on the Cowlitz River in Southwestern Washington, glaciated river water occasionally creates conditions where juveniles cannot see their food. H. Michael (pers. commun.) stated that fish require 12-18" of visibility for feeding during rearing. Reduced feeding can lead to reduced growth rates. Additionally, if glacial water slows enough in the hatchery, glacial sediment may settle and pose a risk to eggs.

**Outflow from Hatcheries**

Washington State upland hatcheries (as opposed to netpens) require NPDES discharge permits to account for all materials released from hatcheries back into the stream. The amount of settleable solids allowed from normal hatchery operations is a monthly average of 0.1 mg/l. For total suspended solids, the monthly average allowed is 5 mg/l. The instantaneous maximum allowed is 15 mg/l (H. Michael, pers. commun.).

Off-line settling basins are used to contain settleable solids from hatchery operations. These ponds are drawn down and sediments are removed on a regular basis. Dredged material is then removed for upland disposal. For the water returned to the creek from off-line settling ponds, the NPDES requirement calls for monthly release rates of 1 mg/l settleable solids, and 100 mg/l total of suspended solids.

**Summary**

Turbid water and related suspended sediment concentrations pose a threat to the health of hatchery fish. Excessive sediment in hatchery water may smother eggs by depriving them of oxygen, and reducing the ability of juveniles to capture prey. While there appears to be no specific measurement guideline for determining when the suspended sediment levels are a danger to eggs and juveniles, hatchery managers have developed methods of visually estimating risk and acting accordingly. Hatcheries are subject to discharge permits which limit the amount of sediment they may release downstream of the facility.

# VIII. Recommendations

Based on this literature review, there are a number of areas where additional research would help managers better assess the effects of suspended sediment on salmonid health, growth, and reproduction.

Regulatory requirements often force managers to focus on meeting a specific requirement at a specific location and point in time. It is difficult to quantify the direct effect of turbidity on salmonids by looking at the effect of one particular disturbance in a watershed. This does not account for cumulative sediment loading throughout the basin nor synergistic effects. If possible, transportation project managers should consider watershed-scale effects in addition to the effect of their particular project. The key questions for managers are: 1) whether there are various scale refugia accessible in the system that will allow salmonids to cope with short term sediment effects; and

2) whether other cumulative and synergistic effects magnify short-term sediment alterations.

Another important consideration is the inconsistency of turbidity measurements. When devising monitoring strategies for transportation projects, Washington State Department of Transportation (DOT) might want to consider collecting baseline TSS data, which then may be correlated with turbidity readings for future monitoring.

### Research, Monitoring, and Management Recommendations

***Measurement***

- Conduct baseline studies measuring "natural" background levels in undisturbed systems and disturbed systems, stratified by biophysical parameters.

- Prior to conducting construction projects, determine TSS concentrations and gather information on size, shape, and composition of sediment.

- Develop new exposure metrics that account for sublethal effects (as opposed to direct mortality).

- Conduct research in the field if possible – most work to date has been performed in laboratories, which may not provide an accurate picture of the effects of suspended sediment on salmonids.

- Consider use of other measurement tools, such as water clarity to determine levels of suspended sediments.

***Sediment Effects***

- Examine the effect of frequent short-term pulses of suspended sediment on salmonids.

- Conduct additional research on correlations between particle size, shape, and composition of sediments to sensitivity effects on salmonids.

- Evaluate how loss of groundwater/surface water interactions affect availability and abundance of salmonid habitat.

- Study relationships between seasonal timing and effect of sediment load on salmon.

- View TSS data on physiological, behavioral, and habitat effects in a layered context, incorporating both the spatial geometry of suitable habitat and the temporal changes associated with life history stage, year class, and climate variability. Spatial and temporal considerations provide the foundation to decipher legacy effects as well as cumulative and synergistic effects on salmonid protection and recovery.

***Management***

- Consider watershed condition when evaluating projects. Examine legacy of land use in watershed and determine how planned disturbance will contribute to cumulative effects.

- Analyze other sources of sediment contribution to the watershed, such as grazing allotments, roads and culverts, and timber harvest areas. Reduce sediment loads from these areas if possible.

- Restore tributaries and off-channel habitat to create potential turbidity refuges.

- Determine whether knowledge of salmonid survival responses to turbid flows can be used to develop mixing zones, work windows, treatment systems, and buffers that will allow fish to perform their necessary life functions during project construction and operation.

- Test a variety of existing and new technologies used to reduce TSS during road construction projects. Collect quantitative data.

Given that salmonids encounter "naturally" turbid conditions in estuaries and glacially-fed streams, as well as during flood events and have developed survival responses for those turbid conditions there are some additional critical questions for consideration . Is there something inherent in "natural" turbidity sources that makes exposure less harmful to fish? For instance, is the "angularity" of suspended sediments a factor? How about particle size ranges? During flood events, does available habitat provide "turbidity" refugia?

**Establishing Baseline Turbidity Values**

The difficulty of establishing overall "natural background turbidities" was discussed earlier in this paper. One possibility for setting baseline turbidity ranges is to measure background turbidity levels in unmanaged or "natural" areas of basins with differing morphologies. Continuous sampling would be required to define turbidity fluctuations under various hydrological conditions (such as a storm event). Once a range of conditions has been identified for the watershed, a distribution may be plotted. This distribution can be used to establish guidelines for similar watersheds.

**Regulatory Suggestions in the Literature**

Lloyd (1987) suggested that a turbidity standard could be used to address the effects of turbidity as an optical property of water and as an indicator of SSC. The effects of sedimentation on lake and stream bottoms could be addressed by separate enforceable settable solid or streambed standards. Lloyd (1987) cites a need to establish or reaffirm the levels of turbidity, and associated suspended solids concentrations that are appropriate as standards for regulating human-induced effects on aquatic systems. Turbidity standards can be tiered or graded (if necessary) to ambient water quality conditions and the level of protection desired for a body of water (Lloyd 1987).

Lloyd (1987) also suggested that any alternative standards account for the primary aspects of turbidity– extinction of light and presence of suspended sediment. Direct measurement is possible of both, but the measure of turbidity was developed to facilitate suspended sediment estimates. Light penetration can be measured in situ with portable photometers and extinction coefficients calculated with simple graphs or equations, but discrete samples cannot be removed and analyzed separately. Sediment concentration can be sampled in the field and measured gravimetrically in a laboratory. Filtering, drying and weighing procedures are required (Lloyd 1987).

Reasonable turbidity criteria that are established to protect aquatic habitats from decreased light penetration may also protect systems from high concentrations of suspended sediments and heavy metals. Separate settleable solids or streambed standards could then be applied to protect aquatic habitats from effects on benthic substrates (Lloyd 1987).

Cairns (1968) suggested that truly responsive regulations should be developed on a drainage-by-drainage basis, and should change with stream flow and other habitat conditions. Lloyd (1987) noted that this type of standard would require enormous baseline studies and almost continuous surveillance and monitoring, and subsequently questioned whether such an approach is feasible in Alaska or elsewhere.

Lloyd (1987) indicated that for salmonids, a “moderate” level of protection (SSC up to 100 mg/l) roughly translates to turbidity values up to 23 NTUs. Recommendations for a “high” level of protection (0-25 mg/l) roughly translate to turbidity values up to 7 NTUs. Stricter limits might be warranted to protect extremely clear waters, due to the dramatic initial effect of turbidity on light penetration. Naturally turbid systems might need tiered or graded standards based on ambient water quality.

USFWS (1998) suggested that managers avoid new road construction in areas vulnerable to mass wasting and in areas that may initiate or exacerbate stream bank erosion. On a larger scale, it was suggested that managers identify land management activities (upland and riparian) that have potential to contribute sediment to spawning and rearing areas above natural levels (USFWS 1998).

Castro and Reckendorf (1995) suggest that fish are not good indicators of excess sedimentation, as separating the effects of sediment from other environmental factors can be impossible in a natural system. While sometimes obvious effects of excessive fine sediment can be viewed, often effects are not apparent. The authors suggested using another indicator species, such as benthic macroinvertebrates, which are more sensitive to small changes in sediment quality and quantity, less mobile, and have shorter life cycles.

## IX. Summary

Protection of Washington State's salmonids requires that transportation officials consider the effect of suspended sediments released into streams during road construction. Numerous studies have shown that the presence of suspended sediments can have a detrimental effect on the physiology, behavior, and habitat of salmonids. Different species and even different life stages of species are susceptible to adverse effects from different levels of sediment and to sediments of different sizes.

Turbidity is the measure most commonly used by agencies to indicate the level of suspended solids in the water column. It is an indirect measure, however, and may not always be correlated with suspended solid concentrations. Turbidity may vary depending on geomorphic, hydrologic, and hydraulic factors.

Although salmonids are found in naturally turbid river systems in the Northwest, this does not necessarily mean that salmonids in general can tolerate increases over time of suspended sediments. An understanding of sediment size, shape, and composition, salmonid species and life history stages, cumulative and synergistic stressor effects, and overall habitat complexity and availability in a watershed is required.

For short-term construction projects, operators will need to measure background turbidities on a case by case basis to determine if they are exceeding regulations. However, transportation projects may also produce long-term, chronic effects. Short-term pulses will presumably have a different effect on salmonids than chronic exposure.

Turbidity standards developed by several states and provinces in this region attempt to consider natural variability in turbidity by requiring the regulated community to measure "background turbidity" upstream of any proposed activity. The background turbidity measured in these situations represents a measurement at one point in time. Regulating turbidity levels based on this type of measurement may not be protective of salmonid health.

## Appendix A. 1999 Washington State Water Quality Data (Web Site Ref. #11)

**Table A-1. Discharge (cfs) and turbidity (NTUs) measured in Western Washington streams during 1988-99** (Web Site Ref. #11)

| Sample month | Skagit River @ Marblemount Cfs NTU | Samish River near Burlington | NF Stillaguamish @Cicero | Stillaguamish R. near Silvana |
|---|---|---|---|---|
| October | 4390 0.6 | 150 6.3 | 1420 6 | 1400 8.3 |
| November | 6330 1.1 | 450 10 | 5300 145 | 5870 60 |
| December | 7600 1.4 | 793 16 | 6600 100 | 7710 55 |
| January | 8360 0.9 | 583 7.7 | 4840 170 | 8810 55 |
| February | 7640 0.5 | 406 5.5 | 1050 19 | 2830 29 |
| March | 6190 0.8 | 359 5.4 | 2260 22 | 5210 29 |
| April | 6230 1.6 | 327 9.6 | 2120 19 | 5890 60 |
| May | 12700 4.8 | 180 6.3 | 3690 60 | 8200 50 |
| June | 7080 3 .2 | 107 3.3 | 2010 8 | 4480 17 |
| July | 10600 2.7 | 78 2.2 | 1300 3.1 | 2460 4.9 |
| August | 8550 2.2 | 62 2.7 | 641 2.1 | 1600 4.2 |
| September | 4290 0.7 | 32 1.1 | 270 1.6 | 574 1.7 |

**Table A-2. Turbidity (NTUs) measured in three Western Washington streams during 1988-99**

| | Yearly Average | Summer Range (May-Oct.) | Winter Range (Nov. – Apr.) |
|---|---|---|---|
| Cedar River | 1.1 | 0.4 – 1.2 | 1.0 – 2.0 |
| Newaukum Creek | 2.4 | 0.7 – 1.5 | 3.1 – 4.0 |
| Springbrook Creek | 22.0 | 13.0 – 44.0 | 13.0 – 35.0 |

**Table A-3. TSS (mg/l) measured in three Western Washington streams during 1988-99**

| | Yearly Average | Summer Range (May-Oct.) | Winter Range (Nov. – Apr.) |
|---|---|---|---|
| Cedar River | 3.6 | 0.6 – 5.0 | 3.5 – 6.2 |
| Newaukum Creek | 5.7 | 1.6 – 5.1 | 7.5 – 8.8 |
| Springbrook Creek | 19.8 | 8.0 – 26.0 | 6.7 – 44.0 |

## Appendix B. Tables from Newcombe and MacDonald (1991)

**Table B-1. Summary of data (in situ observations) on exposures to suspended sediment that resulted in lethal responses in salmonid fishes.** Within species groups, stress indices are arranged in increasing order. For exposure, C= concentration (mg/l) and D = duration (h).

| | ***Exposure*** | | | | | |
|---|---|---|---|---|---|---|
| **Species** | **C** | **D** | **Stress index ($\log^e$* [CxD])** | **Effect** | **Rank of Effect** | **Source** |
| Arctic grayling | 25 | 24 | 6.397 | 6% mortality of sac fry | 10 | Reynolds et al. (1988) |
| | 23 | 48 | 7.007 | 14% mortality of sac fry | 10 | Reynolds et al. (1988) |
| | 65 | 24 | 7.352 | 15% mortality of sac fry | 10 | Reynolds et al. (1988) |
| | 22 | 72 | 7.368 | 15% mortality of sac fry | 10 | Reynolds et al. (1988) |
| | 20 | 96 | 7.560 | 13% mortality of sac fry | 10 | Reynolds et al. (1988) |
| | 143 | 48 | 8.834 | 26% mortality of sac fry | 11 | Reynolds et al. (1988) |
| | 185 | 72 | 9.497 | 41% mortality of sac fry | 12 | Reynolds et al. (1988) |
| | 230 | 96 | 10.002 | 47% mortality of sac fry | 12 | Reynolds et al. (1988) |
| | 20.000 | 96 | 14.468 | 10% mortality of age-0 fish | 10 | McLeay et al. (1987) |
| | 100,000 | 96 | 16.077 | 20% mortality of age-0 fish | 10 | McLeay et al. (1987) |
| Chinook salmon | 488 | 96 | 10.755 | 50% mortality of smolts (high T*C) | 12 | Stober et al. (1981) |
| Coho salmon | 509 | 96 | 10.797 | 50% mortality of smolts (high T*C) | 12 | Stober et al. (1981) |
| Chinook and sockeye salmon | 1,400[b] | 36 | 10.827 | 10% mortality of juveniles | 10 | Newcomb and Flagg (1983) |
| Coho salmon | 1,200 | 96 | 11.654 | 50% mortality of juveniles | 12 | Noggle (1978) |
| | 1,217 | 96 | 11.668 | 50% mortality of pre-smolts (high T*C) | 12 | Stober et al. (1981) |
| Chinook and sockeye salmon | 207,000[b] | 1 | 12.240 | 100% mortality of juveniles | 14 | Newcomb and Flagg (1983) |
| | 9,400 | 36 | 12.732 | 50% mortality of juveniles | 12 | Newcombe and Flagg (1983) |
| Chum salmon | 97 | 3,912[b] | 12.847 | 77% mortality of eggs and alevins | 13 | Langer (1980) |

**Table B-1 (cont.)**. Summary of data (in situ observations) on exposures to suspended sediment that resulted in **lethal** responses in salmonid fishes. Within species groups, stress indices are arranged in increasing order. For exposure, C= concentration (mg/l) and D = duration (h).

| | *Exposure* | | | | | |
|---|---|---|---|---|---|---|
| **Species** | **C** | **D** | **Stress index ($log^e$* [CxD])** | **Effect** | **Rank of Effect** | **Source** |
| Chum salmon | 111 | 3,912[b] | 12.981 | 90% mortality of eggs and alevins | 14 | Langer (1980) |
| Chinook and sockeye salmon | 82,000 | 6 | 13.106 | 60% mortality of juveniles | 12 | Newcomb and Flagg (1983) |
| Coho salmon | 18,672 | 96 | 14.400 | 50% mortality of presmolts | 12 | Stober et al. (1981) |
| Chinook salmon | 19,364 | 96 | 14.436 | 50% mortality of smolts | 12 | Stober et al. (1981) |
| Chum salmon | 28,000 | 96 | 14.804 | 50% mortality of juveniles | 12 | Smith (1939) |
| Coho salmon | 28,134 | 96 | 14.811 | 50% mortality of smolts | 12 | Stober et al. (1981) |
| | 29,580 | 96 | 14.859 | 50% mortality of smolts | 12 | Stober et al. (1981) |
| | 35,000[b] | 96 | 15.027 | 50% mortality of juveniles | 12 | Noggle (1978) |
| Chinook and sockeye salmon | 39,400 | 36 | 15.145 | 90% mortality of juveniles | 14 | Newcombe and Flagg (1983) |
| Chum salmon | 55,000 | 96 | 15.479 | 50% mortality of juveniles | 12 | Smith (1939) |
| Whitefish | 16,613 | 96[b] | 14.282 | 50% mortality of juveniles | 12 | Lawrence and Scherer (1974) |
| Rainbow trout | 200[c] | 24 | 8.476 | 5% mortality of fry | 10 | Hebert and Richards (1963) |
| | 7 | 1,152 | 8.995 | 17% reduction in egg-to-fry survival | 10 | Slaney et al. (1977b) |
| | 21 | 1,152 | 10.094 | 62% reduction in egg-to-fry survival | 13 | Slaney et al. (1977b) |
| | 200[c] | 168 | 10.422 | 8% mortality of fry | 10 | Herbert and Richards (1963) |
| | 90 | 456 | 10.622 | 5% mortality of sub-adults | 10 | Herbert and Merkens (1961) |
| | 68 | 720[b] | 10.799 | 25% reduction in population size | 11 | Peters (1967) |
| | 37 | 1,440 | 10.883 | 46% reduction in egg-to-fry survival | 12 | Slaney et al. (1997b) |
| | 47 | 1,152 | 10.889 | 100% mortality of incubating eggs | 14 | Slaney et al. (1997b) |
| | 57 | 1,440 | 11.315 | 23% reduction in egg-to-fry survival | 11 | Slaney et al. (1997b) |
| | 270[d] | 456 | 11.721 | 10-35% mortality of sub-adults | 11 | Herbert and Merkens (1961) |

**Table B-1 (cont.)**. Summary of data (in situ observations) on exposures to suspended sediment that resulted in **lethal** responses in salmonid fishes. Within species groups, stress indices are arranged in increasing order. For exposure, C= concentration (mg/l) and D = duration (h).

| | *Exposure* | | | | | |
|---|---|---|---|---|---|---|
| **Species** | **C** | **D** | **Stress index (log[e]* [CxD])** | **Effect** | **Rank of Effect** | **Source** |
| Rainbow trout | 270[c] | 456 | 11.721 | 80% mortality of sub-adults | 13 | Herbert and Merkens (1961) |
| | 101 | 1,440 | 11.888 | 98% mortality of eggs (high metals and NH3 levels) | 14 | Turnpenny and Williams (1980) |
| Brown trout | 110 | 1,440 | 11.973 | 98% mortality of eggs | 14 | Scullion and Edwards (1980) |
| Rainbow and brown trout | 300 | 720[b] | 12.283 | 97% reduction in population size | 14 | Peters (1967) |
| Rainbow trout | 1,000-2,500 | 144 | 12.437 | 100% mortality of eggs | 14 | Campbell (1954) |
| | 157 | 1,728 | 12.511 | 100% mortality of eggs | 14 | Shaw and Maga (1943) |
| | 810[d] | 456 | 12.820 | 5-80% mortality of sub-adults | 13 | Herbert and Merkens (1961) |
| | 810[c] | 456 | 12.820 | 80-85% mortality of sub-adults | 14 | Herbert and Merkens (1961) |
| | 200[c] | 2,352 | 13.061 | 50% mortality of fry | 12 | Herbert and Richards (1963) |
| | 1,000-2,500 | 480 | 13.641 | 57% mortality of fingerlings | 12 | Campbell (1954) |
| | 4,250 | 588 | 14.731 | 50% mortality (life stage not specified) | 12 | Herbert and Wakeford (1962) |

# Appendix C.  Individual State Turbidity Standards

The following section illustrates specific turbidity regulations for the states of Alaska, Idaho, Oregon and Washington, and the Province of British Columbia.

### Alaska State Turbidity Standards

According to Lloyd (1987), Alaska does not have a numerical standard for suspended solid concentrations in drinking water supplies.  The state has a narrative standard for sediment.

> No measurable increase in concentrations of sediment including settleable solids, above natural levels. [AAC 1985].

> Alaska has a sediment standard for the propagation of fish and wildlife:

> The percent accumulation of fine sediment in the range of 0.1 mm to 4.0 mm in the gravel bed of waters utilized by anadromous or resident fish for spawning may not be increased more than 5% by weight over natural condition (as shown from grain size accumulation graph).  In no case may the 0.1 mm to 4.0 mm fine sediment range in the gravel bed of waters utilized by anadromous or resident fish for spawning exceed a maximum of 30% by weight (as shown from grain size accumulation graph).  [AAC 1985], taken from (Lloyd 1987)

**Table C-1. Alaska state turbidity standards** (Web Site Ref. #1)

| (1) Fresh Water Uses | Turbidity (not applicable to groundwater) |
|---|---|
| (A) Water Supply (i) drinking, culinary, and food processing | May not exceed 5 nephelometric turbidity units (NTU) above natural conditions when the natural turbidity is 50 NTU or less, and may not have more than 10% increase in turbidity when the natural turbidity is more than 50 NTU, not to exceed a maximum increase of 25 NTU. |
| (A) Water Supply (ii) agriculture, including irrigation and stock watering | May not cause detrimental effects on indicated use. |
| (A) Water Supply (iii) aquaculture | May not exceed 25 NTU above natural conditions. For all lake waters, may not exceed 5 NTU above natural conditions. |
| (A) Water Supply (iv) industrial | May not cause detrimental effects on established water supply treatment levels. |
| (B) Water Recreation (I) contact recreation | May not exceed 5 NTU above natural conditions when the natural turbidity is 50 NTU or less, and may not have more than 10% increase in turbidity when the turbidity is more than 50 NTU, not to exceed a maximum increase of 15 NTU. May not exceed 5 NTU above natural turbidity for all lake waters. |
| (B) Water Recreation (I) secondary recreation | May not exceed 10 NTU above natural conditions when natural turbidity is 50 NTU or less, and may not have more than 20% increase in turbidity when the natural turbidity is greater than 50 NTU, not to exceed a maximum increase of 15 NTU. For all lake waters, turbidity may not exceed 5 NTU above natural turbidity. |
| (C) Growth and Propagation of Fish, Shellfish, Other Aquatic Life, and Wildlife | Same as (1)(A)(iii). |

**Idaho State Turbidity Standards**

The Idaho Division of Environmental Quality adopted turbidity criteria for the protection of cold water biota in 1994. The criteria focus on requirements of salmon as an indicator species. The 50 NTU background turbidity is based on data suggesting that displacement of salmonids occurs at 50 NTU (Lloyd et al. 1987). The 25 NTU for 10 days limit is based on literature showing that salmonid feeding and growth are affected by prolonged exposure to turbidity over 25 NTU (Sigler et al. 1984).

Surface Water Quality Criteria for aquatic life use designations – turbidity, below any applicable mixing zone set by the Department shall not exceed background turbidity by more than fifty (50) NTU instantaneously or more than twenty-five (25) NTU for more then ten (10) consecutive days.

For comparison, turbidity criteria for water supply (measured at a public water intake) is as follows:

(1) No increase by more than five (5) NTU above natural background, measured at a location upstream from or not influenced by any human induced non-point source activity, when background turbidity is fifty (50) NTU or less.

(2) No increase by more than ten percent (10%) above natural background, measured at a location upstream from or not influenced by any human induced non-point source activity, not to exceed twenty-five (25) NTU, when background turbidity is greater than fifty (50) NTU (Web Site Ref. #5).

**Oregon State Turbidity Standards**

Oregon turbidity standards are applied to all watersheds in the state. The requirement may be applied to temporary projects affecting a stream or activities responsible for long-term sediment inputs.

In all basins, no more than 10% cumulative increase in natural stream turbidities shall be allowed, as measured relative to a control point immediately upstream of the turbidity causing activity. The criteria for listing a water body as 303(d) limited due to turbidity is a systematic or persistent increase (of greater than 10%) in turbidity due to an operational activity that occurs on a persistent basis (e.g., dam release, irrigation return) The requirements for listing a water body include collection of TSS data since water year 1986 (10/85) on a frequent enough basis (e.g., daily) to establish a relationship between water quality and a turbidity causing activity (Oregon Administrative Code).

Limited duration activities necessary to address an emergency or to accommodate essential dredging, construction, or other legitimate activities and which cause the standard to be exceeded may be authorized provided “practicable” turbidity control techniques have been applied and one of the following has been granted:

(A) Emergency activities: Approval coordinated by the Department of Environmental Quality with Department of Fish and Wildlife under conditions they may prescribe to accommodate response to emergencies or to protect public health and welfare;

(B) Dredging, Construction or other Legitimate Activities: Permit or certification authorized under terms of Section 401 or 404 (Permits and Licenses, Federal Water Pollution Control Act) or Oregon Administrative Rule 141-085-0100 et seq. (Removal and Fill Permits, Division of State Lands), with limitations and conditions governing the activity set forth in the permit or certificate (Web Site Ref. #7).

**Washington State Turbidity Standards**

**Table C-2. Washington state turbidity standards**

| Class A Waters | Class B Waters |
|---|---|
| Turbidity shall not exceed 5 NTU over background turbidity when the background turbidity is 50 NTU or less, or have more than a 10 percent increase in turbidity when the background is more than 50 NTU. | Turbidity shall not exceed 10 NTU over background turbidity when the background turbidity is 50 NTU or less, or have more than a 20 percent increase in turbidity when the background is more than 50 NTU |

(Web Site Ref. #12)

**British Columbia Standards**

**Table C-3. British Columbia turbidity and suspended sediment standards**

| Water Use | Maximum Induced Turbidity – NTU or % of background | Maximum Induced Suspended Sediments –mg/l or % of background | Streambed Substrate Composition |
|---|---|---|---|
| Drinking Water – raw untreated | 1 NTU when background is less than or equal to 5 | No guideline | No guideline |
| Drinking Water – raw treated | 5 NTU when background is less than or equal to 50 | No guideline | No guideline |
| Recreation and Aesthetics | Maximum 50 NTU ….. secchi disc visible at 1.2 m | No guideline | No guideline |
| Aquatic Life -fresh- -marine- -estuarine- | 8 NTU in 24 hours when background is less than or equal to 8 …. Mean of 2 NTU in 30 days when background is less than or equal to 8 | 25 mg/l in 24 hours when background is less than or equal to 25 …. Mean of 5 mg/l in 30 days when background is less than or equal to 25 | Fines not to exceed -10% as less than 2mm- -19% as less than 3mm- -25% as less than 6.35mm- at salmonid spawning sites |
| Aquatic Life -fresh- -marine- -estuarine- | 8 NTU when background is between 8 and 80 …. 10% when background is greater than or equal to 80 | 25 mg/l when background is between 25 and 250 …. 10% when background is greater than or equal to 250 | Geometric mean diameter not less than 12 mm …. Fredle number not less than 5mm |
| Terrestrial Life -wildlife- -livestock water- Irrigation Industrial | 10 NTU when background is less than or equal to 50 …. 20% when background is greater than or equal to 50 | 20 mg/l when background is less than or equal to 100 …. 20% when background is greater than or equal to 100 | No guideline |

(Web Site Ref. #2)

**European Inland Fisheries Advisory Committee (EIFAC)**

EIFAC (1965) presented five pathways that fine sediments may harm freshwater fishes:

1. By acting directly on the fish swimming in water in which solids are suspended, and either killing them or reducing their growth rate, affecting their resistance to disease
2. Preventing the successful development of fish eggs and larvae
3. By modifying natural movements and migrations of fish
4. By reducing the abundance of food available to the fish
5. By affecting the efficiency of methods of catching fish

Subsequent EIFAC recommendations:

| Level of Protection | Maximum Concentration of Suspended Solids |
|---|---|
| High | 25 mg/l |
| Moderate | 80 mg/l |
| Low | 400 mg/l |
| Very Low | over 400 mg/l |

(Protective levels established based on EIFAC Study.)

## Appendix D. Total Maximum Daily Loads

The Total Maximum Daily Load (TMDL) process was established by section 303(d) of the Clean Water Act. Federal law requires states to identify sources of pollution in waters that fail to meet state water quality standards after all point sources have been permitted and to develop cleanup plans to address pollutants of concern. A TMDL is a calculation of the maximum amount of a pollutant that a water body can receive and still meets state water quality standards. Percentages of the total maximum daily load are allocated to the various pollutant sources. (Web Site Ref. #11).

Uses are identified for each water body, such as drinking water, contact recreation, and aquatic life support. The TMDL is meant to reflect the sum of allowable loads from a single pollutant for all point and non-point sources. TMDL calculations include a "margin of safety" to ensure protection in the case of unforeseen events or unknown sources of the pollutant. Calculation must also account for seasonable variation in background water quality (Web Site Ref. #11).

In Oregon and Washington, few rivers to date have TMDL requirements for 1) turbidity levels or 2) suspended solids.

**Umatilla TMDL (Oregon)**

The Umatilla TMDL for turbidity requires that measurements not exceed 30 NTU for 48 hours. The state collected TSS and turbidity data with automated ISCO samplers in the Umatilla, and determined that the Umatilla needed improvement in this area. The state did not focus on background concentrations. High turbidity levels in the Umatilla are associated with agricultural practices in the watershed. Upstream forested areas did not require a sediment load allocation. The TSS requirement for the Umatilla is 80-110 mg/l, except when stream flow is high (greater than 1.5 times bank) (Wiltsey, pers. commun.).

**Lower Yakima TMDL (Washington)**

The Washington State Department of Ecology conducted a TMDL evaluation of the lower Yakima River basin in 1994 and 1995. The process was conducted with the cooperation of the Yakama Nation and the USEPA. The evaluation focused on total suspended sediment (TSS) and DDT loads from irrigated agricultural areas during the irrigation season. Historical and TMDL data indicated significant correlations between TSS and turbidity, and TSS and DDT. It was assumed reductions in TSS would decrease DDT levels. Turbidity targets were recommended for mainstem and tributary sites on a 15-year implementation schedule (Web Site Ref. #10).

The Department of Ecology needed to build a "narrative criteria" argument because the state water quality criteria were written exclusively for point source rather than non-point source control. There are few turbidity (under 10) listings on the state 303(d) list because the criteria require a "background" turbidity measurement. Few monitoring agencies are equipped to establish a background NTU value when turbid conditions arise from a diffuse set of streams affected by non-point sources. The Palouse River is and example of a river with TSS concentrations in the hundreds and thousands that has escaped 303(d) listing. Glacial headwaters are not helpful in some systems either, as they may produce a high level of natural background turbidity (Joy, e-mail).

The Washington State Class A turbidity criterion was applied to the mainstem to control TSS loading. In-stream turbidity will be limited to a 5 NTU increase in the 86.4 mile reach between the confluence of the Yakima and Naches River and Benton city. A $90^{th}$ percentile turbidity target of 25 NTUs (56 mg/l TSS) for the tributaries and return drains was recommended to significantly reduce t-DDT loads and to protect aquatic communities from TSS effects. The target will require the largest return drains to reduce TSS loads 70% or more during an irrigation season with normal water availability. Based on the current correlation equation, tributary TSS concentrations will need to be further reduced to 7 mg/l to meet the 1 mg/l DDT chronic toxicity criterion for protection of aquatic life. However, more data from tributaries for TSS and t-DDT at lower TSS concentrations are needed to confirm this target (Web Site Ref. #10).

Currently, two systems in Washington State with turbidity problems are targeted for TMDL work: the upper Yakima River and tributaries, and Portage Creek in the Stillaguamish River System. The state is applying narrative type criteria for protection of aquatic life where it is unable to provide background conditions for applying turbidity criteria. (Joy, e-mail).

**Idaho TMDLs**

The State of Idaho has developed a number of TMDLs focused on reducing sediment as a pollutant. (Web Site Ref. #4)

| Watershed/Sub-Basin with sediment | TMDLs done for sediment |
|---|---|
| Paradise Creek (1997) | 1 segment |
| Lower Boise River (1998) | 3 segment |
| MF Payette River (1998) | 1 segment |
| Winchester Lake (1998) and Upper Lapwai (2003) | 1 lake for sediment, 1 river segment for sediment |
| Portneuf River (1998) | 26 segments |
| Lake Walcott (1999) | 3 segments |
| Upper Snake-Rock (1999) | 34 segments |
| Lemhi River (1998) | 7 segments |
| Coeur d'Alene Lake/Lower River (1999) | 7 segments |
| Pend Oreille (1999) | 4 segments |
| Jim Ford Creek (1999 & 2003) | 1 segments |
| Cottonwood Creek (1999 & 2003) | 6 segments |
| Little Lost (1999) | 3 segments |
| Bruneau (2000) | 3 segments |
| Palisades (2000) | 2 segments |

**Summary**

TMDLs offer an opportunity for regulators and stakeholders in a watershed to reduce pollutant loads in the system. In Washington, Oregon, and Idaho, control of sediment is of concern, particularly in agricultural areas. Sediment is a concern both for its direct physical effect on aquatic life and its ability to transport pesticides through the river system.

# Differential effects of turbidity on prey consumption of piscivorous and planktivorous fish

**Alex De Robertis, Clifford H. Ryer, Adriana Veloza, and Richard D. Brodeur**

**Abstract:** Contrast degradation theory predicts that increased turbidity decreases the visibility of objects that are visible at longer distances more than that of objects that are visible at short distances. Consequently, turbidity should disproportionately decrease feeding rates by piscivorous fish, which feed on larger and more visible prey than particle-feeding planktivorous fish. We tested this prediction in a series of laboratory feeding experiments, the results of which indicated that prey consumption by two species of planktivorous fish (juvenile chum salmon (*Oncorhynchus keta*) and walleye pollock (*Theragra chalcogramma*)) is much less sensitive to elevated turbidity than piscivorous feeding by sablefish (*Anoplopoma fimbria*). Planktivorous feeding in the turbidity range tested (0-40 nephelometric turbidity units (NTU)) was reduced at high light intensity, but not at low light intensity. Comparatively low (5-10 NTU) turbidity decreased both the rate at which sablefish pursued prey and the probability of successful prey capture. These results suggest that turbid environments may be advantageous for planktivorous fish because they will be less vulnerable to predation by piscivores, but will not experience a substantial decrease in their ability to capture zooplankton prey.

**Resume :** La theorie de la degradation des contrastes predit qu'une turbidite accrue decroit plus la visibilite d'objets qui sont visibles a de plus grandes distances que celle d'objets visibles a de courtes distances. En consequence, la turbidite devrait faire decroitre de fa9on disproportionnee les taux d'alimentation des poissons piscivores qui se nourrissent de proies plus grandes et plus visibles par comparaison aux taux d'alimentation des poissons planctonophages qui se nourrissent de particules. Une serie d'experiences d'alimentation en laboratoire nous a permis de verifier cette prediction : la consommation de proies de deux especes de poissons planctonophages, de jeunes saumons keta (*Oncorhynchus keta*) et des goberges de l'Alaska (*Theragra chalcogramma*), est beaucoup moins affectee par une augmentation de la turbidite que la consommation de poissons par des morues charbonnieres (*Anoplopoma fimbria*). Dans la gamme des turbidites etudiees (0-40 unites nephelometriques de turbidite, NTU), l'alimentation des planctonophages est reduite aux fortes intensites de lumiere, mais non aux intensites faibles. Des turbidites relativement faibles (5-10 NTU) entrainent une reduction du taux de poursuite ainsi que de la probabilite de capture des proies chez la morue charbonniere. Ces resultats semblent demontrer qu'un environnement turbide peut etre avantageux pour les poissons planctonophages parce qu'ils y sont moins vulnerables a la predation par les poissons piscivores, sans que leur capacite a capturer des proies zooplanctoniques ne soit substantiellement reduite.

## Introduction

Scattering and absorption of light by suspended materials in turbid waters limits visibility in aquatic environments through two primary mechanisms. Under elevated turbidity, light attenuation increases (Kirk 1985), decreasing light penetration, which impairs vision. This process is of particular importance to organisms occupying deeper waters because small turbidity-induced changes in light extinction coefficients have large cumulative effects at depth (Eiane et al. 1999). In addition to reducing ambient light intensity, turbidity can impair visibility by degrading apparent contrast (Lythgoe 1979). Scattering of light by suspended materials reduces the apparent difference in brightness between an object and its background, which decreases the visibility of the object. For an object to be visible, its apparent contrast must exceed a physiological threshold value known as the contrast threshold. The contrast threshold of fish depends on factors such as object size and light intensity (Anthony 1981) but should remain constant for a given prey and illumination. In water, the scattering of light due to suspended particles influences contrast as follows (Duntley 1962):

(1) $C_{\mathrm{a}} = C_0 \mathrm{e}^{-\alpha r}$

where $C_{\mathrm{a}}$ is apparent contrast, $C_0$ is inherent contrast of the object, $\alpha$ is the beam attenuation coefficient for visible light (a measure of water clarity and the sum of the absorption ($a$) and scattering ($b$) coefficients for visible light), and $r$ is the distance between the object and the eye. The degree of contrast degradation thus depends on the optical properties of the water and increases exponentially with the distance between the object and the eye. Thus, for a given increase in turbidity ($\alpha$), contrast degradation will reduce the visibility of large prey such as fish that can be seen at great distances (i.e., large $r$), much more than the visibility of small prey that can only be seen at short distances (i.e., small $r$). Likewise, contrast degradation is likely to be an important factor in near-surface waters during the day when light intensity is relatively high and prey-sighting distances are long and likely to be less important when light intensity is relatively low and prey-sighting distances are short.

Fishes are the primary visual predators in many aquatic systems and are often functionally divided into piscivores and planktivores, based on their primary prey. The ability of visually foraging fish to detect prey depends on light intensity, water clarity, and prey characteristics such as size, pigmentation, and motion (Confer et al. 1978; O'Brien 1987; Aksnes and Utne 1997). Piscivorous and planktivorous fish consume prey of different sizes, and changes in water clarity are likely to affect them in different ways. Piscivores feed on large conspicuous fish, whereas planktivorous fish feed on small, comparatively inconspicuous zooplankton. Under high light intensity in clear water, piscivores are able to detect fish prey at distances much larger than those at which planktivorous fish are able to detect zooplankton prey (Breck 1993). Thus, for a given increase in turbidity, contrast degradation should disproportionately impair prey detection by piscivores relative to planktivores. All other things being equal, moderately turbid waters may be advantageous habitats for planktivorous fish because their encounter rates with piscivorous predators are reduced more than their encounter rates with planktonic prey.

In this study, we examine the effect of turbidity-induced light scatter on feeding rates in a series of laboratory experiments using two species of fish that are planktivorous as juveniles, chum salmon (*Oncorhynchus keta*) and walleye pollock (*Theragra chalcogramma*), and a piscivore, sablefish (*Anaplopoma fimbria*). We test the prediction that increased turbidity depresses the feeding rates of piscivores more than those of planktivores. In addition, we test the hypothesis that feeding by planktivorous fish is more likely to be impaired by increases in turbidity at high light levels when zooplankton prey are visible at longer distances.

## Materials and methods

### Fish collection and maintenance

Chum salmon were raised from eggs collected from wild adults returning to Whiskey Creek, Tillamook County, Oregon, in November 2001. When the chum had completely absorbed their yolk sac, they were transferred to seawater. Juvenile walleye pollock (45-60 mm) were captured in May 2002 from Puget Sound near Port Townsend, Washington, by dip-netting them as they aggregated around a light. Fish were transported to the laboratory and held in 720-L tanks provided with a continuous flow of seawater. Pollock were held in the laboratory for 4-6 weeks before experimentation, and chum were held for 6 months before beginning experiments. Sablefish used as predators in the piscivory experiments were collected as �50-mm juveniles 32 km off the coast of Newport, Oregon, in May 2001 and were held in the laboratory for 13 months. All species were primarily fed formulated foods at rations sufficient to promote growth, but they readily consumed live prey.

### Planktivory experiments

Feeding rates of juvenile chum and pollock were measured under varying levels of turbidity and light intensity in six replicate 50 cm x 50 cm x 50 cm glass tanks supplied with flow-through seawater and located inside a light-proof blind. Each tank was equipped with a feeding tube that allowed prey to be introduced from the other side of the blind with minimum disturbance of the experimental fish. The experimental system has been described in detail elsewhere (Ryer and Olla 1999) and will be described only briefly here. Visible illumination was provided by four green 555-nm light emitting diode (LED) illuminators that could be controlled to produce irradiances between 1.9 x $10^{-7}$ and 1.0 x $10^{-3}$ $\mu E \cdot m^{-2} \cdot s^{-1}$. Green LEDs were selected to mimic the predominant wavelengths of light in coastal marine waters during both day and night (McFarland 1986). Light levels above 1.0 x $10^{-3}$ $\mu E \cdot m^{-2} \cdot s^{-1}$ were achieved by supplementing the LED illuminators with additional light emitted by a rheostat-controlled 40-W incandescent light mounted above each tank and reflected from a white ceiling 150 cm above the tank.

Fish are differentially sensitive to different wavelengths of light, and it is unclear how a shift from green to white light may have affected the response of the planktivores. However, changes in spectral composition of light in the experiments are unlikely to have biased the results to a great degree as in both these and previous experiments (Ryer and Olla 1999), planktivorous feeding in the apparatus occurred well below the change from green to multispectral illumination, and there were no large changes in prey consumption when supplemental light was first used.

Light intensity was measured with a radiometer (model 1700; International Light, Inc., Newburyport, Mass.) equipped with a photosynthetically active radiation filtered, cosine response detector. Measurements were made at the water surface with the detector pointed upwards. Illumination in the six replicate tanks differed by 6-18% depending on light level, and the values reported here represent means of the six measurements. Light measurements were made at the beginning of the study and were periodically checked to confirm that light levels were consistent thought the study period.

Turbidity was controlled by adding a bentonite clay suspension to the experimental tanks. Clays are weakly absorptive of visible light, but highly scattering (Kirk 1994), and often are the primary contributor to reductions in beam attenuation coefficient in turbid environments (Vant 1990). A predetermined amount of clay was mixed into 2 L of seawater, and the suspension was slowly added to the experimental tanks through the feeding tube. In experiments in clear water, seawater without clay was added to the tanks in the same manner. Turbidity was measured with a Hach 2100A turbidimeter (Hach, Loveland, Colo.), which quantifies the amount of light from an incandescent bulb scattered at a 90° angle in nephelometric turbidity units (NTU). Preliminary observations indicated that turbidity was reduced by -50% within 1 h as a result of settling and that fish were agitated by the increase in turbidity for <5 min. To minimize settling during experiments, but allow the fish to acclimate to changes in turbidity, the fish were allowed 30 min to acclimate. A series of preliminary experiments ($n$ = 25) established that turbidity after 35 min (i.e., at the end of trials) was reproducible to within 10% of the average level over the range of 0-40 NTU. Turbidity values reported here represent the mean of these measurements.

**General planktivory protocol**

All planktivory experiments followed a similar experimental protocol: groups of five fish were selected haphazardly from holding tanks and were acclimated to experimental tanks for 16-20 h. Before starting the experiments, the lights were set to the desired intensities, and the flow-through seawater was turned off. To prevent the loss of prey through the outflow drains, the water level in the tank was siphoned down to a height of 37 cm, which is 5 cm below the tank drain. This reduced the water volume in the tank to 93 L. The fish were allowed to acclimate for 60 min before prey introduction.

Live *Artemia salina* were used as a proxy for zooplankton prey in planktivory experiments. Prey cultures were initiated 3-4 days apart, and a subsample of 25 prey was measured daily to ensure that prey size (-2.5 mm) did not vary appreciably between trials. In each trial, 100 prey were counted and placed in a beaker containing 300 mL of seawater. The prey were poured into the experimental tank through a funnel at the end of the feeding tube, and the beaker was rinsed with 750 mL of seawater, which was then poured into the feeding tube. The fish were allowed to feed for 5 min, and the experiment was then terminated by entering the blind and rapidly removing the fish with a dip net. Any prey removed with the fish were quickly separated. Fish were measured and returned to holding tanks and were not reused in subsequent trials. The remaining prey were removed by methodically straining the tank with a fine-mesh dip net for 5 min. Preliminary trials in which prey were added to the tanks without fish and subsequently recovered indicated that almost all prey ($\bar{x}$ ± standard deviation (SD), 98.9 ± 0.3%, $n$ = 6) added through the feeding tubes were recovered, and the number of prey missing at the end of the feeding trial was taken to be the number of prey consumed. Experimental temperatures were �11 °C and ranged between 9.9 °C and 11.8 °C. Five replicate trials were conducted for a given treatment, and the order of trials was randomized in blocks of 2 and 3.

A series of preliminary experiments (5.02 x $10^{-1}$ μE·m$^{-2}$·s$^{-1}$, 0 NTU) were videotaped from above to investigate the possibility of quantifying the distance at which prey were detected by planktivores. Analysis of video records indicated that both chum and pollock began making rapid forward movements of up to 10-20 cm followed by sharp turns shortly after prey were introduced. Although prey were generally not resolved in the video records, in several cases we were able to confirm that prey were consumed as the planktivores turned. These observations suggest that prey-sighting distances by both planktivores were on the order of 20 cm at high light intensity in clear water. However, because position of individual prey could not be reliably resolved, we did not further characterize the distance at which prey were detected in the planktivory experiments.

**Light threshold of chum salmon**

Although the thresholds for visual feeding by sablefish and pollock have been previously established (Ryer and Olla 1999), the threshold for visual feeding by chum salmon, which was required to design the turbidity experiments, was unknown. We thus established the threshold for visual feeding by chum salmon in clear water (0.2 NTU, no added bentonite) by recording prey consumption at 1.14, 1.16 x $10^{-1}$, 1.20 x $10^{-2}$, 0.98 x $10^{-3}$, 1.17 x $10^{-4}$, and 0.91 x $10^{-5}$ μE·m$^{-2}$·s$^{-1}$ and in complete darkness (<1.0 x $10^{-8}$ μE·m$^{-2}$·s$^{-1}$). Mean *Artemia* length ranged from 2.2 mm to 2.6 mm. Fish length was 42.0 ± 3.3 mm ($\bar{x}$ ± SD), and the mean size of fish did not vary with illumination (analysis of variance (ANOVA), $F_{[6,168]}$ = 1.55, $p$ = 0.17). Prey consumption was analyzed by one-way ANOVA after a square-root transformation to homogenize variance (Bartlett's test $p$ = 0.21) in order to meet ANOVA assumptions. A posteriori multiple comparisons were made using Tukey's test.

**Effect of turbidity on planktivory**

We investigated the effects of elevated turbidity on planktivory by chum and pollock at two light intensities. A high light intensity was selected such that additional light would not increase feeding rates, and a lower light intensity was selected such that feeding rates were below those observed at high light intensity but above those in the dark. Based on the results of the light threshold of experiment for chum salmon and previous studies of pollock in the same apparatus (Ryer and Olla 1999), trials were conducted at 5.02 x $10^{-1}$ (high light) and 4.80 x $10^{-4}$ μE·m$^{-2}$·s$^{-1}$ (low light). These light levels correspond approximately to illumination at the water surface during sunrise or sunset and under a half moon, respectively (Macy et al. 1998).

For each species, trials were conducted at 0.2 (no added bentonite), 5.1, 9.3, 19.6, and 39.9 NTU under both high and low light conditions. To remove the confounding effects of decreased light intensity in the turbid treatments (up to 59% reduction, measured at the bottom of the tank), illumination was increased such that the measured light level at the center of the tank was approximately constant (within 5%) over all turbidity levels.

Chum used in turbidity trials averaged 47.0 ± 5.2 mm in length, and size did not vary among treatments (ANOVA, $F_{[9,240]}$ = 0.87, $p$ = 0.55). Pollock averaged 71.6 ± 7.8 mm in total length, and size did not vary among treatments (ANOVA, $F_{[9,240]}$ = 0.345, $p$ = 0.96). Mean prey size ranged between 2.2 and 2.6 mm in chum experiments and between 2.4 and 2.9 mm in pollock experiments. Prey consumption was analyzed by two-way ANOVA after a square-root transformation to homogenize variance (Bartlett's test, $p$ > 0.05 in both cases) to meet ANOVA assumptions. A posteriori multiple comparisons were made using Tukey's test.

**Piscivory experiments**

We investigated the effects of turbidity on piscivory by studying predation by 1-year-old sablefish on juvenile chum salmon at 0.4 ± 0.2, 5.1 ± 0.5, and 10.0 ± 0.5 ($\bar{x}$ ± SD) NTU, which correspond to the three lowest turbidity levels tested in the planktivory experiments. Before use in experiments, sablefish were fed shiner surfperch (*Cymatogaster aggregata*) for a week to habituate them to live prey, and then they were starved for 7-12 days to ensure that they would be motivated to feed. Six replicate trials at each turbidity level were conducted in three identical indoor flow-through circular tanks (1.3 m deep, 3 m diameter). To ensure that predator and prey would be visible to overhead video cameras under turbid conditions, water depth was held at 0.5 m at all times by means of an external standpipe. The experimental volume was 2700 L. One replicate at each of the three turbidity levels was tested in a single day, with the order of trials randomized within that day. The tanks were lit with overhead fluorescent lights, which produced a light intensity ranging from 1.29 to 1.45 $\mu E \cdot m^{-2} \cdot s^{-1}$ at the water surface. The highest turbidity level reduced light levels at the bottom of the tank by <15%, and no compensation was made for decreased light intensity in turbid treatments.

In each trial, two sablefish predators (mean length ± SD, 353.8 ± 17.8 mm) were haphazardly drawn from a holding tank and introduced to the arena to acclimate for 16-20 h. Before each trial, an overhead partition was lowered to confine the predators to half of the tank, and the seawater supply was turned off. A turbid suspension was prepared by adding pulverized kaolin to 120 L of seawater. Kaolin was used to produce the desired turbidity rather than bentonite because it was found that settling of kaolin was negligible over a period of 1-2 h. Half of the suspension was pumped into each side of the experimental tank, and an additional 30 L of seawater was used as a rinse. Preliminary turbidity measurements showed that the kaolin suspension mixed through small holes in the partition and dispersed evenly throughout the tank within several minutes. In the 0.4 NTU trials, water without kaolin was pumped into the tanks as a control. After introducing the suspension into the arena, six chum salmon (82.9 ± 11.5 mm) were drawn from a holding tank, measured, and added to the tank opposite the predators. The fish were then allowed to acclimate to conditions in the arena for 70 min. Trials were initiated by turning on the videotape recorders and raising the partition 50 cm above the water surface with a pulley system from a location outside of the field of view of the fish. Predator and prey were allowed to interact for a period of 15 min. After the conclusion of experiments, the lengths of the predators and remaining prey were measured, as were water temperature and turbidity. Tanks were drained and refilled before further use. Fish used in experiments were not used in subsequent trials. Predator size (ANOVA, $F_{[2,33]} = 0.24$, $p = 0.79$) and prey size (ANOVA, $F_{[2,105]} = 0.98$, $p = 0.38$) were not significantly different among turbidity treatments. Experimental temperatures ranged between 9.3 °C and 9.9 °C. Significant changes in prey consumption were identified using the Kruskal-Wallis test, followed with a posteriori multiple comparisons using the Nemenyi test.

To determine whether turbidity affected predator-prey encounter rates or capture success, the number of pursuits was quantified from the video records of experimental trials. Pursuits could be clearly distinguished from routine swimming by sudden acceleration, rapid changes in direction, and prey responses. In some of the clear-water trials, the predators consumed all of the prey in <15 min, and the number of encounters was normalized by the time until all prey were consumed. Capture success was calculated by dividing the number of pursuits by the number of prey consumed. Significant changes in pursuit rate and encounter rates were identified using the Kruskal-Wallis test, followed with a posteriori multiple comparisons using the Nemenyi test.

**Effect of type of suspended material**

The experiments with planktivores and piscivores differed in the material used to increase turbidity levels, which were measured in NTU. The beam attenuation coefficient of kaolin and bentonite suspensions was measured at nine turbidity levels ranging from 0 to 40 NTU with a Wetlabs C-Star 25 cm path length transmissometer (Wet Labs, Philomath, Oreg.). This instrument measures the sum of absorption and scattering coefficients at a wavelength of 660 nm.

To confirm that kaolin and bentonite had a similar effect on planktivory, the feeding rates of groups of five chum salmon on *Artemia* prey (mean length 2.7-2.9 mm) were measured at 0.3 NTU (no kaolin) and at 9.8 NTU of kaolin-induced turbidity and compared with the results of trials using bentonite (described above). Experiments were conducted at 5.02 x $10^{-1}$ $\mu E \cdot m^{-2} \cdot s^{-1}$. Experimental fish averaged 78.9 ± 12.2 mm ($\bar{x}$ ± SD) in length, and fish size did not vary between treatments (*t* test, $t_{48} = 1.40$, $p = 0.17$). Five trials were conducted at each turbidity level.

## Results

**Light threshold of chum salmon**

The relationship between prey consumption by juvenile chum salmon and log light intensity was sigmoidal (Fig. 1). There was a significant decrease in prey consumption at low light intensities (ANOVA, $F_{[6,34]} = 33.5$, $p < 0.001$; Fig. 1). The threshold illumination at which feeding increased was between $10^{-5}$ $\mu E \cdot m^{-2} \cdot s^{-1}$ and $10^{-4}$ $\mu E \cdot m^{-2} \cdot s^{-1}$ (-5 x $10^{-5}$ $\mu E \cdot m^{-2} \cdot s^{-1}$). Prey consumption reached a maximum at -1 x $10^{-1}$ $\mu E \cdot m^{-2} \cdot s^{-1}$ and did not increase with further illumination.

**Effect of light and turbidity on planktivory**

Turbidity at the tested levels of 0-40 NTU did not have a strong effect on prey consumption by juvenile chum salmon and walleye pollock except at the highest turbidity at the high illumination (Figs. 2*a*, 2*b*). Although there was a strong light effect for both species, there was a significant interaction between light and turbidity (Tables 1, 2), indicating that the effect of turbidity on prey consumption depends on light intensity. Pairwise comparisons (Tables 1, 2) identified significant turbidity effects only at the higher light intensity.

**Effect of turbidity on piscivory**

The number of chum salmon consumed by sablefish decreased significantly under elevated turbidity (Kruskal-Wallis test, $H = 13.0$, df = 2, $p < 0.001$). Pairwise comparisons revealed that the number of prey consumed was significantly higher at 0 than at 10 NTU, but prey consumption at these

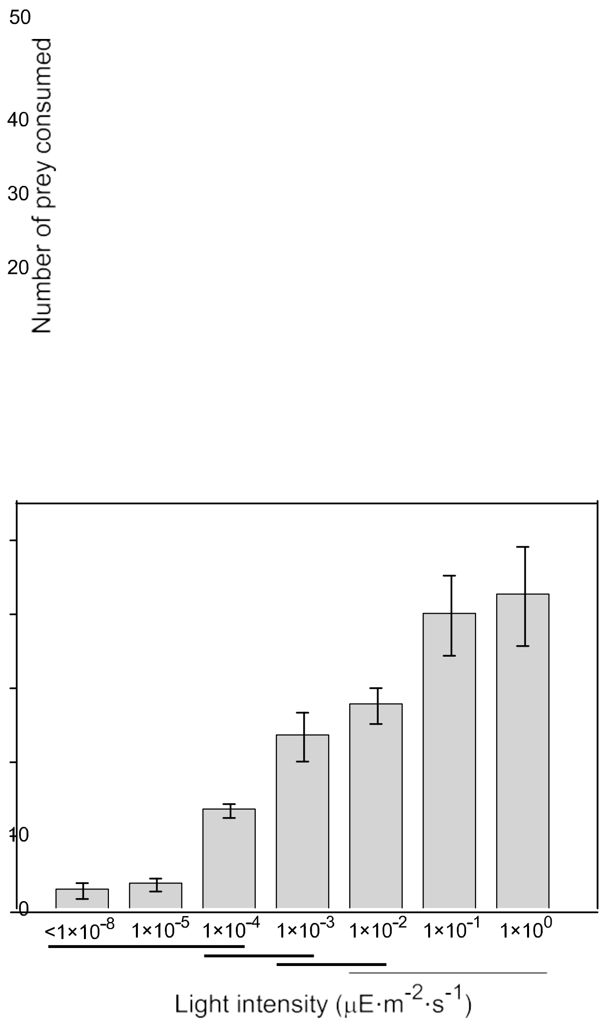

**Fig. l.** Mean number of prey (± standard error) consumed by groups of five juvenile chum salmon (*Oncorhynchus keta*) in clear (0.2 nephelometric turbidity units (NTU)) water at illuminations ranging from <1 x $10^{-8}$ (darkness) to 1 μE·m$^{-2}$·s$^{-1}$. Prey consumption at underlined light intensities does not differ significantly (Tukey's test, $p$ < 0.05). Five replicate trials were conducted at each illumination, with 100 prey per trial and fish allowed 5 min to feed.

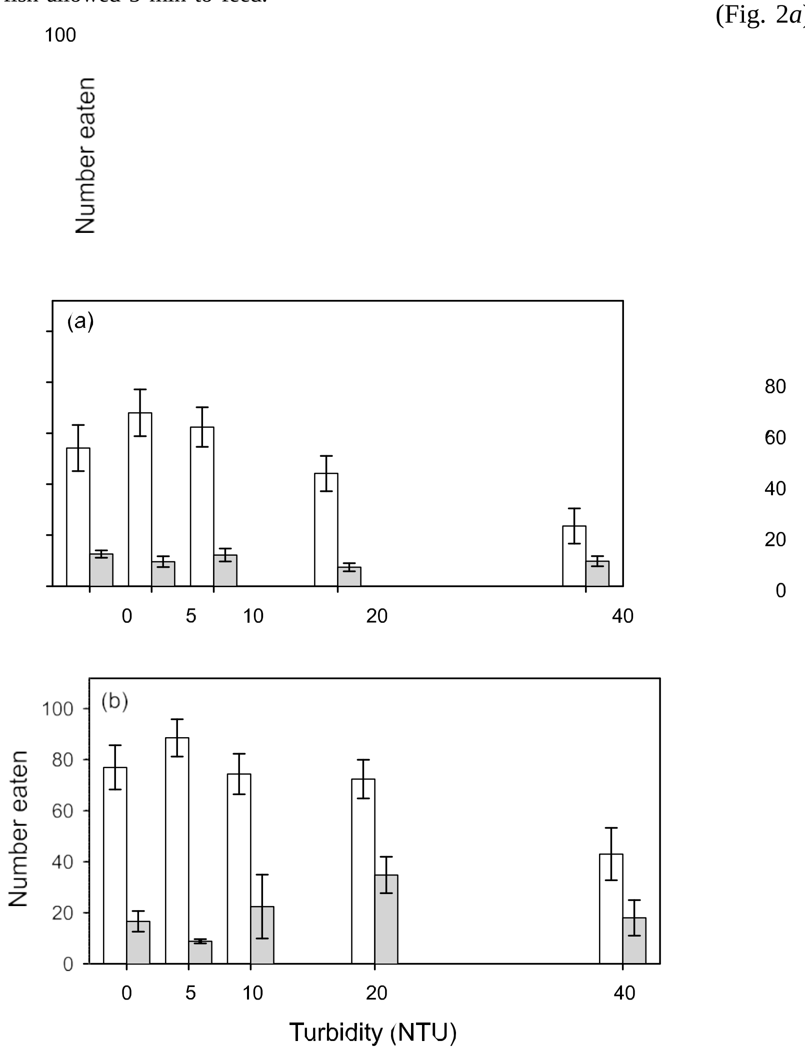
turbidities could not be distinguished from that at 5 NTU (Nemenyi test). Predation rates were about threefold lower at 5 NTU than in clear water, and no prey were consumed in the 10 NTU trials (Fig. 3).

Analysis of the video records indicated that as turbidity increased, sablefish pursued the chum prey less often ($H$ = 9.76, df = 2, $p$ = 0.008; Fig. 4*a*). Pairwise comparisons revealed that pursuit rates were higher at 0 than at 10 NTU, but pursuit rates at neither of these turbidities could be statistically distinguished from those at 5 NTU (Nemenyi test). In clear water, the sablefish generally responded to the chum immediately after the barrier was raised, crossing the tank and initiating pursuit. Under elevated turbidity, the sablefish did not respond as rapidly to the chum and were often observed to swim around the periphery of the tank as they typically did when no prey were present in the tank. In many cases, the prey tended to occupy the central areas of the tank while the sablefish, which appeared not to detect the prey, swam around the periphery of the tank. In addition to reducing the frequency of pursuits, elevated turbidity reduced the rate of prey capture ($H$ = 11.92, df = 2, $p$ = 0.003; Fig. 4*b*). Pairwise comparisons revealed that pursuit rates were significantly higher at 0 than at 10 NTU, but capture success at either turbidity could not be statistically distinguished from that at 5 NTU (Nemenyi test).

The sablefish did not exhibit stereotyped orienting responses before pursuing chum prey, making it difficult to establish when prey detection occurred. This precluded the calculation of prey-sighting distances from the video records. However, the ability of sablefish to detect prey appeared to decrease substantially as turbidity increased. At 0 NTU, the predators often crossed the 3-m-diameter tank to pursue prey, indicating that prey were visible at distances of over 3 m. At 5 NTU, pursuits were initiated at predator-prey distances of

**Fig. 2.** Effect of turbidity (in nephelometric turbidity units (NTU)) on planktivory by juvenile (*a*) chum salmon (*Oncorhynchus keta*) and (*b*) walleye pollock (*Theragra chalcogramma*). Bars indicate the mean number (± standard error) of prey consumed by groups of five fish at five turbidity levels and two light intensities. Open bars indicate high light conditions ($5.02 \times 10^{-1}$ $\mu E \cdot m^{-2} \cdot s^{-1}$) and shaded bars indicate low light conditions ($4.80 \times 10^{-4}$ $\mu E \cdot m^{-2} \cdot s^{-1}$). Five replicate trials were conducted at each illumination, with 100 prey per trial and fish allowed 5 min to feed.



less than 1 m, and pursuit ended when predator and prey were separated by more than 1 m. Pursuits at 10 NTU were initiated when predator and prey were separated by <40 cm.

**Effect of type of suspended material**

The beam attenuation coefficient ($\alpha$) measured at 660 nm was linearly related to turbidity in NTU for both the benton- ite ($y = 1.44x$, $r^2 = 0.99$) and kaolin ($y = 0.63x$, $r^2 = 0.99$) suspensions. Given that the bentonite suspension had a higher $\alpha$ at a given NTU value, this indicates that bentonite is more absorptive than kaolin at this wavelength. However, the ef- fect of elevated turbidity on the feeding rates of chum salmon was similar regardless of the material used to generate the turbidity. At high light intensity, chum salmon consumed 56.8 ± 10.0 ($\bar{x}$ ± standard error (SE)) prey in clear water compared with 75.4 ± 6.6 at a kaolin-induced turbidity of 10 NTU. Prey consumption in clear water and 10 NTU of kaolin-induced turbidity was not significantly different ($t_8 = 1.52$, $p = 0.16$). Although these fish were �30 mm larger than the fish used in bentonite planktivory trials (see above), the observed 33% increase in prey consumption at kaolin-induced turbidity of 10 NTU relative to control fish of the same size in clear water is comparable to the 15% increase above control observed at 10 NTU generated using bentonite (Fig. 2*a*).

**Table l.** Two-way analysis of variance of juvenile chum salmon prey consumption at turbidities ranging from 0 to 40 NTU (nephelometric turbidity units) at light intensities of 5 x $10^{-4}$ and 5 x $10^{-1}$ µE·m$^{-2}$·s$^{-1}$. Turbidity levels are listed in order of descending prey consumption. Prey consumption at the underlined turbidity levels does not differ significantly (Tukey's test, $p$ < 0.05). ## Discussion

These experiments indicate that piscivorous feeding by sablefish is substantially more sensitive to elevated turbidity than planktivorous feeding by chum salmon and walleye pollock. At 10 NTU, sablefish did not successfully consume juvenile chum salmon in 15-min trials, whereas feeding by both of the planktivores was unaffected relative to clear water conditions at this turbidity level. Our behavioral observations of sablefish are consistent with the interpretation that their ability to detect and capture prey was substantially impaired at this turbidity level. Although our experiments were designed to measure prey consumption, our observations of foraging fish are similar to previous reports that at high light in clear water, piscivores are able to detect their prey at distances of metres (Breck 1993; Vogel and Beauchamp 1999), whereas planktivores are able to detect prey at distances of 10s of centimetres (O'Brien 1987; Utne 1997).

Our results are consistent with contrast degradation theory, which predicts that the visibility of objects that can be seen at a large distance in clear water will be disproportionately reduced in turbid waters compared with that of objects that are visible at a shorter distance in clear water. This effect is analogous to the familiar situation where fog has little effect on short-range vision but can greatly diminish the visibility of objects at a distance (Lythgoe 1979). These results

**Fig. 3.** Effect of turbidity (in nephelometric turbidity units (NTU)) on piscivory by sablefish (*Anoplopoma fimbria*). Bars indicate the mean (± standard error) number of chum salmon consumed by pairs of sablefish in 15-min trials ($n$ = 6), with six prey per trial.

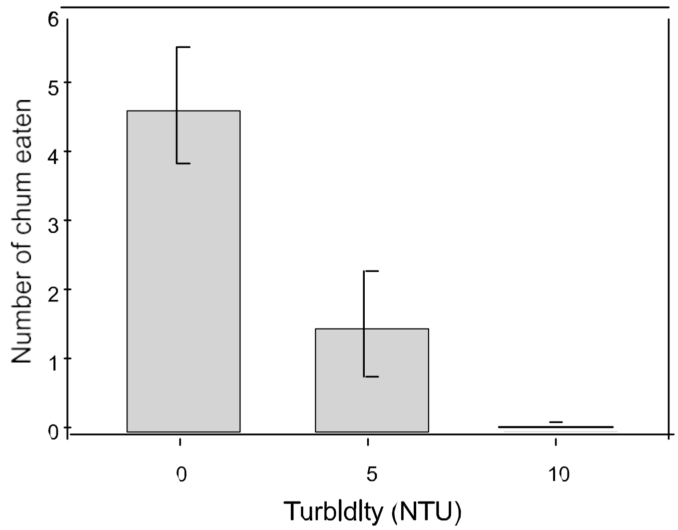

**Fig. 4.** Effect of turbidity (in nephelometric turbidity units (NTU)) on mean (± standard error) (*a*) pursuit frequency and (*b*) capture success of sablefish (*Anoplopoma fimbria*) feeding on chum salmon (*Oncorhynchus keta*) in 15-min trials ($n$ = 6).

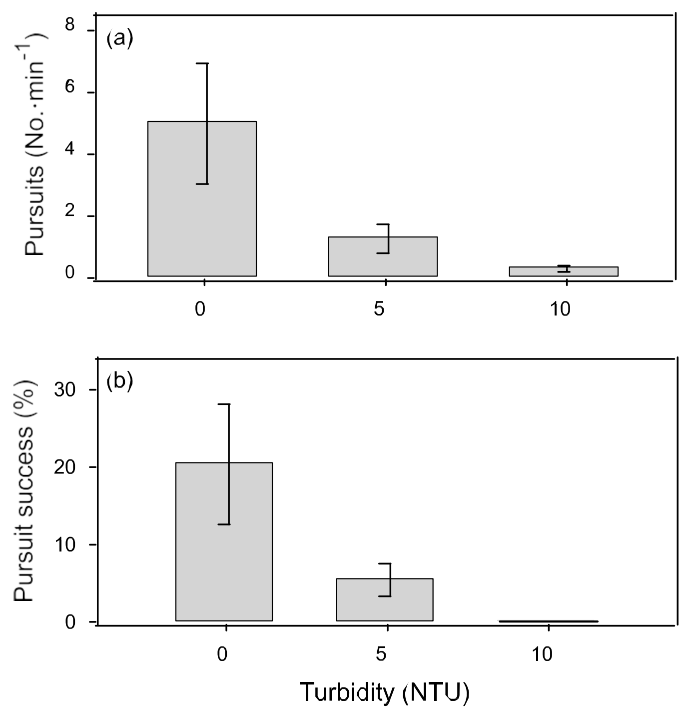

support the "turbidity as cover" hypothesis (Gregory 1993) and suggest that elevated turbidity may be advantageous for planktivorous fish because they will be less vulnerable to piscivores but will not experience a substantial decrease in feeding opportunity. Although our experiments were conducted with saltwater species, the implications of contrast degradation should be generally applicable and should also apply to freshwater species.

Increased turbidity decreased both the rate at which sablefish pursued chum prey and the probability of prey capture. The reduction in pursuits likely reflects reduced predator-prey encounter rates resulting from a decrease in visibility. Capture success averaged -20% in clear water, and no successful pursuits were observed at 10 NTU. The generally low capture success reflects the high mobility and maneuverability of the chum prey. Reduced capture success at elevated turbidity indicates that lower prey consumption in turbid water cannot be attributed solely to a reduction in encounter rate, as has been proposed previously (Gregory and Levings 1996). Increased turbidity likely decreases capture success by increasing the probability that prey escape responses will displace the prey outside of an attacking predator's field of view. Visual encounter models based on piscivore reactive distances (e.g., Beauchamp et al. 1999), which implicitly assume constant capture success, will overestimate feeding opportunities under turbid conditions if capture success decreases in turbid environments.

Our experiment was designed to eliminate the confounding effect of decreased ambient light intensity due to light attenuation under elevated turbidities, and the effects of turbidity on planktivorous feeding observed in the experiments can be attributed primarily to increased scattering of light by suspended materials. High turbidity significantly decreased prey consumption by the two planktivores at the higher illumination, but not at the lower illumination. At lower illuminations, prey will be visible at shorter distances (Aksnes and Utne 1997), which will reduce the effects of contrast degradation relative to high illuminations resulting from a decreased path length between predator and prey. It should be noted that prey depletion over the course of planktivory experiments has the potential to result in an underestimation of prey consumption, particularly in the high light trials in which larger fractions of available prey were consumed. However, given that the trends observed in chum salmon are similar to those of pollock, which consumed more prey, the effects of prey depletion should not alter our primary conclusion that feeding by planktivores is less sensitive to turbidity than piscivores.

Although we did not observe a strong effect of turbidity on prey consumption by planktivores, lower levels of turbidity than those tested here will substantially increase light attenuation with depth. Decreased light penetration will restrict feeding by visually foraging planktivorous fish to shallower water where light levels are higher (Eiane et al. 1999). Because light attenuation increases exponentially with depth (Kirk 1985), the effects of light attenuation will be most pronounced for species that live at greater depths. As a result, the primary effect of turbidity on feeding by planktivorous fish in all but the most turbid waters may be to reduce illumination at depth and thus limit the depth at which fish are able to feed effectively.

The experiments with planktivores and piscivores differed in the material used to manipulate turbidity. The beam attenuation coefficient at 660 nm at a given turbidity (NTU) was measured to be higher for a bentonite than for a kaolin suspension. Given that NTUs are a measure of light scatter, this indicates that bentonite absorbs more light at this wavelength. This suggests that bentonite may be more disturbing to the visual system than kaolin, although this depends on light absorption at other wavelengths, the spectral distribution of ambient light, and the spectral sensitivity of the fish. If this were the case, then our interpretations would be conservative, as the experiments with planktivores were conducted with more visually disturbing suspended materials than experiments with piscivores. However, at 10 NTU, neither bentonite nor kaolin resulted in a significant change in prey consumption by chum salmon, which indicates that the use of different suspended materials does not introduce a substantial bias and cannot account for the difference in turbidity-induced prey consumption between piscivores and planktivores.

In our experiments, we used model species to simulate natural predator-prey interactions. Although all predator species are able to consume prey in complete darkness, they should be considered primarily visual predators as feeding rates in well-illuminated conditions are substantially higher than in the dark (Ryer and Olla 1999; this study). Thus, the results are primarily applicable to fish that visually search for individual prey. Although the *Artemia* used as prey were approximately the same size as natural prey consumed by juvenile chum salmon and walleye pollock (Bailey et al. 1975; Schabetsberger et al. 2000), *Artemia* have poorly developed escape responses and are less likely to escape once attacked by a planktivore. When visibility is poor, prey with more developed escape responses may decrease capture success by moving outside of the predator's reduced field of vision. Thus, although the use of *Artemia* as prey may adequately reflect encounter rates with small prey, their limited escape responses may bias our experiments as consumption of *Artemia* may be overestimated at low light intensity and high turbidity compared with consumption of more evasive prey. However, given that turbidity at the levels tested had only weak effects on planktivore feeding rate, it is unlikely that elevated turbidity greatly reduced the planktivore's visual field to the point that it would have greatly increased the ability of more evasive prey to escape. Even if *Artemia* never successfully escape planktivores and the results of the planktivory experiments can be ascribed purely to changes in encounter rate, this does not invalidate the conclusion that piscivores are more sensitive to increases in turbidity than planktivores, as significant decreases in pursuit rate by piscivorous sablefish were observed at 10 NTU, whereas no changes in prey consumption by the two planktivores were observed at this turbidity level.

A substantial body of work has demonstrated that high turbidity decreases the distance at which planktivorous fish are able to detect prey (e.g., Vinyard and O'Brien 1976; Confer et al. 1978; Utne 1997). Turbidity in many of these studies was measured based either on light absorbance or on measures of visibility to human observers, and these studies are thus not directly comparable to our experiments. Studies of particle-feeding planktivorous fish in which turbidity was measured in a comparable manner support our conclusions, as they suggest that relatively high turbidity is required to reduce prey consumption. In a comparative study of diadromous planktivores, a significant decrease in feeding rate was observed in three species at turbidities of 20, 160, and 640 NTU, whereas three other species were unaffected by turbidities as high as 640 NTU (Rowe and Dean 1998). Feeding of juvenile chinook salmon on adult *Artemia* decreases at >150 NTU, although prey-sighting distance decreases by -50% by 25 NTU (Gregory and Northcote 1993). Planktivory by bluegills is reduced at turbidities of 60 NTU (Gardner 1981). Overall, these studies indicate that moderately high levels of turbidity are required to impair feeding by planktivorous fish.

The distance at which fish are able to respond to other fish is known to decrease sharply with small increases in turbidity. Measurements of the reactive distance of lake trout to salmonid prey indicate that turbidities as low as 3 NTU will decrease reactive distances by -40% under well-illuminated conditions (Vogel and Beauchamp 1999). The distance at which bluegills are able to detect largemouth bass predators is highly dependent on turbidity, decreasing from -210 cm in clear water to �35 cm at 5 NTU (Miner and Stein 1996). These measurements are consistent with our results and suggest that turbidity greatly impairs the ability of fish to detect large, visible objects. However, previous experimental studies of prey consumption by piscivores (Vandenbyllaardt et al. 1991; Reid et al. 1999) have demonstrated statistically significant decreases in prey consumption only at substantially higher turbidities than those tested in this study (37 NTU and 100 NTU), respectively. Gregory and Levings (1996) did not detect a significant difference in predation by cutthroat trout on juvenile salmonids at turbidities as high as 87 NTU. These results may be attributable to methodological differences. Previous studies used comparatively long experimental periods (1-162 h), which constrained highly mobile predators in fairly small volumes for extended periods, and predator satiation may have masked changes in predator-prey encounter rates (Gregory and Levings 1998). This experimental bias is consistent with previous experiments in which elevated turbidity was observed to decrease feeding by piscivores in 1-h but not 4-h trials (Vandenbyllaardt et al. 1991). In addition, the piscivores in our experiments were starved, which motivated them to feed.

Increases in turbidity alter the background against which a prey item is viewed and can lead to increases in the inherent contrast between the prey and the background. This makes the prey more visible and can compensate for turbidity-induced degradation of apparent contrast. However, this does not appear to be a primary effect in our study, as piscivory by sablefish decreased sharply at elevated turbidity, and prey consumption by both species of planktivores was not significantly elevated in turbid vs. clear water. The relative importance of turbidity in increasing prey background inherent contrast decreases sharply with the distance at which prey can be seen (Fiksen et al. 2002). Thus, turbidity-induced changes in prey inherent contrast should be most important for larval fish and least important for piscivorous fish. This prediction is consistent with studies of larval fish that have shown that under well-lit conditions, elevated turbidity either has a minor effect on feeding rate (Breitburg 1988) or leads to an increase in feeding rate (Boehlert and Morgan 1985; Miner and Stein 1993).

If, as our experiments suggest, feeding by piscivores is substantially more sensitive to elevated turbidity than feeding by planktivores, then turbid habitats may be favorable for planktivorous fish, as they will be less vulnerable to attack by piscivores. Recent studies indicating that elevated turbidity makes planktivores less susceptible to predation by piscivores (Gregory and Levings 1998; Beauchamp et al. 1999; Johnson and Hines 1999) support the notion that turbid waters may be favorable habitats for planktivores. This is consistent with the distribution of small fishes in both freshwater and marine environments, where small fish are often associated with more turbid waters (e.g., Blaber and Blaber 1980; Heege and Appenzeller 1998). For example, 16 of 20 species of juvenile fishes studied in a turbid estuary were disproportionately found in waters with turbidities exceeding 10 NTU (Cyrus and Blaber 1987). In addition, planktivorous fish may respond to turbid water by decreasing predator-avoidance behaviors (Gregory 1993; Miner and Stein 1996; Abrahams and Kattenfeld 1997). This may be advantageous, as predator-avoidance behavior often comes at the cost of decreased feeding opportunities (Gilliam and Fraser 1987; Lima and Dill 1990).

Turbidity levels sufficient to reduce the effectiveness of piscivory are more likely to occur in freshwater and estuarine environments than in marine environments. Turbidity in these habitats is often high as a result of inputs of inorganic particles from land (Kirk 1985). However, turbidity may have a locally important effect in productive coastal marine habitats during dense phytoplankton blooms (Lovvorn et al. 2001), in river plumes (Grimes and Kingsford 1996), or in areas where bottom sediments are resuspended (Churchill et al. 1994). Estuaries serve as nursery areas for many marine fishes; turbidity in these habitats may often be sufficient to reduce vulnerability to visual predators (Blaber and Blaber 1980; Miller et al. 1985; Vant 1990). For instance, turbidity has the potential to reduce the mortality of juvenile salmon, such as the chum used as both predator and prey in our experiments, which often inhabit turbid freshwater and estuarine habitats. Salmonids are often associated with river plumes in the coastal ocean during their first months in the ocean, and decreased visibility in these environments is unlikely to affect planktivorous feeding but may be sufficient to reduce vulnerability to piscivorous fish and seabirds. Focused field studies (e.g., Gregory and Levings 1998) should be conducted to evaluate if turbidity reduces predation risk for planktivorous fish exposed to natural environmental conditions and predator assemblages.

In conclusion, turbidity decreases visibility in aquatic systems by decreasing light penetration and reducing apparent contrast. Our experiments suggest that there is an asymmetry in how turbidity-induced contrast degradation affects the feeding rates of visually hunting piscivorous and planktivorous fish. This asymmetry has important ecological implications, as moderately turbid aquatic environments may provide an advantage for planktivorous fish. Increased turbidity will decrease predation risk substantially more than the ability to feed on zooplankton prey. Our inferences are limited in scope because they are based on experiments with two species of planktivores and a single piscivore. However, we anticipate that our results are broadly relevant to these two trophic levels, as the expectation that piscivores are more sensitive to turbidity is based on fundamental optical principles.

## Acknowledgements

We thank Michelle Ottmar, Mara Spencer, and Richard Titgen for assistance with aquarium facilities, prey culture, and electronics, respectively. This work would not have been possible without the support of Allan Stoner and Edmundo Casillas, which is sincerely appreciated. The comments of Robert Emmett, Thomas Hurst, Dan Kreeger, and Anne Utne Palm improved the manuscript. A.D.R. was supported by a National Research Council Postdoctoral Fellowship, and A.V. was supported by Minority Summer Internship in Fisheries Behavioral Ecology by the Equal Employment Opportunity Office of the National Marine Fisheries Service, National Oceanic and Atmospheric Administration.

---

**Executive Summary**
Dissolved copper is a ubiquitous surface water pollutant that causes a range of adverse acute, chronic, and sublethal effects in fish as well as in aquatic invertebrates and algae. This technical white paper is a summary and targeted synthesis regarding sensory effects to juvenile salmonids from low-level exposures to dissolved copper (dCu). As such, the material presented in this paper does not reflect official policy of the National Marine Fisheries Service, but serves to summarize research on dCu and its impacts on salmonid sensory systems. This document is a snap shot of the existing information; undoubtedly, new information will become available that enhances our understanding of copper's effect on listed salmonids and their supporting habitat.

A large body of scientific literature has shown that fish behaviors can be disrupted at concentrations of dCu that are at or slightly above ambient concentrations (i.e. background). In this document, background is defined as surface waters with less than 3 ug/L dCu as experimental water had background dCu concentrations as high as 3 ug/L dCu. Sensory system effects are generally among the more sensitive fish responses and underlie important behaviors involved in growth, reproduction, and ultimately survival (i.e. predator avoidance). Recent experiments on the sensory systems and corresponding behavior of juvenile salmonids contribute to more than four decades of research and show that dCu is a neurotoxicant that directly damages the sensory capabilities of salmonids at low concentrations. These effects can manifest over a period of minutes to hours and can persist for weeks.

In this paper, benchmark concentrations (BMC) were calculated for dCu using an U.S. Environmental Protection Agency (EPA) methodology to provide examples of effect thresholds to assist in .evaluating effects of activities that deliver dissolved copper to surface waters. Benchmark concentrations ranged from 0.18 – 2.1 µg/L corresponding to reductions in predator avoidance behavior from approximately 8 – 57%. The BMC examples represent the dCu concentration (above background [where background is less than or equal to 3 ug/L]) expected to affect juvenile salmonids' ability to avoid predators in fresh water. These concentration thresholds for juvenile salmonid sensory and behavioral responses fall within the range of other sublethal endpoints affected by dCu such as behavior, growth, and primary production, 0.75-2.5 µg/L.

Point and non-point source discharges from anthropogenic activities frequently exceed these thresholds by one, two, and sometimes three orders of magnitude and can occur for hours to days. The United States Geological Survey (USGS) ambient monitoring results for dCu representing 811 sites across the U.S. detected concentrations ranging from 1-51 µg/L with a median of 1.2 µg/L. Additionally, typical dCu concentrations originating from road runoff from a California study were 3.4 - 64.5 µg/L, with a mean of 15.8 µg/L. Taken together, the information reviewed and presented herein indicates that impairment of sensory functions important to survival of juvenile salmonids is likely to be widespread in many freshwater aquatic habitats. Impairment of these essential behaviors may occur following ten minutes of exposure and continue for hours to days depending on concentration and duration. Due to these acute, sublethal responses i.e. within minutes, it is unlikely that avoidance or acclimation play significant roles in reducing the

effects of short term anthropogenic increases of dCu to juvenile salmonid sensory systems.

We also discuss the bioavailability of copper in aquatic habitats including the effects of water chemistry on olfactory toxicity. Avoidance behavior studies on salmonids exposed to dCu are summarized as well as representative studies of acute, chronic, and sublethal effects to salmonids. Given the large body of literature on copper and responses of aquatic ecosystems, we focused on a subset of fish sensory system studies relevant to anadromous salmonids.

**Abstract:**

Dissolved copper (dCu) is a ubiquitous, toxic pollutant in U.S. surface waters. Four decades of research with dCu, indicate toxicity to multiple fish endpoints including fish sensory systems and behaviors. This document summarizes literature on the effects of dCu to salmonid sensory systems and conducts a targeted analysis on a recent sensory system behavioral dataset. The review portion of the document discusses peer reviewed and gray literature (see Appendix) on the effects of dCu on salmonid sensory systems, associated sensory-mediated behaviors, and physiology and is intended to facilitate understanding of the effects of dCu on sensory system mediated behaviors that are important to survival, reproduction, and distribution of salmonids. The review does not address the effects of dCu on salmonid habitats although copper is also highly toxic, at low ug/L concentrations, to aquatic plants and invertebrates.

The targeted analysis was conducted with data from a recent experiment on fish olfaction and predator avoidance behavior. Results from this experiment showed that increases in dCu impaired the ability of juvenile salmonids to smell and by extension reduced their capacity to detect and respond to alarm signals (conspecific skin extracts). Impaired olfaction manifested over a period of minutes in juvenile coho. Olfaction and behavioral impairment endpoints were significantly correlated ($r^2 = 0.94$) and indicated statistically significant effects (alpha =0.05) at all concentrations tested for olfaction (2, 5, 10, 20 ug/L) and at 5, 10, and 20 µg/L for alarm response (inhibition of swimming speed reductions). However, no experimental treatments were tested below 2 µg/L which corresponded to an approximately 50% reduction in olfactory function and a 47% reduction in alarm response.

To address this critical uncertainty, we conducted a benchmark concentration (BMC) analysis with the olfactory dataset. The analysis produced BMC estimates ranging from 0.18 ($BMC_{10}$) - 2.1 ($BMC_{50}$) µg/L which corresponded to approximately 8 – 57% estimated reductions in predator avoidance response. These results indicate juvenile salmonid sensory systems and their mediated ecologically relevant behaviors are particularly sensitive to low ug/L increases. Impairment of olfaction in juvenile salmonids can manifest in minutes, last for minutes to weeks (depending on dose), and potentially result in population level consequences. These sensory effects are discussed in the context of site specific issues including the bioavailability of dCu.

## Acronyms and Glossary

Acute exposure – short term continuous exposure generally 96 hrs or less

BLM- Biotic Ligand Model

Chronic exposure – longer term continuous or pulsed exposures generally greater than 96 hrs

Confidence interval (CI) - A confidence interval is a random interval constructed from data in such a way that the probability that the interval contains the true value can be specified before the data are collected.

dCu – dissolved copper

DOC- dissolved organic carbon

$EC_p$ – effective concentration adversely affecting (p) percent of the test population or percent of measured response, e.g., 10% for an $EC_{10}$, etc.

EOG- Electro-olfactogram

$LC_{50}$ - the aqueous concentration that kills 50% of the test population

Lower-bound 90% confidence interval - is the lower half of the 90% confidence interval of the mean

Lower-bound 95% confidence interval - is the lower half of the 95% confidence interval of the mean

LOEC - Lowest observable effect concentration

Mean - is the average of the response values in a treatment population. Numerically it represents the sum of the individual response values divided by the number of individuals in a treatment.

mV- millivolts

NOAEL - No observable adverse effect level

NOEC- No observable adverse effect concentration

ORN- olfactory receptor neuron

ppb – part(s) per billion, equivalent to ug/L

Relative departure - is a prescribed change in response e.g. the concentration at which a 10% effect is predicted.

Statistical departure – uses statistical methods to select a prescribed change e.g. applying the 90% or 95% lower-bound confidence interval of the mean of the control response to select the value at which an individual salmonid's olfaction is impaired.

## Introduction

Copper, a naturally occurring element, is an essential micronutrient for plants and animals, but is also recognized as a priority pollutant under the U.S. Clean Water Act. Historical and current anthropogenic activities have mobilized significant quantities of copper. Vehicle emissions and brake pad dust [1], pesticides [2], industrial processes, mining, and rooftops [3, 4] are a few of the sources that contribute copper to the environment. These uses may lead to the unintended and, in some circumstances, intended introduction of copper into aquatic ecosytems [5, 6]. Once introduced into the aquatic environment, copper is detected in multiple forms. It can be dissolved or bound to organic and inorganic materials either in suspension or in sediment. This so called speciation of copper is dependent on site specific abiotic and biotic factors. Copper is an element, so once introduced, it will persist indefinitely, cycling through ecosystems. Copper in its dissolved state is worthy of particular scrutiny as it is highly toxic to a broad range of aquatic species including algae, aquatic invertebrates, and fishes (including anadromous salmon and steelhead within the *Oncorhynchus* and *Salmo* genera).

Currently, anadromous salmonid populations inhabit waters of Alaska, Oregon, Washington, California, Idaho, and Maine (Atlantic salmon [*Salmo salar*]). Dissolved copper (referred to as dCu herein) is consistently detected in salmonid habitats including areas important for rearing, migrating, and spawning [7, 8]. Dissolved copper is known to affect a variety of biological endpoints in fish (e.g. survival, growth, behavior, osmoregulation, sensory system, and others; reviewed in [9]). More than forty years of experimental results show that sensory systems of salmonids are particularly sensitive to dissolved copper. Recent experimental evidence showed that juvenile sensory system mediated behaviors are also affected by short term exposures to dCu.

Given the ecological significance of these behaviors to salmonids, it is important to characterize the potential effects from dCu. The growing body of scientific literature indicates that dCu is a potent neurotoxicant that directly damages the sensory capabilities of salmonids at low concentrations (see discussion below). These concentrations may stem from anthropogenic inputs of dCu to salmonid habitats. Salmonid sensory systems mediate ecologically important behaviors involved in predator avoidance, migration, and reproduction. Impairment of these behaviors can limit an individual salmonid's potential to complete its lifecycle and thus may have adverse population level consequences.

The purpose of this paper is to: (1) summarize information on the effects of dCu to the sensory systems of juvenile salmonids in freshwater (also see Appendix); (2) conduct a benchmark concentration analysis to generate examples of dCu effect thresholds; and (3) to discuss site-specific considerations for sensory system effects. As such, this white paper focuses on a single contaminant (dCu), two relevant sensory system endpoints (olfaction and alarm response behavior), and a single salmonid life stage (juvenile, < 10 months old).

## Previous studies on the effects of copper

Examples of copper's effect on a suite of selected biological endpoints from laboratory and field exposures are presented in Table 1. Additionally, the Appendix contains a targeted review and summary of some of the previous studies showing copper's effect on salmonid behavior, including avoidance and migratory disruptions. A supplemental bibliography is also attached for further information on salmonid sensory systems. The following analysis of sensory effects on juvenile salmonids primarily emphasizes recent and ongoing research conducted at the National Oceanic Atmospheric Administration's Northwest Fisheries Science Center. However, the phenomenon that copper and some other trace metals can interfere with chemoreception, alter behaviors, and influence the movements of fish was first described at least 40 years ago, and a large body of knowledge on the adverse effects of dCu has subsequently developed (Table 1).

Table 1. Selected examples of adverse effects with copper to salmonids or their prey.

| **Species (lifestage)** | **Effect** | **Effect concentration (µg/L) (Note A)** | **Effect statistic** | **Hardness (mg/L) (Note B)** | **Exposure duration** | **Source/ Notes** |
|---|---|---|---|---|---|---|
| | **Sensory and behavioral effects** | | | | | |
| Coho salmon (juvenile) | Reduced olfaction and compromised alarm response | 0.18 - 2.1 | $EC_{10}$ - $EC_{50}$ | 120 | 3 hours | [10] |
| Chinook salmon (juvenile) | Avoidance in laboratory exposures | 0.75 | LOEC | 25 | 20 minutes | [11] |
| Rainbow trout (juvenile) | Avoidance in laboratory exposures | 1.6 | LOEC | 25 | 20 minutes | [11] |
| Chinook salmon (juvenile) | Loss of avoidance ability | 2 | LOEC | 25 | 21 days | [11] |
| Atlantic salmon (juvenile) | Avoidance in laboratory exposures | 2.4 | LOEC | 20 | 20 minutes | [12] |
| Atlantic salmon (adult) | Spawning migrations in the wild interrupted | 20 | LOEC | 20 | indefinite | [12] |

| Species (lifestage) | Effect | Effect concentration (μg/L) (Note A) | Effect statistic | Hardness (mg/L) (Note B) | Exposure duration | Source/ Notes |
|---|---|---|---|---|---|---|
| Chinook salmon (adult) | Spawning migrations in the wild apparently interrupted | 10 – 25 | LOEC | 40 | indefinite | [13] |
| Coho salmon | Delays and reduced downstream migration of dCu-exposed juveniles | 5 | LOEC | 95 | 6 day | [14, 15] |
| Rainbow trout | Loss of homing ability | 22 | LOEC | 63 | 40 weeks | [16] |
| | **Ecosystem effects** | | | | | |
| | Ecosystem function: Reduced photosynthesis | 2.5 | LOEC | 49 | ~ 1 year | [17] |
| | Ecosystem structure: loss of invertebrate taxa richness in a mountain stream | 5 | LOEC | 49 | ~ 1 year | [18] |
| | **Other sublethal effects** | | | | | |
| Chinook salmon | Reduced growth (as weight) | 1.9 | $EC_{10}$ | 25 | 120 days | [19] |
| Rainbow trout | Reduced growth (as weight) | 2.8 | $EC_{10}$ | 25 | 120 days | [20] |
| Coho salmon | Reduced growth (as weight) | 21 – 22 | NOEC | 24 - 32 | 60 days | [21] |
| Steelhead | Reduced growth (as weight) | 45 – > 51 | NOEC | 24 - 32 | 60 days | [21] |
| | **Direct Lethality** **(**Note C**)** | | | | | |
| Chinook salmon (fry) | Death | 19 | $LC_{50}$ | 24 | 96 h | [22] |
| Coho salmon (fry) | Death | 28 – 38 | $LC_{50}$ | 20 – 25 | 96 h | [15] |

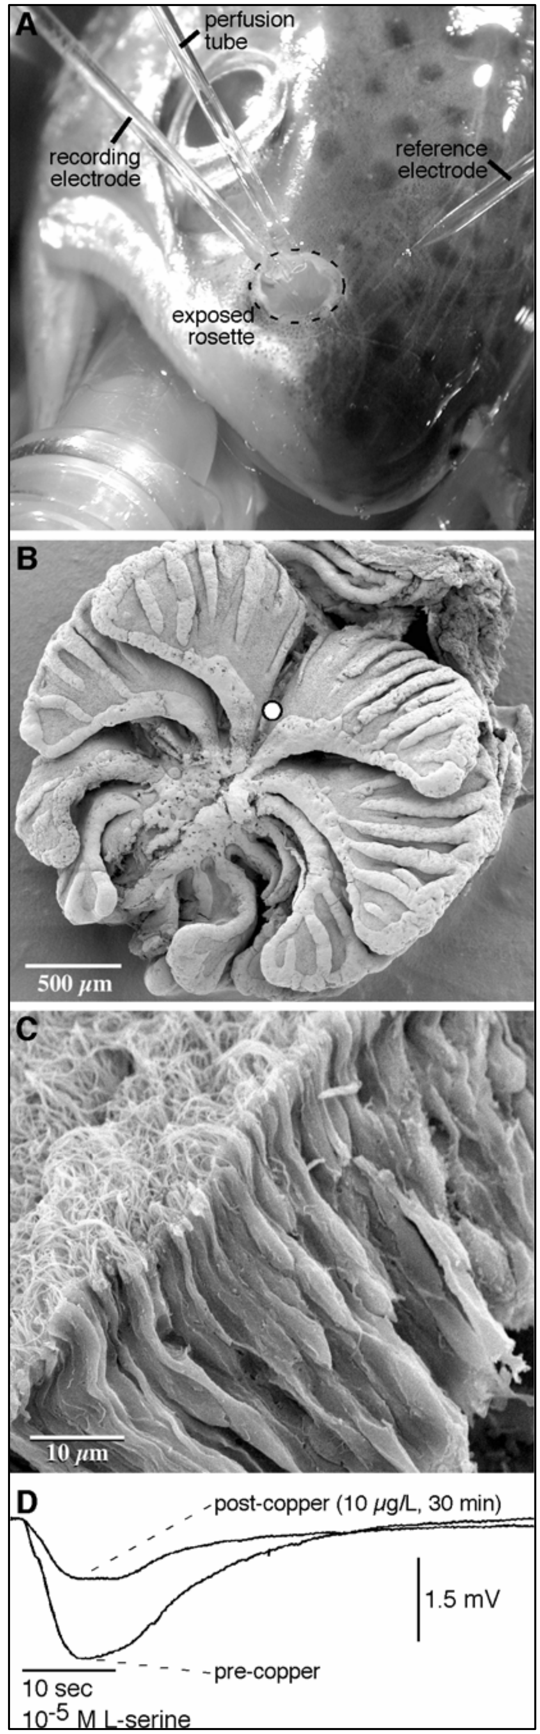
| Species (lifestage) | Effect | Effect concentration (μg/L) (Note A) | Effect statistic | Hardness (mg/L) (Note B) | Exposure duration | Source/ Notes |
|---|---|---|---|---|---|---|
| Steelhead/ Rainbow trout (fry) | Death | 9 – 17 | $LC_{50}$ | 24 – 25 | 96 h | [22, 23] |
| Coho salmon (adult) | Death | 46 | $LC_{50}$ | 20 | 96 h | [24] |
| Steelhead (adult) | Death | 57 | $LC_{50}$ | 42 | 96 h | [24] |
| Coho salmon (juvenile) | Death | 21 – 22 | NOEC | 24 – 32 | 60 days | [21] |
| Steelhead (juvenile) | Death | 24 – 28 | NOEC | 24 - 32 | 60 days | [21] |
| Steelhead (egg-to-fry) | Death | 11.9 | $EC_{10}$ | 25 | 120 days | [19] |

**Abbreviations:** LOEC – Lowest observed adverse effect concentration. Most LOEC values given are not thresholds, but were simply the lowest concentration tested; NOEC – No observed adverse effect concentration; $LC_{50}$ – the concentration that kills 50% of the test population; ECp – effective concentration adversely affecting (p) percent of the test population or percent of measured response, e.g., 10% for an EC10, etc.; Indefinite – field exposures without defined starting and ending times
**Note:** A. Effects and exposure durations stem from laboratory and field experiments, therefore in some experiments multiple routes of exposure may be present i.e. aqueous and dietary, and water chemistry conditions will likely differ (see reference for details).
**Note:** B. Hardness is reported as it can influence the toxicity of copper.
**Note:** C. Acute sensitivity of salmonids to copper probably varies by life-stage, and the swim-up fry stage is probably more sensitive than older juvenile life stages such as parr and smolts, or adults.

### Effects to anadromous salmonids' sensory systems exposed to dissolved copper

The salmonid olfactory sensory system relies on neurons (ciliated receptors) to detect and respond to cues in the aquatic environment. The receptors are in direct contact with the aqueous environment. Olfactory receptors detect chemical cues that are important in finding food, avoiding predators, navigating migratory routes, recognizing kin, participating in reproduction, and avoiding pollution. A pair of olfactory rosettes composes the peripheral portion of the olfactory system in a fish's nose (Figure 1A). Each rosette contains olfactory sensory neurons that respond to dissolved odors in water as they pass through the olfactory chamber (Figure 1B) where the olfactory receptors lie (Figure 1C). These chemical cues convey important information about the surrounding environment and underlie salmonid behaviors critical to completion of anadromous lifecycles.

Figure 1. Recording methods and features of the salmon peripheral olfactory system. A) Photograph showing the rostrum of a coho salmon during the recording of electro-olfactograms (EOGs). The mouthpiece provides chilled, anaesthetized water to the gills, while the perfusion tube delivers odor-containing solutions to the olfactory cavity. The recording electrode in the olfactory cavity and reference electrode in the skin monitor the response of the olfactory system to an odor. B) Scanning electron micrograph showing a rosette, located within an olfactory chamber of a juvenile coho salmon. Each rosette consists of lamellae (lobes) covered by an epithelium containing regions of sensory neurons. The open circle denotes the location and approximate size of the tip of the recording microelectrode. C) Scanning electron micrograph showing a cross-section from a region of sensory epithelium of a lamella. In the upper left is the apical surface containing the cilia and microvilli of the olfactory receptor neurons (ORNs). The dendrites and somata of the ORNs appear in the center within the epithelium, while the axons of the ORNs emerge from the basal surface at the lower right to produce the olfactory nerve. D) Typical odor-evoked EOGs obtained from a salmon before and after exposure to copper. A 10-second switch to a solution containing $10^{-5}$ M L-serine is shown with a horizontal bar. The EOG evoked by the odor pulse consists of a negative deflection in the voltage. A 30-minute exposure to copper reduced the amplitude of the EOG evoked in the same fish by 57%. Figure adapted from Baldwin and Scholz [25].



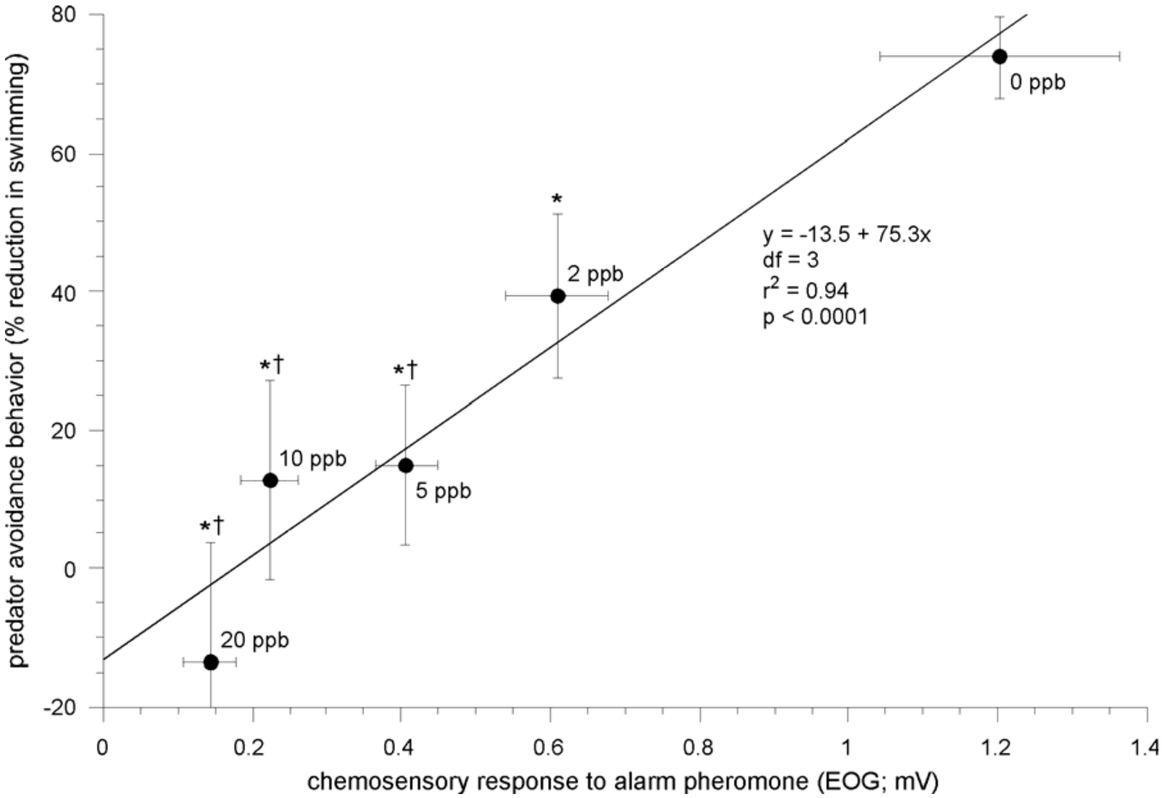
The precise mechanism by which dCu damages the olfactory system remains unknown, although direct exposure to dCu can impair and destroy olfactory sensory neurons [10, 26-28]. Impairment of olfaction (i.e. smell) can be measured by an electrophysiology technique called the electro-olfactogram (EOG) (Figure 1) [25, 28, 29]. The EOG measures olfactory receptor function in fish. Reductions in the amplitude of the EOG of copper-exposed fish compared to unexposed fish reflect functional losses in sensory capabilities. Dissolved copper's toxic effect to olfactory sensory neurons is observable as a reduction in or elimination of the EOG amplitude to a recognizable odor (Figure 1D).

Several recent studies highlight some important aspects of copper olfactory toxicity [10, 27, 30]. Baldwin et al. [27] found that the neurotoxic effects of copper in coho manifest over a timescale of minutes. At 10 minutes, EOG amplitude reductions were observed in juvenile coho exposed to 2, 5, 10, and 20 μg/L dCu above experimental background (3 μg/L). After 30 minutes at 2 μg/L dCu above experimental background, the EOG amplitude from juvenile coho salmon to odors was reduced by approximately 25% compared to controls; in 20 μg/L dCu after 30 minutes by approximately 80%. Sandahl et al. [30] found similar effects following 7 days of exposure (both in EOG reductions and copper concentrations). This result indicated that the juvenile olfactory system cannot adapt to, and correct for, continuous copper exposure for durations up to 7 days.

Recently, using EOG measurements in combination with a predator avoidance assay, Sandahl et al. [10] presented the first evidence that impaired olfaction (smell) resulted in a direct suppression of predator avoidance behavior (alarm response) by juvenile coho at environmentally relevant dCu exposures (≥2.0 μg/L; 3 hr exposure). Unexposed juveniles (control treatment) reduced their swimming speed on average by 74% (alarm response) in response to an alarm odor (conspecific skin extract). A reduction in swimming speed is a typical predator avoidance response for salmonids and many other fish. In unexposed fish, the alarm odor elicited a mean EOG response of 1.2 mV. Juvenile coho exposed to 2-20 μg/L copper exhibited measurable reductions in both EOG (50-92%) and alarm response (47 - >100%) [derived from Figure 2 in Sandahl et al., [10]]. Juvenile coho exhibited statistically significant decline in antipredator behavior at 5, 10, and 20 μg/L dCu (Figure 2).

Importantly, no concentrations of dCu below 2 μg/l were tested. This is particularly troubling because all concentrations tested (between 2-20 μg/L) significantly affected olfaction e.g. reductions in EOG amplitudes of ~ 50 - 92%. Because individual juvenile coho were significantly affected at the lowest concentration tested (2 μg/L), uncertainty remains at what concentrations salmonid olfaction is first impaired. The results of this last study provide evidence that juvenile salmon exposed to sublethal dCu concentrations at 2 μg/L (resulting in approximately 50% reductions in EOG), and likely even lower, might not recognize and respond to a predation event, and therefore have an increased risk of being eaten by other fishes or birds, an event referred to as ecological death [31].

Figure 2. Copper-induced reductions in juvenile salmonid olfactory physiology and behavior are significantly correlated. Fish exposed to dCu (3h) showed reduced olfactory sensitivity and corresponding reduction in predator avoidance behavior. Values represent treatment means (with copper exposure concentration labeled to the right); error bars represent one standard error; n=8-12 individual coho salmon; * represents a statistically significant difference in olfactory response (EOG data) compared to controls (one-way ANOVA with Dunnett post hoc test, $p<0.05$); †represents statistically significant difference in behavioral response to skin extract (% reduction in swimming) compared to controls (one-way ANOVA with Dunnett post hoc test, $p <0.05$). The line represents a statistically significant linear regression based on treatment means ($n = 5$; $p < 0.0001$; $r^2 = 0.94$). 1 ppb = 1 μg/l. Adapted from Figure 2C Sandahl et al [10].



Typically dCu concentrations in road runoff are well within the range affecting anti predator behavior (3.4 - 64.5 μg/L, with a mean of 15.8 μg/L [8]). The length of exposure is also likely to be sufficient, as stormwater runoff durations may range from a few minutes to several hours [5]. Fish may regain their capacity to detect odors fairly quickly in some cases; physiological recovery of olfactory neuron function is dose-dependent and occurs within a few hours at low copper concentrations (i.e., <25 μg/L dCu; [27]). However long-term damage is also documented. In the case of olfactory neuron cell death (i.e. ≥25 μg/l copper [11, 26]) recovery is on the order of weeks [32] and in some cases months [33].

Interestingly, another fish sensory sytem, the lateral line, is also sensitive to dCu. It is composed of mechanosensory neurons (hair cells) that collect data from the aquatic environment. Specifically, the neurons detect vibrations and other forms of water movement in the aquatic environment; thereby mediating shoaling, pursuit of prey, predator avoidance, and rheotaxis (flow orientation). In a recent study, dissolved copper (i.e., ≥20 µg/L; 3 hr exposure) killed 20% of zebra fish hair cells [34]. As mentioned earlier, juvenile Chinook olfactory epithelial cells may also be killed by increases in dCu, highlighting the similar sensitivity of olfactory and lateral line receptors to dCu. Consequently, dCu may damage or destroy either or both of these important sensory systems. Currently, we are not aware of any research on the effects of dCu to salmonid lateral lines, although the comparable sensitivities of olfactory and lateral line neurons suggest dCu affects these neurons as well.

In this paper, a benchmark dose (concentration) analysis [35] is applied to recent data from dose-response experiments on juvenile salmonids exposed to dCu [10] to determine the exposure concentrations that may adversely affect salmonid sensory systems . In previous studies, BMCs were determined for olfactory responses, however concomitant behavioral responses were not measured [27, 30]. The BMC analysis conducted herein determined concentrations of dCu that could be expected to affect juvenile salmonid olfaction and, by extension, alarm response behavior involved in predator avoidance.

## Application of the benchmark concentration analysis

The benchmark concentration (BMC), also referred to as a Benchmark dose method, has been used since 1995 by agencies such as the Environmental Protection Agency (EPA) to determine No Observable Adverse Effect Level (NOAEL) values. The method statistically fits dose-response-data to determine NOAEL values [35]. This is in contrast to other methods (e.g. using an analysis of variance) that rely on finding a No Observable Effect Concentration (NOEC) and Lowest Observable Effect Concentration (LOEC) to establish the NOAEL. Multiple difficulties arising from the traditional approach of selecting a NOAEL from dose-response data were previously identified by EPA. Specific short comings associated with traditional methods included: 1) arbitrary selection of a NOAEL based on scientific judgments; 2) experiments involving fewer animals produced higher NOAELs; 3) dose-response slopes were largely ignored; and 4) the NOAEL was limited to the doses tested experimentally [35]. These as well as other concerns with selection of an NOAEL led to the development of an alternative approach, the BMC analysis. The BMC approach uses the complete dose-response dataset to identify a NOAEL, thereby selecting an exposure concentration that may not have been tested experimentally.

The BMC is statistically defined as the lower confidence limit for a dose that produces a predetermined adverse effect relative to controls. This effect is referred to as the benchmark response [BMR]) [35]. Unlike the traditional method of selecting the NOAEL (e.g. establishing a NOEC) the BMC takes into account the full range of dose-response data by fitting it with an appropriate mathematical model. These can be linear, logarithmic, sigmoidal, etc. The BMR is generally set near the lower limit of responses (e.g. an effect concentration of 10%) that can be measured directly in exposed, or affected, animals.

In the present context, a BMC approach was used to estimate thresholds for dCu's sublethal effects on the chemosensory physiology and predator avoidance behaviors of juvenile coho salmon [10]. An example of this approach is shown in Figure 3. This methodology has been used previously to determine toxicity thresholds in Pacific salmon [27, 30, 36]. The dose-response relationship for copper's effect on the EOG was described by fitting the data with a sigmoid logistic model:

$$y = m/[(1+(x/k)^n]$$

where m = maximum EOG amplitude (fixed at the control mean of 1.2 mV)

y = EOG amplitude

x = copper concentration

k = copper concentration at half-maximum EOG amplitude ($EC_{50}$)

n = slope

For this non-linear regression, the average olfactory response of the control fish to a natural odor was used to constrain the maximum odor evoked EOG (m in the above equation). Consequently, the control fish were not used in the regression other than to set *m*. The regression incorporated the individual response of each exposed fish (n = 44 total) rather than the average values for each exposure group. As shown in Figure 3, the sigmoid logistic model was a very good fit for both the sensory and behavioral data ($r^2$= 0.94; p<0.0001). Benchmark concentrations were then determined based on the concentration at which the estimated curve intersected benchmark responses.

## Results of the benchmark concentration analysis

Examples of benchmark concentrations and responses are presented in Figure 3 and Table 2. The EPA methodology recommends using the concentration that represents a 10% reduction in response compared to controls when limited biological effects data are available [37]. This is the $BMC_{10}$ and is synonymous with the concentration producing an effect of 10% ($EC_{10}$), in this case a 10% reduction in the recorded amplitude of the salmon's chemosensory response (EOG). Since the predicted fish EOG response at the $BMC_{10}$ falls well within the olfactory response of unexposed juveniles i.e. 95% CI (control fish; Figure 3), it is more than likely that this individual response (1.08 mV) at the $BMC_{10}$ (0.18 ug/L) would not be detectable or biologically significant as an adverse response. This highlights that a BMC based purely on a relative departure (e.g. $BMC_{10}$) may not account for the variability of olfactory responses in unexposed fish.

Other BMCs were derived using statistical criteria to determine benchmark responses. For example, Table 2 shows two BMCs that were determined using the statistical departure of the lower-bound confidence interval (CI) of the control mean (unexposed fish), 1.2 mV (either the 90 or 95% CI). The selection of different CIs results in different BMCs. The CI derived BMCs represent a reasonable estimate of when an individual salmonid is likely to have a significant reduction in olfaction and a concomitant reduction in predator avoidance behavior. The relative departures from controls in Table 2 are equivalent to effective concentrations for olfactory inhibition, i.e. at the lower-bound 90% CI a BMC of 0.59 µg/L equates to a $BMC_{24.2}$. Said another way, the BMC analysis predicts a substantial 24.2 % reduction in olfaction (i.e. EOG amplitude) at 0.59 µg/L dCu. At the lower-bound 95% CI a 29.2% reduction in olfaction is predicted to occur at 0.79 ug/L.

The $BMC_{50}$ is equivalent to the $EC_{50}$ for olfactory responses (2.1 µg/L) and is very similar to the lowest observable effect concentration (LOEC) of 2 µg/L. Since the EC50 approximately equals the LOEC, it is almost certain that effects to juvenile salmonid's olfaction will occur at lower concentrations than those measured. Therefore it is appropriate and useful to apply a BMC analysis to these data to predict effects occurring between 0 and 2 µg/L dCu. The predicted effect thresholds for sensory responses in juvenile coho ranged from 0.18 - 2.1 µg/L which corresponded to reductions in predator avoidance behavior (i.e. reduced alarm response) of 8 - 57%. Comparatively, the other two studies that conducted a BMC approach with salmon olfaction datasets (e.g. EOG measures) estimated dCu BMCs from 3.6 – 10.7 ug/L ($BMC_{20}$-$BMC_{50}$) [17] and 2.3 - 3.0 ug/L ($BMC_{25}$) [15].

Together these three studies highlight that different experimental conditions including age of fish, exposure duration, and experimental background of dCu may influence BMCs. Importantly, of the three experiments that derived BMCs for olfactory impairment, the Sandahl et al [10] (i.e. the data set used in this white paper) empirically linked impaired olfaction to an ecologically relevant behavior i.e. reduced alarm behavior (Figure 2). Therefore, we believe that the dCu BMC analysis in this white paper is the most ecologically relevant of the three studies.

Figure 3. Using a benchmark concentration approach to estimate a threshold for dCu toxicity in the salmonid olfactory system. Filled circles represent treatment means; error bars represent the 95% confidence interval for each mean (n = 8-12 individual coho salmon). An asterisk indicates a statistically significant difference in the size of the olfactory response (EOG data) compared to controls (one-way ANOVA with Dunnett post hoc test, $p<0.05$). The line represents a statistically significant non-linear regression based on individual fish ($n = 44$; $p < 0.0001$; $r^2 = 0.55$). The gray band shows the 95% confidence band for the non-linear regression. The regression used a standard sigmoid function with the maximum constrained to the control mean (1.2 mV; indicated by the upper horizontal dashed line). Therefore, the control fish were not included in the non-linear regression. The lower bound of the 95% confidence interval of the control mean (0.85 mV) is indicated by the lower horizontal dashed line and is an example of a benchmark response (BMR). The large open circle shows where the regression line crosses the BMR and denotes the corresponding benchmark concentration (BMC) which, in this case, is a dCu concentration of 0.79 ug/L. Horizontal and vertical lines through the open circle highlight the 95% confidence intervals for the BMC based on the results of the non-linear regression. The small open circle shows where the regression line crosses the BMR (1.08 mV) and denotes the corresponding $BMC_{10}$ (0.18 ug/L) at which a 10% reduction in olfactory capacity is expected. Data from Sandahl et al. [10].

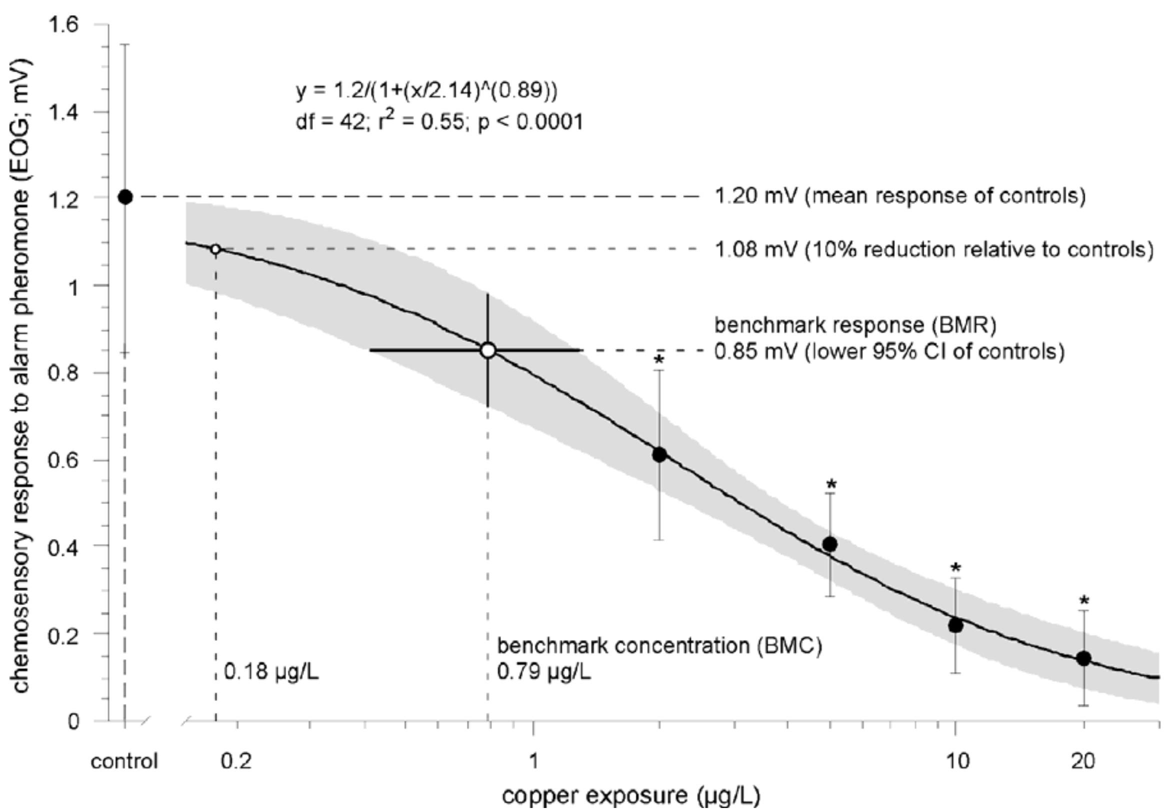


Table 2. Benchmark concentrations and benchmark responses for juvenile salmon exposed to dCu for 3 hr. Response values are a loss of olfactory function, or reduction in a chemosensory response to an alarm pheromone as measured via EOG recordings. Behavioral impairment indicates a predicted decrease in predator recognition and avoidance as indicated by a reduced alarm response. CI = confidence interval; NA = not applicable.

| **Benchmark Responses**[1] | | **Benchmark Concentrations**[2] | | **Behavioral Impairment (predicted)**[3] |
|---|---|---|---|---|
| Departure from mean of controls | | | | Departure from mean of controls |
| Statistical[4] (CI of control mean) | Relative[5] (% reduction in olfactory response) | Value[6] (µg/l) | 95% CI[7] (µg/l) | Relative[8] (% reduction in alarm response) |
| NA | 10.0 | 0.18 | 0.06 - 0.52 | 8.3 |
| Lower 90% | 24.2 | 0.59 | 0.30 - 1.16 | 25.6 |
| Lower 95% | 29.2 | 0.79 | 0.44 - 1.42 | 31.8 |
| NA | 50.0 | 2.10 | 1.60 - 2.90 | 57.2 |

## Discussion of site specific considerations for sensory system effects

Below, we identify several issues to consider when applying the benchmark concentrations to real world aquatic ecosystems.

*These BMCs reflect expected impairment of chemosensory systems from short term increases of dCu above ambient concentrations.*
Specifically, the BMCs are predicated on anthropogenic increases of dCu to salmon habitats. Effects to juvenile salmonid olfaction are expected following a few minutes of exposure. Salmonids are capable of regulating the amount of internal copper via uptake

and elimination processes. These so called homeostatic mechanisms (such as metallotheionein induction) can reduce copper's toxic effects and may result in acclimation. Consequently, fish may tolerate certain copper exposures without showing overt toxicological responses, however at higher levels these mechanisms ultimately fail. The BMC examples presented in Table 2 are not expected to be alleviated by juvenile salmonid homeostatic mechanisms. This is supported by the effect concentrations presented in Table 1 and the Appendix.

Although acclimation could theoretically reduce the toxicity of dCu to the salmon olfactory system, initial evidence indicates that this is not likely for pulsed or short term exposures lasting less than a week [11]. For other measures of copper toxicity from long term exposures, evidence suggests that acclimation may not occur (Table 1, Appendix).

These BMC examples represent short term increases of dCu above ambient concentrations in surface waters (defined here as < 3 μg/L) [10, 27, 30]. It is uncertain whether fish sensory systems acclimated to higher ambient concentrations (i.e. >3 μg/L) will respond differently to additional anthropogenic loading, which might then lead to different threshold concentrations for olfaction and behavior.

*These BMCs reflect the impact of dissolved copper on olfaction and predator avoidance behavior.*
In salmonid habitats fish are rarely exposed to dCu only. In fact, exposure to complex mixtures of other toxic compounds (e.g. metals, pesticides, PAHs, etc.,) in conjunction with other multiple stressors (e.g. elevated temperatures, low dissolved oxygen, etc.,) is the norm. Equally important are exposure routes other than the water column, such as consumption of contaminated prey items (dietary) or contact with contaminated sediments. Threshold examples (BMCs) presented here are based solely on juvenile salmonids exposed to dCu. Presently, these thresholds are uncertain for multiple routes of exposure and complex mixtures of contaminants for olfaction. That being said, several studies demonstrate greater than expected toxicity to other fish endpoints from mixtures of metals [12, 38]. For example, mixtures containing zinc and copper were found to have greater than additive toxicity to a wide variety of aquatic organisms including freshwater fish [9], and other metal mixtures also yielded greater than additive toxic effects at low dissolved metal concentrations [39]. The toxic effects of metals to salmonids are also likely to be exacerbated by poor water quality conditions, including elevated temperatures, low dissolved oxygen, pesticides, and polycyclic aromatic hydrocarbons. While the interactions of multiple stressors and mixtures are beyond the scope of this document, they warrant careful consideration in site specific assessments.

*These BMCs were derived from experiments using a single freshwater source (de-chlorinated, soft municipal water).* Hardness, alkalinity, and dissolved organic carbon (DOC) are known to alter the bioavailability of dissolved copper in surface waters to the gills of fish. These water chemistry parameters can therefore influence the potential for dCu exposure in the field to cause an acute fish kill. Acute copper lethality via the gill route of exposure is typically estimated using the Biotic Ligand Model (BLM; reviewed by [40]). However, recent unpublished research by McIntyre et al. [41] suggest that these parameters may have less influence on olfactory responses especially when compared to ambient levels of hardness, alkalinity, and DOC.

The USGS has monitored hardness, alkalinity, and DOC for more than 10 years in many West Coast river basins including the Willamette River Basin, Puget Sound Basin, Yakima River Basin, and the Sacramento-San Joaquin River Basin (National Water Quality Assessment Program [NAWQA]. Several at risk species of anadromous salmonids inhabit these basins. The monitoring data indicate that surface waters within these basins typically have very low hardness and alkalinity and seasonally-affected DOC concentrations. Hardness, alkalinity, and DOC levels found in most freshwater habitats occupied by Pacific salmonids would be unlikely to confer substantial protection against dCu olfactory toxicity [27], [41-43].

Recent experimental results suggest that significant amelioration of olfactory toxicity due to hardness is unlikely in typical Pacific salmonid freshwater habitats. The experiment showed that hardness at 20, 120, and 240 mg/L Ca (experimentally introduced as $CaCl_2$) did not significantly protect juvenile coho from olfactory toxicity following 30 minute laboratory exposures to 10 µg dCu/L above an experimental background of 3 µg/L [27]. In another experiment, a 20 µg dCu/L exposure (30 minutes) in water with low hardness and alkalinity and no DOC produced an 82% inhibition in juvenile coho olfactory function [41]. A hardness of ≥ 82 mg/L Ca was needed to reduce the level of olfactory inhibition to ≤50% at 20 ug/l dCu [41]. However, 82 mg/L was never exceeded in any of the surface water samples from USGS sampled NAWQA basins [41].

Typical alkalinity values from Pacific Northwest and California streams are also unlikely to protect salmonids from olfactory toxicity (NAWQA surface water data). In fact, 0.4% of stream samples contained alkalinity levels sufficient to cut dCu's toxic impact to juvenile salmonids olfactory system in half [41]. Decreases in dCu's olfactory toxicity were obtained with large increases in alkalinity [41]. However, increasing water hardness and alkalinity had some protective effect against the olfactory neurotoxicity of dCu in coho salmon, but the effects were small with olfactory function rising to ~30% of normal (or 15% increase in olfactory function) across the range of average hardness and alkalinity levels in sampled NAWQA basins [41]. Bjerselius et al., [43] and Winberg et al., [42] found that hardness and alkalinity provided limited amelioration of olfactory responses in juvenile Atlantic salmon exposed to dCu.

Increases in DOC showed greater protection to dCu compared to increases in alkalinity and hardness. Twenty-nine percent of USGS surface water samples from West Coast basins had a DOC concentration sufficient to limit olfactory impairment to 50 percent or less at 20 µg dCu /L [41]. However, only 2% of all samples contained a DOC concentration (8 mg/L) sufficient to completely protect the olfactory responses of juvenile coho at 20 µg dCu /L [41]. This information underscores the importance of evaluating site specific DOC data to address its potential influence on olfactory toxicity.

Accordingly, we consider the BMC thresholds presented in this document to be broadly applicable to most Pacific salmonid freshwater environments as typical hardness, alkalinity, and DOC concentrations are unlikely to confer substantial protection against dCu olfactory toxicity.

*Dissolved copper's effect on salmonid olfaction in saltwater environments remains a recognized data gap and it is unclear whether the derived BMC thresholds apply to salt water environments.* Estuarine and near shore salt water environments, despite their higher salinity (in part due to increased cation concentrations) and hardness may or may not confer protection against dCu-induced olfactory toxicity. One source of this uncertainty is whether or not free copper ($Cu^{2+}$) is the sole species of copper responsible for olfactory toxicity. In freshwater, evidence suggests that $Cu^{2+}$ is not the only toxic species that adversely affects olfaction [41] and other fish endpoints including mortality [40]. Other copper species e.g. CuOH ($Cu^{1+}$) will also bind to the gill producing copper toxicity [40]. While the physiology of a salmonid's olfaction in freshwater environments is well characterized, it is unclear whether the physiological changes to olfactory systems in estuarine and marine environments alter the toxicity of dCu.

*Using the Biotic Ligand Model we calculated an acute Criterion Maximum Concentration (CMC).* The United States Environmental Protection Agency (EPA) sets acute water quality criteria by calculating an acute Criterion Maximum Concentration (CMC) [44]. The CMC is an estimate of the highest concentration of a material in surface water to which an aquatic community can be exposed briefly without resulting in an unacceptable effect [45].We calculated an acute CMC using the Biotic Ligand Model (BLM) [46]. Interestingly, the estimated acute CMC based on the BLM using measured and estimated water quality parameters from Sandahl et. al. [10] was 0.63 µg/L with a range from 0.34 to 3.2 µg/L, while the EPA hardness-based acute CMC [45] was 6.7 µg/L. Because the BLM-based acute criterion is sensitive to pH and DOC, the range of measured test pH values (6.5 to 7.1) and the range of estimated DOC values (0.3 to 1.5 mg/L) produced this range of BLM-based acute criterion values. It is also interesting that the acute CMC range (0.34 - 3.2 ug/L) overlapped with the olfactory based BMC range (0.18 – 2.1 ug/L).

*Juvenile salmonids may or may not be able to avoid short term increases in dCu.* Salmonids will actively avoid water containing dCu if they can detect it. However, if salmonids avoid optimal rearing and spawning habitats reductions in growth and reproductive success may occur. One study showed that chinook salmon no longer avoided copper following a 20 day exposure at a low, environmentally realistic concentration (2 ug/L) [11]. Since salmonids have the ability to avoid areas with elevated copper, in theory, if these areas were limited and did not interfere with migratory routes, juveniles might simply bypass them. Smith and Bailey [47] and Mebane [13] give examples of deriving regulatory "zones of passage" around wastewater discharges that were based upon salmonid avoidance responses. However, in areas with diffuse, nonpoint source pollution, or multiple point source discharges it may be difficult to determine "zones of passage", or available zones of passage may not even exist. Environmental circumstances may force fish to be exposed to copper they would otherwise detect and avoid, or fish will avoid using important habitats. The "zones of passage" concept would likely not apply to rearing or spawning habitats affected by dCu.

Anthropogenic loading of dCu to surface waters often occurs as stormwater runoff and other types of short term, pulsed inputs lasting a few minutes to hours and in some cases days. In this context, dCu's effect on olfaction manifests in as little as 10 minutes [27]. Recovery of affected olfactory sensory function will require hours to weeks depending on the extent of olfactory damage, which depends on both concentration and duration of exposure [28]. Acute exposure can inhibit olfactory function for months if exposure is sufficient to cause death to sensory neurons (25ug/L [11,26]) [33]. The impacts of copper on fish olfaction will likely be cumulative if full recovery is not achieved between pulses of exposure.

*These BMCs were derived using data from juvenile coho salmon.*
The examples of BMC thresholds were derived from data based on juvenile Coho salmon (4-5 month old; mean of 0.9 grams [wet weight]). These BMC examples are generally applicable to juvenile salmonids. Three hour exposures of four month old steelhead to a similar range of dCu produced comparable reductions in EOG as seen in four month old coho (Baldwin et al.,personal communication). Studies on 10 month old juvenile coho had similar reductions in olfaction compared to 4 month old fish [27, 30]. Juvenile chum salmon (2-3 month old) also showed a dose dependent reduction in EOG amplitude following exposure to dCu (3-58 ug/L) [28]. Taken together these data support applying the BMC threshold examples broadly to juvenile salmonids. While olfaction is certainly critical to all salmonid lifestages, the application of these thresholds to other life stages (i.e. smolts and adults) remains uncertain.

**Conclusions**

Dissolved copper (dCu) is a ubiquitous, bioavailable pollutant that can directly interfere with fish sensory systems and by extension important behaviors that underlie predator avoidance, juvenile growth, and migratory success (see appendix). Recent research shows that dCu not only impairs sensory neurons in a salmonid's nose, but also impairs juvenile salmonids' ability to detect and respond to predation cues. A juvenile salmonid with disrupted predator avoidance behaviors stands a much greater risk of being eaten and therefore the likelihood of surviving to reproduce is reduced. Whether this individual behavioral effect impacts a given population will depend, in part, on the number of the individuals affected and the status of the population (numbers, distribution, growth rate, etc.).

In this paper, benchmark concentrations (BMC) were calculated using an EPA methodology to provide effect threshold examples for juvenile salmonids' sensory systems. The BMC examples represent the dCu concentration (above background or ambient levels [where background is less than or equal to 3 ug/L) expected to affect juvenile salmonids' ability to avoid predators in fresh water. Benchmark concentrations ranged from 0.18 – 2.1 µg/L corresponding to reductions in predator avoidance behavior (an alarm response) from approximately 8 – 57%. Taking into account the olfactory responses of unexposed fish (e.g. control treatment), a more biologically relevant range of BMCs is 0.59 – 2.1 ug/L (Table 2). This second range of BMC thresholds for juvenile salmonid sensory and behavioral responses is similar to or slightly less than documented effect concentrations to other copper-affected sublethal endpoints such as behavior, and growth., 0.75 - 2.5 µg/L. These levels may also affect other organisms in the ecosystem upon which salmonids depend, for feeding and sheltering (Table 1 and Appendix).

The primary objective of this paper was to present examples of threshold concentrations for effects of dCu on a critical aspect of salmonid biology, olfaction. A secondary objective of this paper was to summarize a selection of recent and historical information related to the effects of dCu on salmonid sensory systems. Importantly, this overview is not a comprehensive summary of the myriad effects of copper to anadromous salmonids. However, several conclusions were made based on the studies reviewed thus far and in the appendix concerning juvenile salmonids. First, salmonid's and other fish's behavior can be disrupted at dCu concentrations in the low ppb range. Second, reduced growth and impaired swimming performance resulted following dCu exposures as discussed in the appendix. These effects may result in increased susceptibility to predation and may result in population level consequences. Third, in some freshwater systems it is likely that acute toxicity occurs from brief pulses of elevated dCu concentrations.

Taken together, the information reviewed and presented herein indicates that significant impairment of sensory functions important to survival of threatened and endangered juvenile salmonids is likely to be widespread in many freshwater aquatic habitats. Impairment of these essential behaviors may occur following ten minutes of exposure and continue for hours to weeks depending on concentration and duration. Due to these acute, sublethal responses i.e. within minutes, avoidance or acclimation are unlikely to reduce the effects of short term anthropogenic increases of dCu to juvenile salmonids.

It remains uncertain how and to what degree these short term dCu exposures of juvenile salmonids affect salmonid populations. What is certain is that salmonids use their sense of smell to avoid predation events, participate in reproduction, migrate, avoid poor water quality, and feed. Each of these olfactory-mediated behaviors is important for successful lifecycle completion.

This technical white paper is a summary and targeted synthesis regarding sensory effects to juvenile salmonids from low-level exposures to dissolved copper (dCu). As such, the material presented in this paper serves to summarize research on dCu and its impacts on salmonid sensory systems. This document is a snap shot of the existing information; undoubtedly, new information will become available that enhances our understanding of copper's effect on salmonid populations and their supporting habitat.

## Appendix:
## Other salmonid sensory effects of dissolved copper

In this appendix, results are highlighted from several studies that we thought were particularly relevant, including comparing the concentrations that have caused sensory effects to concentrations causing lethality or growth reductions in field and laboratory experiments. As such, the following review is not an exhaustive summary of copper's adverse effects to anadromous salmonids. We emphasize studies that were conducted in waters with low alkalinity and hardness (< 50 mg/L as calcium carbonate), and if reported, low concentrations of dissolved organic material. These conditions were emphasized since we believe these are the most relevant water quality conditions for an area of particular concern to us – freshwater habitats used by juvenile salmonids in the Pacific Northwest and California, USA.

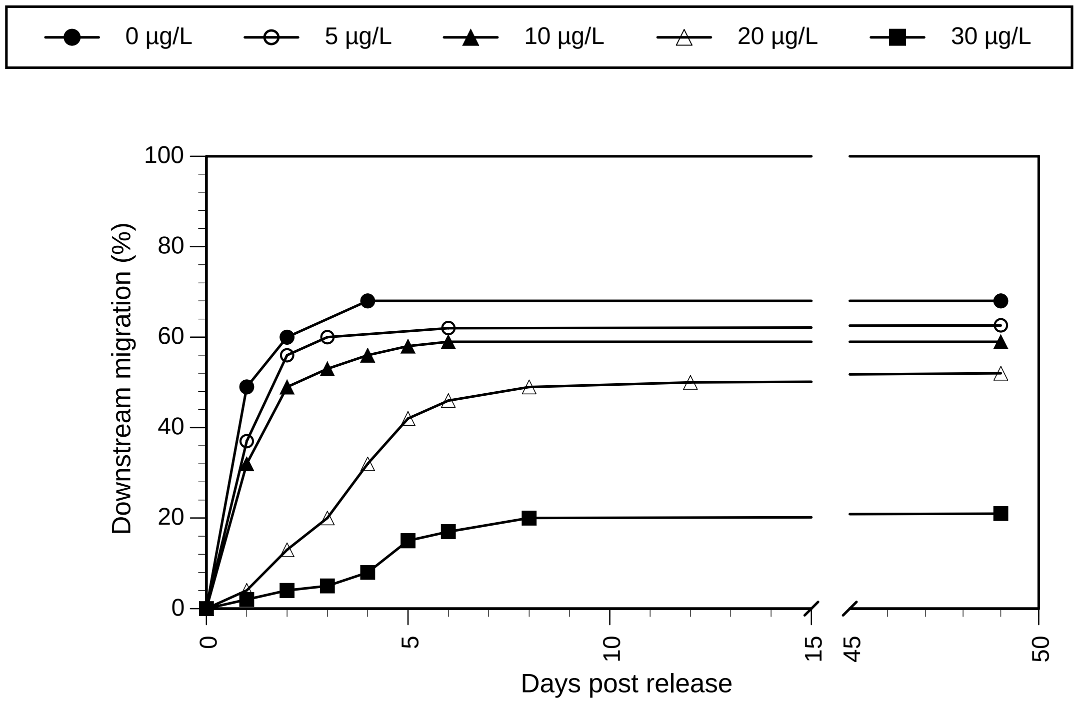
**Migratory disruption**

Laboratory and field experiments with salmonids have shown avoidance of low concentrations of copper, disruption of downstream migration by juvenile salmonids, loss of homing ability, and loss of avoidance response to even acutely lethal concentrations of copper follow long term habituation to low level copper exposure. Saucier et al. [16] examined the impact of a long-term sublethal copper exposure (22 ug/L; 37-41 weeks in duration) on the olfactory discrimination performance in rainbow trout. When controls were given a choice between their own rearing water or other waters, they significantly preferred their own rearing water, whereas both copper-exposed groups showed no preference. They concluded that their results demonstrate that a long-term sublethal exposure to copper, as it commonly occurs under "natural" conditions, may result in olfactory dysfunction with potential impacts on fish survival and reproduction.

Field studies have reported that copper impairs both upstream spawning migration of salmonids and downstream out migration of juveniles. Avoidance of copper in the wild has been demonstrated to delay upstream passage of Atlantic salmon moving past copper-contaminated reaches of the river to their upstream spawning grounds, unnatural downstream movement by adults away from the spawning grounds, and by increased straying from their contaminated home stream into uncontaminated tributaries. Avoidance thresholds in the wild of 0.35 to 0.43 toxic units were about 7-times higher than laboratory avoidance thresholds (0.05 toxic units) perhaps because the laboratory tests used juvenile fish rather than more motivated spawning adults. For this study 1.0 toxic unit was defined as an incipient lethal level, ILL (essentially a time independent $LC_{50}$), of 48 µg/l in soft water [12, 48]. Studies of home-water selection with returning adult salmon showed that addition of 44 µg/l copper to their home-water reduced the selection of their home stream by 90% [49]. Releases of about 20 µg/l from a mine drainage into a salmon spawning river resulted in 10 - 22% repulsion of ascending salmon during four consecutive years compared to 1- 2% prior to mining [49]. The upstream spawning migration of Chinook salmon in Panther Creek, Idaho may have been interrupted during the 1980s and early 1990s when the fish encountered dCu concentrations of 10- 25 µg/l. In Panther Creek, the majority of spawning habitat and historical locations of Chinook spawning were high in the watershed, upstream of copper discharges. However, Chinook were only observed spawning below the first major diluting tributary, a point above which copper concentrations averaged about 10- 25 µg/l during the times of the spawning observations [13, 50].

Sublethal copper exposure has been shown to interfere with the downstream migration to the ocean of yearling coho salmon. Lorz and McPherson [14, 15] and Lorz et al. [51] evaluated the effects of copper exposure on salmon smolts' downstream migration success in a series of 14 field experiments. Lorz and McPherson [14, 15] exposed yearling coho salmon for six to 165 days to nominal copper concentrations varying from 0 - 30 µg/l. They then marked and released the fish during the normal coho migration period and monitored downstream migration success. The fish were released simultaneously, allowing for evaluation of both copper exposure concentrations and exposure duration on migration success. All dCu exposures resulted in reduction of migration compared with unexposed control fish. Migration success decreased with both increasing copper concentrations and increased exposure time for each respective concentration. Exposure to 30 µg/l dCu for as little as 72 hours caused a considerable reduction in migration (~60%) compared to control fish. The reductions in migration following short-term exposures to dCu are illustrated in Figure 4, which was re-drawn from Lorz and McPherson [14]. Following exposure to 30 ug/L dCu, 80% of coho did not reach the migratory point in 49 days. These concentrations (5-20 ug/L) were one-tenth to one-third the 96-hour $LC_{50}$ for the same stock of juvenile coho salmon in the same water. Lorz et al. [51] further tested downstream migration with yearling coho salmon previously exposed to copper, cadmium, copper-cadmium mixtures, zinc, and copper-zinc mixtures. Copper concentrations in all tests were held at 10 µg/l. In all cases, the copper exposed fish again had poorer migratory success than did controls. The other metals did not show the dose-dependent result found for copper. These studies suggest that exposure to copper concentrations at levels found in streams subject to nonpoint copper pollution may impair downstream migration, a result of direct and indirect effects to salmon smolts, including reproductive success.

Figure 4.  Reduction in downstream migration of yearling coho salmon following 6-days exposure to copper at various concentrations.  Redrawn from Lorz and McPherson [14], their figure 19.



## Laboratory avoidance studies

Studies have shown that salmonids can detect and avoid copper at low concentrations when tested in troughs or streams that allow them to choose between concentration gradients.  To our knowledge, the lowest copper concentration reported to cause avoidance in laboratory conditions was 0.1 µg/L [52].  However, these results may have low applicability to ambient conditions because copper exposure concentrations were not analytically verified. Avoidance thresholds of 2 µg/l copper have been reported for Atlantic salmon (*Salmo salar*), concentrations that are less than one-tenth of acute LC50 values [48].  Giattina et al. [53] reported that rainbow trout appeared to detect copper concentrations down to 1.4 to 2.7 µg/L, because declines in residence time started to occur at these lower concentrations.  However, the responses were only statistically significant at 4.4 to 6.4 µg/l depending on whether fish were exposed to a gradually increasing or abruptly increasing concentration gradient respectively.  At exposure to extremely high dCu levels e.g. 330-390 µg/L, trout showed diminished avoidance and sometimes attraction to acutely lethal concentrations [11,53,54].

Chapman [54] reported that long-term sublethal copper exposures had impaired the avoidance performance of salmonids.  Steelhead trout, acclimated to low copper levels by surviving about three-months early life stage toxicity testing, subsequently failed to avoid much higher, acutely lethal concentrations.  Following about three-month continuous exposure to 9 µg/l copper (from fertilization to about 1-month after swim up) the copper-acclimated fish and control fish with no previous copper exposure were exposed to a range of copper concentrations from 10 to 80 µg/l in avoidance-preference testing. The tests used the same counter flow avoidance-preference test chambers described by Giattina et al. [53]. The acclimated trout failed to avoid even the highest copper concentrations while most of the unexposed fish avoided all concentrations.

Hansen et al. [11] and Marr et al. [55] conducted a variety of behavioral and other toxicity studies with Chinook salmon and rainbow trout exposed to copper. In these studies they used well water that was diluted with deionized water and spiked with copper to obtain a hardness, alkalinity, and pH that simulated those in Panther Creek, a mine-affected stream in Idaho. The avoidance response of the Chinook salmon was statistically significant for 0.8 and 2.8 -22.5 µg/L copper but was not significant for a 1.6 µg/L copper treatment. Since the avoidance responses (percent time spent in test water) were similar between the 0.8, 1.6, and 3 µg/L treatments, but the 1.6 µg/L treatment had fewer replicates than the other treatments (10 vs. 20), the lack of statistical significance for the 1.6 µg/L treatment was probably an artifact of the different sample sizes than a true lack of response. Rainbow trout consistently avoided copper at concentrations of 1.6 µg/L and above. To simulate avoidance responses that might result upon exposing fish to background levels of copper, Hansen et al. [11] acclimated both Chinook salmon and rainbow trout to 2 µg/L copper for 25 days, and repeated the avoidance experiments. They observed that the avoidance response of Chinook salmon was greatly dampened such that no copper treatments resulted in statistically significant responses. In contrast, the avoidance response of rainbow trout was unaffected by the acclimation. This dramatic difference between Chinook salmon and rainbow trout avoidance was so unexpected that Hansen et al. [11] ran a second set of experiments that yielded the same results. Background dCu concentrations (<4 µg/L) are commonly observed in natural waterways, yet Chinook salmon failed to avoid any higher dCu concentrations following an acclimation to a nominal 2 µg dCu/L. Importantly, if Chinook salmon will not avoid any dCu concentrations following acclimation to low dCu concentrations, the behavioral defense against chronic and acute exposures to dCu is lost, and high mortality or chronic physiological effects are probable if subsequent higher levels of dCu exposure occur. Unlike Chinook salmon, dCu-acclimated rainbow trout preferred clean water and avoided higher dCu concentrations. Other differences between Chinook salmon and rainbow trout avoidance responses to copper were that addition of 4 and 8 mg/L dissolved organic carbon (DOC) did not appreciably affect the avoidance response of Chinook salmon to copper, nor did altering pH across a range of 6.5 to 8.5. In contrast, the addition of DOC (4 and 8 mg/L) did reduce the avoidance response of rainbow trout to copper. Although variable, avoidance responses of rainbow trout were slightly stronger at pH 7.5 and 8.5 than at 6.5 [55].

A further repeated finding from these laboratory avoidance tests was that although rainbow trout, steelhead, and Chinook salmon avoided low concentrations of dCu, they were apparently intoxicated and sometimes attracted to very high concentrations [11, 53, 54]. The direct relevance of laboratory avoidance studies to the behaviors of fish in the wild is debatable since in natural waters fish likely select and move among habitats based on myriad reasons such as access to prey, shelter from predators, shade, velocity, temperature, and interactions with other fish. In contrast, laboratory preference/avoidance tests are commonly conducted under simple, highly artificial conditions to eliminate or minimize confounding variables other than the water characteristic of interest. Laboratory tests may overestimate the actual protection this behavior provides fish in heterogeneous, natural environments [56-58].

However, at least one study suggested that experimental avoidance responses observed with salmonids are relevant to fish behaviors in the wild. From 1980-1982, sub-lethal levels of a contaminant (fluoride) from an aluminum mill at the John Day Dam on the Columbia River were associated with a significant delay in salmon passage and decreased survival [59]. Salmon took an average of 36 hours to pass up the fish ladder at the Bonneville and McNary dams compared to 157 hours delay at the John Day Dam. Greater than 50% mortality occurred between the Bonneville and McNary dams (above and below the John Day dam), compared to about 2% mortality associated with the other dams. Damkaer and Dey [59] introduced similar levels of the contaminant in streamside test-flumes alongside a salmon spawning stream (Big Beef Creek, Washington). Significant numbers of adult Chinook salmon failed to move out of their holding area and continue upstream; those that did move upstream chose the non-contaminated side of the flume. By adjusting the dose, Damkaer and Dey [59] predicted a threshold detection limit for avoidance by salmon. The mill subsequently reduced its release of the contaminant to below these experimental threshold levels that did not show a response in the streamside tests. Afterwards, fish passage delays and salmon mortality between the dams decreased to 28 hours and <5%, respectively [59]. This study suggested that the delay due to avoidance of a chemical affected the spawning success of migrating adult salmonids. These results are also consistent with the field studies of salmon migration in copper-contaminated streams and from laboratory avoidance/preference testing. Experimental avoidance/preference testing thus appears to be relevant to fish behavior in nature.

### Other adverse effects

The focus of this literature synthesis is sensory effects of copper on juvenile salmonids. However, other adverse effects of copper to salmonids reported in the literature include weakened immune function and disease resistance, increased susceptibility to stress, liver damage, reduced growth, impaired swimming performance, weakened eggshells, and direct mortality [19, 20, 60-66] . While a comprehensive review of other adverse effects of copper on fish is beyond the scope of this synthesis, we discuss several studies of interest below.

Stevens [65] reported that pre-exposure to sublethal levels of dCu interfered with the immune response and reduced the disease resistance in yearling coho salmon. Juvenile coho salmon were vaccinated with the bacterial pathogen *Vibrio anguillarum* prior to copper exposure to investigate the effects of copper upon the immune response and survival. Following copper exposure (9.6 - 40 μg/L), surviving juveniles were challenged under natural conditions to *V. anguillarum*, the causative agent of vibriosis in fish. Vibriosis is a disease commonly found in wild and captive fish from marine environments and has caused deaths of coho and Chinook salmon. Coho were exposed to constant concentrations of dCu for about one month at levels that covered the range from no effect to causing 100% mortality, 9.6 - 40 µg/L. The antibody titer level against *V. anguillarum* was significantly reduced in fish exposed to 13.9 µg/L of dCu when compared to that developed in control fish. The survivors of the dCu bioassays were then exposed in saltwater holding ponds for an additional 24 days to the *V. anguillarum* pathogen. The unvaccinated, non-dCu exposed control fish had 100% mortality and the vaccinated, non-dCu exposed fish had the lowest mortality. The vaccinated, dCu-exposed fish had increasing mortality corresponding to the lower antibody titer levels which in turn corresponded to the increasing dCu exposure levels. Therefore, dCu exposure can significantly reduce a fish's immune function and disease resistance at concentrations as low as 13.9 µg/L following 30 days of exposure [65].

Schreck and Lorz [60] studied the effects of copper exposure to stress resistance in yearling coho salmon. Fish that were exposed for 7 days to 15 µg/L dCu and unexposed control fish were subjected to severe handling and confinement stress. Copper-exposed fish survived this additional stress for a median of 12-15 hours while control fish experienced no mortality at 36 hours. Schreck and Lorz concluded that exposure to copper placed a sublethal stress on the fish which made them more vulnerable to handling and saltwater adaptation. Further, they hypothesized that dCu exposure may make salmonids more vulnerable to secondary stresses such as disease and pursuit by predators.

Exposure of brook trout eggs to 17.4 µg dCu/L for 90 days resulted in weakened chorions (eggshells) and embryo deformities. After hatching, poor yolk utilization and reduced growth were demonstrated. These overall weakened conditions may reduce survival chances in the wild [67, 68]. Copper accumulation in the liver of rainbow trout caused degeneration of liver hepatocytes, which resulted in reduced ability to metabolize food, reduced growth, or eventual death [17, 63, 69]. Waiwood and Beamish [61], Chapman [19], Seim et al. [70], McKim and Benoit [62], and Marr [20] have also observed reduced growth of salmonids in response to chronic copper exposures as low as 1.9 ug/L. Waiwood and Beamish [66] reported that rainbow trout exposed to copper levels had reduced swimming performance (10, 15, 20, 30 ug/L dCu) and reduced oxygen consumption (25, 40 ug/L dCu) apparently due to gill damage and decreased efficiency of gas exchange.

In sum, there is a large body of literature showing that behavior of salmonids and other fishes can be disrupted at concentrations of dCu that are only slightly elevated above background concentrations. Further, dCu stress has been shown to increase the cost of maintenance to fish and to limit oxygen consumption and food metabolism. Reduced growth may result in increased susceptibility to predation, and impaired swimming ability may result in reduced escape reaction and prey hunting, with a possible consequence of reduced survival at the population level. We summarize selected examples of effect concentrations reported with copper for several different types of effects in Table 2. In general, typical copper exposures probably do not kill juvenile salmonids directly until concentrations greater than about 10 times that of sensory thresholds, and then only if the concentrations are sustained for at least several hours. In selecting these examples, we sought to list representative effects and concentrations rather than extreme values that could be gleaned from the literature. However, the selected examples do not constitute an exhaustive review of the effects of copper to fish; more general reviews of effects of copper to fish and other aquatic organisms are available elsewhere [9, 17, 46, 71].

## Abstract

From 5 April – 21 September 2012 we monitored the distribution, abundance and productivity of the federally Threatened Western Snowy Plover (*Charadrius nivosus nivosus*) along the Oregon coast. From north to south, we surveyed and monitored plover activity at Sutton Beach, Siltcoos River estuary, the Dunes Overlook, North Tahkenitch Creek, Tenmile Creek, Coos Bay North Spit, Bandon Snowy Plover Management Area, New River HRA and adjacent lands, and Floras Lake. Our objectives for the Oregon coastal population in 2012 were to: 1) estimate the size of the adult Snowy Plover population, 2) locate plover nests, 3) determine nest success, 4) use mini-exclosures (MEs) to protect nests from predators as needed, 5) determine fledging success, 6) monitor brood movements, 7) collect general observational data about predators, and 8) evaluate the effectiveness of predator management.

We observed an estimated 290-91 adult Snowy Plovers; a minimum of 231-238 individuals was known to have nested. The adult plover population was the highest estimate recorded since monitoring began in 1990. We monitored 314 nests in 2012; the highest number of nests since monitoring began in 1990. Overall apparent nest success was 45%. Exclosed nests (n = 22) had an 82% apparent nest success rate, and unexclosed nests (n = 289) had a 42% apparent nest success rate. Nest failures were attributed to unknown depredation, unknown cause, corvid depredation, abandonment, one egg nests, wind/weather, mammalian depredation, overwashing, adult plover depredation, and infertility. We monitored 154 broods, including 11 from unknown nests, and documented a minimum of 173 fledglings. Overall brood success was 70%, fledging success was 43%, and 1.37 fledglings per male were produced.

Continued predator management, habitat improvement and maintenance, and management of recreational activities at all sites are recommended to achieve recovery goals.

**TABLE OF CONTENTS**

## Introduction

The Western Snowy Plover (*Charadrius nivosus nivosus*) breeds along the coast of the Pacific Ocean in California, Oregon, and Washington and at alkaline lakes in the interior of the western United States (Page *et al.* 1991). Loss of habitat, predation pressures, and disturbance have caused the decline of the coastal population of Snowy Plovers and led to the listing of the Pacific Coast Population of Western Snowy Plovers as Threatened on March 5, 1993 (U.S. Fish and Wildlife Service 1993). Oregon Department of Fish and Wildlife lists the Western Snowy Plover as threatened throughout the state (ODFW 2009).

Oregon Biodiversity Information Center (ORBIC, formerly Oregon Natural Heritage Information Center) completed our 23$^{nd}$ year of monitoring the distribution, abundance, and productivity of Snowy Plovers along the Oregon coast during the breeding season. In cooperation with federal and state agencies, plover management has focused on habitat restoration and maintenance at breeding sites, non-lethal and lethal predator management, and management of human related disturbances to nesting plovers. The goal of management is improved annual productivity leading to increases in Oregon's breeding population and eventually sustainable productivity and stable populations at recovery levels. Previous work and results have been summarized in annual reports (Stern *et al.* 1990 and 1991, Craig *et al.* 1992, Casler *et al.* 1993, Hallett *et al.* 1994, 1995, Estelle *et al.* 1997, Castelein *et al.* 1997, 1998, 2000a, 2000b, 2001, and 2002, and Lauten *et al.* 2003, 2005, 2006, 2006b, 2007, 2008, 2009, 2010, and 2011). Our objectives for the Oregon coastal population in 2012 were to: 1) estimate the size of the adult Snowy Plover population, 2) locate plover nests, 3) determine nest success, 4) use mini-exclosures (MEs) to protect nests from predators as needed, 5) determine fledging success, 6) monitor brood movements, 7) collect general observational data about predators, and 8) evaluate the effectiveness of predator management. The results of these efforts are presented in this report.

## Study Area

We surveyed Snowy Plover breeding habitat along the Oregon coast, including ocean beaches, sandy spits, ocean-overwashed areas within sand dunes dominated by European beachgrass (*Ammophila arenaria*), open estuarine areas with sand flats, a dredge spoil site, and several habitat restoration/management sites. From north to south, we surveyed and monitored plover activity at Sutton Beach, Siltcoos River estuary, the Dunes Overlook, North Tahkenitch Creek, Tenmile Creek, Coos Bay North Spit (CBNS), Bandon Snowy Plover Management Area (SPMA), New River (extending from private land south of Bandon SPMA to the south end of the New River Area of Critical Environmental Concern (ACEC) habitat restoration area), and Floras Lake (Figure 1). A description of each site occurs in Appendix A. For the purposes of this report and for consistency with previous years' data, we define Bandon Beach as the area from China Creek to the mouth of New River, and Bandon SPMA as all the state land from the north end of the China Creek parking lot south to the south boundary of the State Natural Area south of the mouth of New River.

## Methods

### Abundance

In 2012, state and federal agency personnel and volunteers conducted pre-breeding window surveys at historical nesting sites between Clatsop Spit, Clatsop Co. and Pistol River, Curry Co (Elliott-Smith and Haig 2007). Pre-breeding surveys have been implemented since 2001 to locate any plovers attempting to nest at historic (currently inactive) nesting areas. Agency personnel also assisted surveying plovers during breeding season window surveys in late May and early June. Breeding season window surveys were implemented at both currently active and historic nesting areas (Elliott-Smith and Haig 2007). Historic nesting areas surveyed in either early spring or during the breeding window survey include: Clatsop Spit, Necanicum Spit, Nehalem Spit, Bayocean Spit, Netarts Spit, Sand Lake South Spit, Nestucca Spit, Whiskey Run to Coquille River, Sixes River South Spit, Elk River, Euchre Creek, and Pistol River.

**Monitoring**

Breeding season fieldwork was conducted from 5 April to 21 September 2012. Survey techniques, data collection methodology, and information regarding locating and documenting nests can be found in Castelein *et al.* 2000a, 2000b, 2001, 2002, and Lauten *et al.* 2003 and are in Appendix D. No modifications to survey techniques were implemented in 2012.

We report three measures of population size: the total number of Snowy Plovers present, the total number identified breeding, and the total number of plovers resident during the breeding season. We estimated the number of Snowy Plovers on the Oregon coast during the 2012 breeding season by determining the number of uniquely color-banded adult Snowy Plovers observed, and added an estimate of the number of unbanded Snowy Plovers present. We used the 10 day interval method described in Castelein *et al.* 2001 to estimate a minimum number of unbanded plovers, however, based on nesting records and daily observational data this method underestimates the actual number of unbanded plovers present. We use this number to give a minimum range of the number of unbanded plovers in the population. We estimated the breeding population by tallying the number of known breeding plovers. Not all plovers recorded during the summer are Oregon breeding plovers; some plovers are recorded early or late in the breeding season indicating that they are either migrant or wintering birds. Plovers that were present throughout or during the breeding season but were not confirmed breeders were considered Oregon resident plovers. We estimated an overall Oregon resident plover population by adding the known breeders with the number of plovers present but not confirmed nesting during the breeding season.

We determined the number of individual banded female and male plovers and the number of individual unbanded female and male plovers that were recorded at each nesting area along the Oregon coast from the beginning to the end of the 2012 breeding season. Data from nesting sites with a north and south component (Siltcoos, Overlook, and Tenmile) were pooled because individual plovers use both sides of these estuaries. Data from CBNS nesting sites were pooled for the same reason. We separated data from Bandon SPMA, New River HRA, and Floras Lake because of different management at these sites, despite plovers frequently moving between these areas. The total number of individual plovers recorded at each site indicates the overall use of the site, particularly where plovers congregate during post breeding and wintering. We also determined the number of individual breeding female and male plovers for each site. The number of individual breeding adults indicates the level of nesting activity for each site.

Using all nests, we calculated overall apparent nest success, which is the number of successful nests divided by the total number of nests, for all nests and for each individual site. We also calculated apparent nest success for exclosed and unexclosed nests and used Chi-squared analysis to compare the success of exclosed and unexclosed nests.

Male Snowy Plovers typically rear their broods until fledging. In order to track the broods we banded most nesting adult males, females that tended to broods, and most hatch-year birds with both a

USFWS aluminum band and a combination of colored plastic bands. Trapping techniques are described in Lauten *et al.* 2005 and 2006 (Appendix D). We monitored broods and recorded brood activity or adults exhibiting broody behavior at each site (Page et al. 2009). Chicks were considered fledged when they were observed 28 days after hatching.

We calculated brood success, the number of broods that successfully fledged at least one chick; fledging success, the number of chicks that fledged divided by the number of eggs that hatched; and fledglings per male for each site. Statistical analysis of nest, chick, and adult survival will be published in a refereed journal.

We continue to review plover productivity prior to lethal predator management activities compared to productivity after implementation of lethal predator management. We specifically continue to evaluate the changes in hatch rate, fledging rate, productivity index, and fledglings per male from years prior to lethal predator management compared to years with lethal predator management. The productivity index is a measure of overall effort based on how many eggs the plovers laid divided by the number of fledglings produced. If plovers produced high numbers of fledglings compared to eggs laid, then their productivity was high for the amount of effort (eggs laid) and the productivity index would be high. If plovers produced low numbers of fledglings compared to high numbers of eggs laid, then their productivity was low and the productivity index would be low. Data for brood success, fledging success, and fledglings per male were all normally distributed. We used t-test to compare the mean brood success, the mean fledging rate and the mean number of fledglings per male prior to predator management (1992-2001) to post predator management (2004-2011). We did not include the years 2002 and 2003 in the analysis because three sites (CBNS, Bandon Beach, and New River) had predator management in those years but all other sites did not.

**Exclosures**

From mid-May to August, we used a limited number of mini-exclosures (MEs, Lauten *et al.* 2003) to protect plover nests at North and South Overlook, North Tahkenitch, Bandon SPMA and New River as outlined in our exclosure use protocol (Appendix C). No exclosures were used on plover nests found during April and into early May due to concerns related to raptor migration (Castelein *et al.* 2001, 2002, Lauten *et al.* 2003). Exclosure use was limited in 2012 due to good unexclosed hatch rates at Siltcoos, Overlook, North Tahkenitch, and Coos Bay North Spit and due to adult plover depredation concerns in and around ME's, particularly at Tenmile. No exclosures were used at North and South Siltcoos, North and South Tenmile, Coos Bay North Spit, and Floras Lake.

**Predator Management**

Lethal predator management occurred at all active nesting areas; corvids (*Corvus sp.*) were targeted at all nesting sites. Some mammal trapping, specifically targeting red fox (*Vulpes vulpes*), striped skunks (*Mephitis mephitis*), and coyote (*Canis latrans*) occurred at specific sites. In 2011 a trapping effort targeting deer mice (*Peromyscus maniculatus*) was implemented at CBNS (Lauten *et al.*, 2011). In 2012 deer mice were again targeted on a portion of the habitat restoration area (HRA) by several students from Southwest Oregon Community College. Rodent trapping was limited to March, before the plovers were nesting. This trapping effort helped to assess the rodent population compared to the previous year's results while also potentially reducing rodent depredations on plover eggs. For information regarding the predator management program, see Burrell (2012).

## Results and Discussion

### Abundance and Monitoring

#### Window Surveys

During the pre-breeding April surveys of beaches with no current nesting activity, one plover was recorded along the Whiskey Run to Coquille River (Coos Co.) survey route, the first time a plover was detected since the pre-breeding surveys were implemented in 2001. During the May window surveys, two plovers were detected in Clatsop County; one at Fort Stevens State Park, and one at Necanicum Spit (USFWS unpublished data). Clatsop spit (Clatsop Co.), the first two plovers to be detected on the north coast during spring window surveys since 2002. The annual breeding window survey in late May counted 206 plovers (Table 1), the highest number of plovers ever detected.

#### Breeding Season Monitoring

During the 2012 breeding season, we estimated a 290-291 adult Snowy Plovers at breeding sites along the Oregon coast (Table 1). Of 290-291 plovers, 270 (93%) were banded. The number of unbanded plovers estimated by the 10 day interval method was 20-21 individuals. For the breeding season we observed 128 banded females, 142 banded males, 17-18 unbanded females, and 3 unbanded males. The totals include two banded males, one banded female, and one unbanded female plover that were killed in or around an exclosed nest, and a minimum of four other banded males and three banded female that disappeared during the breeding season.

Of the total estimated population, 231-238 plovers (79-82%) were known to have nested (Table 1), similar to the mean percentage for 1993-2011 (79%). A minimum of 94 banded females and 119 banded males nested. Approximately 12-17 unbanded females nested and 7 unbanded males were known to have nested; the number of known unbanded males that nested indicates that the 10-day interval method of estimating unbanded plovers underestimates the true number of unbanded plovers present. An additional 21 banded females and 19 banded males were present during the breeding season but were not confirmed nesting. The minimum estimated Oregon resident plover population was 271-278.

For the first time since monitoring began in 1990, all three indices to the Snowy Plover population on the Oregon coast were above 200 individuals (Table 1). The number of plovers recorded by all three indices was the highest since monitoring began in 1990 and continues to show an increasing trend in the Oregon population (Table 1). The window survey count increased by 38 individuals and the total number of plovers present increased by 37-42 individuals, while the number of breeding plovers increased by 17-24 individuals. As we have noted in previous years, increasing plover numbers and densities on the nesting area has resulted in some difficulties positively identifying all nesting individuals (Lauten *et al.*, 2010 and 2011), therefore the number of breeding individuals was likely higher than the total tallied because some individuals were not positively identified at a nest but still likely nested based on their presence throughout the breeding season. The number of resident plovers in 2012 increased by 38-45 individuals, similar to the increase in the window survey count and the total number of plovers present. In 2012, the Oregon coastal plover population was above the recovery goal set for the state. Recovery goals have not been met in other states. (U.S. Fish and Wildlife Service 2007).

#### Overwinter Survival

Adult overwinter survival is very important to maintaining and increasing populations (Sandercock 2003, USFWS 2007, Dinsmore *et al.* 2010, Lauten *et al.* 2010 and 2011). In 2011 the estimated adult plover population was 247-253, of which 220 were banded. Of these 220 banded adult plovers, 59 (27%) were not recorded in Oregon in 2012, and we received no reports of these individuals being sighted elsewhere in the range. Thus they are presumed not to have survived winter 2011-12. The overwinter return rate based on returning banded adult plovers was 73%, above the 1994-2011 mean of 64% and the fourth consecutive year the adult return rate was above 70% (Lauten *et al.*, 2008, 2009, 2010, and 2011).

Due to analysis of hatch year returns, we adjusted the 2011 fledgling total to 168 from 172. Ninety-one of the 172 hatch-year plovers from 2011 (HY11) returned to Oregon in 2012. The return rate was 53%, slightly higher than the average return rate (Table 2, 47%). Of the returning 2011 HY11 birds, 42 (46%) were females and 49 (54%) were males. Seventy of the HY11 returning plovers attempted to nest (77%), and they accounted for 34% of the banded adults. These HY11 returns exceeded the number of banded adults that did not return in 2012.

The number of unbanded plovers was lower than previous years (n = 19-24 in 2012, n = 27-33 in 2011 and n = 27-31 in 2010), and the number of adult plovers banded outside of Oregon was the same as the previous two years (n = 18 in 2011 and 2010), indicating that immigration had a limited role in the increase in plover numbers. The increase in the population in 2012 was due to a combination of high adult and juvenile return rates. As we noted in 2011 (Lauten *et al.*, 2011), studying and managing plovers in winter could result in positive management practices that have beneficial effects on plover overwinter survival and thus population levels (Brindock and Colwell 2011, Dinsmore *et al.*, 2010).

Emigration from Oregon continues to be important to smaller plover populations in Washington and Humboldt Co., California. Colwell *et al.* (2008, 2009, 2010, 2011, and 2012) has noted that Humboldt Co. populations are maintained by immigration, and Washington populations are also maintained by immigration into that population (S. Pearson, pers. comm.). High reproductive output from Oregon plovers benefits these neighboring plover populations.

During the 2012 season, we captured and rebanded 33 banded adult plovers that either had worn bands or brood band combinations which needed to be updated to unique adult combinations. Nineteen of these were males and 11 were females. We banded eight unbanded adult male plovers, three unbanded adult female plovers and 335 chicks.

## Distribution

Table 3 shows the number of individual banded and unbanded adult plovers and the number of breeding adult plovers recorded at each nesting area along the Oregon coast in 2012. Sutton Beach had no recorded plovers in 2012. The overall number of breeding plovers at Siltcoos was the same as in 2011. The number breeding was similar to the recent past (Table 3, 26 in 2011, 23 in 2010, and 24 in 2009). Overlook had slightly more plovers present and slightly more breeding plovers as compared to 2011 (Table 3, 89 plovers present and 49 breeding in 2011). This indicates a relatively stable population after several years of population increases at this site (Lauten *et al.* 2011). At North Tahkenitch in 2012, the number of plovers and the number of breeding plovers increased by about 10 individuals compared to 2011 (Table 3, 58 present and 22 breeding in 2011). Some plovers nesting at North Tahkenitch in 2012 moved from Tenmile after unsuccessfully attempting to nest at Tenmile. The number of plovers and the number of breeding plovers at Tenmile in 2012 was also similar to 2011 (Table 3, 61 plovers present, 25 breeding in 2011). CBNS had the highest increase in plover numbers and breeding plovers in 2012. There were approximately 20 more individual plovers and 20 more breeding plovers at CBNS in 2012 compared to 2011 (Table 3, 69 plovers present and 59 breeding in 2011). The number of plovers using Bandon SPMA generally reflects the number of plovers using the entire Bandon Beach/New River/Floras Lake area, as the majority of plovers from these areas tend to spend the non breeding season at Bandon SPMA. The estimated number of plovers using Bandon SPMA in 2011 (minimum 56-60) was slightly lower to the total number of plovers using Bandon SPMA in 2012 (Table 3). The number of breeding plovers in 2012 for the Bandon Beach/New River/Floras Lake area was 46, slightly below the number of breeding plovers for 2011 (n = 50). In 2012, Overlook and CBNS had the highest number of plovers for all sites, approximately 31-32% of the total plover population for each site. We recorded a total of 10 individuals at Floras Lake, including five breeding individuals, the first breeding plovers since 2009.

The increasing plover population has resulted in plovers occupying available habitat adjacent to the traditional nesting areas (Lauten *et al.* 2010 and 2011), particularly the beach between South Siltcoos to Overlook and Overlook to North Tahkenitch. In 2012 plovers continued to use these sections of beach for both nesting and brooding (Figures 2 to 4). First year nesting plovers will tend to return to areas where they successfully hatched chicks, therefore we would expect continued use of these beach areas for plover nesting and brooding in the future. Lauten *et al.* (2011) noted that the increasing plover population would likely result in plovers occupying additional beaches that were adjacent to current nesting beaches such as South Tahkenitch to the Umpqua jetty, the beach north of North Tenmile, and CBNS beach north of the FAA tower. In 2011 and 2012 plovers did nest north of the North Tenmile spit (Figure 5). At CBNS in 2012, we found one nest north of the FAA towers (Figure 6) and late in the season we found two very recently fledged unbanded birds from an unknown brood north of the FAA towers that likely came from the beach north of access point one. We also found two nests at Floras Lake in 2012 including the first nests on the CMA in 10 years, as well as two nests along the beach north of Floras Lake and south of Clay Island breach. For the first time since spring surveys have been conducted on the north coast, two plovers were detected at Clatsop spit, although they were not detected on subsequent surveys. A few banded plovers were also reported in late summer and fall along the north coast by birdwatchers (*fide* Oregon Birders On Line).

**Nest Activity**

With an increasing plover population, the number of nests found continues to increase. We located 314 nests during the 2012 nesting season (Table 4, Figures 2-9), the highest number of nests found since monitoring began in 1990. In addition we recorded a minimum of 11 broods from nests that we did not locate prior to hatching. Nest distribution was similar to 2011 (Table 4). Siltcoos, Overlook and Tenmile had similar numbers of nests in 2012 compared to 2011. North Tahkenitch had 13 more nests in 2012 compared to 2011; the increase in nests was a result of larger numbers of plovers using this site in 2012 compared to 2011. CBNS had similar numbers of nests in 2012 compared to 2011 despite an increase in the number of plovers at this site. The similar number of nests in 2012 compared to 2011 was due to high nest success and therefore a lack of multiple renest attempts. There were fewer nest attempts on South Beach in 2012 compared to 2011 and more nest attempts on the HRAs in 2012. Bandon SPMA had the highest increase in nest numbers in 2012 (n = 60) compared to 2011 (n = 37). The higher number of nests was due to repeated nest failures resulting in many renesting attempts. There were 48 nests on Bandon Beach and 12 nests on the state portion of New River spit. New River HRA had the largest decline in nest numbers in 2012 (n = 17) compared to 2011 (n = 29). The lower number of nests on the New River HRA was partly due to fewer plovers using the HRA in 2012. We suspect there may have been more nests attempts at New River HRA, but were unable to confirm this because high water early in the season prevented us from conducting as many surveys as needed. High predation pressure by corvids likely resulted in some nest attempts failing before we were able to find and document them. Floras Lake had two nests, the first nests at this site since 2009 and only the second time in 10 years that nests were found here.

The first nests were initiated about 6 April (Figure 10). Nest initiation increased through late-May, and remained high into the beginning of July. The maximum number of active nests (n = 100) during 10-day intervals occurred during 31 May – 9 June, two weeks earlier than 2011 and one week earlier than the average peak nesting period. This was the highest number of active nests during any 10 day time interval since monitoring began in 1990 and the first time 100 nests were active at the same time. The last nest initiation occurred on 19 July.

**Nest Success and Exclosures**

For the sixth consecutive year, the number of days nests were unexclosed was higher than the number of days nests were exclosed (4576 unexclosed days, 323 exclosed days, Figure 11). In 2012, exclosures were used on 8% (n = 25) of the total number of nests (n = 314), and 7% of the total number of exposure days were exclosed (n = 323/4899).

The overall annual apparent nest success rate in 2012 was 45% (Table 5), similar to the average (Table 6). The number of exclosed nests in 2012 (n = 22, 7%) was the lowest since 1991 and the lowest percentage of the total number of nests since monitoring began in 1990. Apparent nest success for exclosed nests in 2012 was 82%, higher than the average for all years ($x$ = 71%, Table 6). The number of unexclosed nests in 2012 (n = 289, 93%) was the highest since monitoring began. Apparent nest success for unexclosed nests in 2012 was 42%, higher than the overall mean ($x$ = 20%, Table 6). Nest success of unexclosed nests in 2012 was significantly lower than nest success of exclosed nests ($\chi^2 = 12.2720$, df = 1, $P < 0.01$).

**Siltcoos**

No exclosures were used at Siltcoos in 2012 (Table 5), the first time no exclosures were used on both sides of the estuary since 1993. Overall nest success for Siltcoos was 53% (Table 5), above the average for these sites (Figure 12). North Siltcoos had 40% nest success and South Siltcoos had 59% nests success. Causes of nest failure are detailed in Table 7. Despite nest depredations being the main cause of nest failure at Siltcoos, no exclosures were used in 2012 due to good corvid management and good overall nest success.

**Overlook**

At Overlook in 2012, the overall nest success was 47% (Table 5). Overall nest success for North and South Overlook was 54% and 42% respectively (Table 5), both slightly above average for these sites (Figure 12). Only four of 59 nests were exclosed at Overlook, including one on the north side and three on the south side. All four exclosed nests hatched (Table 7). Of the 15 nests that failed due to depredations or unknown cause, 10 failed at or prior to mid-May before exclosure use was a management option. The other failed nests due to unknown depredation had no evidence that corvids were responsible. Due to good overall nest success and good corvid management after mid-May, exclosure use was limited at Overlook in 2012.

**Tahkenitch**

Plover activity has increased considerably at North Tahkenitch in the past two years (Table 4). Overall nest success at North Tahkenitch in 2012 was 58% (Table 5), similar to 2011 (61%), and much higher than the average for this site (Figure 12). Of the 36 nests found, only four were exclosed, all of which hatched. Thirty-two nests were unexclosed, and 17 hatched (53%, Table 5). Causes of nest failure are detailed in Table 7. Of the 15 nest failures, five occurred prior to mid-May, so under the exclosure protocol they would not have been exclosed anyway. Due to the good overall nest success and lack of corvid depredations, exclosure use was limited at North Tahkenitch in 2012.

**Tenmile**

In 2012, Tenmile continued to have very poor nest success with only six of 46 nests successfully hatching (13%, Table 5), similar to 2011 and well below the average for these sites (Figure 12). Causes of nest failure are detailed in Table 7. Nest failures attributed to unknown cause were likely also depredated, suggesting that upwards of 88% of the failed nests at Tenmile may have been due to some depredation event. Both field and camera evidence suggests that the main culprit of nest failures at Tenmile is ravens, and we continue to work with Wildlife Services staff to eliminate the corvids. In 2012 we set up a camera on five nests at Tenmile. All five of these nests hatched, though we did record ravens approaching the nests on multiple occasions. The ravens appeared wary, possibly because of the presence of the camera, and despite evidence that the raven was aware of the eggs it did not depredate the nests. While we did not positively record any raven depredations, the video confirms that ravens are using the area and may be wary of human-related items. Despite the high level of depredations and likely depredations, we did not exclose any nests at Tenmile. Great Horned Owls have targeted adult plovers in and around exclosures at this site (Lauten *et al.* 2011), and we did not have time to run surveys to determine the presence or absence of owls. Because adult survival is the primary driver of population growth (Sandercock 2003, USFWS 2007, Dinsmore *et al.* 2010, Lauten *et al.* 2010 and 2011), we felt it was more important to reduce risk to adult survival than to nest survival. Experience from other nest sites indicates that eliminating and successfully managing corvids increases nest success to sustainable rates and allows exclosure use to be reduced, thus reducing or eliminating risks to incubating adult plovers.

**Coos Bay North Spit**

No exclosures were used at CBNS for the sixth consecutive year (Table 5). Overall nest success at CBNS was 87%, similar to 2011 (82%). Nest success at CBNS was well above average (Table 5, Figure 12) for all sites. On the HRAs, 34 of 39 nests hatched (87%), on South Spoil 13 of 15 nests hatched (87%), and on South Beach 6 of 7 nests hatched (86%). In 2012 only one nest failed to depredation. Causes of the remaining nest failures are detailed in Table 7.

**Bandon SPMA**

There were 23 more nests at Bandon SPMA in 2012 compared to 2011 (Table 4). The increase in the number of nests was partly due to poor nest success, which resulted in many renesting attempts (Table 5). Depredations were the main cause of nest failure (79%, Table 7). Many of the unknown depredations were likely caused by corvids, but there was no evidence to determine the exact cause of the depredation. Despite the high levels of nest depredations, we only used nine exclosures in 2012 (seven on the Bandon Beach side and two on the New River spit). Due to previous experience with adult plovers being depredated in and around exclosures at Bandon SPMA (Lauten *et al.*, 2006and 2011), we were cautious about erecting exclosures especially if corvid activity was relatively low. In 2012, corvid activity was often minimal, and then episodically increased resulting in nest depredations before we could erect exclosures. One exclosed nest hatched but the adults were found dead within ca. 25 m of the exclosed nest. The hatching chicks were then transported to the Newport Aquarium. The exclosure had canine tracks around it, and the canine attempted to dig under the exclosure. We believed at the time this was indication that fox had attacked the adults and the hatching nest. Another male plover that was incubating on an exclosed nest during the same period was found with a severely injured left leg. Because of these events, we pulled three of the nine exclosures to reduce the likelihood of further adult injuries or mortalities. Five of the six nests that were exclosed for the duration of incubation hatched (83%); one exclosed nest was abandoned, but may have been abandoned before erection of the exclosure. Unexclosed nest success at Bandon SPMA continues to be very poor, and overall nest success at Bandon SPMA in 2012 was well below average (Figure 12).

**New River**

Overall nest success on non-state lands at New River in 2012 was also low (29%, Table 5), and well below the average for this site (Figure 12). Ten of 18 nests were unexclosed, including one on private land and nine on the HRA; all 10 failed (Table 5). Eight nests were exclosed, and five hatched (Table 5). The causes of nest failure are detailed in Table 7. We believe corvids were the main cause of nest failure as they were present in relatively high densities all summer, particularly on the HRA. While exclosure use at New River does increase nest success, we continue to experience adult mortalities in and around exclosures at this site. In 2012, of the three exclosed nests that failed, two adults were depredated at one, and the other two exclosed nests were abandoned. The adults associated with one of these nests also disappeared, which suggests they were also depredated.

**Floras Lake**

Of the two nests found at Floras Lake, one hatched (Table 5). One nest was found on the Cooperative Management Area (CMA) and successfully hatched without an exclosure. The second nest was north of Hanson breach and was not exclosed; the nest failed to unknown depredation.

**Depredations Around Exclosures**

As of 2011, we have documented a minimum of 46 adult plovers (ca. 5% of all known adult plovers) depredated in or around exclosures (ORBIC, unpubl. data). Due to these adult losses as well as the relatively good success of both nests and broods, we continue to carefully evaluate exclosure use and minimize the number of exclosures used and the amount of time exclosures are protecting nests. In 2012, the number of days unexclosed was the highest since monitoring began, and we reduced the number of days exclosed to 7% of the total number of exposure days (Figure 11). Adult survival is very important for population growth (Sandercock 2003, USFWS 2007, and Dinsmore *et al.* 2010), therefore if nest success is relatively good, evidence of predation pressure is minimal, and fledgling productivity is good, exclosure use is not necessary. Exclosures continue to be a management tool that increases nest success, however with a reasonably large population size and good productivity, exclosure use should be carefully evaluated and minimized to the extent possible.

**Nest Failure**

Exclosed nests in 2012 had an overall failure rate of 18% (4 of 22, Table 8; three nests from Bandon SPMA B\ not included because the exclosures were removed after two adult plovers were found dead outside of an exclosed nest). Of the four failed exclosed nests, two failed to unknown causes, one was abandoned, and one had both adult plovers depredated (Table 8). The banded adult male from one of the exclosed nests that failed to unknown cause disappeared during the incubation period; it is possible he was also depredated. The female to this same nest also disappeared, but she was unbanded so it is unclear if she survived. The number of unexclosed nests that failed in 2012 (n = 167) was higher than the past three years (2011, n = 129; 2010, n = 149; 2009, n = 148). The failure rate of unexclosed nests in 2012 (58%) was similar to 2011 (54%) but lower than previous years (77% in 2010, 73% in 2009, and 73% in 2008). In 2012, the main causes of nest failure for unexclosed nests were unknown depredations, unknown cause, corvid depredations, abandonment, one egg nests, and wind/weather (Tables 7 and 8). Overall nest failures were attributed to unknown depredation, unknown cause, corvid depredation, abandonment, one-egg nests , wind/weather , mammalian depredation , overwashed , adult plover depredation , and infertility (Table 7).

In 2012, the number of one-egg nests (n = 14) and abandoned nests (n = 17) was similar to previous years (Lauten *et al.* 2007, 2008, 2009, 2010, and 2011). Since the number of these nests has been relatively stable for the past six years, we continue to believe that the causes of these abandonments are natural and are not due to exclosure use (only 9% of these nests have been exclosed), or recreational activity which remains low within the nesting areas, or monitoring activity.

**Predator Management**

No rodent depredations of nests were confirmed in 2012, the second consecutive year with no or low rodent depredations (Lauten *et al.*, 2011). In 2012, 201 deer mice were captured at CBNS (Burrell 2012) during March. Nest success at CBNS in 2012 was again very high (Table 6). It is unclear whether the rodent trapping had any real effect on nest success, however the effort does give an indication of rodent population levels. Similar rodent trapping and removal in the future would at a minimum help us gauge and understand rodent population levels and cycles at CBNS.

Corvid depredations continue to be the main source of known nest depredations (Table 8). Of the 57 unknown depredations, 32 (56%) were at Bandon SPMA and New River HRA where corvid activity was persistent all summer. Corvids were likely responsible for most of these unknown depredations. Predator management continues to have a positive effect on reducing corvid numbers, however controlling corvids is a difficult and time consuming task. Despite apparent reductions in corvid numbers, they continue to be consistently present particularly between Siltcoos to Tahkenitch, Tenmile, Bandon Beach and New River. Due to the amount of area that needs to be covered and the distance between nesting sites, we continue to recommend that Wildlife Services be funded to support three agents. See Burrell (2012) for a complete discussion of the predator management program.

**Fledging Success and Productivity**

We monitored 154 broods in 2012 including 11 broods from undiscovered nests, six more broods than in 2011 (Lauten *et al.* 2011) and the highest number of broods since monitoring began in 1990. A minimum of 173 fledglings was confirmed (Table 9), the highest number since monitoring began. Overall fledging success was 43%, near the overall average (Table 10). The overall brood success rate was 70% (Table 11), slightly higher than the average (66% +/- 10). The overall number of fledglings per male was above the recovery goal at 1.37 (Table 11). Considering data from known nests from Siltcoos to New River only (Tables 12-18), the mean fledglings per male was 1.186, near the average (Table 10). Despite good overall productivity, productivity varied between sites (Table 11).

**Siltcoos**

At Siltcoos in 2012 (Table 12), the number of eggs laid and the hatch rate were similar to 2011. There was one more brood than in 2011, and 61% of these broods successfully fledged at least one chick (Table 11). Four more chicks fledged than in 2011, which increased the fledging success rate, the productivity index, and the number of fledglings per male. However, the fledging success rate, the productivity index, and the number of fledglings per male for 2012 were below the post predator management averages for Siltcoos. Fledging success was better on the South Spit, but the North Spit had a small sample size (Table 11).

**Overlook**

At Overlook in 2012 the number of eggs laid and the number of eggs hatched were similar to 2011 (Table 13). The hatch rate was slightly lower than 2011 but similar to the post predator management average. Overlook had 31 broods, two less than 2011, and 28 were successful (Table 11). The fledging success rate, productivity index, and the number of fledglings per male were slightly lower than in 2011 but still higher than the post predator management averages.

**Tahkenitch**

North Tahkenitch had the largest increase in plover activity of any site on the Oregon coast in 2012 as measured by the number of eggs laid and the number of known breeding males compared to 2011 (Table 14). The hatch rate was lower than 2011 but slightly higher than the post predator management average. North Tahkenitch had 21 broods, seven more than in 2011, and 18 were successful (Table 11). The number of fledglings produced was the highest since monitoring began in 1993. While the fledging success rate, productivity index, and number of fledglings per male were all lower than in 2011, all three indices were higher than the post predator management averages, and Tahkenitch produced six more fledglings than in 2011. Overall productivity at this site was above recovery goals.

**Tenmile**

The effort at Tenmile as measured by the number of eggs laid in 2012 was similar to the previous three years (Table 15), however for the second consecutive year the productivity was very poor. Despite laying a minimum of 104 eggs, only 18 hatched, the second consecutive year of very low hatch rates and well below the post predator management average. Tenmile had six broods, one less than 2011, and overall brood success was 83% (Table 11). The fledging success rate improved to 50%, higher than the post predator management average. However the number of fledglings compared to the number of eggs laid was very low, and resulted in a very poor productivity index, well below the post predator management average. The number of fledglings per male was above the post predator management average, however this number is influenced by the number of known breeding males and since most nests failed, many males who unsuccessfully hatched at Tenmile were never identified. If more males had been identified, the actual number of fledglings per male would be much lower. Tenmile continues to be the only site where productivity has not increased since implementation of predator management. Poor nest success is a continuing problem at Tenmile (Table 5), especially given the number of plovers using this site (Table 3).

**Coos Bay North Spit**

The hatch rate at CBNS in 2012 was the highest on the coast, the highest since predator management was implemented in 2002, and well above the post predator management average (Table 16). CBNS had 58 broods, nine more than in 2011, and overall brood success rate was 59%. While the hatch rate was high and the number of fledglings similar to 2011, the fledging success rate declined from 2011 to 37%, below the post predator management average. This was largely due to low fledging rates on South Spoil and the HRAs. Fledging success on the beach was much higher (Table 11). The productivity index was similar to 2011 and nearly the post predator management average. Despite the relatively good productivity, the number of fledglings per male declined from 2011 and was well below the post predator management average. CBNS continues to be the most productive site on the Oregon coast.

**Bandon SPMA**

Bandon SPMA had the largest increase in the number of eggs laid compared to 2011 (Table 17). This was not due to more individual plovers but due to poor hatch rates and thus increased renesting attempts. The hatch rate was much lower than in 2011 and well below the post predator management average. Bandon SPMA had 11 broods, six fewer than in 2011, and overall brood success was 67%. The fledging success rate was slightly above the post predator management average, but the productivity index was very poor, indicating that few fledglings were produced compared to the number of eggs laid. The number of fledglings per male was near the post predator management average, and just below the recovery goal.

**New River**

The number of plovers using the New River HRA has declined since 2010, and therefore the number of eggs laid has also declined (Table 18). The hatch rate in 2012 was much lower than in 2011 and only half of the post predator management average. There were seven broods on the New River HRA; four of these fledged at least one chick. The number of young fledged has also declined since 2009 and the fledging success rate was the lowest since implementation of predator management and well below the post predator management average. The productivity index was very low and also well below the post predator management average. The number of fledglings per male was the lowest since implementation of predator management and well below the post predator management average. Corvids continue to be persistent at Bandon SPMA and New River HRA and are likely the main cause of low productivity at these sites. We recommend efforts to remove corvids at all nesting sites as they continue to be the main cause of known nest failures (Table 7) and are likely responsible for some chick mortality.

**Floras Lake**

Floras Lake had two broods, one of which was successful (Table 11). The two fledglings produced by the one successful brood were the first fledglings from Floras Lake since 2000. Due to the paucity of data from Floras Lake, we have not calculated hatch rates, fledgling rates, and productivity indices for this site.

Post predator management hatch rates have declined for Overlook, Tenmile, CBNS, Bandon SPMA, and New River HRA, but this is the result of many more nests remaining unexclosed and unexclosed nests have a lower nest success than exclosed nests (Table 6). Since the implementation of predator management, the average brood success rate (2004-2012, 72.2%) was significantly higher than the average pre predator management brood success rate, (1991-2001, 62.9%, t-stat = 2.32, df = 18, $P$ = 0.02). The overall mean post predator management fledging success rate (0.47) was significantly higher than the mean pre predator management fledging success rate (0.39, t = 1.75, df = 17, $P$ = 0.05). The post predator management fledging success rate has improved for Siltcoos, Overlook, CBNS, Bandon SPMA, and New River (Table 19). Tahkenitch and Tenmile have decreased but are still within acceptable levels. The overall mean number of fledglings per male after implementation of predator management (2004-2012; $x$ = 1.31) was significantly higher than the mean number of fledglings per male prior to the implementation of predator management (1992-2001; $x$ = 1.06, t = 2.37, df = 17, $P$ = 0.01). The mean number of fledglings per male has improved at all sites except Tenmile where it has remained relatively stable (Table 19). Productivity as measured by the average fledging success rate has improved at all sites except Tahkenitch and Tenmile since implementation of predator management (Table 19). The overall productivity data has generally improved since the implementation of predator management, and we continue to recommend that predator management be funded, as this is critical to increasing and maintaining the plover population.

**Brood Movements**

**Siltcoos, Overlook, and Tahkenitch**

Only one of four broods at North Siltcoos in 2012 was successful, and that brood remained within the nesting area for the duration of the brood rearing period.

As plover numbers have increased they have occupied available habitat along the beaches between South Siltcoos and North Tahkenitch (Lauten *et al*. 2009, 2010, and 2011). In 2012, plover nests were found along the beach south of Waxmyrtle trail, near the Carter Lake trail area, and between South Overlook and North Tahkenitch, particularly near the Overlook Loop trail (Figures 3 and 4). While many of the broods that originated on the nesting areas at South Siltcoos, Overlook and North Tahkenitch remained on or near the roped nesting areas, there was consistent brood activity on all portions of the beach between the main nesting areas. At South Siltcoos, at least two broods moved south along the beach to the Carter Lake area. Broods that originated south of Waxmyrtle trail stayed along the beach, and one brood that originated at Carter Lake moved south to North Overlook. Three broods that originated along the beach north of North Overlook also generally stayed along the beach from Carter Lake to the north end of North Overlook. At least two broods that originated from North Overlook moved to South Overlook. At least five broods from South Overlook moved south along the beach to the Overlook Loop trail area, and one of these broods even moved south to North Tahkenitch. Most broods at North Tahkenitch that originated on the nesting area stayed within and around the nesting area, although one brood moved north along the beach. Two broods that originated from the beach north of the nesting area stayed along the beach and another brood that hatched on the beach moved south to the nesting area.

**Tenmile**

There were four broods at North Tenmile in 2012, three that originated on the HRA and one that originated on the beach north of the HRA. All three broods that originated on the HRA remained on the HRA and adjacent spit area, and the brood from north of HRA moved south to the HRA and spit area and remained there until fledgling. There were only two successful broods at South Tenmile in 2012, and both broods stayed within the vicinity of the HRA.

**Coos Bay North Spit**

At CBNS brood movements are varied and often difficult to ascertain partly due to the complex structure of the nesting area in conjunction with berms along the foredune road and vegetated foredune. Broods originating from the 95HRA have the shortest distance to travel to access the beach, and some of these broods would move onto the beach and back onto the 95HRA mostly in the area of the Olson shipwreck where the foredune vegetation is still sparse in some areas. We have documented a general trend of broods originating on South Spoil, the 94HRA and 98EHRA to move westward toward the beach (Lauten *et al*. 2009, 2010, and 2011). In 2012 some broods originating from east of the foredune road did move west to the 95HRA and eventually South Beach, however some broods remained throughout the brood period on the South Spoil and HRAs. In 2012 we had definitive evidence that broods can and will use the foredune road to attempt to access the beach. In late June, BLM staff reported a male with two young chicks on the foredune road just south of the FAA towers. We found the brood well north of the 95HRA and south of the FAA towers in the middle of the foredune road and herded the brood back to the north gate at the HRAs and then onto the 95HRA. This brood had hatched from South Spoil two days prior to finding them on the foredune road. We are uncertain if the brood moved directly north of the South Spoil and onto the reroute road and then north on the foredune road, or whether they moved north along the foredune road behind the gate and further north towards the FAA tower. This brood demonstrates that broods can move several miles within a few days of hatching, and also suggests that some broods may be attempting to gain access to the beach via other routes than west to the 95HRA and over the foredune. In previous years, we have noted older broods using the foredune road in the vicinity of the north jetty (Lauten *et al*. 2011). This example suggests broods are capable of using the foredune road to access the beach. Brood use on South Beach in 2012 was extensive. We noted broods using the beach near the jetty where vehicle access is permitted, and we had multiple broods move as far north as north of the FAA towers. One brood from an undiscovered nest was found north of the FAA towers at about the time of fledgling. Based on the age of the fledglings, the brood was local, and since we did not encounter the brood along South Beach from Access point one to the north jetty, we believe it is possible the brood originated from north of the FAA towers (possibly north of Access point one).

**Bandon SPMA**

There were a total of 11 broods at Bandon SPMA in 2012, nine on the Bandon Beach side and two on the New River spit side. Two broods on the Bandon Beach side hatched below the China Creek parking lot, and both broods immediately moved south and stayed along the foredune. All the remaining broods on the Bandon Beach side also remained along the foredune or on the HRA, with brood activity as far south as the mouth of New River. We did observe brood use of the cutouts created in winter 2010-11 despite the cutouts being fairly heavily vegetated. No broods crossed the river in either direction. Both broods from the New River spit side remained at the north end of the spit. There was no brood activity north of China Creek in 2012.

**New River and Floras Lake**

There were seven broods that originated on the New River HRA in 2012. One brood remained close to the area of the nest at the northern end of the HRA and one remained fairly close to the area of the nest near Hammond breach at the south end of the HRA. Two other broods wandered fairly extensively from north of Croft Lake breach to south of New Lake breach. South of Clay Island breach, a brood that hatched along the foredune eventually moved south to Floras Lake and was noted using the beach south of the CMA. It eventually fledged west of the CMA. One other brood from Floras Lake hatched on the CMA and spent the brood period between the CMA area and upwards of a quarter mile south along the beach.

**Sightings of Snowy Plovers Banded Elsewhere**

Eighteen adult plovers banded in California were observed in Oregon in 2012. Eleven were females and seven were males. Twelve of the 18 plovers were known to have nested in Oregon in 2012. Four females were not confirmed nesting however two were present during the breeding season and may have attempted to nest but were not confirmed. Two males were not confirmed nesting however one was present all summer at Bandon SPMA and likely attempted to nest but was never confirmed; the other male appeared at the end of July and was a post breeding individual. Three females and two males originally hatched in Oregon and were subsequently rebanded at coastal nest sites in California. Fourteen other plovers, eight females and six males, were originally banded in California. One female was a hatch year 2006 bird from Salinas, Monterey Co. that has been recorded in Oregon in previous years; she nested at Overlook in 2012. Two females were hatch year 2011 plovers, one from Moss Landing Salt Ponds, Monterey Co. and one from Marina State Beach, Salinas Co. Both nested in Oregon in 2012, one at Floras Lake and one at Bandon Beach and New River. Another female was a hatch year 2011 plover from Fort Ord, Monterey Co.; she was only seen once in Oregon in 2012. The other four California originated females included a hatch year 2006 from Humboldt Co. who has been nesting at Bandon Beach and New River since 2007; an adult banded in 2008 in Humboldt Co. that has nested in Oregon in 2011 but was not confirmed nesting in 2012; another adult that was banded in 2010 in Humboldt Co. and nested in 2011 and 2012; and a hatch year 2010 plover banded in Humboldt Co. who was present in Oregon in 2011 but no known nest was confirmed in either 2011 or 2012. Of the five California originated males, one was a hatch year 2004 bird from Salinas, Monterey Co., that has been present at New River since 2005 and successfully nested at New River in 2012; one was a male banded in 2009 at Salinas, Monterey Co., who wintered at Bandon SPMA in the past two years and arrived at Bandon SPMA in late July 2012; one was a hatch year 2010 plover from Salinas, Monterey Co., who successfully nested at CBNS in 2012; one was a hatch year 2010 plover from Moss Landing Salt Ponds, Monterey Co., who nested at Bandon SPMA in 2012; and one was from Oceano Dunes, San Luis Obispo Co., who nested at Overlook in 2012.

## Habitat Restoration and Development Projects

**Sutton**

The USFS contracted the Northwest Youth Corp to handpull beachgrass on 12 acres of habitat south of Holman Vista, Sutton Beach in the winter of 2011-12. Some shellhash was mechanically spread on the HRA. In addition, 3.8 miles of beach cleanup was conducted at Baker Beach with the help of the Emerald Empire Back Country Horseman group. Seventeen people participated in this event and collected 900 pounds of trash.

**Siltcoos**

At Siltcoos, 12 acres of beachgrass was hand pulled by the Northwest Youth Corp on both sides of the estuary in winter 2011-12. Beachgrass hummocks near areas covered by oyster shell were mechanically treated. Some oyster shell was spread on both the north and south side of the estuary.

**Overlook**

At Overlook 20 acres of beachgrass was handpulled on the south side in winter 2011-12. Herbicides were sprayed on 20 acres of beachgrass on both the north and south side. Beachgrass hummocks near areas covered by oyster shell were mechanically treated. Some oyster shell was spread on both the north and south side.

**Tahkenitch**

At Tahkenitch, 40 acres of beachgrass was handpulledand an additional 40 acres were sprayed with herbicides in winter 2011-12. Beachgrass hummocks near areas covered by oyster shell were mechanically treated. Some oyster shell was spread on the HRA.

**Tenmile**

At Tenmile, beachgrass was handpulled on 10 acres on the north side and 23 acres on the south side in the winter of 2011-12. Herbicides were sprayed on 23 acres on South Tenmile. Some shellhash was spread on North Tenmile.

**Coos Bay North Spit**

At CBNS in winter 2011-12, BLM disked 148 acres of habitat restoration area and parts of the spoil. Some hand pulling of sea rocket was also completed. Shell hash (ca. 300 cubic yards) was spread on 26 acres of previously treated habitat and 3 additional acres on BLM lands.

**Bandon SPMA**

At Bandon SPMA there was no habitat restoration work in winter 2011-12.

**New River**

At New River HRA, BLM bulldozed and improved 20 acres of habitat from the north end of Hammond breach to the south end of New Lake breach. A breach naturally occurred at Clay Island.

## Recommendations

### Signing of Restricted Areas

Signing and roping for the 2013 nesting season should again be implemented to inform the public of plover nesting habitat and direct the public away from the nesting areas. Ropes and signs should be installed as early in the season as practical so that the closed sections of beach are adequately protected throughout the season and the public understands which sections of beach are closed and the message is consistent throughout the nesting season and from year to year. Installing ropes and signs at the beginning of the season also reduces the need to respond to individual nests that are within closed beach sections but not roped and signed. This reduces the disturbance to those nests when ropes and signs have to be installed after a nest is found. High tides early in the season often make posting areas a challenge, and while it is important to have signs in place beginning on 15 March, in areas where the ocean is regularly lapping against the foredune, signs should not be erected or placement should be delayed. Maintenance of signs is important to keep violations to a minimum. To maximize the effectiveness of signs and ropes, each site should continue to be evaluated and ways to improve the signing and ropes should be considered.

### General Recommendations

Below are general recommendations. We also provide additional site-specific comments and management recommendations in Appendix B.

Maintaining, improving, and expanding the nesting areas is essential to maintaining a healthy and sustainable plover population. Despite years of treatment, European beachgrass continues to annually resprout resulting in degraded nesting habitat. When new habitat is created, such as the cutouts at Bandon SPMA (Lauten *et al.*, 2011), it is important to annually maintain the habitat or it quickly degrades resulting in reduced plover use. With an increasing plover population, any reduction in available nesting habitat can result in high nest densities which may attract predators or result in plovers nesting on open beach and along the foredune where disturbance from recreational activity is more likely. Increased nest density could lead to density dependent predator relationships which could cause increased nest depredations. Increased chick numbers on the landscape may attract additional avian predators (Neuman *et al.* 2004). Expansion of the nesting areas would increase the available habitat for plovers and could help alleviate predation pressure. Creation of cutouts along sections of beach that have nesting plovers but no nesting area behind the foredune would give the plovers safe areas to nest and brood away from recreational activity on the beach. We continue to support additional shell hash on any nesting area as it has proven to be a beneficial management technique. We continue to recommend that additional habitat be created and maintained at South Overlook, North Tenmile, Bandon SPMA and New River HRA. We support any efforts to find new and effective treatments of European beachgrass that could result in reduced resprouting, less density of beachgrass, and ultimately reduced need to annually treat nesting areas and therefore reduced funding for annual habitat maintenance.

The OPRD Habitat Conservation Plan (ICF International 2010) will be fully implemented at occupied Snowy Plover Management Areas (SPMAs) and Recreation Management Areas (RMAs) in

2013. Seasonal recreation restrictions (March 15 - September 15) include no dogs in these occupied areas.. Educating the public about the new rules will be essential both before and during the nesting season. Staff dedicated to recreational monitoring and volunteers continue to help reduce violations and educate the public about plovers and dog related issues, and we recommend that these aspects of management continue and be funded. At Siltcoos and Bandon Beach where parking lots and recreational activities are adjacent to nesting plovers, monitoring by staff and volunteers is essential to improving plover success and reducing disturbance issues.

- Continue intensive breeding season monitoring; continue monitoring plover populations and productivity to ensure recovery goals are maintained.
- Maintain, enhance and expand habitat restoration areas. Spread shell hash to enhance nesting substrate.
- Selectively use mini-exclosures in conjunction with predator management to reduce the risks to adult plovers, decrease the time monitors spend around individual nests, and decrease disturbance to plovers. Determine exclosure use dependent on predation pressure, density of plover nests, and nest locations.
- Expand use of cameras to help determine causes of nest failures; coordinate with Wildlife Services to set up and maintain cameras.
- Increase and/or maintain predator management at all sites and explore ways of better understanding the activity patterns and population levels of predators, particularly corvids. Fully fund three Wildlife Services employees.
- Continue to coordinate with federal and state agency employees regarding time frames of any habitat management work to be completed to minimize disturbance to nesting activity and broods.
- Coordinate agency activities in restricted areas with plover biologists to minimize disturbance to nesting and brood rearing.
- Continue and explore ideas to document and monitor human disturbance by various recreational users in plover nesting areas.
- Continue to expand and refine volunteer efforts to monitor recreational use.
- Design educational programs to inform and educate the local communities and annual visitors about plover issues.
- Design informative/interactive presentations for school children.

## Acknowledgments

We would like to thank Josh Novotny, Andrew Walch, and Mike Burrell of Wildlife Services for their assistance in the field and thoughtful insight about predators; Chris Bryers, Chuck Littlejohn, Greg McUne, Jerry Phillips, RJ Rapelje, and Trisha Wymore of OPRD for their hours educating the public and monitoring recreational activity on the beach; Morgan Bell and Theresa Bolch of BLM for their diligence monitoring recreational activity at CBNS; Andrew Testo of BLM and Cathy Boden and Statia Ryder of South Coast Watershed Association for monitoring and education with recreationists and campers at New River and Floras Lake; Crystal Mullins and Rachel Lytton of Forest Service for their many hours maintaining signs and ropes, monitoring recreational activity and interacting with the public; volunteers John and Sue Ewan, Kim and Else Ireland, Gary and Mary Van Hooser, Michael and Diane Chacon, Lester and Pam Trout, Larry and Mollie Folmar, Bonnie Womble, John and Bonnie Gee, and Doug and Gloria Williams spent numerous hours educating the public at China Creek parking lot on Bandon Snowy Plover Management Area; volunteers Carol Blysma, Mike and Pat Brooks, Calvin and Beth Smith, and Brian and Gail Ogram for USFS; field rangers from the Forest Service's Valuing People and Places Program provided snowy plover information to visitors at the Dunes Day Use Area; Ted Gage and Carrie Pope of BLM Law Enforcement, Tim Slater of Coos County Sheriff's Department, Oliver Grover, Tyler Smith, and Sara Wassam of the USFS Dunes National Recreation Area Law Enforcement , and Ed Lagrone of Lane Co. Sheriffs's Department; Liz Kelly, Madeleine Vander Heyden, and Laura Todd of the US Fish and Wildlife Service; Mark Stern, Ken Popper, and Karen Gleason of The Nature Conservancy; Stuart Love, Bill Kinyoun, and Martin Nugent of the Oregon Department of Fish and Wildlife; Charlie Bruce, retired ODFW volunteer; Kip Wright, Steve Langenstein, Kerrie Palermo, Sharon Morse, Megan Harper, and all the managers at Coos Bay BLM District whose support is invaluable; Calum Stevenson, Larry Becker, and Vanessa Blackstone of the Oregon Parks and Recreation Department; Ben Fisher and his staff at Bullard's Beach State Park; Cindy Burns, Melissa Shelley and Paul Thomas of the USFS Mapleton Ranger District; Dave Williams of Wildlife Services; Sean McAllister and Ron LeValley in Humboldt Co., CA,; Mark Colwell and students at Humboldt State Univ., Arcata, CA,; Jim Watkins of US Fish and Wildlife Service, Humboldt Co.; Gary Page, Lynne Stenzel, Doug George, Kris Neumann, Jenny Erbes, and Carlton Eyster of Point Reyes Bird Observatory; special thanks to Frances Bidstrup of Point Reyes Bird Observatory who coordinates all banding information and who is essential to the project; to anyone and everyone who we may have accidentally forgotten – we sincerely appreciate the support, assistance, and input of all, without which the program would not be a success.

**Table 1.** Population estimates of the Western Snowy Plover on the Oregon Coast, 1990-2012. For Window Survey, first number is counted plovers minus duplicate band combos and unidentified plovers, number in parenthesis is total head count without considering duplicate combos or unknown plovers.

| YEAR | WINDOW SURVEY | # SNPL BREEDING | # SNPL PRESENT |
|---|---|---|---|
| 1990 | 59 | - | - |
| 1991 | 35 | - | - |
| 1992 | 28 | - | - |
| 1993 | 45 | 55-61 | 72 |
| 1994 | 51 | 67 | 83 |
| 1995 | 64 (67) | 94 | 120 |
| 1996 | 85 | 110-113 | 134-137 |
| 1997 | 73 (77) | 106-110 | 141 |
| 1998 | 57 (59) | 75 | 97 |
| 1999 | 49 (51) | 77 | 95-96 |
| 2000 | NC | 89 | 109 |
| 2001 | 71 (85) | 79-80 | 111-113 |
| 2002 | 71 (76) | 80 | 99-102 |
| 2003 | 63 | 93 | 102-107 |
| 2004 | 82 (83) | 120 | 136-142 |
| 2005 | 100 | 104 | 153-158 |
| 2006 | 91 | 135 | 177-179 |
| 2007 | 125 | 162 | 181-184 |
| 2008 | 98-105 | 129 | 188-200 |
| 2009 | 136-143 (139-146) | 149-150 | 199-206 |
| 2010 | 158 | 175 | 232-236 |
| 2011 | 168 | 214 | 247-253 |
| 2012 | 206 | 231-238 | 290-291 |

**Table 2.** Number of Snowy Plover fledglings, number of previous year fledglings returning, return rate, number nesting, and percent nesting in first year of return along the Oregon coast, 1990 - 2012.

| Year | # of Fledglings | # of HY birds from previous year sighted on OR coast | Return Rate (#HY/#Fled) | # that nested on OR coast | % nested on OR coast |
|---|---|---|---|---|---|
| 2012 | 173 | 91 | 53% | 70 | 77% |
| 2011 | 172[a] | 53 | 63% | 45 | 85% |
| 2010 | 84 | 54 | 50% | 38 | 70% |
| 2009 | 107 | 35 | 48% | 26 | 74% |
| 2008 | 73 | 52 | 42% | 27 | 52% |
| 2007 | 124 | 32 | 29% | 26 | 81% |
| 2006 | 110 | 29 | 37% | 23 | 79% |
| 2005 | 78 | 43 | 40% | 33 | 77% |
| 2004 | 108 | 26 | 43% | 21 | 81% |
| 2003 | 60 | 14 | 45% | 14 | 100% |
| 2002 | 31 | 18 | 56% | 15 | 83% |
| 2001 | 32 | 23 | 53% | 14 | 61% |
| 2000 | 43 | 31 | 58% | 25 | 81% |
| 1999 | 53 | 18 | 56% | 12 | 67% |
| 1998 | 32 | 14 | 34% | 11 | 79% |
| 1997 | 41 | 30 | 64% | 18 | 60% |
| 1996 | 47 | 18 | 32% | 10 | 55% |
| 1995 | 57 | 37 | 66% | 13 | 35% |
| 1994 | 56 | 16 | 44% | 8 | 50% |
| 1993 | 36 | 10 | 30% | 6 | 60% |
| 1992 | 33 | 6* | 38% | 2 | 33% |
| 1991 | 16 | No chicks banded in 1990 | | | |
| 1990 | 3 | x | x | | |

* - minimum number sighted

| | |
|---|---|
| Average return rate = 47% | 47% |
| SD = 11.3% | 0.113143 |
| Average percent of returning HY birds that nest in first season = 69% | 69% |
| SD = 16.9% | 0.169162 |

[a] - adjusted from 168 to 172 based on hatch year returns

% Brood success = # broods with at least 1 chick fledged / total # of broods
% Fledging Success = # of young fledged / # of eggs hatched
* Includes broods from undiscovered nests:
** Does not include fledglings from undiscovered nests because we do not know how many eggs hatched from those nests.
[a] – number of known individual breeding males for each site
[b] – number of known breeding males in entire population; this is not a tally of known males from each site as some males may have nested at more than one location
[c] – number of fledglings for both sites combined and number of known individual breeding males for both sites combined Sample size of males in parenthesis.

**Table 12. Productivity of Snowy Plovers at Siltcoos, Lane Co., Oregon coast, 1993-2012.**
**Number of eggs laid, number hatched, hatch rate, # fledged, fledging success rate, and productivity index based on all known nests. Number of fledglings per male based on nests with known adult males only, therefore number of fledglings may vary from total number of fledglings.**

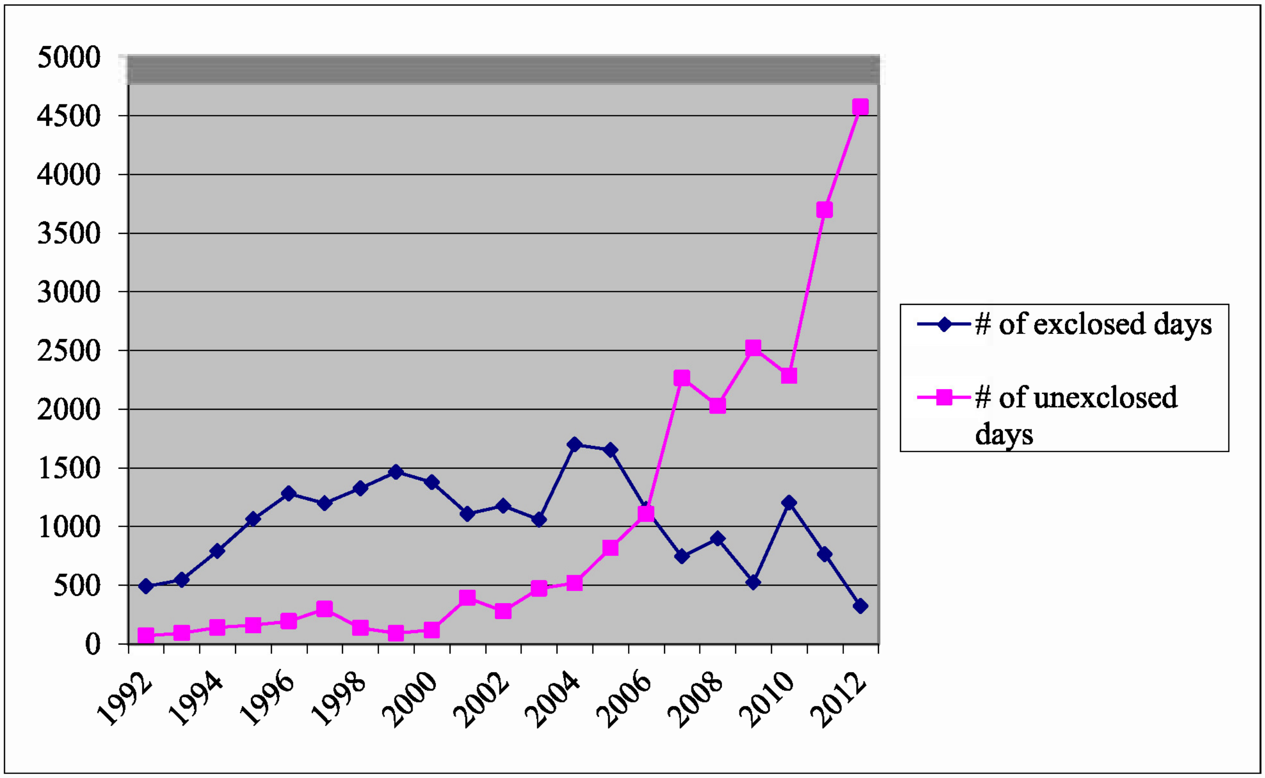

Figure 12. Mean percent nest success for Snowy Plovers along the Oregon coast, 1990-2012, with standard error bars. Number above each bar is the sample size.

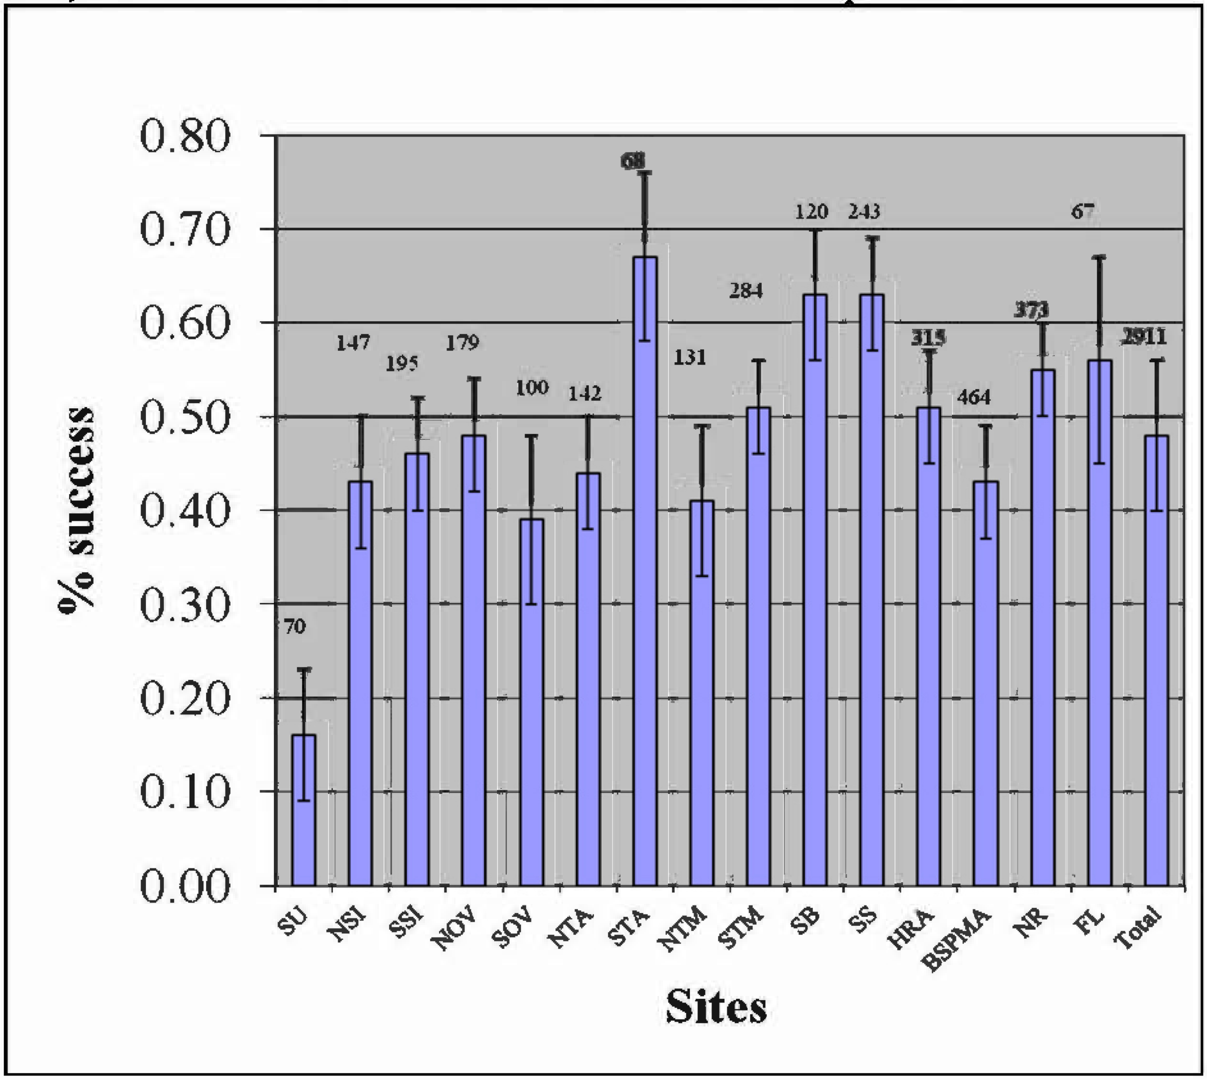

## APPENDIX A.

**Study Area**

The study area encompassed known nesting areas along the Oregon coast including all sites between Berry Creek, Lane Co., and Floras Lake, Curry Co. (Fig. 1). Survey effort was concentrated at the following sites, listed from north to south:

**Sutton Beach**, Lane Co. - the beach north of Berry Creek south to the mouth of Sutton Creek.

**Siltcoos**: North Siltcoos, Lane Co. (Figure 2). - the north spit, beach, and open sand areas between Siltcoos River mouth and the parking lot entrance at the end of the paved road on the north side of the Siltcoos River; and South Siltcoos, Lane Co. - the south spit, beach, and open sand areas between Siltcoos River mouth and south to Carter Lake trail beach entrance.

**Dunes Overlook Clearing**, Douglas Co. (Figure 3). – the area directly west of the Oregon Dunes Overlook off of Hwy 101 including the beach from Carter Lake trail to the north clearing, and south to the Overlook trail south of the south clearing.

**Tahkenitch Creek**, Douglas Co. (Figure 4) - Tahkenitch North Spit - the spit and beach on the north side of Tahkenitch Creek including the beach north to Overlook trail.

**Tenmile**: North Tenmile, Coos and Douglas Cos. (Figure 5) - the spit and ocean beach north of Tenmile Creek, north to the Umpqua River jetty; and South Tenmile, Coos Co. - the south spit, beach, and estuary areas within the Tenmile Estuary vehicle closure, and continuing south of the closure for approximately 1/2 mile.

**Coos Bay North Spit (CBNS)**, Coos Co. (Figure 6): South Beach - the beach between the north jetty and the F.A.A. towers; and South Spoil/HRAs - the south dredge spoil and adjacent habitat restoration areas (94HRA, 95HRA, 98HRA);

**Bandon Snowy Plover Management Area**, Coos Co. (Figure 7): This site includes the Bandon SPMA and all nesting areas from north of China Creek to the south end of state land south of the mouth of New River.

**New River**, Coos Co. (Figure 8) - the privately owned beach and sand spit south of Bandon Snowy Plover Management Area south to BLM lands, and the BLM Storm Ranch Area of Critical Environmental Concern habitat restoration area (HRA).

**Floras Lake**, Curry Co. (Figure 9) – the beach and overwash areas west of the confluence of Floras Creek and the beginning of New River, north to Hansen Breach.

The following additional areas were either surveyed in early spring or the breeding window survey: Clatsop Spit, Necanicum Spit, Nehalem Spit, Bayocean Spit, Netarts Spit, Sand Lake South Spit, Nestucca Spit, Whiskey Run to Coquille River, Sixes River South Spit, Elk River, Euchre Creek, and Pistol River.

## APPENDIX B.

**Recommendations for Management of Recreational Activities and Habitat Restoration for sites with Snowy Plovers along the Oregon Coast - 2012.**

**Sutton:**

- Continue to manage the nesting areas particularly at the Sutton Beach HRA; consider spreading shell hash or woody debris to improve the nesting substrate.
- Continue predator management when and if plovers are nesting to reduce predation pressure on broods, particularly corvids.
- Rope and sign around Sutton Beach HRA; rope and sign any other areas if plovers are detected using the beach.
- Place signs notifying people of current dog regulations.

**Siltcoos North and South Spits:**

- Continue predator management to reduce the number of corvids using the nesting area. Continue to reduce the feral cat population in the area. Continue to monitor and possibly remove coyotes that are using and possibly denning near the nesting area.
- Continue signage along river, especially east of nesting area and on any "islands" that may develop to alert kayak/canoe users about plover management activities.
- Continue to post the area with updated maps of the estuary and beach at several locations. These areas include the Stagecoach Trailhead, the north parking lot, and both ends of the Waxmyrtle Trail.
- Erect ropes and signs prior to 15 March, to be as effective as possible. Place signs and ropes on east and south side of the north spit nesting area as well as continued signage to the west and north.
- Enforce dog regulations on the spits and near the estuary during nesting season.
- Continue the use of campground plover hosts/volunteers to educate people and restrict them from closed areas. Use hosts/volunteers, especially during peak periods on weekends, and stagger their hours to cover evenings. Have hosts/volunteers in contact with Law Enforcement Officers to improve enforcement of the closures, and have them engage people on the beach before violations occur.
- Continue to extend appropriate signing to both riverbanks, to prevent hikers from walking up the closed estuary.
- Rope and sign along the foredune south of Waxmyrtle trail access to the Carter Lake trail area; monitor this area for roosting, nesting and brooding plovers.

**Overlook:**

- Continue predator management to control corvid use of the area. Monitor Northern Harrier and Great Horned Owl use of the area and consider removal if harriers and owls continue to pose problems to breeding plovers.
- Continue to rope and sign both north and south closures for Snowy Plover nesting habitat by 15 March.
- Continue to improve and enlarge the restoration area, especially to the south towards Tahkenitch.
- Erect and maintain interpretive signing at the beginning of the Overlook trailhead (near viewing platforms). This signing is intended to provide more information on the ecology of the Snowy Plover and the reasoning for current management techniques and restricted areas.
- Enforce current dog regulations.

**Tahkenitch:**

- Continue to maintain and improve the habitat.
- Continue predator management to control corvid use of the area. Identify if Great Horned Owls or other avian predators are hunting the area. Remove if necessary.
- Continue to rope and sign all suitable habitat. Place signs along east and south edge outside of the roped area to prevent hiking and camping near nesting area.
- Enforce current dog regulations.

**Tenmile North and South Spits:**

- Continue predator management to control corvid use of the area; continue to monitor coyote use and possibly remove coyotes if warranted. Monitor and remove Great Horned Owls if necessary. Evaluate rodent populations and depredations.
- Continue to maintain and improve the south side for nesting. Consider expanding and improving habitat on the north side.
- Continue to rope and sign plover nesting habitat on both north and south spits.
- Enforce vehicle closure to prevent violators from driving in the habitat restoration areas.
- Enforce current dog regulations.

**Coos Bay North Spit:**

- Continue predator management of the area for corvids, feral cats, skunks, and raccoons; monitor the coyote population and remove coyotes if warranted; continue early season rodent trapping to reduce rodent population.
- Continue to improve and maintain the habitat restoration areas. Continue to spread shell hash to improve nesting substrate.
- Maintain gaps in the berm along the 95HRA to facilitate brood movement from the 94HRA and 98WHRA to the 95HRA and to the beach. Maintain small vegetation free gaps in the foredune to facilitate brood access to the beach without destabilizing the foredune.
- Continue to rope and sign the beach as early in the nesting season as possible; avoid erecting signs where the ocean is repeatedly lapping against the foredune to reduce sign loss.
- Clearly sign all entrance points on the spit that the beach is street legal vehicles only.
- Continue closure of the foredune road through the nesting area. Consider a permanent reroute of the foredune road.
- Enforce current dog regulations.

**Bandon:**

- Continue predator management to control mammal and corvid populations.
- Continue to improve and maintain the habitat restoration area north of New River/Twomile Creek. Maintain and improve "cutouts" along the foredune to increase available nesting habitat for plovers; consider additional cutouts along foredune.
- Sign and rope the entire beach from China Creek overwash to the Habitat Restoration Area near the mouth of Twomile Creek/New River before the nesting season.
- Enforce current dog regulations.
- Monitor hiker use from Bandon to Blacklock Point, and check the beach and HRA on weekends for illegal camping activity. Consider beginning a permit system for hikers and campers.

- In 2012, there was probable take of two adult plovers at an exclosed nest at Bandon SPMA. There have been ongoing violations and vandalism at this site. We recommend frequent ranger patrols of this area and continued use of volunteers in the parking lot.
- Based on BLM registrations and monitors' observations, the number of hikers along the coast trail between Bandon SPMA and Floras Lake was reduced in 2012, however, there was some illegal camping along the New River area. New signs with maps have helped educate hikers. We recommend this education effort be continued.

**New River:**

- Continue predator management to control mammal and corvid populations.
- Continue to improve and maintain the habitat restoration area.
- Sign the foredune north of the HRA along the foredune.
- Place interpretive signs near the Lower Fourmile access along the river to inform the public of plover activity.
- Sign State Parks lands on the open spit south of the mouth of New River.
- Enforce current dog regulations.
- Use interpretive specialist to help monitor recreational activities in the area and explain the management efforts in the area.
- Continue to close the gate at the Storm Ranch for 15 April- 15 September.
- Illegal camping continues in the New River area although new signs and maps have. Hikers will need to continue to be informed about new regulations regarding dogs. We recommended that a permit process be considered to help educate hikers, limit their numbers, ensure that they do not have dogs, are legally camping, and are in compliance .

**Floras Lake:**

- Monitor the site for any plover activity.
- Enforce dogs on leash rules at all times.
- Continue to hire an on-site interpretive specialist, to contact the public, monitor the beach, and present slide shows.

## APPENDIX C

**Recovery Unit 1 (Oregon & Washington)**
**Exclosure Use Guidelines Developed by Oregon Biodiversity Information Center for the Western Snowy Plover Working Team**
**2/27/2012**

Nest exclosures are mesh fences that surround a Western Snowy Plover (*Charadrius nivosus nivosus*) nest and act to keep out predators. Nest exclosures have been used in Oregon since 1991 to protect plover nests from depredation by mammalian and avian predators. Prior to implementation of comprehensive predator management, plovers have suffered high rates of nest depredation. Exclosures have been successful at increasing nest success rates (Table 1) (Stern *et al.* 1990, 1991, Craig *et al.* 1992, Casler *et al.*1993, Hallett *et al.*1994, 1995, Estelle *et al.*1997, Castelein *et al.*1997, 1998, 2000a, 2000b, 2001, 2002, Lauten *et al.*2003, 2005, 2006, 2006b, 2007, 2008, 2009, 2010, 2011). Predators that prey on snowy plover eggs include mammalian predators such as skunk (*Mephitis sp.*), red fox (*Vulpes vulpes*), coyote (*Canis latrans*), raccoon (*Procyon lotor*), mice (*Peromyscus* sp.), and weasel (*Mustela sp.*); and avian predators, mostly American crows (*Corvus brachyrhynchos*) and common ravens (*Corvus corax*).

Since 1990, we have found 2650 snowy plover nests along the Oregon coast, of which 1057 (40%) have been exclosed. Over the years we have had to adapt exclosure techniques in response to predator behavior around exclosures. (see Castelein *et al.*2000a, 2000b, 2001, Lauten *et al.*2003).

In 1995 we began seeing evidence of adult snowy plover depredations in or immediately outside exclosures. From 1995 to 2011 we documented a minimum of 48 adult losses associated with exclosure use. These losses include 21 cases where blood, feathers, or plover body parts were found in or adjacent to exclosures and 27 cases where incubating adults disappeared from an established, exclosed nest. Forty-eight adult losses associated with 1057 exclosed nests indicate that exclosures subject adult plovers to additional predation risk (approximately 4%). Similar threats associated with exclosures have been reported in other plover populations (Murphy *et al.*2003, Hardy and Colwell 2008, Pearson *et al.*2009). We do not have information on how many adults may be lost at nests not associated with exclosures.

Predator exclosures increase snowy plover hatching success and the number of chicks hatched per male, but not fledging success or the number of chicks fledged per male (Neuman *et al.*2004). In Oregon, they pose an additional risk to incubating adults and may negatively impact adult survival. As in Washington, exclosure use in Oregon has been a management technique, not part of a study of their effectiveness in increasing the overall plover population. We are working with Steve Dinsmore (Department of Natural Resource Ecology and Management, Iowa State University) to evaluate the effectiveness of exclosure use on nest success and adult survival. Preliminary results indicate that, predictably, exclosure use has a strong positive impact on nest success. Further analysis is underway to determine potential impacts of exclosure use on adult success and fledging success (Dinsmore et al., unpublished data) (see Pearson *et al.*2009, Neuman *et al.*2004).

Scott Pearson *et al.* (2009) conducted a search of existing literature on the effects of nest exclosures on nest success for plovers and other ground nesting species (primarily shorebirds). Their findings are summarized below:

- Nest survival of exclosed nests was significantly higher in ten studies (Rimmer and Deblinger 1990, Melvin *et al.*1992, Estelle *et al.*1996, Johnson and Oring 2002, Lauten *et al.*2004, Niehaus *et al.*2004, Isaksson *et al.*2007, Hardy and Colwell 2008, Pauliny *et al.*2008, Pearson *et* *al.*unpublished), and there was no difference in two studies (Nol and Brooks 1982, Mabee and Estelle 2000).

- Exclosed nests appear to be only vulnerable to reptilian and small mammal predators while unexclosed nests are vulnerable to predators of all sizes (Mabee and Estelle 2000).
- No difference in fledging success between exclosed and unexclosed nests in four studies (Hardy and Colwell 2008, Pauliny *et al.*2008, Lauten *et al.*2004, Pearson *et al.* unpublished data) and higher fledging success for exclosed nests in two studies (Larson *et al.*2002, Melvin *et al.*2002). There was no difference in fledging success between exclosed and unexclosed nests for all studies involving snowy plovers.
- Adult mortality associated with exclosures was reported in six of the eight studies that included or mentioned this response variable (Murphy *et al.*2003, Lauten *et al.*2004, Isaksson *et al.*2007, Hardy and Colwell 2008, Pauliny *et al.*2008, Pearson *et al.*unpublished). Only three studies compared adult mortality between exclosed and unexclosed nests and two reported significant increases in adult mortality associated with exclosures (Murphy *et al.*2003 and Isacsson 2007) and one reported no difference (Pauliny *et al.*2008).
- Adult mortality appears to be largely attributable to raptors and appears to be episodic (Murphy *et al.*2003, Neuman et a. 2004, Hardy and Colwell 2008) and differs among habitats (Murphy *et al.*2003).
- Larson *et al.*2002 examined the effect of exclosures on population growth for piping plovers and found the effect to be positive.
- Abandonment was higher for exclosed nests in two studies where this was compared directly (Isaksson et al., 2007, Hardy and Colwell 2008).
- Abandonment was not associated with the construction process, size, shape, mesh size and fence height (Vaske *et al.*1994). Covered exclosures are more likely to be abandoned than uncovered exclosures (Vaske *et al.*1994).
- Exclosures increased incubation length by one day but did not influence chick condition (Isaksson *et al.*2007).
- Egg hatchability was higher in three studies (Melvin *et al.*1992, Isaksson *et al.*2007, Pauliny *et al.*2008) but no difference was observed in one study (Hardy and Colwell 2008).
- Breeding adults may receive false messages regarding site quality and encouragement to continue to breed in sink habitats (Hardy and Colwell 2008). This is an important research question that should be examined but no data support this contention.

Our data and that of others (Murphy *et al.*2003, Hardy and Colwell 2008, Pearson *et al.*2009) indicate that adult plovers are at increased risk of predation while in exclosures. In the absence of research to quantify that risk, and based on the above information, we developed the following guidelines for exclosure use in Oregon:

- Since raptors appear to be the primary threat to adult plovers in exclosures, delay use of exclosures until peak raptor migration has passed. Currently, we have identified May 15 as a suitable cutoff, but this date could be altered as needed.

- Delaying exclosure use until May 15 allows field personnel time to assess causes of early nest failures, although weather conditions can make accurate assessment difficult. During this time, and contingent on funding, we recommend an owl survey be run at each site.

- If nests are being lost primarily to mice, exclosures will not help the problem, and may pose additional risk if the mice are being preyed upon by raptors. In this case exclosure use is not appropriate.

- If corvids and/or large mammals are identified as the main predator at a site, removal of the predators should be the primary goal with exclosures used as a supplemental measure to help protect nests.

- Any use of exclosures should be accompanied by close monitoring to evaluate their effectiveness (Hardy and Colwell 2008) and to detect predators of adult plovers early (Pauliny *et al.*2008). Weather permitting, exclosed nests should be checked at least twice per week. If conditions do not allow checks twice a week, exclosure use should be seriously reconsidered.

- Adult predation associated with exclosures is often episodic (Castelein *et al.* 2000b, Lauten *et al.* 2006). Once adult predation is suspected, all exclosures should be removed from the site and their use discontinued for the season.

- To minimize the risk of episodic predation on adult plovers, additional caution should be used when placing exclosures within sight of each other (this puts multiple adults at risk).

- Exclosures should not be placed along the foredune.

- Exclosures should not be placed in a windy location that might result in nest drifting. Since the ME's are 4 feet per side, the nest is only about 2 feet from each sidewall. If the nest begins to drift, it could come close to a sidewall, and a predator such as a raccoon could reach in and grab the eggs. If an exclosed nest is in a potentially windy location, it must be monitored frequently to ensure the safety of the nest and adults (especially on windy days).

# Appendix D

## Snowy Plover Monitoring Methods

### Nest Surveys

Monitoring began the first week in April and continued until all broods fledged, typically by mid-September. We used two teams of two biologists; one team covering Tenmile and sites north, and the other covering Coos Bay North Spit and sites south (Fig. 1). In some years this division has been modified to accommodate staff needs. All data collected in the field was recorded in field notebooks and later transferred onto computer. Surveys were completed on foot and from an all-terrain vehicle (ATV). Data recorded on nest surveys included:

- site name
- weather conditions
- start time and stop time
- direction of survey
- number of plover seen, broken down by age and sex
- band combinations observed
- potential predators or tracks observed
- violations/human disturbance observed

Weekly surveys were attempted, but were not always possible due to increasing workload associated with an increased plover population. Additional visits were made to check nests, band chicks, or monitor broods.

### Population Estimation

We estimated the number of Snowy Plovers on the Oregon Coast by determining the number of individually color banded adult Snowy Plovers recorded during the breeding season, and then adding an estimated number of unbanded Snowy Plovers. We determined the number of unbanded Snowy Plovers observed within ten-day intervals during the breeding season, selected the highest count of unbanded birds and then subtracted the number of adults that were banded subsequently. We also determined the number of plovers known to have nested at the study sites, including marked birds and a conservative minimum estimate of the number of unbanded plovers.

### Nest Monitoring

We located nests using methods described by Page et al. (1985) and Stern et al. (1990). We found nests by scoping for incubating plovers, and by watching for female plovers that appeared to have been flushed off a nest. We also used tracks to identify potential nesting areas. We defined a nest as a nest bowl or scrape with eggs or tangible evidence of eggs in the bowl, i.e. egg shells. We predicted hatching dates by floating eggs (Westerkov 1950) and used a schedule, developed by G. Page based on a 29-day incubation period (Gary Page, pers comm). We attempted to monitor nests once a week at minimum. We checked nests more frequently as the expected date of hatching approached. We defined a successful nest as one that hatched at least one egg. A failed nest was one where we found buried or abandoned eggs, infertile eggs, depredated eggs, signs of depredation (e.g. mammalian or avian tracks or eggshell remains not typical of hatched eggs or nest cup disturbance) or eggs disappeared prior to the expected hatch date and were presumed to have been predated. In some instances we found nests with only one egg; often there was no indication of incubation or nest defense, and it was uncertain to what extent the nest was abandoned, or simply a "dropped" egg. Because it was difficult to make this determination, we considered all one egg clutches as nest attempts, and classified them as abandoned when there was no indication of incubation or nest defense. Data recorded at nest checks included:

- nest number
- number of eggs in nest
- adult behavior
- description of area immediately around nest
- whether or not the nest is exclosed
- GPS location

**Brood Monitoring**

We monitored broods during surveys and other field work, and recorded brood activity or males exhibiting brood defense behavior at each site. "Broody" males will feign injury, run away quickly or erratically, fly around and/or vocalize in order to distract a potential threat to his chicks. Information recorded when broods were detected included:

- Number of adults and chicks
- Band combinations of adults/chicks seen
- Sex of adults
- Behavior of adults
- Brood location

**Banding**

Adults were normally trapped for banding on the nest, during incubation, using a lilly pad trap and noose carpets. Lilly pad traps are small circular traps made of hardware cloth with a blueberry net top. The traps have a small door that the plover will enter. Noose carpets are 4" x 30" lengths of hardware cloth covered with small fishing line nooses. Plovers walk over the carpets and the nooses snag their legs. We limited attempts to capture adults to 20 minutes per trapping attempt. Chicks were captured for banding by hand, usually in the nest bowl. Banding was completed in teams of two to minimize time at the nest and disturbance to the plovers.

## Abstract

From 26 March – 19 September 2013 we monitored the distribution, abundance and productivity of the federally Threatened Western Snowy Plover (*Charadrius nivosus nivosus*) along the Oregon coast. From north to south, we surveyed and monitored plover activity at Sutton Beach, Siltcoos River estuary, the Dunes Overlook, North and South Tahkenitch Creek, Tenmile Creek, Coos Bay North Spit, Bandon Snowy Plover Management Area, New River HRA and adjacent lands, and Floras Lake. Our objectives for the Oregon coastal population in 2013 were to: 1) estimate the size of the adult Snowy Plover population, 2) locate plover nests, 3) determine nest success, 4) use mini-exclosures (MEs) to protect nests from predators as needed, 5) determine fledging success, 6) monitor brood movements, 7) collect general observational data about predators, and 8) evaluate the effectiveness of predator management.

We observed an estimated 304 adult Snowy Plovers; a minimum of 190-191 individuals was known to have nested. The adult plover population was the highest estimate recorded since monitoring began in 1990. We monitored 381 nests in 2013; the highest number of nests since monitoring began in 1990. Overall apparent nest success was 24%. Exclosed nests (n = 18) had an 83% apparent nest success rate, and unexclosed nests (n = 362) had a 21% apparent nest success rate. Nest failures were attributed to unknown depredation, unknown cause, avian depredation, corvid depredation, one-egg nests, wind/weather, abandonment, mammalian depredation, overwashed, infertility, and adult plover depredation. We monitored 101 broods, including eight from unknown nests, and documented a minimum of 103 fledglings. Overall brood success was 71%, fledging success was 39%, and 1.04 fledglings per male were produced.

Continued predator management, habitat improvement and maintenance, and management of recreational activities at all sites are recommended to maintain recovery goals.

**TABLE OF CONTENTS**

## Introduction

The Western Snowy Plover (*Charadrius nivosus nivosus*) breeds along the coast of the Pacific Ocean in California, Oregon, and Washington and at alkaline lakes in the interior of the western United States (Page *et al.* 1991). Loss of habitat, predation pressures, and disturbance have caused the decline of the coastal population of Snowy Plovers and led to the listing of the Pacific Coast Population of Western Snowy Plovers as Threatened on March 5, 1993 (U.S. Fish and Wildlife Service 1993). Oregon Department of Fish and Wildlife lists the Western Snowy Plover as threatened throughout the state (ODFW 2009).

Oregon Biodiversity Information Center (ORBIC, formerly Oregon Natural Heritage Information Center) completed our 24$^{th}$ year of monitoring the distribution, abundance, and productivity of Snowy Plovers along the Oregon coast during the breeding season. In cooperation with federal and state agencies, plover management has focused on habitat restoration and maintenance at breeding sites, non-lethal and lethal predator management, and management of human related disturbances to nesting plovers. The goal of management is improved annual productivity leading to increases in Oregon's breeding population and eventually sustainable productivity and stable populations at recovery levels. Previous work and results have been summarized in annual reports (Stern *et al.* 1990 and 1991, Craig *et al.* 1992, Casler *et al.* 1993, Hallett *et al.* 1994, 1995, Estelle *et al.* 1997, Castelein *et al.* 1997, 1998, 2000a, 2000b, 2001, and 2002, and Lauten *et al.* 2003, 2005, 2006, 2006b, 2007, 2008, 2009, 2010, 2011, and 2012). Our objectives for the Oregon coastal population in 2013 were to: 1) estimate the size of the adult Snowy Plover population, 2) locate plover nests, 3) determine nest success, 4) use mini-exclosures (MEs) to protect nests from predators as needed, 5) determine fledging success, 6) monitor brood movements, 7) collect general observational data about predators, and 8) evaluate the effectiveness of predator management. The results of these efforts are presented in this report.

## Study Area

We surveyed Snowy Plover breeding habitat along the Oregon coast, including ocean beaches, sandy spits, ocean-overwashed areas within sand dunes dominated by European beachgrass (*Ammophila arenaria*), open estuarine areas with sand flats, a dredge spoil site, and several habitat restoration/management sites. From north to south, we surveyed and monitored plover activity at Sutton Beach, Siltcoos River estuary, the Dunes Overlook, North and South Tahkenitch Creek, Tenmile Creek, Coos Bay North Spit (CBNS), Bandon Snowy Plover Management Area (SPMA), New River (extending from private land south of Bandon SPMA to the south end of the New River Area of Critical Environmental Concern (ACEC) habitat restoration area), and Floras Lake (Figure 1). A description of each site occurs in Appendix A. For the purposes of this report and for consistency with previous years' data, we define Bandon Beach as the area from China Creek to the mouth of New River, and Bandon SPMA as all the state land from the north end of the China Creek parking lot south to the south boundary of the State Natural Area south of the mouth of New River.

## Methods

### Abundance

Pre-breeding surveys have been implemented since 2001 to locate any plovers attempting to nest at historic (currently inactive) nesting areas. In 2013, pre-breeding window surveys at historical nesting sites between Clatsop Spit, Clatsop Co. and Pistol River, Curry Co (Elliott-Smith and Haig 2007) were not conducted due to budget restraints. Agency personnel assisted surveying plovers during breeding season window surveys in late May. Breeding season window surveys were implemented at both currently active and historic nesting areas (Elliott-Smith and Haig 2007). Historic nesting areas surveyed in either early spring or during the breeding window survey include: Clatsop Spit, Necanicum Spit, Nehalem Spit, Bayocean Spit, Netarts Spit, Sand Lake South Spit, Nestucca Spit, Whiskey Run to Coquille River, Sixes River South Spit, Elk River, and Euchre Creek. Pistol River was not surveyed in 2013.

**Monitoring**

Breeding season fieldwork was conducted from 26 March to 19 September 2013. Survey techniques, data collection methodology, and information regarding locating and documenting nests can be found in Castelein *et al.* 2000a, 2000b, 2001, 2002, and Lauten *et al.* 2003 and are in Appendix D. No modifications to survey techniques were implemented in 2013.

We report three measures of population size: the total number of Snowy Plovers present, the total number identified breeding, and the total number of plovers resident during the breeding season. We estimated the number of Snowy Plovers on the Oregon coast during the 2013 breeding season by determining the number of uniquely color-banded adult Snowy Plovers observed, and added an estimate of the number of unbanded Snowy Plovers present. We used the 10 day interval method described in Castelein *et al*. 2001 to estimate a minimum number of unbanded plovers, however, based on nesting records and daily observational data this method likely underestimates the actual number of unbanded plovers present. We estimated the breeding population by tallying the number of known breeding plovers. Not all plovers recorded during the summer are Oregon breeding plovers; some plovers are recorded early or late in the breeding season indicating that they are either migrant or wintering birds. Plovers that were present throughout or during the breeding season, whether or not they were confirmed breeders, were considered Oregon resident plovers. We estimated an overall Oregon resident plover population by adding the known breeders with the number of plovers present but not confirmed nesting during the breeding season.

We determined the number of individual banded female and male plovers and the number of individual unbanded female and male plovers that were recorded at each nesting area along the Oregon coast from the beginning to the end of the 2013 breeding season. Data from nesting sites with a north and south component (Siltcoos, Overlook, Tahkenitch, and Tenmile) were pooled because individual plovers use both sides of these estuaries. Data from CBNS nesting sites were pooled for the same reason. We separated data from Bandon SPMA, New River HRA, and Floras Lake because of different management at these sites, despite plovers frequently moving between these areas. The total number of individual plovers recorded at each site indicates the overall use of the site, particularly where plovers congregate during post breeding and wintering. We also determined the number of individual breeding female and male plovers for each site. The number of individual breeding adults indicates the level of nesting activity for each site.

Using all nests, we calculated overall apparent nest success, which is the number of successful nests divided by the total number of nests, for all nests and for each individual site. We also calculated apparent nest success for exclosed and unexclosed nests and used Chi-squared analysis to compare the success of exclosed and unexclosed nests.

Male Snowy Plovers typically rear their broods until fledging. In order to track the broods we banded most nesting adult males, females that tended to broods, and most hatch-year birds with both a USFWS aluminum band and a combination of colored plastic bands. Trapping techniques are described in Lauten *et al*. 2005 and 2006 (Appendix D). We monitored broods and recorded brood activity or adults exhibiting broody behavior at each site (Page *et al*. 2009). Chicks were considered fledged when they were observed 28 days after hatching.

We calculated brood success, the number of broods that successfully fledged at least one chick; fledging success, the number of chicks that fledged divided by the number of eggs that hatched; and fledglings per male for each site.

We continue to review plover productivity prior to lethal predator management activities compared to productivity after implementation of lethal predator management. We specifically continue to evaluate the changes in hatch rate, fledging rate, productivity index, and fledglings per male from years prior to lethal predator management compared to years with lethal predator management. The productivity index is a measure of overall effort based on how many eggs the plovers laid divided by the number of fledglings produced. If plovers produced high numbers of fledglings compared to eggs laid, then their productivity and the resulting index was high for the amount of effort (eggs laid). If plovers produced low numbers of fledglings relative to high numbers of eggs laid, then their productivity and the resulting index was low. Data for brood success, fledging success, and fledglings per male were all normally distributed. We used t-test to compare the mean brood success, the mean fledging rate and the mean number of fledglings per male prior to predator management (1992-2001) to post predator management (2004-2013). We did not include the years 2002 and 2003 in the analysis because three sites (CBNS, Bandon Beach, and New River) had predator management in those years but all other sites did not.

**Exclosures**

From mid-May to August, we used a limited number of mini-exclosures (MEs, Lauten *et al.* 2003) to protect plover nests at South Siltcoos, North Overlook, North Tenmile, Bandon SPMA and New River as outlined in our exclosure use protocol (Appendix C). No exclosures were used on plover nests found during April and into early May due to concerns related to raptor migration (Castelein *et al.* 2001, 2002, Lauten *et al.* 2003). Exclosure use was limited in 2013 because presence of avian predators (Northern Harriers (*Circus cyaneus*) and Great Horned Owls (*Bubo virginianus*)) resulted in concerns about depredations of adult plovers in and around ME's. No exclosures were used at North Siltcoos, South Overlook, North and South Tahkenitch, South Tenmile, and Coos Bay North Spit.

**Predator Management**

Lethal predator management occurred at all active nesting areas; corvids (*Corvus sp*.) were targeted at all nesting sites. Mammal trapping targeting red fox (*Vulpes vulpes*) and striped skunks (*Mephitis mephitis*) occurred at Bandon SPMA and New River (Burrell 2013). In 2011 and 2012 a trapping effort targeting deer mice (*Peromyscus maniculatus*) was conducted at CBNS (Lauten *et al*., 2011 and 2012). In 2013 there was a less extensive effort to trap deer mice on a portion of the habitat restoration area (HRA) by several students from Southwest Oregon Community College. Rodent trapping was limited to March, before the plovers were nesting (Burrell 2013).

## Results and Discussion

### Abundance and Monitoring

#### Window Surveys

During the May breeding window surveys, no plovers were detected outside of the current known nesting areas (USFWS unpublished data). The annual breeding window survey in late May counted 215 plovers (Table 1), the highest number of plovers ever detected.

#### Breeding Season Monitoring

During the 2013 breeding season, we estimated 304 adult Snowy Plovers at breeding sites along the Oregon coast (Table 1). Of 304 plovers, 281 (92%) were banded. The number of unbanded plovers estimated by the 10 day interval method was 23 individuals. For the breeding season we observed 126 banded females, 155 banded males, 14 unbanded females, and 9 unbanded males. The totals include nine banded males and six banded females, all resident or breeding individuals, which disappeared during the breeding season.

Of the total estimated population, 190-191 plovers (63%) were documented nesting (Table 1), below the mean percentage for 1993-2012 (79%). A minimum of 83 banded females and 84 banded males nested. Approximately 14-15 unbanded females nested and nine unbanded males were known to have nested. An additional 42 banded females and 67 banded males were present during the breeding season but were not confirmed nesting. The estimated Oregon resident plover population was 299-300.

The total number of plovers present and the window survey totals were the highest numbers since monitoring began in 1990 (Table 1), though the rate of population increase was smaller than in the recent past. The number of plovers detected breeding declined by approximately 43 individuals (Table 1) due to difficulties positively identifying all nesting individuals. In 2013, many nests failed early in the incubation period, resulting in an inability to positively identify the associated adults. The actual number of breeding individuals was certainly higher as nearly all adults that are resident birds attempt to nest (ORBIC, personal obs.). The number of resident plovers in 2013 was higher than in 2012 (n = 271-278). The number of resident plovers is likely a better index of the estimated number of plovers breeding along the Oregon coast. In 2013, the Oregon coastal plover population was above the recovery goal set for the state (U.S. Fish and Wildlife Service 2007).

#### Overwinter Survival

As has been noted in the past, adult overwinter survival has an important effect on population size (Sandercock 2003, USFWS 2007, Dinsmore *et al*. 2010, Lauten *et al*. 2010, 2011, and 2012). Of the 273 banded plovers recorded in 2012 (corrected from 270 in Lauten *et al.* 2012), 96 (40%) were not recorded in 2013 and we received no reports of these individuals being sighted elsewhere in the range. The overwinter return rate based on returning banded adult plovers was 65%, equal to the 1994-2013 mean of 64.8% but below the previous four years (2009 = 72%, 2010 = 78%, 2011 = 75%, and 2012 = 72%; Lauten *et al*., 2009, 2010, 2011, and 2012).

Based on returns of chicks banded in 2012, we adjusted the 2012 fledgling total to 172 from 180. Ninety-one of the 180 hatch-year plovers from 2012 (HY12) returned to Oregon in 2013. The return rate was 51%, slightly above the average return rate (Table 2, 47%). Of the returning HY12 birds, 40 (44%) were females and 51 (56%) were males. Fifty-one of the HY12 returning plovers were confirmed breeding (56%), and they accounted for 31% of the banded breeding adults. The relatively low rate of confirmed breeding by HY12 plovers was likely due to nests failing early in the incubation period, before monitors could identify nesting adults, and not due to HY12 plovers not attempting to nest. The number of HY12 returns was slightly less than the number of banded adults that did not return in 2013. The average return rates for both adults and hatch year birds contributed to maintaining the plover population, but because the return rates were not above average, the overall plover population did not substantially increase from 2012 (Table 1).

During the 2013 season, we captured and rebanded 18 banded adult plovers with brood band combinations that needed to be updated to unique adult combinations. Thirteen were males and five were females. We banded two unbanded adult male plovers, one unbanded adult female plover and 196 chicks.

**Distribution**

Table 3 shows the number of individual banded and unbanded adult plovers and the number of breeding adult plovers recorded at each nesting area along the Oregon coast in 2013. Sites with high levels of nest loss early in the incubation period resulted in lower numbers of documented breeding plovers. Positive identification of nesting adults increases with nest age because monitors have multiple opportunities to identify nesting adults and because both adults are often present when nests hatch. Five plovers were recorded at Sutton Beach in 2013; there were no plovers recorded at Sutton Beach in 2012. The number of plovers at Siltcoos increased from 67 in 2012 to 91 in 2013. The number of breeding plovers at Siltcoos was similar to previous years (Table 3, 27 in 2012, 26 in 2011, 23 in 2010, and 24 in 2009). Fewer plovers were recorded at Overlook in 2013 compared to 2012 (83 in 2013 compared to 94 in 2012), however the number of breeding adults documented was considerably less (16 in 2013 compared to 51-53 in 2012). More plovers were recorded at Tahkenitch in 2013 (n = 82) compared to 2012 (n = 67-68), however the number of breeding plovers was lower (22 in 2013 compared to 31-32 in 2012). The number of plovers recorded at Tenmile in 2013 increased compared to 2012 (72 in 2013 compared to 58-59 in 2012) and the number of breeding plovers also increased (34-35 in 2013 compared to 20-21). The increase in the number of breeding plovers was related to improved nest success at this site. The number of plovers recorded at CBNS in 2013 was the same as 2012 (n = 92), however the number of breeding plovers declined from 77-78 in 2012 to 52 in 2013. The number of plovers using Bandon SPMA in 2013 slightly increased compared to 2012 (76 in 2013 compared to 68-69 in 2012) and the number of breeding plovers increased (46 in 2013 compared to 29 in 2012). The increase in the number of breeding plovers is partially attributed to higher nest success in 2013 compared to 2012. The number of plovers recorded at New River HRA in 2013 was the same as in 2012 (n = 24). The number of breeding plovers increased from 14 in 2012 to 22 in 2013; the increase in breeding adults was attributed to much higher nest success in 2013 compared to 2012. Only one plover was recorded at Floras Lake in 2013.

We have noted in previous reports that the increased plover population has resulted in plovers occupying available habitat adjacent to the traditional nesting areas (Lauten *et al*. 2010, 2011, and 2012). Lauten *et al*. (2011 and 2012) noted the possibility that the increasing plover population would likely result in plovers occupying additional beaches, such as South Tahkenitch to the Umpqua jetty, the beach north of North Tenmile, and CBNS beach north of the FAA tower. As in 2011 and 2012, plovers did nest north of the North Tenmile spit (Figure 5). At CBNS in 2012, we found one nest north of the FAA towers; in 2013 we found nine nests north of the FAA towers (Figure 6). In 2013 six nests and one brood from an undiscovered nest were found at South Tahkenitch south of Threemile Creek. Plovers and nest scrapes were observed on the beach south of South Tenmile and north of Horsefall Beach, but no nests were found.   The plover population size did not increase substantially between 2012 and 2013 (Table 1).  The increased nesting attempts north of the FAA tower and at South Tahkenitch were mostly due to high nest failure rates; when plovers repeatedly fail they will often move to new locations to renest.  Due to plovers' propensity to nest in subsequent years where they have successfully hatched, and due to the increasing population size, we expect the plovers to continue to occupy and nest on the sections of beach adjacent and between the main nesting sites.

**Nest Activity**

We located 381 nests during the 2013 nesting season (Table 4, Figures 2-9), the highest number of nests found since monitoring began in 1990.  In addition we recorded eight broods from nests that we did not locate prior to hatching.  The increase in the number of nests from 2012 was mostly due to nest failures and therefore repeated renesting attempts.  Sutton had one nest attempt in 2013, the first nest since 2010.  Siltcoos had 11 more nests in 2013 compared to 2012; eight were on the south side (Table 4).  Overlook had a similar number of nests in 2013 compared to 2012.  Tahkenitch had a large increase in nest numbers in 2013 compared to 2012.  There were 16 more nest attempts on the north side of the creek, and for the first time since 2003, plovers were confirmed nesting on the south side of the creek.  The number of plovers and thus the number of nests at Tahkenitch has increased substantially since 2010.  At Tenmile, the north side had a similar number of nests compared to 2012, while the south side had a decrease in the number of nests compared to 2012; in addition four of the broods from undiscovered nests were at North Tenmile.  CBNS had the largest increase in the number of nests; 45 more nests were found in 2013 compared to 2012.  The large number of nests found at CBNS was due to poor nest success and resulting repeated nesting attempts.  South Spoil had similar numbers of nests in 2013 compared to 2012, while the HRAs had an increase of 19 nests.  South Beach also had a large increase in nest attempts (29 more nest attempts in 2013 compared to 2012).  .  Nine nests were found along the open section of beach north of the FAA towers after repeated failed nest attempts either on the nesting area or further south on the beach.  Bandon SPMA had a similar number of nests in 2013 compared to 2012.  There were 44 nests on Bandon Beach and 20 nests on the state portion of New River spit.  The number of nests at New River HRA declined; there were nine nests attempts in 2013 compared to 17 in 2012 and two broods from undiscovered nests were on the New River HRA.  The lower number of nests on the New River HRA was due to increased nest success, as the number of plovers using the New River HRA remained stable.  There were three nests found on private lands along New River, all north of the HRA.  Floras Lake had no nesting activity in 2013.

The first nests were initiated about 26 March (Figure 11).  Nest initiation increased through early May at which time there was a steep decline in nest activity due to nest failure.  Plovers initiated renest attempts in late May into early June, with peak nest activity (n = 109) occurring during the 10 June – 19 June time interval.  This was the highest number of active nests during any 10 day time interval since monitoring began in 1990.  The last nest initiation occurred on 20 July.

**Nest Success and Exclosures**

The number of days nests were unexclosed was higher than the number of days nests were exclosed (Figure 12).  In 2013, exclosures were used on 5% (n = 19) of the total number of nests (n = 381), and 6% of the total number of exposure days were exclosed (n = 253/4548).

The overall annual apparent nest success rate in 2013 was 24% (Table 5), the lowest rate since monitoring began in 1990 (Table 6).  Nineteen nests were exclosed in 2013 (5%), the fewest since 1991.  Apparent nest success for exclosed nests in 2013 was 83%, higher than the average for all years ($x$ = 71%,

Table 6). The number of unexclosed nests in 2013 (n = 362, 95%) was the highest since monitoring began. Apparent nest success for unexclosed nests in 2012 was 21%, near the overall mean ($x$ = 20%, Table 6). Nest success of unexclosed nests in 2013 was significantly lower than nest success of exclosed nests ($\chi^2 = 32.6931$, df = 1, $P < 0.01$).

**Sutton**

There was only one nest at Sutton Beach in 2013 early in the season (Table 5). Two eggs were laid but incubation was not confirmed before it failed quickly due to unknown cause (Table 7). There was no other plover activity at Sutton after April.

**Siltcoos**

No exclosures were used at North Siltcoos in 2013 (Table 5); three of 13 nests successfully hatched (23%). Two exclosures were used at South Siltcoos, and three of 28 unexclosed nests successfully hatched (12%). Overall nest success for Siltcoos was 19% (Table 5), well below the average for these sites (Figure 13). The main cause of nest failure at Siltcoos was unknown cause and unknown depredation (Table 7). Corvid activity at Siltcoos was considered moderate with crows being more prevalent at North Siltcoos and ravens present early and late in the season. One nest was depredated by a Northern Harrier based on tracks at the nest site, and harrier activity was regularly noted. Due to raptor activity and concerns about adult plovers in and around exclosures, we limited the use of exclosures at Siltcoos.

**Overlook**

The overall nest success at Overlook in 2013 was 5% (Table 5). Three of 33 nests hatched at North Overlook (9%) and no nests were successful at South Overlook (Table 5), both well below average for these sites (Figure 13). Only one nest was exclosed at Overlook, on the north side, and it failed after the adult male associated with the nest disappeared. We found raptor tracks around the exclosure, which we believe were Northern Harrier, leading us to conclude the male was depredated. One nest at South Overlook failed with evidence of Northern Harrier at the nest site, and another nest at South Overlook also had evidence of an avian predator but we were uncertain if it was harrier or corvid. Seven total nests failed due to corvids and 36 other nests failed to unknown depredation (Table 7). Six other nests failed due to unknown cause. Six of the seven corvid depredated nests occurred prior to 15 May, before implementation of exclosure use. After 15 May corvid activity was not considered high, but harrier activity was consistently observed. Due to the evidence that harriers were regularly hunting the nesting area, we did not erect exclosures.

**Tahkenitch**

Plover activity continued to increase at Tahkenitch since 2009 (Table 4). There was an increase in the number of nests at North Tahkenitch, but this was due to poor nest success. Only six of 52 nests hatched at North Tahkenitch (12%, Table 5), much lower than the average for this site (Figure 13). Due to nest failures, plovers moved south of the creek and for the first time since 2003 nests were found at South Tahkenitch. Six nests and one brood from an undiscovered nest were found at South Tahkenitch; only one of the nests hatched (17%). The main cause of nest failure at North Tahkenitch was unknown cause and unknown depredation (Table 7). Five nests failed to avian depredation, including three that had evidence of Northern Harrier (at one nest a harrier was filmed depredating the nest). We did not document any corvid depredations at North Tahkenitch. Northern Harrier activity was noted at North Tahkenitch throughout the season. Due to the harrier activity, we did not erect exclosures. In July, we received reports that plovers were nesting along the South Tahkenitch creek area, as far south as Three Mile Creek. A brood was discovered already hatched well south of the Threemile Creek area, and six more nests were found, including one as far south as the south end of Threemile Lake. Raven activity was high in the area (partly due to a large sea lion carcass); two of the nests were found already depredated by ravens and three others failed the day after discovery.

**Tenmile**

For four of the past five years Tenmile has had relatively poor nest and hatch success (Table 15). In 2013, Tenmile had an overall nest success rate of 42%, much higher than in 2012 (13%). Nine of 19 nests successfully hatched at North Tenmile (47%), above the average for this site (Figure 13). Six of 17 nests hatched at South Tenmile (35%), much higher than in 2012 (7%) but below the average for this site (Figure 13). The main causes of nest failure at Tenmile were unknown cause, corvid depredation, and unknown depredation (Table 7). We used only two exclosures at North Tenmile. Exclosure use was minimized due to previous issues with Great Horned Owls at Tenmile targeting plovers around exclosures (Lauten *et al*. 2011). In 2013 Great Horned Owl tracks were noted throughout the season, most often on at South Tenmile. Successful removal of ravens at Tenmile in 2013 contributed to the improved nest success (Burrell 2013). Fewer corvids reduces the need for exclosures, and thus reduces the threat of adults being depredated near exclosures.

**Coos Bay North Spit**

At CBNS in 2013 overall nest success was 27% (Table 5). Nest success on the HRAs was 17% and on South Spoil was 33%, both well below average (Figure 13). Nest success was better on South Beach (42%), but still below average (Figure 13). Of the nine nests north of the FAA towers, only one hatched. Many renest attempts due to low nest success contributed the high number of nests. The main cause of nest failure was unknown depredation (Table 7), however 15 nests were confirmed depredated by Northern Harrier (either video evidence or tracks at the nest site). This is the first year we have confirmed harrier depredations of nests. We suspect that most if not all of the unknown depredations at CBNS were caused by harriers because corvid activity was very low to non-existent all summer. We did not erect any exclosures because we were concerned that the harriers would target and depredate adult plovers. Seven adults disappeared from CBNS this summer, however we cannot be certain these were harrier depredations .Wildlife Services removed two harriers from CBNS, but it was towards the end of the nesting season (Burrell 2013). We hope the removal of these harriers will result in future benefits and better nest success in the coming year.

**Bandon SPMA**

Nest success at Bandon SPMA in 2013 was 33%, much higher than in 2012 (14%) but below the average for this site (Figure 13). Only seven nests of 44 hatched (16%) on the north side of New River (from north of China Creek south to the mouth of New River); 15 of 20 nests hatched on the south side of the New River mouth (75%). Eight total exclosures were erected; four on the north side and four on the south side. Of the four nests that were exclosed on the north side, three successfully hatched, however, a male associated with one of the exclosed nests and one of the chicks disappeared upon hatching. The female successfully raised one of the two remaining chicks. We suspect the male and first chick were depredated near the exclosure when the nest hatched. The fourth exclosed nest was found with one hatched chick and two hatching eggs, but the adults disappeared at hatching and we suspect they were depredated. We collected the hatched chick and two eggs, which were then transported to the Oregon Coast Aquarium (OCA) in Newport, where the eggs were hatched and the three chicks raised to fledge age. They were later released at the New River spit. We did not include this nest in our calculations of nest success in Table 5 since the nest only partially hatched in the field. The cause of the depredations was not known, however we repeatedly noted Great Horned Owl tracks at Bandon SPMA all summer, and we noted both Northern Harriers and Peregrine Falcons hunting the SPMA. Three of the four exclosed nests on the south side hatched; the nest that did not hatch was infertile. The main cause of nest failure was unknown cause and unknown depredation (Table 7). Corvid activity at Bandon SPMA in 2013 was relatively low; however at least three nests were depredated by corvids (all on the north side). In late April, at a time when corvid activity was low and plover nests had been relatively successful, Wildlife Services found a dog running unattended on the nesting area north of the New River mouth. Within days, we found eight of 11 the nests failed, with several eggs removed from the nest bowl but not eaten, and missing eggs at other nests. Poor weather conditions prevented us from determining a cause of these failures, but we suspect the lost dog may have been responsible. We have rarely noted predators leaving or removing eggs from nests without depredating them.. Due to concerns about raptors, and a lack of corvid activity, we minimized the use of exclosures in 2013.

**New River**

Overall nest success on non-state lands at New River in 2013 was very good with two of three nests successfully hatching on private lands (67%) and seven of nine nests successfully hatching on the BLM HRA (78%, Table 5), above the average for this site (Figure 13). One nest was exclosed on private land and five nests were exclosed on the HRA; five of these six nests hatched (83%). Four of six unexclosed nests also hatched (67%). Three nests failed, one to infertility and two to unknown depredation (Table 7). We did not document any adult mortalities around exclosed nests at New River in 2013. Corvid activity, particularly ravens, was fairly consistent until mid to late season when activity was minimal.

**Nest Failure**

Exclosed nests in 2013 had an overall failure rate of 17% (3 of 18, Table 8; one nest from Bandon SPMA is not included because the hatched chick and two unhatched eggs were transported to the OCA when adults disappeared at hatching and were presumed depredated). Of the three failed exclosed nests, two failed to infertility and one had an adult plover depredated and was subsequently abandoned (Table 8). The number of unexclosed nests that failed in 2013 (n = 285) was higher than any previous year. The failure rate of unexclosed nests in 2013 (79%) was higher than in 2012 (58%) and 2011 (54%) but similar to 2008 – 2010 (73%, 73%, and 77% respectively). In 2013, the main causes of nest failure for unexclosed nests were unknown depredation, unknown cause, avian depredation, and corvid depredation (Tables 8). Additional causes of nest failure included one-egg nests, wind/weather, abandonment, mammalian depredation, overwashed, infertility, and adult plover depredation (Table 7).

**Predator Management**

There was a limited effort to trap rodents at CBNS in 2013; 26 deer mice were captured during March (Burrell 2013). It remains unclear whether the rodent trapping has had any real effect on nest success. In the previous two years over 200 rodents were trapped at CBNS (Burrell 2011 and 2012). During these years nest success at CBNS was high (82% in 2011 and 87% 2012; Lauten *et al*., 2011 and 2012). In 2013, despite the limited trapping effort, only two nests on the CBNS HRA had evidence that rodents caused the nest failures (Table 7). Continuing rodent trapping and removal in the future would at a minimum help us gauge and understand rodent population levels and cycles at CBNS.

In the past, corvid depredations have been the main cause of known nest depredations (Stern *et al.* 1990 and 1991, Craig *et al.* 1992, Casler *et al.* 1993, Hallett *et al.* 1994, 1995, Estelle *et al.* 1997, Castelein *et al.* 1997, 1998, 2000a, 2000b, 2001, and 2002, and Lauten *et al*. 2003, 2005, 2006, 2006b, 2007, 2008, 2009, 2010, 2011, and 2012). In 2013, the main known causes of nest failure were avian depredation and corvid depredation (Table 7). Corvids continue to be the most serious threat to plover nests, however in 2013 for the first time we identified Northern Harriers depredating nests. We identified 20 nests that had either harrier prints at the nest site or harriers were captured on remote cameras depredating nests (Table 7). Known harrier depredations occurred at CBNS and from South Siltcoos to North Tahkenitch. At CBNS 15 nests had positive evidence of harrier depredations (either tracks or pictures from cameras), and because corvids were not present at CBNS during this time, suspect that the majority of nests that failed to unknown depredation (n = 38) were likely from harrier. On Forest Service land, one nest at South Siltcoos, two nests at South Overlook, and five nests at North Tahkenitch had positive evidence of harrier depredation. We suspect that some of the unknown depredations particularly at Overlook and North Tahkenitch were caused by harriers. It is possible, despite the distance between South Siltcoos and North Tahkenitch, that the same individual harrier was causing these nest failures. Harriers have been identified depredating plover nests in the Monterey Bay area both in the past and in 2013 (G. Page, pers. comm.) as well as at the San Francisco Bay National Wildlife Refuge (Demers and Robinson-Nilsen 2012). Many depredations attributed to harriers at both CBNS and Forest Service occurred shortly after initiation, indicating that the harriers were very efficient at finding and depredating nests. Burrell (2013) documents Wildlife Services' response and efforts to capture and remove the harriers, particularly from CBNS and North Tahkenitch. At CBNS a female harrier was photographed depredating four plover nests; this female was targeted and removed. Another harrier, a juvenile, was also eventually removed from CBNS. No harriers were removed from Forest Service lands. We are hopeful that the removal of the individual suspected to be causing nest depredations at CBNS will result in improved nest success next season. On Forest Service lands we suspect the harriers will continue to depredate nests. We are also concerned that higher nest densities of plovers on the nesting areas may result in continued attraction of harriers and other potential nest and plover predators (such as Great Horned Owl).

Predator management continues to have a positive effect on reducing corvid numbers at all sites and removing non-native red fox from the Bandon SPMA and New River area. Corvids are an annual problem at all sites. In 2013, Wildlife Services was funded to support three agents, allowing them to more completely cover the occupied nesting sites and provide more effective predator management. We believe this had a positive effect on the plover reproductive success. See Burrell (2013) for a complete discussion of the predator management program.

**Fledging Success and Productivity**

There were a total of 101 broods in 2013 (Table 11), however two broods were not included in productivity data because both broods were transported to the OCA and later release at fledge age. We monitored 99 broods in the field including 8 broods from undiscovered nests, substantially fewer than in 2012 (n = 154 broods, Lauten *et al*. 2012). We confirmed a minimum of 98 fledglings from the 99 broods (Table 11), and a total of 103 fledglings including the five chicks raised at the OCA (Table 9). Overall fledging success was 39%, near the overall average (Table 10). The overall brood success rate was 71% (Table 11), slightly higher than the average (67% +/- 10). The overall number of fledglings per male was 1.04 (Table 11). Considering data from known nests from Siltcoos to New River only (Tables 12-18), the mean fledglings per male was 0.926, below the average (Table 10). We caution that due to many nests failures, and due to the relatively short time many nests were active before failing, we undoubtedly failed to identify all the males that attempted to nest in 2013. As noted above, the documented number of breeding individuals was much lower than the number of resident individuals, indicating that the true number of breeding individuals was higher than the number we positively identified breeding. The failure to identify all known breeding males biases the number of fledglings per male; we believe that the number of fledglings per male is high and would likely be lower if all males who attempted to nest were successfully identified.

**Siltcoos**

There were nine broods at Siltcoos in 2013 (Table 11), half the number of broods as in 2012 (Lauten *et al*. 2012); 44% of the broods were successful compared to 61% in 2012. More eggs were laid in 2013 compared to 2012 (Table 12), however the hatch rate was considerably lower than in 2012 and well below the post predator management average. Only four chicks fledged from known nests in 2013, resulting in the lowest fledge rate at Siltcoos since 2002, well below the post predator management average. Due to the high number of eggs laid and the low number of fledglings produced, the productivity index for Siltcoos in 2013 was extremely low, indicating poor productivity for this site. The number of fledglings per male was well below 1.00 and well below the post predator management average for this site (Table 11 and 12).

**Overlook**

The number of eggs laid at Overlook in 2013 was similar to the previous two years (Table 13), however only nine eggs hatched resulting in the lowest hatch rate ever and well below the post predator management average. There were only three broods at Overlook (Table 11) substantially fewer than the previous two years (n = 31 broods in 2012, n = 33 broods in 2011). Two of the broods were successful and they fledged three chicks (Table 11 and 13). The fledging success rate was well below the post predator management average (Table 13). Due to the high number of eggs laid but few fledglings produced, the productivity index was extremely low, indicating poor productivity for this site. The number of fledglings per male was well below 1.00 and below the post predator management average for this site (Table 11 and 13).

**Tahkenitch**

The number of eggs laid at Tahkenitch was the highest number since monitoring began at this site in 1993 (Table 12), however only 14 eggs hatched resulting in a very low hatch rate well below the post predator management average. Of the nests that hatched, broods were very successful (Table 11) and the fledgling success rate was well above the post predator management average for this site (Table 14). However, the number of fledglings was considerably less than the previous two years (Table 14), and due to the high number of eggs laid, the productivity index was very low, indicating that there was much effort at this site (as measured by the number of eggs laid) but poor productivity (as measured by the total number of fledglings produced). The number of fledglings per male was higher than the post predator management average (Table 14), however this is based on only identifying five males from known nests. Due to the high number of nests at Tahkenitch (Table 4), there were undoubtedly many more males who attempted to nest at Tahkenitch but were not positively identified.

**Tenmile**

Productivity at Tenmile improved by all measures in 2013 and was substantially better than the previous two years (Table 15). The number of eggs laid was slightly less than the previous four years, however the hatch rate was much higher than the previous two years and was near the post predator management average (Table 15). There were 19 total broods, 13 more than in 2012, and brood success was high (Table 11). Twenty-three total fledglings were produced including 19 from known nests, the highest number of fledglings produced at Tenmile since 2007. The fledging success rate was 51%, above the post predator management average (Table 15). The productivity index was 20%, higher than the previous five years and above the post predator management average (Table 15). The number of fledglings per male was above the post predator management average (Table 15).

**Coos Bay North Spit**

Due to high nest failure rates (Table 5), the number of eggs laid at CBNS in 2013 was the highest ever for any year or any individual site (Table 16). The hatch rate was considerably lower than the previous two years, similar to 2010 when the lowest rate ever was recorded for this site, and well below the post predator management average (Table 16). There were 29 total broods at CBNS in 2013, nearly half the number recorded in 2012 (n = 58; Table 11). Brood success was very poor on the South Spoil and the HRAs, however was much better on South Beach (Table 11). Fledging success was also very poor on South Spoil and the HRAs (Table 11); the overall fledging success rate was the lowest ever recorded for CBNS, and substantially below the post predator management average (Table 16). Due to the high level of effort and relatively low number of fledglings, the productivity index was the lowest ever recorded for this site and well below the post predator management average (Table 16). The number of fledglings per male for CBNS was below 1.00 for the first time and well below the post predator management average (Table 16).

**Bandon SPMA**

The number of eggs laid at Bandon SPMA was the highest ever for this site (Table 17). The hatch rate improved from 2012 but was still low and slightly below the post predator management average (Table 17). We monitored 21 broods at the SPMA (not including one brood raised at the OCA and later released), nearly double the number of broods compared to 2012 (n = 11), and they had a very good brood success rate of 71% (Table 11). The fledging success rate was slightly above the post predator management average (Table 17). Despite the improved hatch rate and relatively good fledging success rate, the productivity index was low due to the high number of eggs laid, and was below the post predator management average (Table 17). The number of fledglings per male was near the post predator management average (Table 17), and just below the recovery goal.

**New River**

The number of plovers recorded at the New River HRA and adjacent areas remained similar to 2012 (Table 3; in 2012 n = 24), however the number of eggs laid at this site declined (Table 18). The decline in the number of nests (Table 4) and the number of eggs laid was due to an increase in nest success, and the number of eggs hatched in 2013 and was much higher than the post predator management average (Table 18). The high nest success and hatch rate resulted in fewer nest attempts and therefore a reduction in the number of eggs laid. Brood success was also very good in 2013 (Table 11), and overall fledging success was higher than the post predator management average (Table 18). Due to the number of fledglings produced at New River in 2013, the productivity index was very high and well above the post predator management average. The number of fledglings per male was over 1.00 for the first time since 2009 and above the post predator management average (Table 18).

Post predator management hatch rates declined for Overlook, Tenmile, CBNS, Bandon SPMA, and New River HRA while remaining stable at Siltcoos and Tahkenitch (Table 19). The decline in hatch rates is attributed to the decreased use of exclosures (Figure 12); unexclosed nests have a lower nest success rate than exclosed nests (Table 6). The post predator management average brood success rate (2004-2012, 72.1%) was significantly higher than the average pre predator management brood success rate (1991-2001, 62.9%, t-stat = 2.42, df = 19, $P = 0.01$). The overall mean post predator management fledging success rate (0.46) was higher than the mean pre predator management fledging success rate (0.39, t = 1.60, df = 18, $P = 0.06$). The post predator management fledging success rate has improved for Siltcoos, Overlook, Bandon SPMA, and New River and has remained relatively stable at Tahkenitch and CBNS (Table 19). Tenmile has decreased but was still within acceptable levels. The overall post predator management mean number of fledglings per male (2004-2012; $x = 1.25$) was significantly higher than the pre predator management mean number of fledglings per male (1992-2001; $x = 1.06$, t = 1.91, df = 18, $P = 0.04$). The mean number of fledglings per male has improved at all sites except Tenmile where it has remained relatively stable (Table 19). The overall productivity data has generally improved since the implementation of predator management, and we continue to recommend that predator management be funded, as this is critical to increasing and maintaining the plover population.

**Brood Movements**

**Siltcoos, Overlook, and Tahkenitch**

Plovers (both nests and broods) continue to occupy the beaches between South Siltcoos and North Overlook and South Overlook and North Tahkenitch (see Figures 3-5; Lauten *et al*. 2009, 2010, 2011, and 2012). Due to increasing plover numbers and high nest failures in 2013, plovers also occupied the beach at South Tahkenitch south of Threemile Creek. Since plovers were successful at both nesting and brood rearing along these lengths of beach, we would expect plovers to continue to occupy these areas in the future.

Only one of three broods at North Siltcoos in 2013 was successful, and that brood remained on the spit and within the nesting area for the duration of the brood rearing period. There were six total broods from South Siltcoos, and three were successful (Table 11) including one brood from an undiscovered nest. One of the successful broods hatched on the roped nesting area at South Siltcoos and moved south to the Carter Lake trail area within three days of hatching and then was found at South Overlook six days after hatching. The brood from the undiscovered nest also moved from South Siltcoos to North Overlook over an eight day period.

Two of three broods were successful from North Overlook. One brood hatched on the beach north of North Overlook and remained on the beach until fledged. The other successful brood hatched at the south end of North Overlook and seven days later was noted at South Overlook. The brood remained at South Overlook until fledged.

There were five broods from North Tahkenitch, four from the nesting area and one that hatched along the beach north of the nesting area. The brood that hatched along the beach north of the nesting area stayed along the beach until fledged. One of the broods from the nesting area was confirmed fledged at South Overlook. Two broods remained on the nesting area; one of these broods hatched at the south end of the spit and spent most of the brood rearing period at the north end of the HRA. The fifth brood failed within two days of hatching. There were two successful broods from South Tahkenitch, one from an undiscovered nest. Both of these broods were located in the Threemile Creek area and remained in this area. This area is open to motor vehicle use. Forest Service roped the area and the broods remained in and around the roped section of beach.

**Tenmile**

Of the 13 broods from North Tenmile in 2013, four, including three broods from undiscovered nests, originated on the beach north of the HRA. Three of these broods were successful; two remained on the beach north of the HRA and one of the broods moved south to the HRA. Three broods that originated on the HRA moved north along the beach up to a half mile during the brood period. Most broods that originated on the HRA remained on the HRA and the adjacent spit area. At South Tenmile, all broods originated on the HRA or the beach adjacent to the HRA. Only one brood moved south of the HRA along the beach but remained within the closed area; all other broods remained on or adjacent to the HRA.

**Coos Bay North Spit**

At CBNS in 2013 only one of four broods from the South Spoil and two of 10 broods from the HRAs were successful. The one brood from South Spoil moved west to the 94HRA and 98EHRA where it remained for the brood period. Both broods from the HRAs originated on the 95HRA; one brood remained on the 95HRA until it fledged. The other brood, which hatched early in May, moved immediately to the beach and remained there until it fledged. There was very poor success of broods from South Spoil and the HRAs in 2013 (Table 11). There is no data as to the cause of brood failures due to the difficulty assessing when and why chicks do not survive; however, nest failure data and observational data indicated that Northern Harriers were present on a regular basis. It is possible that harriers were depredating broods as well as nests. In 2013 both the berms along the foredune road and the foredune itself have become wide and covered in dense beachgrass. The dense vegetation prevents brood movement between the east side of the foredune road and the west side, and also from the 95HRA to the beach. Food resources for broods are best on the beach. We believe improving habitat to enhance brood movement west towards the beach would benefit brood and chick survival. We recommend that openings in the berms along the foredune road be created and maintained each season and the width of the berms be reduced to eliminate some of vegetation. We also recommend that pathways be created through the foredune to permit easy access to the beach by broods and some vegetation be removed from the east side of the foredune to reduce the width. We recognize that destabilizing the foredune is not acceptable; therefore we recommend just removal of the top vegetation without lowering the foredune.

Broods on South Beach were much more successful than broods originating from the nesting area (Table 11). Twelve of 15 broods were successful. All broods hatched within the closed area except one brood that hatched just south of access point 2, well north of the FAA towers. This brood failed within a week of hatching. Another brood that hatched near the FAA towers but just south of I-beam also failed within a week of hatching. Seven broods hatched at the far south end of the beach north of the I-beam near the jetty. Three of these broods used the jetty area throughout the brood period including the area open to motor vehicles south of the I-beam to the jetty. Two of these broods repeatedly were noted along the jetty and around the parking area at the base of the jetty. One of the broods was found on the foredune road; one chick was found along the edge of the foredune road near the bay beach. This chick was picked up and returned by monitors to the beach; it was later confirmed fledged. All the remaining broods remained within the closed section of beach.

**Bandon SPMA**

There were six broods, four of which were successful, on the north side of New River at Bandon SPMA. One brood hatched early in the season on the north side of China Creek. The male and one chick remained on the north side of the creek for the first two weeks. The male then disappeared; he was a resident Bandon SPMA bird and we believe he may have been depredated. The chick remained on the north side of the creek by itself until it was fledged. One brood hatched along the west edge of cutout 3 and spent the brood period wandering the beach from the China Creek overwash area south to the area around cutout 3. A third brood hatched along the foredune south of cutout 3. The male and one chick disappeared at hatching; we believe the male was depredated. The female brooded the remaining two chicks, eventually moving south and spending most of the brood period along the south end of the HRA south of the I-beam. She fledged one chick. The fourth brood hatched on the HRA and remained on and adjacent to the HRA for the brood period.

There were 15 broods that originated on the south side of the mouth of New River at Bandon SPMA; 11 were successful. Fourteen of the 15 broods hatched on the north end of the spit; one brood hatched near the southern boundary of the SPMA. Eight of the broods that hatched at the north end of the spit remained on the north half of the spit. Two other broods from the north end of the spit crossed New River and raised their broods on and adjacent to the HRA. The brood that hatched near the southern boundary of the SPMA quickly moved his brood south to just north of the BLM HRA. He remained in this area and successfully fledged one chick.

**New River**

There were two broods that hatched on private land. One brood hatched on Michael Keizer's property just south of the Bandon SPMA. This brood stayed in this vicinity, using both the overwashes and the river side, and eventually at fledge age was noted on the New River spit portion of the Bandon SPMA. A second brood that nested on the beach adjacent to private land between Keizer's property and the BLM HRA moved north along the beach and was noted on near the southern boundary of the Bandon SPMA. The brood was confirmed fledged on the New River spit portion of the Bandon SPMA. Eight of nine broods that originated on the BLM HRA successfully fledged. One brood that hatched along the north end of the HRA disappeared after the first week of the brood period and was later confirmed fledged on the New River spit portion of the Bandon SPMA. We believe the brood had moved north during the brood period and may have even been using the river. Three broods originated north of Croft Lake breach; two broods remained on the HRA and along the beach north of Croft Lake and one brood eventually moved just north of the HRA and fledged. One brood originated north of New Lake breach and moved south, spending the brood period between New Lake and Hammond breaches. Three broods originated south of New Lake breach and remained in this area for the brood period.

**Sightings of Snowy Plovers Banded Elsewhere**

Fifteen adult plovers banded in California were observed in Oregon in 2013. Six were females and nine were males. Nine of the 15 plovers were known to have nested in Oregon in 2013. Four females were confirmed nesting and two were present during the breeding season and may have attempted to nest but were not confirmed. Five males were confirmed nesting and three others were present during the breeding season and may have attempted to nest but were not confirmed. One male arrived post breeding season. Four females and five males originally hatched in Oregon and were subsequently rebanded at coastal nest sites in California. Six other plovers, two females and four males, were originally banded in California. One female was banded as a hatch year 2006 from Humboldt Co. and has been nesting at Bandon Beach and New River since 2007; the second female was banded in 2010 in Humboldt Co. and nested in Oregon in 2011, 2012, and 2013. Of the four California originated males, one was a hatch year 2004 bird from Salinas, Monterey Co., that has been present at New River since 2005 and successfully nested at New River in 2013; one was a hatch year 2010 plover from Moss Landing Salt Ponds, Monterey Co., who nested at Bandon SPMA in 2013; one was a hatch year 2010 bird from Oceano Dunes, San Luis Obispo Co., that was confirmed nesting in 2012 but we did not confirm nesting in 2013; and one was a hatch year 2011 bird from Centerville, Humboldt Co. who arrived at the end of July and was present in August at Bandon SPMA.

## Habitat Restoration and Development Projects

**Sutton**

Beachgrass hummocks were mechanically treated on the Sutton Beach HRA in the winter of 2012-13. Some oyster shell was manually spread on the HRA. In addition, 3.8 miles of beach cleanup was conducted at Baker Beach with the help of the Emerald Empire Back Country Horseman group. Twenty five participated in this event and collected 920 pounds of trash.

**Siltcoos**

At Siltcoos in winter 2012-13, 3 acres of beachgrass was hand pulled by the Northwest Youth Corp on the south side of the estuary in winter 2012-13. Beachgrass hummocks near areas covered by oyster shell were mechanically treated. Some oyster shell was spread on the south side of the estuary. No work occurred on the north side of the estuary due to the Siltcoos River moving north during the winter and losing most of the HRA on the north side.

**Overlook**

At Overlook, 20 acres of beachgrass and hummocks were mechanically treated in winter 2012-13. Some oyster shell was spread on both the north and south side.

**Tahkenitch**

At Tahkenitch, 19 acres of beachgrass and hummocks were mechanically treated in winter 2012-13. Some oyster shell was spread on the HRA.

**Tenmile**

At Tenmile, 12 acres of beachgrass hummocks were mechanically treated on the north side in the winter of 2012-13. Some oyster shell was spread on North Tenmile.

**Coos Bay North Spit**

The 95HRA and 98EHRA at CBNS were disked once in November 2012 and once in February 2013 to limit the amount of invasive beachgrass on all BLM HRAs. Shell hash was purchased from Coos Watershed Association, cleaned of debris, and applied to 6 acres in the 98EHRA and 95HRA to provide improved nesting habitat.

Before the disking occurred in the fall 2012, a botanist collected seeds of sensitive species to be used for restoration work in other coastal areas. Approximately 300,000 pink sandverbena (*Abronia umbellata breviflora*) seeds were collected and spread at other coastal sites. (J. Sperling, pers. com.) In October 2012, the Youth Corp spent 40 hours at the north spit pulling non-native sea rocket, sour dock and dandelion.

There was only limited disking of the 94HRA and South Spoil on ACOE lands.

**Bandon SPMA**

At Bandon SPMA, OPRD conducted maintenance actions on approximately 62 acres of habitat in winter 2012-13. All four cutouts along the foredune were bulldozed and treated with glyphosate. Five acres on the HRA north of the mouth of New River were bulldozed. On the south side of the mouth of New River approximately 58 acres were treated with glyphosate and imazapyr.

**New River**

At New River in winter 2012-13, 15 acres of the HRA were bulldozed between New Lake breach and Croft Lake Breach.

## Recommendations

**Signing of Restricted Areas**

Signing and roping for the 2014 nesting season should again be implemented to inform the public of plover nesting habitat and direct the public away from the nesting areas. Ropes and signs should be installed as early in the season as practical so a clear, consistent message is conveyed to the public throughout the nesting season and between years, and so that the closed sections of beach are adequately protected throughout the season. Installing ropes and signs at the beginning of the season also reduces the need to respond to individual nests that are within closed beach sections but are not roped and signed. This reduces the disturbance to those nests when ropes and signs have to be installed after a nest is found. High tides early in the season often make posting areas a challenge, and while it is important to have signs in place beginning on 15 March, in areas where the ocean is regularly lapping against the foredune, signs should not be erected or placement should be delayed. Maintenance of signs is important to keep violations to a minimum. To maximize the effectiveness of signs and ropes, each site should continue to be evaluated and ways to improve the signing and ropes should be considered.

**General Recommendations**

Below are general recommendations. We also provide additional site-specific comments and management recommendations in Appendix B.

Maintaining, improving, and expanding the nesting areas is essential to maintaining a healthy and sustainable plover population. Despite years of treatment, European beachgrass continues to annually resprout resulting in degraded nesting habitat. When new habitat is created, such as the cutouts at Bandon SPMA (Lauten *et al*., 2011), it is important to annually maintain the habitat or it quickly degrades resulting in reduced plover use. With an increasing plover population, any reduction in available nesting habitat can result in high nest densities which may attract predators or result in plovers nesting in sub-optimal habitat, where predation or disturbance from recreational activity is more likely. Increased nest density could lead to increased nest depredations. Increased chick numbers on the landscape may attract additional avian predators (Neuman *et al*. 2004). Expansion of the nesting areas would increase the available habitat for plovers and could help alleviate predation pressure. Creation of cutouts along sections of beach that have nesting plovers but no nesting area behind the foredune would give the plovers safe areas to nest and brood away from recreational activity on the beach. We continue to support additional shell hash on any nesting area as it has proven to be a beneficial management technique. We continue to recommend that additional habitat be created and maintained at South Overlook, North Tenmile, Bandon SPMA and New River HRA. We support any efforts to find new and effective treatments of European beachgrass that could result in reduced resprouting, less density of beachgrass, and ultimately reduced maintenance costs.

We recommend increased use of cameras to help document causes of nest failure and to positively identify individual raptors that are preying on plovers so land management agencies can effectively manage this threat. We recommend monitoring staff and Wildlife Services staff continue to document raptor activity in and around the nesting areas.

Continued efforts to educate the public about the OPRD Habitat Conservation Plan (ICF International 2010) and beach rules will be essential both before and during the nesting season. Staff dedicated to recreational monitoring and volunteers continue to help reduce violations and educate the public about plovers and dog related issues, and we recommend that these aspects of management continue and be funded. At Siltcoos and Bandon Beach where parking lots and recreational activities are adjacent to nesting plovers, monitoring by staff and volunteers is essential to improving plover success and reducing disturbance issues.

- Continue breeding season monitoring; continue monitoring plover populations and productivity to ensure recovery goals are maintained.
- Maintain, enhance and expand habitat restoration areas. Spread shell hash to enhance nesting substrate.
- Selectively use mini-exclosures in conjunction with predator management to reduce the risks to nests and adult plovers, decrease the time monitors spend around individual nests, and decrease disturbance to plovers. Determine exclosure use dependent on predation pressure, density of plover nests, and nest locations.

- Expand use of cameras to help determine causes of nest failures; coordinate with Wildlife Services to set up and maintain cameras.
- Increase and/or maintain predator management at all sites and explore ways of better understanding the activity patterns and population levels of predators, particularly corvids. Fully fund three Wildlife Services employees.
- Continue to coordinate with federal and state agency employees regarding time frames of any habitat management work to be completed to minimize disturbance to nesting activity and broods.
- Coordinate agency activities in restricted areas with plover biologists to minimize disturbance to nesting and brood rearing.
- Continue and explore ideas to document and monitor human disturbance by various recreational users in plover nesting areas.
- Continue to expand and refine volunteer efforts to monitor recreational use.
- Design educational programs to inform and educate the local communities and annual visitors about plover issues.
- Design informative/interactive presentations for school children.

## Acknowledgments

We would like to thank Micah Bell, Zack Perdue, Jeremiah Psiropoulos and Mike Burrell of Wildlife Services for their assistance in the field and thoughtful insight about predators; RJ Rapelje, and Trisha Wymore of OPRD for their hours educating the public and monitoring recreational activity on the beach; Morgan Bell and Theresa Bolch of BLM for their diligence monitoring recreational activity at CBNS; Grace Larsen of BLM, Park Ranger Emily Erwin, and Cathy Boden and Statia Ryder of South Coast Watershed Association for monitoring and education with recreationists and campers at New River and Floras Lake; Crystal Mullins and Anjanette Butler of Forest Service for their many hours maintaining signs and ropes, monitoring recreational activity and interacting with the public; volunteers Bruce & Mary Lou Dickson, Larry Hudomint, Gary and Mary Van Hooser, Don & Nita Derricott, John Gee, Kim & Else Ireland, and Pat Holper spent numerous hours educating the public at China Creek parking lot on Bandon Snowy Plover Management Area; volunteers Andy and Jan Ogg for USFS; Interpretive Specialists Dave Thompson, Interpretive beach rangers Brian Hoeh, Renee Plourde, Michelle Schuett, Ana Miller-tur-Kuile, Ann Parkin, David Diaz, Meghan Avila, Eliza Spear, and Dylan Wellner from the Forest Service; Ted Gage and Carrie Wostal of BLM Law Enforcement, Adam Slater of Coos County Sheriff's Department, Oliver Grover, Melissa Wise, Tyler Smith, Derrick Scott, and Cody Martin of the USFS Dunes National Recreation Area Law Enforcement , and Ed Lagrone of Lane Co. Sheriffs's Department; Dan Elbert, Madeleine Vander Heyden, and Laura Todd of the US Fish and Wildlife Service; Mark Stern, Ken Popper, and Karen Gleason of The Nature Conservancy; Stuart Love, Bill Kinyoun, and Martin Nugent of the Oregon Department of Fish and Wildlife; Charlie Bruce, retired ODFW volunteer; Kip Wright, Kerrie Palermo, Megan Harper, and all the managers at Coos Bay BLM District whose support is invaluable; Calum Stevenson, Larry Becker, and Vanessa Blackstone of the Oregon Parks and Recreation Department; Ben Fisher, Carl M. Krigbaum, Jerry Phillips, Chuck Littlejohn, Chris Bryers, Nick Schoeppner, Julie Kirby, and all the staff at Bullard's Beach State Park; Cindy Burns, Melissa Shelley and Paul Thomas of the USFS Mapleton Ranger District; Dave Williams of Wildlife Services; Sean McAllister in Humboldt Co., CA,; Mark Colwell and students at Humboldt State Univ., Arcata, CA,; Jim Watkins of US Fish and Wildlife Service, Humboldt Co.; Gary Page, Lynne Stenzel, Doug George, Kris Neumann, Jenny Erbes, and Carlton Eyster of Point Reyes Bird Observatory; special thanks to Frances Bidstrup of Point Reyes Bird Observatory who coordinates all banding information and who is essential to the project; to anyone and everyone who we may have accidentally forgotten – we sincerely appreciate the support, assistance, and input of all, without which the program would not be a success.

% Brood success = # broods with at least 1 chick fledged / total # of broods

% Fledging Success = # of young fledged / # of eggs hatched

* Includes broods from undiscovered nests:

** Does not include fledglings from undiscovered nests because we do not know how many eggs hatched from those nests.

[a] – number of known individual breeding males for each site

[b] – number of known breeding males in entire population; this is not a tally of known males from each site as some males may have nested at more than one location

[c] – number of fledglings for both sites combined and number of known individual breeding males for both sites combined. Sample size of males in parenthesis.

[d] – includes one brood that hatched but chicks later captured and raised at Oregon Coast Aquarium and later release; this brood not included in calculations.

[e] – includes one brood that was raised at Oregon Coast Aquarium and later released; this brood not included in calculations.

[f] – includes two broods raised at Oregon Coast Aquarium; these broods not included in calculations.

[g] – includes 5 fledglings raised at Oregon Coast Aquarium.

**Table 12. Productivity of Snowy Plovers at Siltcoos, Lane Co., Oregon coast, 1993-2013.**
**Number of eggs laid, number hatched, hatch rate, # fledged, fledging success rate, and productivity index based on all known nests. Number of fledglings per male based on nests with known adult males only, therefore number of fledglings may vary from total number of fledglings.**

## APPENDIX A.

**Study Area**

The study area encompassed known nesting areas along the Oregon coast including all sites between Berry Creek, Lane Co., and Floras Lake, Curry Co. (Fig. 1). Survey effort was concentrated at the following sites, listed from north to south:

**Sutton Beach**, Lane Co. (Figure 2) - the beach north of Berry Creek south to the mouth of Sutton Creek.

**Siltcoos**: North Siltcoos, Lane Co. (Figure 3). - the north spit, beach, and open sand areas between Siltcoos River mouth and the parking lot entrance at the end of the paved road on the north side of the Siltcoos River; and South Siltcoos, Lane Co. - the south spit, beach, and open sand areas between Siltcoos River mouth and south to Carter Lake trail beach entrance.

**Dunes Overlook Clearing**, Douglas Co. (Figure 4). – the area directly west of the Oregon Dunes Overlook off of Hwy 101 including the beach from Carter Lake trail to the north clearing, and south to the Overlook trail south of the south clearing.

**Tahkenitch Creek**, Douglas Co. (Figure 5) - Tahkenitch North Spit - the spit and beach on the north side of Tahkenitch Creek including the beach north to Overlook trail; and South Tahkenitch – from the south side of Tahkenitch Creek to south of Threemile Creek north of the north Umpqua River jetty.

**Tenmile**: North Tenmile, Coos and Douglas Cos. (Figure 6) - the spit and ocean beach north of Tenmile Creek, north to the Umpqua River jetty; and South Tenmile, Coos Co. - the south spit, beach, and estuary areas within the Tenmile Estuary vehicle closure, and continuing south of the closure for approximately 1/2 mile.

**Coos Bay North Spit (CBNS)**, Coos Co. (Figure 7): South Beach - the beach between the north jetty and the F.A.A. towers; and South Spoil/HRAs - the south dredge spoil and adjacent habitat restoration areas (94HRA, 95HRA, 98HRA);

**Bandon Snowy Plover Management Area**, Coos Co. (Figures 8 and 9): This site includes the Bandon SPMA and all nesting areas from north of China Creek to the south end of state land south of the mouth of New River.

**New River**, Coos Co. (Figures 9 and 10) - the privately owned beach and sand spit south of Bandon Snowy Plover Management Area south to BLM lands, and the BLM Storm Ranch Area of Critical Environmental Concern habitat restoration area (HRA).

**Floras Lake**, Curry Co. – the beach and overwash areas west of the confluence of Floras Creek and the beginning of New River, north to Hansen Breach.

The following additional areas were either surveyed in early spring or the breeding window survey: Clatsop Spit, Necanicum Spit, Nehalem Spit, Bayocean Spit, Netarts Spit, Sand Lake South Spit, Nestucca Spit, Whiskey Run to Coquille River, Sixes River South Spit, Elk River, Euchre Creek, and Pistol River.

## APPENDIX B.

**Recommendations for Management of Recreational Activities and Habitat Restoration for sites with Snowy Plovers along the Oregon Coast - 2013.**

**Sutton:**

- Continue to manage the nesting areas particularly at the Sutton Beach HRA; consider spreading shell hash or woody debris to improve the nesting substrate.
- Continue predator management when and if plovers are nesting to reduce predation pressure on broods, particularly corvids.
- Rope and sign around Sutton Beach HRA; rope and sign any other areas if plovers are detected using the beach.

**Siltcoos North and South Spits:**

- Continue predator management to reduce the number of corvids using the nesting area. Continue to reduce the feral cat population in the area. Continue to monitor and possibly remove coyotes that are using and possibly denning near the nesting area.
- Continue signage along river, especially east of nesting area and on any "islands" that may develop to alert kayak/canoe users about plover management activities.
- Continue to post the area with updated maps of the estuary and beach at several locations. These areas include the Stagecoach Trailhead, the north parking lot, and both ends of the Waxmyrtle Trail.
- Erect ropes and signs prior to 15 March, to be as effective as possible. Place signs and ropes on east and south side of the north spit nesting area as well as continued signage to the west and north.
- Enforce dog regulations on the spits and near the estuary during nesting season.
- Continue the use of campground plover hosts/volunteers to educate people and restrict them from closed areas. Use hosts/volunteers, especially during peak periods on weekends, and stagger their hours to cover evenings. Have hosts/volunteers in contact with Law Enforcement Officers to improve enforcement of the closures, and have them engage people on the beach before violations occur.
- Continue to extend appropriate signing to both riverbanks, to prevent hikers from walking up the closed estuary.
- Rope and sign along the foredune south of Waxmyrtle trail access to the Carter Lake trail area; monitor this area for roosting, nesting and brooding plovers.

**Overlook:**

- Continue predator management to control corvid use of the area. Monitor Northern Harrier and Great Horned Owl use of the area and consider removal if harriers and owls continue to pose problems to breeding plovers.
- Continue to rope and sign both north and south closures for Snowy Plover nesting habitat by 15 March.
- Continue to improve and enlarge the restoration area, especially to the south towards Tahkenitch.
- Erect and maintain interpretive signing at the beginning of the Overlook trailhead (near viewing platforms). This signing is intended to provide more information on the ecology of the Snowy Plover and the reasoning for current management techniques and restricted areas.
- Enforce current dog regulations.

**Tahkenitch:**

- Continue to maintain and improve the habitat.
- Continue predator management to control corvid use of the area. Identify if Great Horned Owls or other avian predators are hunting the area. Remove if necessary.
- Continue to rope and sign all suitable habitat. Place signs along east and south edge outside of the roped area to prevent hiking and camping near nesting area.
- Enforce current dog regulations.

**Tenmile North and South Spits:**

- Continue predator management to control corvid use of the area; continue to monitor coyote use and possibly remove coyotes if warranted. Monitor and remove Great Horned Owls if necessary. Evaluate rodent populations and depredations.
- Continue to maintain and improve the south side for nesting. Consider expanding and improving habitat on the north side.
- Continue to rope and sign plover nesting habitat on both north and south spits.
- Enforce vehicle closure to prevent violators from driving in the habitat restoration areas.
- Enforce current dog regulations.

**Coos Bay North Spit:**

- Continue predator management of the area for corvids, feral cats, skunks, and raccoons; monitor the coyote population and remove coyotes if warranted; continue early season rodent trapping to reduce rodent population.
- Continue to improve and maintain the habitat restoration areas. Continue to spread shell hash to improve nesting substrate.
- Maintain gaps in the berm along the 95HRA to facilitate brood movement from the 94HRA and 98WHRA to the 95HRA and to the beach. Maintain small vegetation free gaps in the foredune to facilitate brood access to the beach without destabilizing the foredune.
- Continue to rope and sign the beach as early in the nesting season as possible; avoid erecting signs where the ocean is repeatedly lapping against the foredune to reduce sign loss.
- Clearly sign all entrance points on the spit that vehicle use on the beach is limited to street legal vehicles only.
- Continue closure of the foredune road through the nesting area. Consider a permanent reroute of the foredune road.
- Enforce current dog regulations.

**Bandon:**

- Continue predator management to control mammal and corvid populations.
- Continue to improve and maintain the habitat restoration area north of New River/Twomile Creek. Maintain and improve “cutouts” along the foredune to increase available nesting habitat for plovers; consider additional cutouts along foredune.
- Sign and rope the entire beach from China Creek overwash to the Habitat Restoration Area near the mouth of Twomile Creek/New River before the nesting season.
- Enforce current dog regulations.
- Monitor hiker use from Bandon to Blacklock Point, and check the beach and HRA on weekends for illegal camping activity. Consider beginning a permit system for hikers and campers.

**New River:**

- Continue predator management to control mammal and corvid populations.
- Continue to improve and maintain the habitat restoration area.
- Sign the foredune north of the HRA along the foredune.
- Place interpretive signs near the Lower Fourmile access along the river to inform the public of plover activity.
- Sign State Parks lands on the open spit south of the mouth of New River.
- Enforce current dog regulations.
- Use interpretive specialist to help monitor recreational activities in the area and explain the management efforts in the area.
- Continue to close the gate at the Storm Ranch for 15 April- 15 September.
- Consider a permit process for hikers/campers to help educate hikers, limit their numbers, ensure that they do not have dogs, are legally camping, and are in compliance.

**Floras Lake:**

- Monitor the site for any plover activity.
- Enforce dogs on leash rules at all times.
- Continue to hire an on-site interpretive specialist, to contact the public, monitor the beach, and present slide shows.

## APPENDIX C

**Recovery Unit 1 (Oregon & Washington)**
**Exclosure Use Guidelines Developed by Oregon Biodiversity Information Center for the Western Snowy Plover Working Team**
**2/27/2012**

Nest exclosures are mesh fences that surround a Western Snowy Plover (*Charadrius nivosus nivosus*) nest and act to keep out predators. Nest exclosures have been used in Oregon since 1991 to protect plover nests from depredation by mammalian and avian predators. Prior to implementation of comprehensive predator management, plovers have suffered high rates of nest depredation. Exclosures have been successful at increasing nest success rates (Table 1) (Stern *et al.* 1990, 1991, Craig *et al.* 1992, Casler *et al.*1993, Hallett *et al.*1994, 1995, Estelle *et al.*1997, Castelein *et al.*1997, 1998, 2000a, 2000b, 2001, 2002, Lauten *et al.*2003, 2005, 2006, 2006b, 2007, 2008, 2009, 2010, 2011). Predators that prey on snowy plover eggs include mammalian predators such as skunk (*Mephitis sp.*), red fox (*Vulpes vulpes*), coyote (*Canis latrans*), raccoon (*Procyon lotor*), mice (*Peromyscus* sp.), and weasel (*Mustela sp.*); and avian predators, mostly American crows (*Corvus brachyrhynchos*) and common ravens (*Corvus corax*).

Since 1990, we have found 2650 snowy plover nests along the Oregon coast, of which 1057 (40%) have been exclosed. Over the years we have had to adapt exclosure techniques in response to predator behavior around exclosures. (see Castelein *et al.*2000a, 2000b, 2001, Lauten *et al.*2003).

In 1995 we began seeing evidence of adult snowy plover depredations in or immediately outside exclosures. From 1995 to 2011 we documented a minimum of 48 adult losses associated with exclosure use. These losses include 21 cases where blood, feathers, or plover body parts were found in or adjacent to exclosures and 27 cases where incubating adults disappeared from an established, exclosed nest. Forty-eight adult losses associated with 1057 exclosed nests indicate that exclosures subject adult plovers to additional predation risk (approximately 4%). Similar threats associated with exclosures have been reported in other plover populations (Murphy *et al.*2003, Hardy and Colwell 2008, Pearson *et al.*2009). We do not have information on how many adults may be lost at nests not associated with exclosures.

Predator exclosures increase snowy plover hatching success and the number of chicks hatched per male, but not fledging success or the number of chicks fledged per male (Neuman *et al.*2004). In Oregon, they pose an additional risk to incubating adults and may negatively impact adult survival. As in Washington, exclosure use in Oregon has been a management technique, not part of a study of their effectiveness in increasing the overall plover population. We are working with Steve Dinsmore (Department of Natural Resource Ecology and Management, Iowa State University) to evaluate the effectiveness of exclosure use on nest success and adult survival. Preliminary results indicate that, predictably, exclosure use has a strong positive impact on nest success. Further analysis is underway to determine potential impacts of exclosure use on adult success and fledging success (Dinsmore et al., unpublished data) (see Pearson *et al.*2009, Neuman *et al.*2004).

Scott Pearson *et al.* (2009) conducted a search of existing literature on the effects of nest exclosures on nest success for plovers and other ground nesting species (primarily shorebirds). Their findings are summarized below:

- Nest survival of exclosed nests was significantly higher in ten studies (Rimmer and Deblinger 1990, Melvin *et al.*1992, Estelle *et al.*1996, Johnson and Oring 2002, Lauten *et al.*2004, Niehaus *et al.*2004, Isaksson *et al.*2007, Hardy and Colwell 2008, Pauliny *et al.*2008, Pearson *et* *al.*unpublished), and there was no difference in two studies (Nol and Brooks 1982, Mabee and Estelle 2000).

- Exclosed nests appear to be only vulnerable to reptilian and small mammal predators while unexclosed nests are vulnerable to predators of all sizes (Mabee and Estelle 2000).
- No difference in fledging success between exclosed and unexclosed nests in four studies (Hardy and Colwell 2008, Pauliny *et al.*2008, Lauten *et al.*2004, Pearson *et al.* unpublished data) and higher fledging success for exclosed nests in two studies (Larson *et al.*2002, Melvin *et al.*1992). There was no difference in fledging success between exclosed and unexclosed nests for all studies involving snowy plovers.
- Adult mortality associated with exclosures was reported in six of the eight studies that included or mentioned this response variable (Murphy *et al.*2003, Lauten *et al.*2004, Isaksson *et al.*2007, Hardy and Colwell 2008, Pauliny *et al.*2008, Pearson *et al.*unpublished). Only three studies compared adult mortality between exclosed and unexclosed nests and two reported significant increases in adult mortality associated with exclosures (Murphy *et al.*2003 and Isacsson 2007) and one reported no difference (Pauliny *et al.*2008).
- Adult mortality appears to be largely attributable to raptors and appears to be episodic (Murphy *et al.*2003, Neuman et a. 2004, Hardy and Colwell 2008) and differs among habitats (Murphy *et al.*2003).
- Larson *et al.*2002 examined the effect of exclosures on population growth for piping plovers and found the effect to be positive.
- Abandonment was higher for exclosed nests in two studies where this was compared directly (Isaksson et al., 2007, Hardy and Colwell 2008).
- Abandonment was not associated with the construction process, size, shape, mesh size and fence height (Vaske *et al.*1994). Covered exclosures are more likely to be abandoned than uncovered exclosures (Vaske *et al.*1994).
- Exclosures increased incubation length by one day but did not influence chick condition (Isaksson *et al.*2007).
- Egg hatchability was higher in three studies (Melvin *et al.*1992, Isaksson *et al.*2007, Pauliny *et al.*2008) but no difference was observed in one study (Hardy and Colwell 2008).
- Breeding adults may receive false messages regarding site quality and encouragement to continue to breed in sink habitats (Hardy and Colwell 2008). This is an important research question that should be examined but no data support this contention.

Our data and that of others (Murphy *et al.*2003, Hardy and Colwell 2008, Pearson *et al.*2009) indicate that adult plovers are at increased risk of predation while in exclosures. In the absence of research to quantify that risk, and based on the above information, we developed the following guidelines for exclosure use in Oregon:

- Since raptors appear to be the primary threat to adult plovers in exclosures, delay use of exclosures until peak raptor migration has passed. Currently, we have identified May 15 as a suitable cutoff, but this date could be altered as needed.

- Delaying exclosure use until May 15 allows field personnel time to assess causes of early nest failures, although weather conditions can make accurate assessment difficult. During this time, and contingent on funding, we recommend an owl survey be run at each site.

- If nests are being lost primarily to mice, exclosures will not help the problem, and may pose additional risk if the mice are being preyed upon by raptors. In this case exclosure use is not appropriate.

- If corvids and/or large mammals are identified as the main predator at a site, removal of the predators should be the primary goal with exclosures used as a supplemental measure to help protect nests.

- Any use of exclosures should be accompanied by close monitoring to evaluate their effectiveness (Hardy and Colwell 2008) and to detect predators of adult plovers early (Pauliny *et al.*2008). Weather permitting, exclosed nests should be checked at least twice per week. If conditions do not allow checks twice a week, exclosure use should be seriously reconsidered.

- Adult predation associated with exclosures is often episodic (Castelein *et al*. 2000b, Lauten *et al.* 2006). Once adult predation is suspected, all exclosures should be removed from the site and their use discontinued for the season.

- To minimize the risk of episodic predation on adult plovers, additional caution should be used when placing exclosures within sight of each other (this puts multiple adults at risk).

- Exclosures should not be placed along the foredune.

- Exclosures should not be placed in a windy location that might result in nest drifting. Since the ME's are 4 feet per side, the nest is only about 2 feet from each sidewall. If the nest begins to drift, it could come close to a sidewall, and a predator such as a raccoon could reach in and grab the eggs. If an exclosed nest is in a potentially windy location, it must be monitored frequently to ensure the safety of the nest and adults (especially on windy days).

## Appendix D

### Snowy Plover Monitoring Methods

#### Nest Surveys

Monitoring began the first week in April and continued until all broods fledged, typically by mid-September. We used two teams of two biologists; one team covering Tenmile and sites north, and the other covering Coos Bay North Spit and sites south (Fig. 1). In some years this division has been modified to accommodate staff needs. All data collected in the field was recorded in field notebooks and later transferred onto computer. Surveys were completed on foot and from an all-terrain vehicle (ATV). Data recorded on nest surveys included:

- site name
- weather conditions
- start time and stop time
- direction of survey
- number of plover seen, broken down by age and sex
- band combinations observed
- potential predators or tracks observed
- violations/human disturbance observed

Weekly surveys were attempted, but were not always possible due to increasing workload associated with an increased plover population. Additional visits were made to check nests, band chicks, or monitor broods.

#### Population Estimation

We estimated the number of Snowy Plovers on the Oregon Coast by determining the number of individually color banded adult Snowy Plovers recorded during the breeding season, and then adding an estimated number of unbanded Snowy Plovers. We determined the number of unbanded Snowy Plovers observed within ten-day intervals during the breeding season, selected the highest count of unbanded birds and then subtracted the number of adults that were banded subsequently. We also determined the number of plovers known to have nested at the study sites, including marked birds and a conservative minimum estimate of the number of unbanded plovers.

#### Nest Monitoring

We located nests using methods described by Page et al. (1985) and Stern et al. (1990). We found nests by scoping for incubating plovers, and by watching for female plovers that appeared to have been flushed off a nest. We also used tracks to identify potential nesting areas. We defined a nest as a nest bowl or scrape with eggs or tangible evidence of eggs in the bowl, i.e. egg shells. We predicted hatching dates by floating eggs (Westerskov 1950) and used a schedule, developed by G. Page based on a 29-day incubation period (Gary Page, pers comm). We attempted to monitor nests once a week at minimum. We checked nests more frequently as the expected date of hatching approached. We defined a successful nest as one that hatched at least one egg. A failed nest was one where we found buried or abandoned eggs, infertile eggs, depredated eggs, signs of depredation (e.g. mammalian or avian tracks or eggshell remains not typical of hatched eggs or nest cup disturbance) or eggs disappeared prior to the expected hatch date and were presumed to have been predated. In some instances we found nests with only one egg; often there was no indication of incubation or nest defense, and it was uncertain to what extent the nest was abandoned, or simply a “dropped” egg. Because it was difficult to make this determination, we considered all one egg clutches as nest attempts, and classified them as abandoned when there was no indication of incubation or nest defense. Data recorded at nest checks included:

- nest number
- number of eggs in nest
- adult behavior
- description of area immediately around nest
- whether or not the nest is exclosed
- GPS location

**Brood Monitoring**

We monitored broods during surveys and other field work, and recorded brood activity or males exhibiting brood defense behavior at each site. "Broody" males will feign injury, run away quickly or erratically, fly around and/or vocalize in order to distract a potential threat to his chicks. Information recorded when broods were detected included:

- Number of adults and chicks
- Band combinations of adults/chicks seen
- Sex of adults
- Behavior of adults
- Brood location

**Banding**

Adults were normally trapped for banding on the nest, during incubation, using a lilly pad trap and noose carpets. Lilly pad traps are small circular traps made of hardware cloth with a blueberry net top. The traps have a small door that the plover will enter. Noose carpets are 4" x 30" lengths of hardware cloth covered with small fishing line nooses. Plovers walk over the carpets and the nooses snag their legs. We limited attempts to capture adults to 20 minutes per trapping attempt. Chicks were captured for banding by hand, usually in the nest bowl. Banding was completed in teams of two to minimize time at the nest and disturbance to the plovers.

**APPENDIX Q-12**
**Nest Success and the Effects of Predation on Marbled Murrelets**

# Chapter 8
# Nest Success and the Effects of Predation on Marbled Murrelets

**S. Kim Nelson**[1] **Thomas E. Hamer**[2]

**Abstract**: We summarize available information on Marbled Murrelet (*Brachyramphus marmoratus*) productivity and sources of mortality compiled from known tree nests in North America. We found that 72 percent (23 of 32) of nests were unsuccessful. Known causes of nest failure included predation of eggs and chicks ($n$ = 10), nest abandonment by adults ($n$ = 4), chicks falling from nests ($n$ = 3), and nestlings dying ($n$ = 1). The major cause of nest failure was predation (56 percent; 10 of 18). Predators of murrelet nests included Common Ravens (*Corvus corax*) and Steller's Jays (*Cyanocitta stelleri*); predation of a nest by a Great Horned Owl (*Bubo virginianus*) was also suspected. We believe that changes in the forested habitat, such as increased amounts of edge, are affecting murrelet productivity. Successful nests were significantly further from edges ($\bar{x}$ = 155.4 versus 27.4 m) and were better concealed ($\bar{x}$ = 87.2 versus 67.5 percent cover) than unsuccessful nests. The rate of predation on Marbled Murrelet nests in this study appear higher than for many seabirds and forest birds. If these predation rates are representative of rates throughout the murrelet's range, then the impacts on murrelet nesting success will be significant. We hypothesize that because this seabird has a low reproductive rate (one egg clutch), small increases in predation will have deleterious effects on population viability. Rigorous studies, including testing the effects of various habitat features on recruitment and demography, should be developed to investigate the effects of predation on Marbled Murrelet nesting success.

Nesting success in seabirds is influenced by a variety of physical and biological factors, including food availability, habitat quality, energetics, predation, and climatic conditions (Croxall 1987, Nettleship and Birkhead 1985, Vermeer and others 1993). Because the effects of these factors can vary spatially and temporally, seabird nesting success can be highly variable among years (Birkhead and Harris 1985; Boekelheide and others 1990; De Santo and Nelson, this volume). For example, in some years, anomalous warm oceanographic conditions (El Niño) cause a decrease in prey availability, thus impacting nesting attempts and nest success (Ainley and Boekelheide 1990, Hodder and Greybill 1985, Vermeer and others 1979). In addition, disturbance to nesting habitat (e.g., habitat loss, modification) and associated cumulative impacts can affect the ability of seabirds to successfully reproduce (Evans and Nettleship 1985; Gaston 1992, Reville and others 1990).

[2] Research Biologist, Hamer Environmental, 2001 Highway 9, Mt. Vernon, WA 98273

The influence of these biological and physical factors on the nesting success of Marbled Murrelets (*Brachyramphus marmoratus*) is not fully known. In order to completely address this issue, well designed studies investigating the conditions that directly influence murrelet reproduction are needed. However, data are available on murrelet nesting success from tree nests that have been located and monitored in North America. In this paper, we summarize this information on murrelet productivity and sources of mortality. In addition, because predation was the major cause of nest failure, we discuss the implications of predation on this threatened, forest-nesting seabird.

## Methods

We compiled information on nest success and failure from published and unpublished records of 65 Marbled Murrelet tree nests found in North America between 1974 and 1993. The sample size of tree nests were distributed by state and province as follows: Alaska ($n$ = 18), British Columbia ($n$ = 9), Washington ($n$ = 6), Oregon ($n$ = 22), and California ($n$ = 10) (*table 1*). Success and failure of nests were determined through intensive monitoring of nesting activity, or evidence collected at the nest. The outcomes of nests were compared between regions (Alaska versus British Columbia, the Pacific Northwest and northern California). Nests were considered to fail if: (1) the chick or egg disappeared, fell out of the nest, or was abandoned; (2) the chick died; (3) unfaded eggshell fragments were found during the breeding season in nest cups without fecal rings; or (4) predation was documented. Nests were considered or assumed to be destroyed by a predator based on one or more of the following: (1) predation was observed, (2) the egg or chick disappeared prematurely between nest observations and neither were located on the ground after a thorough search of the area, and (3) evidence, such as puncture marks on eggs, or albumen or blood on eggshell fragments, was discovered and predators were aware of the nest location or seen in the immediate area. In addition to data from active nests, information on eggs, nestlings, and hatch-year birds found on the ground were compiled from published and unpublished records between 1900 and the present.

We used a Mann-Whitney U-test to compare the characteristics of nests that were successful with those of nests that failed because of predation. Variables used in the analysis were those that could have an effect on nest exposure or concealment: distance to edge, canopy cover, stand size, percent cover above the nest cup, nest height, distance of the

nest from the trunk, limb diameter at the nest, and nest substrate type (i.e., moss or duff). Edges were defined as unnatural openings, including, but not limited to, roads and clearcuts. Differences in the mean characteristics (ranks) were considered significant at $P < 0.05$.

# Results and Discussion

## Nest Success and Failure

Nesting success or failure was documented at 49 percent (32 of 65) of the nests (*table 2*). Timing of discovery (after the nesting season), limited evidence, or inadequate monitoring prevented conclusions about the outcomes at the remainder of nests. Therefore we limit our discussion to these 32 tree nests.

Seventy-two percent (23 of 32) of the nests were unsuccessful (*tables 1* and *2*). Known causes of nest failure included predation of eggs and chicks, nest abandonment by adults, chicks falling from nests, and nestlings dying (*tables 1* and *3*). Nesting success of 28 percent is lower than reported for 17 other alcid species ( $\bar{x}$ = 57 percent, range = 33–86) (De Santo and Nelson, this volume), and for 11 species of sub-canopy and canopy nesting neotropical landbird migrants ( $\bar{x}$ = 51 percent, range = 20–77) (Martin 1992). However, some species of seabirds (e.g., Xantus' Murrelet [*Synthliboramphus hypoleucus*]) and forest nesting neotropical migrants (e.g., Western Kingbird [*Tyrannus verticalis*]), also experienced low nesting success (33 and 20 percent, respectively) in some years (Martin 1992; Murray and others 1983). Hatching and fledging success of Marbled Murrelet nests were 67 and 45 percent, respectively. Fledging success was also lower than reported for all other alcid species ( $\bar{x}$ = 78 percent, range = 66–100, $n$ = 16) (De Santo and Nelson, this volume).

For all nests, 52 percent of the failures occurred during the egg stage, whereas in Washington, Oregon, and California most (62 percent) failed during the chick stage (*table 3*). The difference in stage of failure between the southern portion of the murrelet's range and all known nests can be explained by greater abandonment of eggs at nests in Alaska (Naslund, pers. comm.). The high incidence of abandonment in eggs in Alaska between 1991 and 1994 may have been related to limited food resources (Kuletz, pers. comm.).

Failure during the egg stage was caused by abandonment and predation. Failure during the chick stage occurred because of predation, death from a burst aorta (Palco nest in California), and falling from the nest. Chicks may fall from nests because nests are located on small platforms, or in response to unfavorable weather conditions, such as high winds, or other natural and unnatural disturbances. In Oregon, a 6-day-old chick may have fallen from its ridgetop nest tree (Five Rivers) because of gusty winds that occurred during a midday storm. Chicks are also occasionally very active on the nest, picking at nesting material, changing positions, snapping at insects, exercising their wings, and pacing on the nest limb (see Nelson and Hamer, this volume a). They could easily fall from the nest platform during these times of activity. In addition, predator activity could cause chicks to fall from the nesting platform.

In addition to failure documented at active nests, nestlings, fledglings, and eggs have been found on the ground during the breeding season at numerous sites throughout North America (*table 4*). Chicks and eggs located on the ground probably fell from nests as indicated above. However, eggs could also be carried by predators and dropped in locations distant from nest sites.

Fledglings have been discovered on the ground at varying distances from the ocean during the breeding season (up to 101 km inland). Many of these birds still retained an egg tooth and small traces of down on their head and back, indicating recent fledging. Marbled Murrelet hatch-year birds

***Table 2—Summary of Marbled Murrelet nest success and failure by state and province***

| State/province | Nest outcome | | |
|---|---|---|---|
| | Successful | Failed | Unknown |
| Alaska | 0 | 9 | 9 |
| British Columbia | 1 | 0 | 8 |
| Washington | 3 | 1 | 2 |

[1] Data from Atkinson, pers. comm.; Confer, pers. comm.; Carter and Erickson 1992; Carter and Sealy 1987b; Hamer, unpublished data; Kuletz, pers. comm.; Leschner and Cummins 1992b; Mendenhall 1992; Nelson, unpublished data; Nelson and others 1992; Rodway and others 1992; S.W. Singer, pers. comm.

are believed to fly directly from inland nest sites to the ocean after fledging (Nelson and Hamer, this volume a; Quinlan and Hughes 1990). Their travel to the ocean may be unsuccessful, however, because of navigational problems or exhaustion. Unlike other alcids, hatch-year Marbled Murrelets must fly relatively long distances to reach the sea without the benefit of past flight experience, wing muscle development that comes with flight, or adult guidance. The large number of juveniles found on the ground while dispersing from nest sites raises questions about the relationship between murrelet energetics, location of the nest in relation to the ocean, and nesting success. Given that some hatch-year birds become grounded each year, and may be unable to take flight again, nest success may actually be much lower than our estimates from nest observations.

### Failure because of predation

The major cause of nest failure was predation. Forty-three percent of all nests and 57 percent of nests in Washington, Oregon and California failed as a result of predation (*table 3*). Predation rates were higher (56 and 67 percent, respectively) when excluding unknown causes of failure, which could have included predation. Known predators of murrelet nests include Common Ravens (*Corvus corax*) and Steller's Jays (*Cyanocitta stelleri*) (Naslund 1993; Singer and others 1991) (*table 1*). Predation of a nest by a Great Horned Owl (*Bubo virginianus*) is also suspected. Other potential predators in forests include several species of forest owls, accipiters and American Crows (*Corvus brachyrhynchos*). No Marbled Murrelet nests are known to have been destroyed by mammalian predators, although raccoons (*Procyon lotor*), marten (*Martes americana*), fisher (*Martes pennanti*), and several species of rodents are potential predators.

Predation rates on murrelet nests appear higher than other alcids, perhaps with the exception of areas with introduced or high numbers of predators. For example, 44 percent of the eggs laid by a population of Xantus' Murrelets on Santa Barbara Island in California were taken by deer mice (*Peromyscus* spp.) during periods of egg neglect (Murray and others 1983). Rates of predation on murrelet nests also appear higher than those observed for many forest birds, with the exception of some species of sub-canopy and canopy nesting neotropical migrants (e.g., $\bar{x}$ = 42 percent, range = 18-67 percent) (Martin 1992). However, the impacts of predation on the nesting success of species that lay clutches of two or more eggs (e.g., Xantus' Murrelets, Yellow-rumped Warbler [*Dendroica coronata*]) may be less than on species that lay only one egg, such as Marbled Murrelets.

Predation on Marbled Murrelet nests has been observed or documented during both the egg and nestling stages, but most (56 percent) occurred during the egg stage (*table 3*). Predation during the egg stage is most likely to occur if an incubating adult neglects or abandons the nest. Seabirds are known to completely abandon their nests during years in which prey availability is limited (i.e., during El Niño events) (Ainley and Boekelheide 1990, Hodder and Greybill 1985, Vermeer and others 1979). In addition, seabirds may neglect their eggs for short periods to maximize foraging time and accumulate sufficient energy reserves for the lengthy incubation shifts (Boersma and Wheelwright 1979, Gaston and Powell 1989, Murray and others 1983). During this time, the eggs are subject to a variety of negative factors including predation, heat loss, and exposure to the elements.

Murrelets have been observed leaving their eggs unattended for short periods of time (2–3 hrs on several days) (Naslund 1993; Nelson and Peck, in press), and during such a time in Oregon (Cape Creek nest), an egg was taken by a predator (most likely a Common Raven). In addition, murrelets regularly left their egg unattended in the afternoon, evening, and early morning hours during a 5-day period at a nest in Alaska (Naked Island 1992), and the nest subsequently failed (Naslund and others, in press). Eggs were also abandoned when adults were flushed from the nest by a predator in California (Opal Creek) and Alaska (Naked Island) (Naslund 1993; Naslund and others, in press; Singer and others 1991). The eggs from these nests were later observed or believed to have been destroyed by a Common Raven and Steller's Jay, respectively.

In Oregon, additional egg predation was determined by finding blood and albumen on eggshell fragments. The egg disappeared from the 1991 Valley of the Giants nest after three weeks of incubation. Upon climbing the nest tree, a large eggshell fragment with blood stains was found in the nest cup. The suspected predator was a Common Raven that flew directly adjacent to the nest branch on its daily foraging forays. At the 1992 Valley of the Giants nest, eggshell fragments with blood and albumen were found at the base of a large Douglas-fir (*Pseudotsuga menziesii*) tree. An empty nest cup was subsequently discovered. The predator was most likely a Common Raven observed near the nest tree on several occasions.

In Oregon, chicks disappeared or were killed by predators at three nests during the 1991 and 1992 breeding seasons. A 3-week-old chick at the Siuslaw #2 nest was killed when its skull was pierced by a predator. Two species of corvids (Steller's Jay or Gray Jay [*Perisoreus canadensis*]) detected in the nest tree and adjacent area are the suspected predators. At the Boulder Warnicke nest, a 3-week-old chick disappeared from the nest. The predator could have been any one of the corvids that were present in the area or landed in the nest tree: Steller's Jays, Gray Jays, or Common Ravens. A 6-day-old chick disappeared at the Valley of Giants 1990 nest between 2100 and 0600 hrs on 6 August. A Great Horned Owl was heard calling from an adjacent tree (within 10 m) during this time period, and is the suspected predator.

Marbled Murrelets have limited defenses and their primary protection against predation at the nest is to avoid detection (Nelson and Hamer, this volume a; Nelson and Peck, in press). Therefore, the nestling depends on its cryptic plumage and the location of the nest for safety. If a predator discovers the nest, the chick will attempt to defend itself with aggressive behaviors as witnessed by Naslund (1993) and Singer and others (1991), when a Steller's Jay attacked a 4-day-old chick at the Waddell Creek nest in California. The chick rotated its sitting position on the nest to constantly face the predator, reared up its body and head, opened its beak, and jabbed at the predator. The chick was unable to ward off the jay and was carried away.

Nesting attempts also may fail because adults have been killed on their way to or at nest sites. In forests of southeast and southcentral Alaska, Sharp-shinned Hawks (*Accipiter striatus*) and Northern Goshawks (*Accipiter gentilis*) are known to prey on adult murrelets (Marks and Naslund 1994; Naslund, pers. comm.). In addition, Peregrine Falcons (*Falco peregrinus*) and Common Ravens have been observed chasing Marbled Murrelets just above and within the forest canopy, respectively (Hamer, unpubl. data; Hunter, pers. comm.; Suddjian, pers. comm.). A Peregrine Falcon was successful in capturing a Marbled Murrelet at one such site in central California (Suddjian, pers. comm.).

Predation of adults at the nest site also can occur. There are two known records from California and Alaska. A Common Raven flushed an adult murrelet from a nest in California (Opal Creek), and was later seen carrying what appeared to be a partial carcass (Naslund 1993, Singer and others 1991). In Alaska, an adult was killed by a Sharp-shinned Hawk seconds after it landed on a suspected nest limb (Naked Island) (Marks and Naslund 1994).

**Potential for Bias**

The Marbled Murrelet nests at which predation has been studied may not be an unbiased sample. The high predation rates recorded at these nests could be biased because many of the nests were located in fragmented areas and near forest edges (*table 5*) rather than in the centers of large, dense stands. Thus, there is the possibility that nest sites located by researchers are also those more easily located by predators (see below). At present we lack information to evaluate this source of potential bias.

In addition, it has been suggested that researchers studying these nests had an impact on their success (see Götmark 1992; Martin and Geupel 1993). We believe the disturbance to the nests was minimal, except at two. In southeast Alaska, researchers approached very close to an unusual murrelet nest located on tree roots near ground level (Brown, pers. comm.). The adult was flushed or disturbed on five occasions, which may have contributed to its failure (egg or newly hatched chick disappeared). The "J" Camp nest in California also failed from direct human intervention (Binford and others 1975). No human impacts are suspected at nests where the chick fell out ($n$ = 1 in Oregon) or died ($n$ = 1 in California), or where nests were found after they had failed ($n$ = 1 each in Washington and Oregon, $n$ = 2 in California). At all other nests, human impacts were also limited because: (1) some nests were monitored infrequently ($n$ = 8 in Alaska and $n$ = 2 in Oregon); (2) predators knew the location of the nest on day of and probably prior to discovery, and, additionally, precautions (e.g., limiting noises and number of observers near nest; see Martin and Geupel 1993) were implemented to minimize disturbance and predator attraction ($n$ = 1 in Oregon, $n$ = 2 in California); and (3) nests were monitored from >25 m horizontal distance from the nest and precautions (see above) were implemented ($n$ = 17). For (2) and (3) above, predators were occasionally attracted to the observer's location on the ground (especially Steller's Jays), but not to the nest site, >18 m above the ground. In contrast, intensive disturbance occurred at three successful nests. In Oregon, the only nest tree that was climbed while active was successful, and in Washington, chicks at two nests fledged despite regular climbing (approximately once a day for 9–20 days) to collect nestling growth and development data.

## Habitat Characteristics and Predation of Nests

The effect of predators on avian nesting success can vary significantly with geographic location, and is dependent upon the species of predators present, accessibility of nests, type and dimension of the habitat, topography, and vegetative complexity (vertical and horizontal diversity) (Chasko and Gates 1982; Martin 1992; Marzluff and Balda 1992; Paton 1994; Reese and Ratti 1988; Yahner 1988; Yahner and others 1989). For example, alcids nesting on islands relatively free of mammalian predators, or on cliffs inaccessible to terrestrial predators, experience lower predation rates than species nesting in accessible sites and with abundant predators (Ainley and Boekelheide 1990; Hudson 1985). Because many species of birds have evolved in association with predators, the long term impacts of predation on avian nesting success are expected to be minimal in natural situations. However, rapid and unnatural changes, such as the introduction of mammalian predators (cats, goats, mice, pigs, raccoons, rats) and habitat modification, can have significant impacts on nesting success of seabirds (Bailey and Kaiser 1993; Ewins and others 1993; Gaston 1992; Murray and others 1983), and neotropical migrants (Chasko and Gates 1982; Martin 1992), respectively. In these cases, predation can be a major factor affecting avian population viability (Martin 1992).

Significant changes have occurred in the forested landscapes of the United States over the past century, including loss of late-successional forests, habitat fragmentation, and increases in the amount of edge (Hansen and others 1991; Harris 1984; Morrison 1988; Perry, this volume; Thomas and Raphael 1993). These changes have affected the abundance and distribution of many avian predators and forest nesting birds. For example, populations of corvids and

Great Horned Owls are increasing in numbers throughout the western United States, especially in response to increases in habitat fragmentation and human disturbance (Johnson 1993; Marzluff 1994; Marzluff and Balda 1992; Robbins and others 1986; Rosenberg and Raphael 1986; Yahner and Scott 1988). In contrast, numerous neotropical migrant species are declining in numbers because they are unable to adjust to fragmentation and rapidly changing habitat conditions (Hagan and Johnson 1992; Hansen and others 1991, Hejl 1992, Martin 1992, Morrison and others 1992, Rosenberg and Raphael 1986). The Marbled Murrelet was listed as a threatened species in 1992 as changes in the forested landscape appear to be negatively impacting their populations (U.S. Fish and Wildlife Service 1992).

Although the relationship between predator numbers, habitat fragmentation, and predation on Marbled Murrelet nests has not been specifically studied, we believe, based on the following data, that changes in their habitat, such as increased amounts of edge, may significantly affect their nesting success. First, evidence from murrelet nests in this study suggests that distance to edge, stand size, canopy closure, percent cover above the nest cup (nest concealment), and distance of the nest from the tree trunk may be affecting predation rates (*table 5*). In a comparison of these habitat characteristics between successful nests ($n$ = 9) and nests that failed because of predation ($n$ = 8, excluding Alaska), we determined that successful nests were located significantly farther from edges (U = 2.9, $n$ = 16 trees, $P < 0.05$) (*table 5*). All successful nests were located >55 m ( $\bar{x}$ = 166.3, $n$ = 8 trees, *s.e.* = 82.3) from an edge (road or clearcut), with the exception of the Nemah nest in Washington, which was located within 10 m of an old road near the center of a 142 ha forest. In contrast, all nests that failed because of predation were located within 64 m ( $\bar{x}$ = 27.4, *s.e.* = 6.0) of an edge. In a review of numerous artificial nest predation studies, Paton (1994) found evidence that predation of bird nests is higher within 50 m of edges. This result supports our hypothesis that murrelet nests near edges may be more vulnerable to predation than those located in the stand interior. In addition, nest concealment was significantly greater at successful nests ( $\bar{x}$ = 87.2 percent, *s.e.* = 3.9) compared with nests that failed because of predation ( $\bar{x}$ = 67.5 percent, *s.e.* = 8.2) (U = 2.3, $n$ = 17, $P < 0.05$) (*table 5*). Nest concealment has been shown to decrease predation rates (Chasko and Gates 1982; Marzluff and Balda 1992; Martin and Roper 1988). Stand size (532.0 versus 407.4 ha, $n$ = 11 stands) and canopy closure near nests (63.6 versus 47.0 percent, $n$ = 16 plots) were higher and nests located closer to the trunk (46.5 versus 163.3 cm) at successful sites, but were not significantly different from nests that failed because of predation.

Second, it has been suggested that changes in forests where boundaries are contiguous with secondary succession may not create the same predation problems as those observed in static, simple forests in urban and agricultural areas that are defined by distinct boundaries (Rosenberg and Raphael 1986; Rudnicky and Hunter 1993). However, numerous studies in the eastern United States provide empirical evidence that edge effects in a forest dominated landscape (forest/clearcut edge) are similar to those in forest/urban or agricultural settings. For example, in studies of eastern neotropical migrants, predation was lower in the forest interior (>50 m from the edge) compared with edge habitat (Chasko and Gates 1982; Yahner and Scott 1988). Predation was also lower in areas with high vegetative heterogeneity and concealing cover (Chasko and Gates 1982).

Evidence from artificial nest studies in forests of the Pacific Northwest also suggests that predation of birds' nests may be affected by habitat fragmentation and forest management. On Vancouver Island, British Columbia, Bryant (1994) demonstrated that artificial ground and shrub nests located along forest/clearcut edges (within 100 m) were subject to higher predation rates than those in the forest interior (100–550 m from the edge). In the Oregon Coast Range, predation on artificial shrub nests was higher in clearcuts and shelterwood (20–30 green tress >53 cm d.b.h./ha) stands than in stands with group selection cuts (1/3 volume removed in 0.2 ha openings) and unmanaged (control) stands (Chambers, pers. comm.). Additionally, in the Oregon Cascades, Vega (1994) found that predation on ground nests was significantly greater in clearcuts compared with retention stands (12 trees/ha and 7.5 snags/ha), and predation on shrub nests was highest in retention stands compared to the other treatment types (clearcuts and mature stands). Steller's Jays, the suspected predator of the shrub nests, were more abundant in the retention stands, where they probably used the remnant trees for perching (see Wilcove 1985; Yahner and Wright 1985).

Third, despite differences in results among nest predation studies (e.g., Rudnicky and Hunter 1993 versus Yahner and Scott 1988), existing evidence strongly indicates that avian nesting success declines near edges (Paton 1994). In addition, regardless of the type of edge, fragmentation of forests often reduces structural complexity and heterogeneity of stands, and exposes remnant patches to edge effects (Hansen and others 1991; Harris 1984; Lehmkuhl and Ruggerio 1991). Because of increases in the amount of edge, productivity of interior forest species is generally impacted (Lehmkuhl and Ruggerio 1991; Reese and Ratti 1988; Yahner and others 1989), and generalist species, which benefit from the ecotone, usually increase in numbers (Yahner and Scott 1988). In addition, as vegetative complexity and canopy volume are reduced through fragmentation, bird nests (especially those located in shrubs or trees) may be more conspicuous and easier for avian predators to locate (Rudnicky and Hunter 1993; Vega 1994; Wilcove 1985; Yahner and Cypher 1987; Yahner and others 1989; Yahner and Scott 1988).

The rates of predation on Marbled Murrelet nests in this study appear higher than for many seabirds and forest birds. If the observed predation rates are representative of predation rates throughout the murrelet's range, then the impacts of predation on murrelet nesting success is significant and of concern (Wilcove 1985). Even if these high predation rates are localized to certain states or areas within states, the combination of low annual nesting success, low fecundity rates (Beissinger, this volume), and low or declining population sizes (Carter and Erickson 1992; Kelson and others, in press; Kuletz, 1994), could impact the survival and recovery of this threatened seabird.

## Conclusions

Results from this study suggest that predation on murrelet nests may be relatively high compared with many alcids and forest nesting birds. Because Marbled Murrelets have no protection at nest sites other than the ability to remain hidden (Nelson and Hamer, this volume a), the availability of safe nest sites will be imperative to their survival. If logging and development (e.g., clearing land, creating patches of habitat, thinning stands) within the murrelet’s range has resulted in increased numbers of predators or predation rates, and has made murrelet nests easier to locate because of increased amounts of edge and limited numbers of platforms with adequate hiding cover, then predation on murrelet nests could be significantly higher in such situations. In addition, areas heavily used by humans for recreational activities (i.e., picnic and camping grounds) can attract corvids (Marzluff and Balda 1992, Singer and others 1991) and may increase the chance of nest predation within these areas. Therefore, we hypothesize that because this seabird has low reproductive rates (one egg clutch), small increases in predation will have deleterious effects on murrelet population viability.

Rigorous studies should be developed to investigate the effects of predator numbers, predator species, predator foraging success, landscape patterns, habitat types, and forest structural characteristics on Marbled Murrelet nesting success. In implementation of these studies, hypotheses on the effects of various habitat features on fitness components (recruitment and demography) should be tested (Martin 1992, Paton 1994). At the same time, the effects of these hypotheses on coexisting species and the interacting effects these species have on one another should be evaluated (Martin 1992).

## Acknowledgments

We are grateful to the biologists who kindly shared their data with us; special thanks go to Jim Atkinson, Alan Burger, Stephanie Hughes, John Hunter, Paul Jones, Kevin Jordan, John Kelson, Steve Kerns, Kathy Kuletz, Irene Manley, Ray Miller, Nancy Naslund, Bill Ritchie, Steve and Stephanie Singer, and David Suddjian for their time and generosity. We also thank Alan Burger, George Hunt, John Marzluff, Robert Peck, Steve Speich, and several anonymous reviewers for providing valuable comments on earlier drafts of this manuscript. Support for preparation of this manuscript was provided by the Oregon Department of Fish and Wildlife, USDA Forest Service, USDI Bureau of Land Management, and the U.S. Fish and Wildlife Service, U.S. Department of the Interior. This is Oregon State University Agricultural Experiment Station Technical Paper 10,540.

## TABLE OF CONTENTS

# ACKNOWLEDGMENTS

U.S. Fish and Wildlife Service, Department of Defense (Ft Lewis and McChord Air Force Base), The Nature Conservancy, Washington Department of Natural Resources, and Washington Department of Transportation provided funding for the research associated with this document. Ft. Lewis and The Nature Conservancy provided funding for producing this document. Kevin Fort, Randy Moore, Douglas J. Robinson, and Derek Stinson all provided helpful comments on previous versions of this document. Mark Hopey and Hannah Anderson provided helpful suggestions and comments and Hannah produced figures 1 and 2. Derek Stinson created the cover layout. Thank you all!

# INTRODUCTION

The Streaked Horned Lark (*Eremophila alpestris strigata*) is a rare subspecies of the Horned Lark that breeds and winters in Oregon and Washington. Recent Streaked Horned Lark research has focused on documenting changes in the subspecies breeding range (Rogers 2000), inventorying and locating current breeding (Altman 1999, Rogers 1999, MacLaren and Cummins 2000, Pearson and Hopey 2004, 2005) and wintering (Robinson and Moore unpubl., Pearson et al. 2005) populations in Oregon and Washington, identifying breeding and foraging habitat (Altman 1999, Rogers 2000, Pearson 2003, Pearson and Hopey 2004, 2005), and experimenting with methods to improve Lark habitat (Pearson and Hopey 2005). In addition, British Columbia recently completed a status report on the Lark (Beauchesne and Cooper 2003) and another has been drafted by Washington Department of Fish and Wildlife (Stinson 2005).

The goal of this report is not to duplicate the efforts of others but to provide a range-wide review of the current wintering and breeding range, list of habitat requirements and estimates of wintering and breeding population numbers. In addition, we identify population threats, recommendations for addressing these threats and we present a preliminary conservation strategy. Because others have attempted to reconstruct this subspecies historic wintering and breeding ranges and to describe its life history (Rogers 2000, Beauchesne and Cooper 2003, Stinson 2005), we spend little effort on these topics. The management recommendations and conservation strategy presented here are initial thoughts and need critical review, revision and development. If the subspecies is listed as Endangered in Washington as recommended, a recovery strategy will be developed for the State. Canada is currently writing a recovery plan. In addition to these efforts, we strongly recommend developing a range-wide conservation plan (including a metapopulation model) and establishing a range-wide (Oregon, Washington, British Columbia) working group to develop recovery strategies and facilitate recovery actions.

Several lines of evidence suggest that the Streaked Horned Lark is vulnerable to extinction and should be a conservation priority. The Streaked Horned Lark is a recognized subspecies of the Horned Lark (AOU 1957) and genetic data indicate that the Streaked Horned Lark is unique, isolated, and has little genetic diversity (Drovetski et al. in press). The breeding range of the Lark has contracted over time; it no longer breeds in the northern Puget trough (San Juan Islands and other Puget Sound sites north of Tacoma), southern British Columbia, along the Washington Coast north of Grays Harbor, and in the Rogue River Valley (Rogers 2000, Beauchesne and Cooper 2003, Stinson 2005). Although no systematic range-wide attempt has been made to estimate the total population of this subspecies, results from winter and breeding surveys suggest that the entire population of this subspecies is likely less than 1,000 birds (see discussion below). Remaining breeding populations and their habitats face imminent threats posed by land development, incompatible land uses, human activities, predation, and non-native species. Wintering populations are potentially threatened by stochastic events and by a lack of suitable habitat in the Willamette Valley. Very few of the sites used by the Lark for breeding or wintering are protected and no sites are managed primarily for Larks.

Conservation efforts to date, have focused on identifying and monitoring Lark populations, identifying habitat features important to successful breeding, testing methods for creating appropriate breeding habitat, restoring degraded habitats, and restricting some human uses on breeding sites. For example, Ft. Lewis has restricted recreational activities on a breeding site and Olympia Airport has modified mowing dates and times to minimize impacts to Lark nests.

Because the subspecies migrates between Oregon and Washington and because the remaining breeding populations are found in the Puget lowlands, Columbia River/coastal Washington, and Willamette Valley, we recommend that local and regional recovery strategies consider range-wide population dynamics and threats so that recovery actions can be coordinated and focused on the activities that are most likely to result in increased Lark populations.

## TAXONOMY

The Horned Lark (*Eremophila alpestris*) is a member of the family Alaudidae (larks) in the order Passeriformes. Of the 76 species of lark, it is the only lark native to North America. The Horned Lark has 21 described subspecies in North America based on differences in size and plumage color (American Ornithologists' Union 1957). There is a high degree of overlap in plumage and color between many subspecies (Behle 1942). The breeding range of the Streaked Horned Lark appears to be allopatric with other subspecies (Behle 1942). The size and color of the Streaked Horned Lark approaches that of *E. a. insularis* and *E. a. sierrae* to the south but is smaller and more brightly colored (brighter yellows and reddish browns) than *E. a. alpina* which breeds above treeline in the Olympic and Cascade Mountains.

Drovetski et al. (in press), collected tissue samples from 32 Streaked Horned Larks in the Puget lowlands, Washington coast and the Columbia River and the haplotype from these samples was compared to those from 60 horned larks from Alaska, alpine Washington, eastern Washington and Oregon and coastal California. Although, the Streaked Horned Lark was found to be closely related to coastal California birds, it is genetically unique and isolated. Streaked Horned Larks appear to have remarkably low genetic diversity; all 32 sampled shared the same haplotype. All other localities sampled had multiple haplotypes despite smaller sample sizes. These genetic data indicate that the Streaked Horned Lark is unique, isolated, and has little genetic diversity and suggests that it is a conservation priority.

## CONSERVATION STATUS

- Listed as a federal Candidate species under the U.S. Endangered Species Act
- Committee On the Status of Endangered Wildlife Species in Canada lists the Streaked Horned Lark as Endangered
- On the Red list in British Columbia. This list includes any indigenous species or subspecies that have or are candidates for Extirpated, Endangered, or Threatened status in British Columbia
- Listed as a candidate for listing as Threatened, Endangered or Sensitive by Washington Department of Fish and Wildlife (28 October 1998). The Washington Department of Fish and Wildlife recently recommended that the Streaked Horned Lark be listed as Endangered in the State of Washington (Stinson 2005).
- Listed as State Sensitive by the Oregon Department of Fish and Wildlife (Critical Status; Oregon Sensitive Species List, 1997)
- A priority species for conservation by Oregon-Washington Partners in Flight (Altman 2000) and British Columbia Partners in Flight (Fraser et al. 1999)
- NatureServe rounded global conservation status is a G5T1 indicating that it is a critically imperiled subspecies of a widespread and common species.

## HISTORIC BREEDING RANGE

The Streaked Horned Lark historically bred in prairie and open coastal habitats from the southwestern corner of British Columbia (southeastern Vancouver Island, lower Fraser River Valley; Fraser et al. 1999) through the Puget trough and Willamette Valley (as far south as Eugene, Oregon) and into the Rogue River Valley (from Medford north to Eagle Point; Figure 1). In addition, Larks were found on open coastal habitats in western Washington (Smith et al. 1997, Jewett et al. 1953; Figure 1). For a detailed description of the Larks historic breeding range refer to Rogers 2000, Beauchesne and Cooper 2003, and Stinson 2005.

## CURRENT BREEDING RANGE

In Washington, Rogers (1999) identified 124 townships to survey for Larks and 31 were considered high priority because of recent Lark records (1960 or later) or because they contained suitable habitat. Rogers (1999) detected 49 singing males in 11 of the 86 townships surveyed. MacLaren and Cummins (2000) re-surveyed these occupied sites, the two remaining high priority sites that were not surveyed by Rogers (2000), and an additional 33 lower priority sites. MacLaren and Cummins (2000) did not locate additional occupied sites but did detect 65 Larks at the previously identified 11 occupied sites. Additional surveys by Pearson and Hopey (2004, 2005) on Ft. Lewis, the outer coast of Washington and lower Columbia River resulted in the identification of additional sites occupied by Larks (Appendix I). It is unlikely that many additional occupied sites will be identified in Washington because all of the high priority and many of the lower priority sites have been surveyed. In addition, requests to birding listserves asking birders to report sightings of Horned Larks in western Washington have not resulted in the location of any additional populations.

Altman (1999) conducted a broad-scale survey for Larks and other grassland birds in the Willamette Valley in 1996 and 1997. This survey consisted of 544 roadside point count stations along with more intensive survey methods consisting of transects, territory mapping and nest monitoring. Altman (1999) selected point count stations where target species (Oregon Vesper Sparrow, Streaked Horned Lark, Western Meadowlark, Grasshopper Sparrow, and Common Nighthawk) were known to occur or where appropriate habitat occurred. In addition, he attempted to spread his sampling points throughout the valley floor and foothills of the Willamette Valley and a broad range of potentially suitable habitat. Using this approach, he detected 154 Streaked Horned Larks within 100 m of point count stations.

To our knowledge, similar types of surveys have not been conducted in British Columbia. Campbell et al. (1997) considered the Streaked Horned Lark to be extremely rare in the lower Fraser River Valley and Fraser et al. (1999) considered it extirpated on southeastern Vancouver Island. Beauchesne (2002) conducted a survey for Vesper Sparrows on southern Vancouver Island, which uses habitat similar to the Lark, and noted a single male Streaked Horned Lark on the Nanaimo Airport on Vancouver Island but it was not located again in 2003 despite intensive searching. Today the Streaked Horned Lark is believed to be extirpated from British Columbia (Beauchesne 2003).

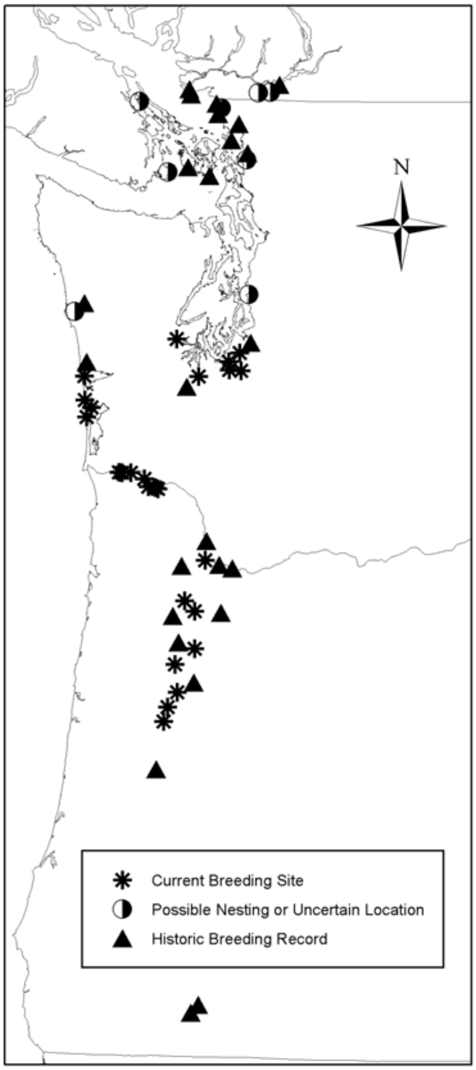

**Figure 1. Current and historic Streaked Horned Lark breeding localities and possible historic nesting or uncertain breeding season locations. Information from Altman (1999), Rogers (2000), Pearson and Hopey (2005), Stinson (2005).**

Results from these U.S. and Candian surveys indicate that the Streaked Horned Lark currently breeds on prairie remnants (n = 2) and airports (n = 4) in the southern Puget lowlands, on beaches and accreted lands near Grays Harbor and Willapa Bays (n = 4), on dredge spoil islands in the Columbia River (n = 6), an industrial site along the lower Columbia River in Oregon, and on a number of agricultural, pasture, grass, and mudflat habitats in the Willamette Valley from Portland to Eugene (Figure 1, Appendix I). In addition, the Streaked Horned Lark has been reported as an irregular breeder on the south jetty of the Columbia River (M. Patterson personal communication).

The Lark no longer breeds in southern British Columbia, the northern Puget trough (San Juan Islands and other coastal areas north of Tacoma), along the Washington Coast north of Grays Harbor, and in the Rogue River Valley (Rogers 2000, Beauchesne and Cooper 2003, Stinson 2005.).

## CURRENT WINTER RANGE

In Oregon, Robinson and Moore (2004) surveyed 18 5-minute lat/long Willamette Valley blocks selected at random and a total of 295 point counts within those blocks during the winter of 2003-2004. To locate larks, they drove every non-major highway road (roads other than Interstate 5) in each block and they located 15-20 point count stations in every block. Using this method, they detected only 19 Streaked Horned Larks from 6 point count Stations. In addition, they conducted additional surveys on large expanses of agricultural land that were known or suspected to be occupied by Larks. They found Streaked Horned Larks to be present in the Willamette and Columbia River valleys throughout the winter. Most of the Streaked Horned Larks were found in open agricultural lands of Linn, Benton, Polk, and Marion Counties. The only other substantial group of Streaked Horned Larks was located at the Port of Portland in Multnomah County on a large dredge spoil expanse.

Pearson et al. (2005) conducted a winter (2004/2005) inventory of known wintering and breeding localities in Washington and Oregon. They conducted 51 visits to 28 sites [Puget Sound n = 5, Washington coast n = 4, Columbia River n = 7, Willamette and Rogue Valleys n = 12 (Figure 2, Appendix II)]. No Streaked Horned Larks were observed at twelve of the 28 sites surveyed. Larks were found in large flocks consisting of Streaked Horned Larks and other subspecies of

Horned Lark (up to 170 birds in a flock) in the Willamette Valley, variable sized flocks of Larks on Columbia River islands (1-69 birds) and Oregon Coast (12-30 birds) and in pairs or small flocks (4-5 birds) in the Puget lowlands (Appendix II). Of the 542 Streaked Horned Larks observed during this survey, 72% were observed in the Willamette Valley, 20% on Columbia River islands or floodplain, 8% on Washington coast, and 1% on a Puget Sound airport and prairie (see Appendix II). In addition to these confirmed winter sightings, the Streaked Horned Lark may over winter on the southern Oregon coast (Coos County; subspecies unknown but may be *strigata*; Contreras 1998). On the northern Oregon coast it appears to be an annual migrant in fall and occasional (irregular) wintering species (M. Patterson personal communication).

Several lines of evidence suggest that birds in the Puget lowlands are migrating south for the winter: 1) only 3 birds were observed in the southern Puget lowlands during the 2004-2005 winter survey (Pearson et al 2005) and there were likely more than 216 breeding birds in the lower Puget trough during the previous breeding season (Pearson and Hopey 2005); and 2) birds banded in the southern Puget Sound region during the breeding season were re-sighted to the south in the Willamette Valley during the winter (Pearson et al. 2005). Multiple re-sights of banded birds throughout the winter in the Willamette Valley, Columbia River and on the Washington Coast suggests that some of these birds are staying in these regions throughout the winter.

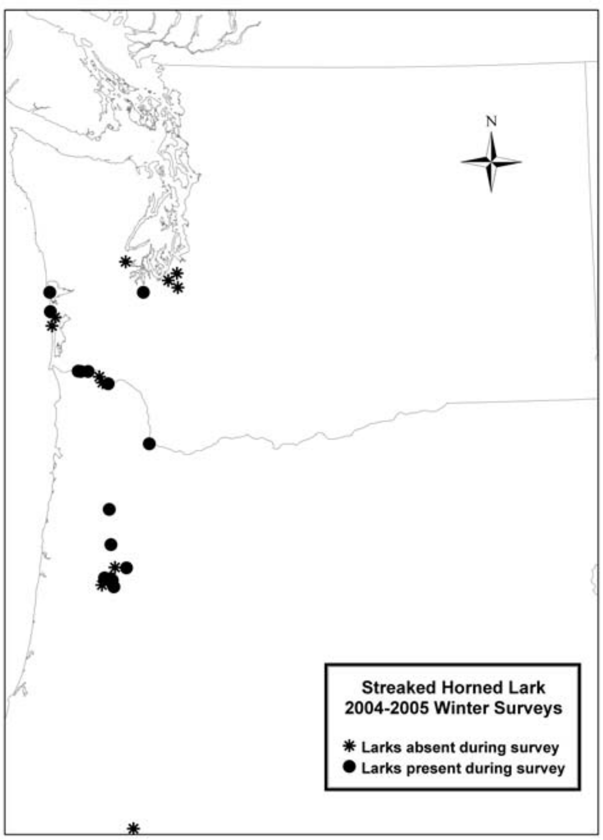

**Figure 2. Oregon and Washington localities where Streaked Horned Larks were present and absent during 2004-2005 winter surveys (Pearson et al. 2005).**

## HABITAT REQUIREMENTS

### Breeding Habitat

For a detailed description of Lark breeding habitat see Altman (1999) and Pearson and Hopey (2005).

**Puget Trough** (Pearson and Hopey 2005)

- Large expanses of grass dominated habitat (airports or native prairies; minimum area has yet to be determined) with very few or no trees or woody shrubs.
- Sparsely vegetated habitat dominated by relatively short annual grasses and native bunch grasses (3.9 – 13.3 inches tall).

- Avoided areas with sod forming (rhizomatous) grasses.
- Relatively high percent of bare ground (16%; particularly associated with dirt, gravel and cobbles) as the ground cover as opposed to a moss/lichen or thatch dominated ground cover.
- Around the nest site (0.5 m radius around the nest), females are selecting areas within territories with fewer non-vegetated areas and less cover of annual and perennial grass.
- Unvegetated habitats (dirt roads, taxiways or runways) used for foraging, singing and take-off sites for flight displays.

**Washington Coast and Lower Columbia River** (Pearson and Hopey 2005)

- Sparsely vegetated expanses of sand adjacent to the ocean or Columbia River. Areas dominated by grasses and forbs with few or no trees and shrubs.
- Selecting sparsely vegetated areas with more wood and cover of annual grasses with less algae (indicator of areas effected by very high tides) than adjacent areas in the same habitat type.
- Ground layer is dominated by sand (approx. 68%) with little thatch; moss or lichen are absent on the coast but present on the Columbia River islands.
- Sparsely vegetated (approximately 35% of the area with no vegetation).
- Dominated by relatively short annual grasses (0.6 – 8.7 inches).
- Around the nest site (0.5 m radius around the nest), females are selecting areas with fewer non-vegetated areas, more thatch and perennial forbs and shorter vegetation.

**Willamette Valley** (Altman 1999)

- Large expanses of herbaceous dominated habitat (cultivated grass fields, moderate to heavily grazed pasture, fallow fields, roadside shoulders), Christmas tree farms and wetland mudflats.
- Dominated by short grasses (0-6 inches).
- Relatively high percent of bare ground (17%) for territories.
- A higher percent cover of bare ground (31%) for nest sites.

## Winter Habitat

**Puget Trough** (Pearson et al. 2005)

- Only three wintering Larks were observed in the Puget lowlands. Two were found on the Olympia Airport (1 male and 1 female) and one bird was observed on 13$^{th}$ Division Prairie. All three birds were using the same habitats that are used by breeding birds and that is described above.

**Washington Coast and Lower Columbia River** (Pearson et al. 2005)

- On the Washington coast, Larks were found on dune and beach habitat adjacent to open water with few or no trees and shrubs.
- Larks on the lower Columbia River were primarily found on sparsely vegetated dredge spoils (see description under breeding habitat above).

**Willamette Valley** (Robinson and Moore 2004, Pearson et al. 2005)

- High percent of bare ground (sites with flocks > 20 birds averaged greater than 85% bare ground) and large expanse of treeless area. Most birds use agricultural fields, particularly rye grass fields with sparse ground cover.
- Winter habitats used in Willamette Valley are very unusual with respect to characteristics of dominant land cover. Larks are using fields that have apparently been fallow for a few months. The fields have sparse, patchy weedy cover with very little rye grass. Occasionally they are in annual rye grass fields with sparse cover, but more typically they avoid those fields. Perennial rye grass is almost universally avoided during winter.

## Breeding Season Foraging Habitat

**Puget Trough** (Rogers 2000, SFP and Mark Hopey pers. obs.)

- On Puget prairies, Larks select sites with low vegetation (mean = 4.2 inches), and with low vegetation density (Rogers 2000).
- Forages in sparsely vegetated prairie and grasslands, gravel roads, and runway and taxiway aprons on airports.

**Washington Coast and Lower Columbia River** (SFP and Mark Hopey pers. obs.)

- Sparsely vegetated dunes and beaches (same habitat that is used for territories and nesting).
- Forage in the wrack line and intertidal habitat.
- Sparsely vegetated dredge spoils along the Columbia River.

**Willamette Valley** (Altman 1999)

- Recently plowed or burned fields
- Row crops and vegetable fields with dirt rows between vegetation

# BREEDING POPULATION ESTIMATES

Rogers 2000, Pearson (2003) and Pearson and Hopey (2004, 2005) estimated the number of territories and total numbers of breeding birds at 16 sites in the Puget lowlands (n = 6), Washington coast (n = 4), and Columbia River islands (n = 6) (Appendix I). This work included intensive territory mapping and nest monitoring (n = 8 sites, > 10 visits/site/season) and estimates of the number of territories and the number of breeding birds during surveys (n = 8 sites, 1-5 visits/site/season) (see Appendix I).

As discussed above, Altman (1999) conducted a broad-scale survey for Larks and other grassland birds in the Willamette Valley in 1996 and 1997. This survey consisted of 544 roadside point count stations and more intensive survey methods (transects, territory mapping and nest monitoring) at additional sites. During point count surveys, birds occurred in 16 of the 41 regions established. Abundance was <0.5 birds/count in all regions except one, which had a relative abundance of 0.7 birds/count. We used the number of birds counted during point counts, intensive territory mapping and those observed outside of these activities (B. Altman's field notes) to estimate the number of birds in the Willamette Valley during the breeding season.

Using information from these studies and surveys, we estimate that there are approximately 774 Streaked Horned Larks with 222 birds (29%) in the Puget lowlands, 86 birds (11%) on the Washington coast, 68 birds (9%) on the lower Columbia River, and 398 birds (51%) in the Willamette Valley (Appendix I). These numbers should be used cautiously as population estimates because: 1) all populations and birds may not have been counted; 2) multiple techniques and different amounts of effort went into generating population estimates at different locations; 3) surveys were conducted by different people in the Willamette Valley than in other locations; and 4) inventories occurred during different years, some nearly 8 years apart; and 5) populations may be spatially and temporally dynamic (especially in the Willamette Valley where birds breed in agricultural fields that are managed differently over time). These data were gathered in such a way that it is very difficult if not impossible to put confidence intervals around these estimates.

## WINTER POPULATION ESTIMATES

As discussed above, Robinson and Moore (2004) conducted a Streaked Horned Lark survey during the winter of 2003/2004 and found Streaked Horned Larks at 16 sites on the islands and flood plain of the lower Columbia River and in agricultural fields in the Willamette Valley. They identified 382 confirmed Streaked Horned Larks with an additional 209 Streaked Horned Larks for a potential total of 591 Streaked Horned Larks.

As discussed above, Pearson et al. (2005) conducted a winter (2004/2005) inventory of known wintering and breeding localities in Washington and Oregon. They conducted 51 visits to 28 sites [Puget Sound n = 5, Washington Coast n = 4, Columbia River n = 7, Willamette and Rogue Valleys n = 12 (Figure 2, Appendix II)]. Using the maximum Streaked Horned Lark count during any one visit to a site, we estimate that the maximum number of Streaked Horned Larks at all of the sites we surveyed was 542 birds (Appendix II).

Caution should be used when using either of these winter counts as an estimate of the total Streaked Horned Lark population for two reasons: 1) not all potential wintering locations were surveyed suggesting that this may be a low estimate; and 2) the re-sighting of banded birds in different locations during the winter suggest that birds move among Columbia River islands and between Columbia River islands and the Washington coast during the winter. The movement of birds among sites could result in double counting birds and ultimately an overestimate of the population size.

## THREATS

Below and in Appendix III, we describe the threats observed while conducting winter (2 years) and breeding season (5 years) research.

### Human Activities

- Streaked Horned Larks are actively establishing territories and breeding from late March to early August. The following activities appear to influence Lark behavior by causing them to become alert or fly or the activities directly destroy nests (Pearson and Hopey 2004): mowing, moving vehicles (including ORVs), model airplane flying (and likely kite flying), fireworks, dog walking, and gatherings of people and/or vehicles. Activities that keep Larks away from nests for extended periods of time (more than an hour) are particularly disruptive and may result in nest abandonment.

- Flush distances depend on breeding stage and type of disturbance. In general, activities that occur within 30 m (mean + 1 SD of the mean flushing distance) are more likely to cause flush events than more distant activities (Pearson and Hopey 2004). Our observations suggest that birds are more likely to flee in response to pedestrian and dog activity than vehicle activity.
- Activities associated with the deposition of dredge spoils immediately adjacent to breeding and wintering birds could negatively affect nesting (increase nest abandonment or prevent nesting) and foraging (cause birds to flee or to spend more time alert and less time foraging). On Miller Sands, two nests were abandoned after equipment was staged immediately next to them. Also on Miller Sands, the deposition of dredge spoils on a known Lark breeding area 2004 likely resulted in nest failure.
- Because Larks nest on the ground and often near dirt roads, their nests are vulnerable to vehicle traffic especially along active airport taxiways, roads on Puget prairie sites, beaches with vehicle traffic, and roads adjacent to agricultural sites. Loss of nests associated with vehicle activity has been documented in the Willamette Valley (Altman 1999) and Puget lowlands.
- Mowing may be both a blessing and curse for the Streaked Horned Lark. All of the airport sites are mowed and the mowing may be partially responsible for maintaining suitable habitat at these sites. At the same time, mowing results in direct mortality of nests and may cause some nest abandonment (Pearson and Hopey 2005). Gray Army Airfield reduced the frequency of mowing and adjusted the timing of mowing to minimize impacts to larks for three breeding seasons. Olympia Airport continues to modify its mowing regime to minimize impacts to breeding larks.
- Between 1985 and 2004, there were 1,422 Horned Lark collisions with US Air Force aircraft, which was the highest number of aircraft collisions for any species (BASH 2004). However, there were only 228 Horned Lark collisions out of 51,154 strikes with civilian aircraft reported between 1990 and 2003 (Cleary et al. 2004). None of the civilian aircraft collisions resulted in injury and the total cost associated with Horned Lark collision damages was estimated to be $250 (Cleary et al. 2004). Larks currently breed on Shelton and Olympia Airports and Gray Army Airfield and McChord Air Force Base and have been found dead along the runways at McChord Air Force Base and Gray Army Airfield.

## Pesticides and Herbicides

- Beason (1995) reports direct mortality of Horned Larks from exposure to Carbofuran (a carbamate pesticide) and Fenthion (an organophosphorus cholinesterase-inhibiting insecticide applied to crops).

## Habitat Loss or Change

### Historic Habitat Loss

- *British Columbia*: historical habitat was likely restricted to sparsely-vegetated sites such as spits, beaches, and grasslands. Due primarily to the conversion to agriculture and urban development, the grasslands associated the Gary oak ecosystem of British Columbia has declined by at least 95% (Hebda and Aitkens 1993). The amount of open dune, grass and bryophyte areas on Vancouver Island have declined by 6 – 52% depending on the site (Beauchesne and Cooper 2003). An inventory of sensitive ecosystems on Vancouver Island and the Gulf Islands indicates that naturally occurring, sparsely vegetated habitats (e.g., sand dunes, gravel and sand spits) are the rarest terrestrial ecosystem in eastern Vancouver Island (Ward et al. 1998). Page (2003) compared aerial photographs of sand dune habitats over a 40-year period and estimated that the amount of dune habitats on southern Vancouver Island declined by 6 to 50% depending on locality.

- *Washington*: In the Puget lowlands, historic Lark habitat was confined to prairie habitats associated with gravelly outwash soils. Crawford and Hall (1997) estimated the historic distribution of grasslands in the southern Puget Sound region by mapping grassland soils. Currently, grasslands occupy approximately 22% of their historic area and prairies dominated by native species occupy approximately 3% of their historic area. The loss of these grasslands has been attributed to urban development (33%), forest invasion or conversion (32%) and agriculture conversion (30%; Crawford and Hall 1997). Along the coast, Lark habitat was historically and is currently associated with sparsely vegetated beach habitat (foredune). Although we know of no estimates of the amounts of sparsely vegetated dune and open beach habitat that has been lost to the invasion of non-native beachgrasses (*Ammophila spp.*), it is likely considerable. Non-native beachgrass cover has increased by 574% in a fifty-year period in portions of the Pacific coast (Buell et al. 1995) and is the dominant foredune vegetation in the range of the Lark on the Washington coast (Seabloom and Wiedemann 1994). Once dune and beach habitat is densely vegetated by beachgrasses, it is no longer used by Larks (Pearson and Hopey 2004).
- *Oregon*: More than 99% of the pre-settlement grasslands used by Larks in the Willamette Valley have been lost (Johannessen et al. 1971, Towle 1982). Initially these grasslands were lost to agriculture but, despite the habitat change, Larks continued to use appropriate agricultural lands. More recently, there has been extensive urban/residential development in Willamette Valley, which is replacing the agricultural fields and other fallow fields used by breeding and wintering Larks. There has also been conversion of suitable agricultural habitat such as pastures or fallow fields to non-suitable agricultural lands such as rowcrops, orchards, and nurseries.

**Ongoing Habitat Loss or Change**

- To maintain and deepen the Columbia River shipping channel, the Army Corps of Engineers deposits dredge spoils on many of the islands used by breeding Larks. The timing, location and the amount of deposited materials can have dramatic impacts on the Lark. The un-vegetated landscape created by depositing dredge spoils is not used by Larks for the first year or two after deposition. Consequently, depositing spoils on Lark breeding or wintering sites can have negative impacts on Lark use of a site. Once the spoils are sparsely vegetated, they are quickly colonized by Larks (especially island spoils where ORV traffic does not occur)
- Sandy habitats on the coast of Washington continue to be colonized by non-native beachgrasses (*Ammophila spp*). Larks do not use habitats with a dense covering of beachgrass for breeding or over-wintering.
- Robinson and Moore counted 61 Streaked Horned Larks at the Multnomah County site (see Appendix II) during the winter of 2004/2005 but counted 150-200 Larks in the previous two years. This decline may be the result of changes in habitat conditions. Some grading occurred at the site in preparation for development resulting in completely unvegetated habitat and other parts of the site continued to be colonized by vegetation resulting in a higher percent cover of vegetation, which made it less suitable to wintering

Larks. In addition, there are survey markers on the site indicating that it will likely be developed in the near future.

- In the Willamette Valley, over-wintering site fidelity appears to be low among years. Pearson et al (2005) re-surveyed all sites during the 2004/2005 winter where Larks were found during the 2003/2004 winter. They found Larks to be present at only one of these previously occupied sites during the 2004/2005 winter. This low site fidelity may occur because of the dynamic nature of over wintering habitat. Sites with Larks and appropriate habitat in 2003/2004 had inappropriate habitat and no Larks in 2004/2005. These sites moved from being fallow in 2003/2004 to being densely vegetated with annual rye grass in 2004/2005. During the winter, Larks appear to move across the landscape in search of appropriate habitat and, when appropriate habitat is discovered, they use it. During the winter of 2004/2005, very few agricultural fields were in a condition appropriate for over wintering Larks suggesting that this habitat type may be limiting.
- The Olympia Airport is currently extending the runway and is planning on building several new hangars. In addition, they have proposed developing a considerable portion of the remaining open grassland habitat with buildings, roads and taxiways which may make the site unsuitable to breeding and wintering Larks.
- Gray Army Airfield is currently extending the West ramp into areas used by breeding Larks in previous years.

## Lack of Protected Habitat

- Agricultural habitats and suitable horned Lark habitat in the Willamette valley are almost entirely privately owned and land uses can vary dramatically from year to year.
- Many of the islands in the Columbia River and on the coast of Washington are publicly owned offering opportunities for strategic conservation planning.
- The primary purpose of municipal and military airfields is for air traffic and military training. Larks are perceived as being at odds with aircraft safety because Horned Larks collide with aircraft (see discussion above). To minimize bird-aircraft collisions, McChord AFB regularly flies falcons to scare birds off the airfield and started also using dogs in 2005. These dogs walk and run through Lark habitat and cause the birds to become alert and fly. Gray Army Airfield is planning on adding an additional 130 rotary wing aircraft to the airfield within the next year. These aircraft are a different type than what is currently using the site. The air temperature and wind velocity of the rotor and engine down blasts from these new aircraft may impact Lark use of the site.

## Predation

- Over 200 Lark nests have been monitored in the Puget lowlands, Washington coast, Columbia River and in the Willamette Valley and predation was the primary source of nest failure at nearly all sites studied to date (Pearson and Hopey 2005, Altman 1999). The predation rates at the Puget lowland sites and Columbia River/Washington coast sites are considerably higher than that reported for other grassland breeding birds.

## Stochastic and Small Population Threats

- There appear to be very few Streaked Horned Larks remaining in the world (probably between 500 and 1000 birds) and preliminary genetics work suggests that the remaining birds have little genetic diversity. This result suggests that the Streaked Horned Lark population may already be experiencing the deleterious effects of inbreeding or the results of a small founder population. The remaining populations are vulnerable to all of the threats small populations commonly face (e.g., vulnerability to environmental and demographic variability and to the loss of genetic variability).

- Most of the over-wintering streaked horned Larks are found on the lower Columbia River and Willamette Valley suggesting the importance of these habitats to wintering Larks. Birds in these two regions are found in large flocks (up to 125 Streaked Horned Larks in a single flock in the Willamette Valley and up to 61 Streaked Horned Larks in a single flock on the Lower Columbia) that are vulnerable to changes in habitat or stochastic events (e.g., weather events such as ice storms).

## Ecological Processes

- On the Washington coast, breeding and over-wintering Larks use sparsely vegetated sandy areas. The dynamic process of erosion and accretion of sandy soils create this habitat type. After new land is created through accretion, it gradually becomes vegetated and is ultimately colonized by non-native beach grasses. There is a fairly narrow window of time when the habitat is sparsely vegetated and appropriate for Larks. Consequently, maintaining the dynamic process of accretion and erosion along the coast and within Grays Harbor and Willapa Bays is critical to maintaining Lark habitat (and Snowy Plover habitat). This process can be altered by activities that reduce the amount of sand export or effect the movement of sand along the coast (e.g., changes in hydrology and currents).
- Fire was historically important in maintaining open grassland habitats in the Puget lowlands and Willamette Valley. Larks preferentially use recently burned habitats in the late summer (Pearson and Hopey 2005). Ft. Lewis uses prescribed fire as a management tool to improve lark habitat at 13$^{th}$ Division Prairie.

# RECOMMENDATIONS FOR ADDRESSING THREATS

## Human Activities

- Alter the timing or location of the activities that disturb breeding birds (listed above) to avoid Lark breeding habitats.
- When possible, we recommend that most activities within 30 m of breeding Larks be restricted.
- To avoid disturbing (flushing, reducing the amount of time foraging and increasing the amount of time spent fleeing or being alert) breeding Larks or to avoid nest abandonment associated with disturbance, we recommend that dredge spoils not be deposited on active breeding localities during the breeding season.
- To minimize the negative impacts of mowing on Larks, we recommend that mowing occur during non-peak breeding times: before breeding starts in mid-April, the second week of June, and at the end of the breeding season (late July – early August). The early and late mowings occur outside the breeding season and we recommend the mid-season mowing because the curve of clutch initiation dates suggests that there is a break in clutch initiations between the first and second clutches, which occurs in the first or second week of June (Pearson and Hopey 2005). We recommend waiting until the second week of June when more of the fledglings are likely to be able to flee from an approaching mower. We also recommend mowing very low before and/or after the breeding season and higher (6-8 inches) during the breeding season. We have noted that mowing with the mowing deck very close to the ground results in more nests being destroyed.

- In the Willamette Valley, we recommend encouraging farming practices that create and maintain bare ground within grass and forb dominated fields.
- On coastal sites, we recommend that beach access be restricted to daytime foot traffic only and that if dogs are allowed they should only be allowed on a leash.
- We recommend using volunteers along the coast (especially at Midway Beach and Damon Point) to encourage people to avoid Lark (and Snowy Plover) nesting areas and to educate users about the bird's vulnerability and sensitivity to human activities.
- We do not recommend the creation of additional trails, facilities or access to Lark breeding sites on publicly owned sites (especially at Damon Point and Midway Beach).

## Habitat Loss or Change

- Spoils that are sparsely vegetated with annual grasses and a mixture of forbs are used by over-wintering Larks. Consequently, keeping an adequate amount of habitat in appropriate successional stages is critical to maintaining Columbia River Lark populations.
- In addition to creating new wintering and breeding habitat, dredge spoils can be used to convert unsuitable habitats into suitable habitats. For example, if spoils are colonized by Scotch broom (*Cytisus scoparus*) or horsetail (*Equisetum sp.*) (habitats not used by Larks) they can be converted to appropriate habitats by depositing additional spoils.
- Control non-native beachgrasses on coastal areas and Scotch broom and non-native rhizomatous grasses on Puget lowland sites. Experimental control of beachgrasses has occurred in Oregon and Washington to improve Snowy Plover habitat.
- The use of sparsely vegetated agricultural fields in the Willamette Valley by wintering Larks indicates the need to maintain this habitat type in the long-term.
- For breeding habitat, maintain relatively short grasses and forbs with little or no woody vegetation [0-6 inches (Altman 1999); 3.9 – 13.3 inches (Person and Hopey 2005)] and a relatively high percent of bare ground [17% (Altman 1999); 16% (Pearson and Hopey 2005)]. Altman (1999) recommended a higher percent cover of bare ground (31%) for Streaked Horned Lark nest sites. For foraging, Streaked Horned Larks select sites with low vegetation (mean = 4.2 inches), and with low vegetation density during the breeding season (Rogers 2000). A review of the effects of management practices on the Horned Lark (Dinkins et al. 2003) also indicates that Larks prefer areas with short, sparse herbaceous vegetation with little or no woody vegetation.
- Altman (2000) provided a list of specific recommendations for the Willamette Valley including: maintain or provide small patches of suitable habitat within native and agricultural grasslands that have 20-50% cover of bare or sparsely vegetated ground, herbaceous vegetation <12 in (30 cm) tall, and located where minimum human or environmental disturbances occur.

## Lack of Protected Habitat

- Create incentives for private land owners to maintain appropriate Lark habitats in the Willamette Valley.
- Consider expanding National Wildlife Refuge status to some of the islands created by dredge spoils on the lower Columbia River so that they can be actively managed for Lark habitat.

## Predation

- See research needs below.

- Predator numbers (especially corvids) increase in response to increased food availability. Eliminating human sources of food in proximity to breeding locations (e.g., State Parks and parking areas adjacent to coastal breeding areas and fast food restaurants adjacent to airport sites) such as uncovered garbage and littered food scraps may indirectly help reduce predator numbers or help prevent their numbers from increasing.

## Stochastic and Small Population Threats

- Increase the amount and spatial extent of Lark wintering habitat to reduce the potential for severe population loss associated with stochastic events (sudden changes in habitat or weather events).
- Increase the number of breeding populations with high reproductive success and high post-fledging survival.
- Altman (2000) recommended establishing >10 breeding populations (>20 pairs/population) in the Willamette Valley. In addition, Altman (2000) recommended delineating 11 Grassland Bird Conservation Areas in the Valley to focus conservation efforts.

## Ecological Processes

- Maintain the dynamic processes that create accreted habitats on the Washington coast and in Willapa Bay and Grays Harbor.
- On Puget prairies, fire appears to improve post-breeding habitat for Larks (Pearson and Hopey 2005) and may improve breeding habitat conditions. We recommend the use of late summer (late August or early September) prescribed fires where and when it is likely to result in appropriate habitat structure and species composition. Conifers colonize Puget prairies in the absence of fire or mechanical tree removal (Lang 1961).

# RESEARCH NEEDS

- Develop a metapopulation model (including populations in the Willamette Valley, lower Columbia River/Washington coast and Puget lowlands) to identify population sources and sinks. This model is critical to the development of recovery goals.
- Use the population model to set population goals by subpopulation (Willamette Valley, lower Columbia River/Washington coast, Puget lowlands, northern Puget trough/Georgia Basin).
- Explore methods for creating a functioning Lark metapopulation on the lower Columbia River using dredge spoils.
- Identify Lark nest predators and develop a strategy to reduce predation
- Evaluate survivorship of fledglings and sources of fledgling mortality because post-fledgling survival is often critical to population growth in birds
- Quantify over-wintering habitat selection
- Examine the relative importance of different wintering sites to Lark survival
- Further quantify movement patterns between breeding sites and movement patterns among wintering sites
- Research methods for controlling non-native beachgrasses on the coast and non-native pasture grasses on Puget prairie sites

- Determine whether the processes of accretion and erosion on the outer Washington coast and in Grays Harbor and Willapa Bays are adequate for maintaining Lark habitat over time.
- Develop a population monitoring strategy that includes a direct or indirect measure of fitness (reproduction and survival).

# PROPOSED CONSERVATION STRATEGY

Because the threats faced by the Streaked Horned Lark vary regionally, we recommend a regionally based conservation strategy and the establishment of a region-wide working group (British Columbia, Washington, and Oregon) to develop recovery goals and objectives. Ultimately, we recommend developing time-lines and specific actions for all proposed strategies. In addition, we recommend developing methods for evaluating the outcome of each action.

Successful implementation of specific conservation strategies ultimately requires landowner and public involvement and commitment. Consequently, we recommend engaging landowners and the public in developing a conservation strategy.

For our conservation strategy, we have intentionally divided the historic and current breeding/wintering range into five regions that are geographically and ecologically distinct. However, the lower Columbia River and Washington coast could be combined into a single recovery region because banded birds appear to move freely between these areas during the winter and breeding season suggesting that this area functions as a metapopulation.

## Northern Puget trough and Georgia Basin

**First Priority**

- Identify sites that have suitable breeding habitat or that can be restored for Lark reintroduction.

**Second Priority**

- Protect identified sites.
- Manage sites for lark habitat (appropriate structure and species composition).
- Conduct Lark reintroduction feasibility study.
- Investigate reintroduction techniques.

**Third Priority**

- Reintroduce larks to restored and protected habitats if determined appropriate and feasible.

## Puget Lowlands

**First Priority**

- On Puget prairie breeding sites, control Scotch broom and invasive grasses and reinstate the use of late summer fire.
- Investigate methods for reducing Lark nest predation rates.
- At breeding sites, limit vehicle access and activities that disturb breeding larks (dogs off leash, fireworks, kite flying, large gatherings of people, trampling, etc.).

- On airport sites, alter mowing regimes (where possible and where it would not conflict with safety) as recommended above and minimize human activities adjacent to breeding sites.
- Also on airport sites, minimize development on remaining grasslands or immediately adjacent to remaining grasslands.
- Develop a population monitoring strategy that includes a direct or indirect measure of fitness (reproduction and survival).
- Conduct Lark reintroduction feasibility study
    - Identify sites (number to be determined by metapopulation model) for lark reintroductions
    - At identified introduction sites, initiate management activities that create appropriate habitat conditions (appropriate structure and species composition).
    - Investigate methods for translocating Larks.

**Second Priority**

- Once the habitat is appropriate for Larks at the reintroduction sites and methods for translocation have been developed, initiate passive reintroduction program (playbacks with decoys). If the passive introduction fails, then attempt to translocate birds.

## Washington Coast

**First Priority**

- Control invasive beachgrasses at known breeding sites. This activity will also benefit snowy plovers that nest adjacent to Larks.
- At breeding sites, limit vehicle access and activities that disturb breeding larks (dogs off leash, fireworks, kite flying).
- Limit human access to nest sites.
- Reduce the amount of food available to crows and ravens.
- Investigate methods for reducing Lark and Snowy Plover nest predation rates.

**Second Priority**

- Develop a plan to maintain the dynamic processes of erosion and accretion along the outer coast and within Grays Harbor and Willapa Bays.
- Develop a core group of volunteers along the coast (especially at Midway Beach and Damon Point) to encourage people to avoid Lark (and Snowy Plover) nesting areas and to educate users about the bird's vulnerability and sensitivity to human activities.
- Develop a population monitoring strategy that includes a direct or indirect measure of fitness (reproduction and survival).

**Third Priority**

- Develop education signs along beach access points about the sensitivity of Larks and Snowy Plovers to specific activities (off leash dog walking, pedestrian, vehicle or horseback riding in nesting areas, etc.).

## Columbia River

**First Priority**

- Prevent additional deposition of dredge spoils on known lark breeding sites until a comprehensive strategy is developed.

**Second Priority**

- Develop a temporally and spatially explicit plan for the deposition of dredge spoils that maintains well distributed habitats (numerous sites along the length of the lower Columbia River from the confluence with the Willamette to the River's mouth) in the appropriate habitat condition (see description above) over time.
- Develop a population monitoring strategy that includes a direct or indirect measure of fitness (reproduction and survival)

**Third Priority**

- Develop a series of protected islands within the USFWS refuge system along the lower Columbia River

## Willamette Valley

**First Priority**

- Secure commitment and designate three areas as lands managed for Lark habitat (e.g., public lands such as refuges, parks, The Nature Conservancy preserves). These areas will be necessary to serve as permanent core areas for population maintenance and sources for population expansion.

  Birds in the Willamette Valley use human managed habitats that provide appropriate habitat conditions. These sites are ephemeral in nature both between seasons and within seasons (as vegetation matures from late winter through summer). Thus we recommend establishing sites dedicated to Lark habitat that would be managed to provide appropriate habitat year round. This core population would then be supplemented by breeding birds finding appropriate habitats in the dynamic landscape outside the core.

**Second Priority**

- Secure commitment from private landowners either voluntarily or through incentives or cost-share programs for management activities that create or maintain breeding or wintering habitat These areas will be necessary to serve as short-term satellite areas for population distribution and expansion. The location of these sites should be evaluated based on the presence of existing Lark populations, the proximity to existing populations, or the ability of the site to support breeding and/or wintering Larks.

**Third Priority**

- Encourage land management that supports populations of Horned Larks through education and outreach activities. Lands outside the core and satellite areas that are purposefully or incidentally managed for Horned Larks should be considered as marginal habitat because of the uncertainity of their suitability from year to year due to changes in field type.

# APPENDIX III

**Imminence and magnitude of threats to the Streaked Horned Lark populations in the Puget lowlands, Washington coast, lower Columbia River, and Willamette Valley.**

| Population | Threat Category | Specific Threats | Magnitude[1] | Immediacy[2] |
|---|---|---|---|---|
| **Puget Lowlands** | | | | |
| | Habitat loss/change | Development of Lark habitat is occurring at Gray Army Airfield and Olympia Airport (nesting and foraging habitat is being paved and structures are being built). Development is planned for foraging areas outside of the Gray Army Airfield and additional development is planned for the grasslands at the Olympia Airport | High | Imminent |
| | Human activities | Events such as Rodeo and the air show at McChord AFB, planned increase in helicopter activity and change in type of aircraft used at Gray Army Airfield, collisions with aircraft, and use of dogs to remove birds from airports. | Moderate to High | Imminent |
| | Predation | Documented threat in Pearson and Hopey (2005) | High | Imminent |
| | Ecological processes | Loss of fire on prairie sites but it is being reintroduced at 13th Division Prairie | Moderate | Imminent |
| | Non-native species | Invasive and nonnative species such as Scotch broom, rhizomatous grasses, and spotted knapweed. Results in change in habitat structure and loss of appropriate breeding habitat | High | Imminent |
| **Washington Coast** | | | | |
| | Habitat loss/change | Suitable habitat is succeeding to non-native beachgrasses dominated habitat not used by larks. | Moderate | Imminent |
| | Human activities | Pet dogs off leash, dogs and people in nesting areas, horses, kite flying, fireworks, off road vehicles | Moderate | Imminent |
| | Predation | Documented in Pearson and Hopey (2005) and Pearson and Hopey (unpubl.) | Moderate in 2004<br>High in 2005 | Imminent |
| | Ecological processes | Change in accretion and erosion patterns associated with dams, dikes, channeling, etc. | ?? | ?? |
| | Non-native species | Beach grasses (coastal Washington sites) results in change in habitat structure and loss of appropriate breeding habitat. | High | Imminent |
| **Columbia River** | | | | |
| | Habitat loss/change | Development occurring at the Rivergate site. Habitat succession to inappropriate habitat is ongoing. | Moderate | Imminent |
| | Human activities | Activities associated with dredging appeared to result in the failure of at least 2 nests on Miller Sands in 2005 | Low to Moderate | Imminent |
| | Predation | Documented in Pearson and Hopey (2005) | Moderate in 2004<br>High in 2005 | Imminent |
| | Ecological processes | Loss of flooding along the lower Columbia River | ?? | ?? |
| | Non-native species | Scotch broom, others? | Moderate to low | Imminent |
| **Willamette Valley** | | | | |
| | Habitat loss/change | Urban and suburban development, changes in farming practices | High | Imminent |
| | Human activities | Vehicle and farm equipment (Altman 1999) | Moderate | Imminent |
| | Predation | Documented in Altman (1999) | High | Imminent |
| | Ecological processes | Loss of fire | Low | Imminent |
| | Non-native species | On prairie sites - Scotch broom, rhizomatous grasses, Himalayan blackberry | Moderate to Low | Imminent |
| | Pesticides | Potential associated with farming (documented for the species but not the subspecies | ?? | Non-imminent |
| **Overall** | | | | |
| | Small Population | Small population size has been documented (certainly less than 1000 birds and probably less than 850 birds – see above), little or no genetic variability suggesting inbreeding or population bottleneck (Drovetski et al in press). | High | Imminent |
| | Winter concentration | Most of the worlds population can be found in a couple of flocks in the Willamette Valley and lower Columbia River during the winter making them vulnerable to stochastic events | ?? | Non-imminent |

[1]High magnitude threats are threats that are likely to reduce the overall population, decrease the reproductive potential of the population, or significantly decrease the area used for foraging and breeding. These changes are likely to lead to extinction, local extirpation, or significant declines in local populations. Low magnitude threats negatively impact population size, reproductive success, or survival but are not likely to lead to extinction, extirpation, or significant population declines in the short term.
[2]Imminent threats are occurring and non-imminent threats have the potential to occur but have not yet occurred.

# Sensitivity of early life stages of white sturgeon, rainbow trout, and fathead minnow to copper

David W. Vardy · Johanna Oellers · Jon A. Doering · Henner Hollert · John P. Giesy · Markus Hecker

Accepted: 18 October 2012 / Published online: 5 November 2012

**Abstract** Populations of white sturgeon (WS; *Acipenser transmontanus*) are in decline in several parts of the United States and Canada, attributed primarily to poor recruitment caused by degradation of habitats, including pollution with contaminants such as metals. Little is known about sensitivity of WS to contaminants or metals such as copper (Cu). Here, acute (96 h) mortalities of WS early life stages due to exposure to Cu under laboratory conditions are reported. Two standard test species, rainbow trout (*Oncorhynchus mykiss*) and fathead minnow (*Pimephales promelas*), were exposed in parallel to determine relative sensitivity among species. Swim-up larvae [15 days post-hatch (dph)] and early juveniles (40–45 dph) of WS were more sensitive to Cu ($LC_{50} = 10$ and 9–17 μg/L, respectively) than were yolksac larvae (8 dph; $LC_{50} = 22$ μg/L) and the later juvenile life stage (100 dph; $LC_{50} = 54$ μg/L). WS were more sensitive to Cu than rainbow trout and fathead minnow at all comparable life stages tested. Yolksac larvae of rainbow trout and fathead minnow were 1.8 and 4.6 times, respectively, more tolerant than WS, while swim-up and juvenile life stages of rainbow trout were between 1.4- and 2.4-times more tolerant than WS. When plotted in a species sensitivity distribution with other fishes, the mean acute toxicity value for early life stage WS was ranked between the 1st and 2nd centile. The WS life stage of greatest Cu sensitivity coincides with the beginning of active feeding and close association with sediment, possibly increasing risk. WS early life stages are sensitive to aqueous copper exposure and site-specific water quality guidelines and criteria should be evaluated closely to ensure adequate protection.

**Keywords** Fish · Metal · Ecotoxicology · Early life stage sensitivity

## Introduction

Sturgeon (Acipenseridae) are among the largest freshwater fish in the world. Some species can live more than

100 years, weigh more than 800 kg and reach lengths of more than 6 m. Sturgeon are also among the most archaic fish species with prehistoric ancestors dating back an estimated 175 million years (UCWSRI 2002). Presently, however, populations of sturgeon are threatened globally and have been decreasing over the past century in Northern Europe, Asia, and North America (Birstein 1993; Coutant 2004; Gisbert and Williot 2002). In North America, populations of white sturgeon (WS; *Acipenser transmontanus*) have been reported to be declining in the northwestern United States and British Columbia, Canada. Populations of WS have been listed as endangered in parts of Canada (COSEWIC 2012) and the USA (U.S. Fish and Wildlife Service 2012). Decreases in populations of sturgeon in the Columbia, Fraser, and Sacramento–San Joaquin rivers and their tributaries have been attributed primarily to poor annual recruitment (Coutant 2004; DFO 2007; Scott and Crossman 1998; UCWSRI 2002). Results of some simulation models of population trends and demographics have predicted that without implementation of successful remedial efforts WS will become virtually extinct in these rivers within 50 years (DFO 2007; Irvine et al. 2007; Paragamian et al. 2005; Paragamian and Hansen 2008; UCWSRI 2002).

Possible hypotheses for failures of recruitment of WS include, among others, overharvesting, habitat alteration, changes in flow regime, decreased water quality, such as temperature, turbidity, total dissolved gases, pollution, poor nutrition, genetic bottlenecks or inbreeding depression, predation by introduced species such as walleye (*Sander vitreus*), inter-specific competition, pathogens, and disease (Birstein 1993; Coutant 2004; Gisbert and Williot 2002; Irvine et al. 2007; Kruse and Scarnecchia 2002; Luk'yanenko et al. 1999; Paragamian and Hansen 2008; UCWSRI 2002). In some of the larger North American rivers, such as the Columbia, metals are of particular concern due to past and present activities of mines, metallurgical facilities, pulp and paper mills, as well as other industrial and municipal sources (UCWSRI 2002). Copper (Cu), for example, is often found in contaminated systems at concentrations that are greater than naturally occurring levels (Grosell 2012; Kamunde and Wood 2003; Niyogi and Wood 2003). Concentrations of Cu in clean natural freshwaters are typically in the lower µg/L range (e.g. 0.2–2 µg/L), but thresholds for lethality on fishes can occur at concentrations that are only 10-fold greater (Grosell 2012; Wood 2001). In addition, effects on more sensitive endpoints, including behaviour, chemosensory, and olfaction, have been recorded within the lower µg/L concentration range (Grosell 2012). In general, little is known about the potential toxicity of metals, such as Cu, to WS, or the tolerance of WS relative to other fishes.

Water quality guidelines and criteria are typically based upon effects concentrations (e.g. $LC_{50}$s) for aquatic organisms and are estimates of the concentration of a contaminant in the environment that is expected to protect 95 % of a group of diverse genera, assuming an appropriate number and variety of taxa are used for calculations (CCME 2007, EPA 1985). In cases where a species is deemed commercially or recreationally important and its threshold value is more sensitive than the calculated guideline or criteria, that particular species mean acute value (SMAV) will supersede (EPA 1985). These estimates, however, are only based upon species for which there are existing toxicity data that meet acceptable standards and often do not consider life stage specific sensitivities unless existing data indicates significant differences. Consequently, there is uncertainty whether an endangered species such as the WS that is recreationally, commercially, and culturally important (UCWSRI 2002) but has little to no existing toxicity data is protected by current guidelines and criteria.

Fish are generally most sensitive to effects of contaminants such as metals during early life stages (Hutchinson et al. 1998; McKim 1977). Previous work has indicated differences in sensitivity among early life stages of WS (Vardy et al. 2011), and studies of the effects of contaminants and life stage-specific sensitivities are important for making informed regulatory decisions. Life stage-specific sensitivity of WS is of particular interest given their early life history strategies. Early life stages of sturgeon inhabit benthic habitats, on surface sediments or in interstitial space between stones. There is some debate among researchers over the exact timing and sequence of certain behavioral events during WS early life stage development, these events possibly being influenced by differences in availability of appropriate substrata (McAdam 2011), but there is a general acceptance that early life stages of WS are in close contact with the substratum and exhibit distinct hiding and drifting phases (Brannon et al. 1983, 1985; Deng et al. 2002; Kynard and Parker 2005). Yolksac stage WS tend to hide/burrow in refugia (Brannon et al. 1983, 1985; Gessner et al. 2009; McAdam 2011; Richmond and Kynard 1995; personal observation in the laboratory). Prior to transitioning to exogenous feeding, sturgeon swim up in the water column (presumably to be transported by currents to more suitable foraging grounds; Auer and Baker 2002; Gessner et al. 2009; McAdam 2011) before returning to the bottom during the juvenile life stage, where they begin to scavenge and prey on benthic species and spend much of their life closely associated with sediments. Therefore, in addition to exposure to pollutants in the water column, sturgeon can be exposed to contaminants associated with sediments (Feist et al. 2005; Kruse and Scarnecchia 2002) or contaminants released into the sediment–water interface. Sediments are sinks for pollutants and often contain high concentrations of metals, which can be released back into porewater and the water column following remobilization

(Salomons et al. 1987; Sullivan and Taylor 2003). Thus, WS could be exposed chronically to lesser concentrations of metals, or, during certain life stages and for shorter periods of time, to greater concentrations of metals at the sediment–water interface. For this reason, and to generate data to develop species sensitivity distributions (SSDs) in support of deriving protective acute water quality guidelines and criteria, it is necessary to determine both acute and chronic toxicity of metals to WS. The results of chronic studies on survival and growth have been presented previously (Vardy et al. 2011).

The primary objective of this study was to establish acute toxicity data for the effect of Cu on early life stages of WS that can be used in risk assessments. Early life stage WS were exposed to increasing concentrations of dissolved Cu, bracketing environmentally relevant concentrations and those expected to be lethal. In addition, rainbow trout (*Oncorhynchus mykiss*) and fathead minnow (*Pimephales promelas*) were exposed to Cu in the laboratory, in parallel to WS, to provide paired information for use in species sensitivity comparisons.

## Methods

### Test materials

Copper(II) sulfate pentahydrate (Chemical Abstracts Service (CAS) number 7758-99-8; purity 99.995 %) was obtained from Sigma-Aldrich (Oakville, ON, Canada) and was dissolved in laboratory reverse osmosis water.

### Experimental fish

Fertilized WS eggs were collected at the Kootenay Trout Hatchery, Fort Steele, BC, Canada, from a minimum of four breeding pairs of adult WS caught in the Columbia River near Waneta, Canada. Fertilized eggs were transported to the Aquatic Toxicology Research Facility (ATRF), University of Saskatchewan, Saskatoon, SK, Canada where the embryos were raised under standard culturing conditions (Conte et al. 1988) until the desired life stages were achieved. Eyed embryos of rainbow trout were obtained from the Trout Lodge (Summer, WA, USA) and incubated in McDonald-type hatching jars (Aquatic Ecosystems, Apopka, FL, USA) until hatch. Fathead minnows were obtained from Osage Catfisheries (Osage Beach, MO, USA) and several generations were produced to insure healthy progeny.

### Exposure methods

Acute (96 h) toxicity of Cu was determined in accordance with the methods described by the American Society for Testing and Materials (ASTM 2007), with minor modifications. The exposure design consisted of sets of laboratory-based 96 h static renewal tests with mortality as the measurement endpoint. Laboratory water (carbon and biofiltered city water) was adjusted to simulate natural conditions of the Columbia River near Trail, BC, Canada. Target hardness of ~65 mg/L and dissolved organic carbon (DOC) concentrations of ~2.5 mg/L were achieved by mixing laboratory water with reverse osmosis water in a 1:1 ratio. Target temperatures of 12 ± 1, 16 ± 1 and 20 ± 1 °C for rainbow trout, WS, and fathead minnows, respectively, were achieved by immersing the exposure chambers in chilled or heated water baths or by use of environmental control chambers. All fish were tested under a 16:8 h light:dark cycle of illumination by use of standard daylight fluorescent lighting. Culture conditions for the fish (DOC, hardness, temperature, photoperiod) were the same as exposure conditions with the difference that fish were fed between one and four times a day, depending on life stage. For testing the yolksac life stage (8 dph) fish were exposed to increasing concentrations of Cu in 0.5 L high-density polyethylene (HDPE) test containers. Identical but larger 5 and 20 L test containers were used during toxicity tests with later life stages. Loading densities remained less than the recommended 0.5 g/L and fish were not fed during the acclimation and exposure period (ASTM 2007). The various life stages, expressed as dph, and species tested are described in Table 1.

Concentrated stock solutions of Cu were prepared separately in individual HDPE carboys and allowed to equilibrate for 48 h prior to making dilutions to obtain test solutions. Exposures were conducted in triplicate or quadruplicate for each treatment group; each test chamber contained 10–15 individuals with 50 % solution renewal every 12 h. Fish were acclimatized to the exposure chambers for 24 h prior to the addition of test solutions. Exposure chambers were cleaned once a day and dead fish were removed, length and weight measured, and preserved for potential use in future experiments.

### Water chemistry analyses

Basic water quality parameters, including temperature, pH, dissolved oxygen and conductivity, were measured daily by use of Symphony Electrodes (VWR, Mississauga, ON, Canada, Cat No. 11388-328) or YSR electrodes (YSR Inc., Yellow Springs, OH, USA). Typically, subsamples were collected during water changes from each replicate of each concentration and used for individual analysis. Hardness, alkalinity, ammonia, nitrates, nitrites, and chlorine were collected following a similar sampling scheme but only at the initiation and termination of experiments, and analyzed by use of LaMotte colorimetric and titrator test kits

**Table 1** Acute median lethal concentrations ($LC_{50}$s) for Cu exposure for white sturgeon (*Acipenser transmontanus*), rainbow trout (*Oncorhynchus mykiss*), and fathead minnow (*Pimephales promelas*) early life stages expressed in days post-hatch (dph)

96 h $LC_{50}$ for copper exposure (µg/L)

| Fish species | Life stage | | | | | | Water quality criteria | |
|---|---|---|---|---|---|---|---|---|
| | Yolksac (8 dph) | Swim-up (15 dph) | Juvenile (40 dph) | Juvenile (45 dph) | Later Juvenile (100 dph) | SMAV[a] | CMC[b] | CWQG[c] |
| White sturgeon (*Acipenser transmontanus*) | 22 (20–25) | 10 (8–12) | 9 (7–12) | 17 (14–21) | 54 (47–62) | 18 | 7.9 (±1.5) | 2 |
| Rainbow trout (*Oncorhynchus mykiss*) | 40 (34–46) | 21 (18–23) | 22 (20–25) | 24 (20–28) | | 26 | 8.5 (±3.0) | 2 |
| Fathead minnows (*Pimephales promelas*) | 102 (78–135) | | | | | 102 | 11.8 | 2 |

Values in parentheses for LCs represent 95 % CI, values in parentheses for water quality criteria represent SD

[a] SMAV refers to the species mean acute value

[b] CMC refers to the Criteria Maximum Concentration for fresh water species. The mean freshwater criteria is presented and calculated from the various life stage experiments for each specie using the Biotic Ligand Model (EPA 2007b)

[c] CWQG refers to the Canadian Water Quality Guidelines for the protection of aquatic life adjusted to the present study's hardness (CCME 2003)

(Chestertown, MD, USA) or samples were sent to Columbia Analytical Services (CAS; Kelso, WA, USA) for external analyses. Water samples for analysis of concentrations of Cu in exposure chambers were also collected following the same sampling scheme at initiation and termination of the experiment. Water for Cu analysis was collected from each treatment group into acid-cleaned polyethylene bottles and filtered through a 0.45 µm polycarbonate filter. Filtered water was acidified with ultrapure nitric acid to pH $< 2$. Quantification of Cu was performed by use of inductively coupled plasma mass spectrometry (ICP-MS) following EPA method 6020 and ILM05.2D (Creed et al. 1994). All calculations and reported values pertaining to Cu concentrations are based on the average measured concentrations in the treatment groups. DOC analysis was performed using a TOC analyzer (TOC-5050A, Shimadzu, Mandel Scientific, Guelph, ON, Canada).

### Data analysis and statistics

Mortality was calculated and the proportion of fish dead in each of the exposure chambers of a given Cu concentration was compared to that of the controls. $LC_{50}$s for each of the species were calculated by use of TOXSTAT® software (Western EcoSystems Technology 1996). To assess the relative sensitivity of early life stages of WS to Cu, relative to those of other fishes, a species sensitivity distribution (SSD) was calculated for Cu (Posthuma et al. 2002). The SSD for freshwater fishes was derived based on toxicity data obtained from: EPA's ECOTOX database (EPA 2007a), information on Cu sensitivity of three different sturgeon species published by Dwyer et al. (2005), and the data obtained during this study. Data considered for the derivation of the SSD were exclusively from 96 h toxicity studies that reported $LC_{50}$ values. Species mean (geomean) acute values (SMAVs) were calculated where data from multiple studies were available. If only one data point was available for a species, this was used as the SMAV in the SSD. To facilitate comparisons among tests without confounding the comparison by differences in hardness, all data included in the SSD were adjusted to a hardness of 50 mg $CaCO_3$/L by use of the Criteria Maximum Concentration (CMC) regression equation for Cu, as outlined by the US EPA for calculating freshwater dissolved metals criteria that are hardness dependent (EPA 2009).

## Results

### Exposure verification

Measured concentrations of Cu (Table 2) were comparable to nominal concentrations, and on average, were within 95 % of each other (see Supplementary Data). However, there were small detectible concentrations of Cu in the controls, but these concentrations were less than the least dose of each metal concentration. Generally, measured concentrations were less than nominal concentrations.

### Water quality

Average water temperatures for all treatment groups during the WS, rainbow trout, and fathead minnow exposures were 16 °C (±0.9), 13 °C (±0.5), and 22 °C (±0.1), respectively. The average dissolved oxygen saturation, pH,

**Table 2** Mean ± standard deviation (SD; numbers in parentheses) measured exposure concentrations for copper during acute (96 h) static renewal exposure experiments with white sturgeon (WS; *Acipenser transmontanus*), rainbow trout (RT; *Oncorhynchus mykiss*), and fathead minnow (FM; *Pimephales promelas*) early life stages expressed as days post-hatch (dph)

[a] SD was not calculated due to lack of concentration measurements

and conductivity for all treatment groups were 86 % (±8.7), 7.5 (±0.2), and 187 μS/cm (±25.5), respectively. Mean hardness was 57 mg/L $CaCO_3$ (±12.4) and the concentration of dissolved organic carbon was 2.2 mg/L (±0.5). The average total concentration of ammonia, expressed as nitrogen (N) for all treatment groups was less than the limit of detection (<0.025 mg/L). There were no significant differences in all other measured water quality parameters among treatment groups of any given experiment (summary of analytical methods, method detection limits, method blanks, and mean water quality parameters for individual exposures are provided as Supplementary Data).

## Lethal concentrations

$LC_{50}$s were successfully calculated for all life stages of each species that was tested (Table 1). Average survival of unexposed control fish was 90 % or greater in all experiments (see supplementary data for summary of mean mortality for individual exposures). WS were most sensitive to Cu at 15 and 40 dph, followed by 45 and then 8 dph. WS exposed to Cu at a later life stage (100 dph) were more tolerant than were earlier life stages (Fig. 1). $LC_{50}$s for toxicity of Cu to WS were less than those for rainbow trout and fathead minnows for all comparable life stages tested (Fig. 1; Table 1). $LC_{50}$s for WS swim-up larvae and juvenile life stages were between 1.4- and 2.4-times more sensitive than rainbow trout. Rainbow trout were least sensitive at 8 dph, followed by the later life stages, which exhibited comparable sensitivities to each other. Fathead minnow (8 dph) were more tolerant than WS and rainbow trout at all life stages tested.

## Species sensitivity distribution

The SSD that was developed based on 59 freshwater fishes, including the data of the various life stages of the three species studied here (Fig. 2), demonstrated that WS that were 8, 15, 40, 45, or 100 dph were ranked in the 14th, 1st, 2nd, 3rd, and 28th centile, respectively. The SMAV for WS ranked in the 2nd centile. Rainbow trout from the present study at 8, 15, 40, and 45 dph ranked in the 22nd, 13th, 9th, and 10th centile, respectively. The SMAV for rainbow trout calculated solely from the present study, when averaged among all life stages, ranked in the 8th centile, the SMAV for rainbow trout calculated solely from the ECOTOX database ranked in the 23rd centile, and the overall SMAV for rainbow trout, calculated from the ECOTOX database and values generated during the present study, ranked in the 16th centile. Based on the results of the present study, fathead minnow (8 dph) ranked in the 46th centile, while the SMAV for fathead minnow,

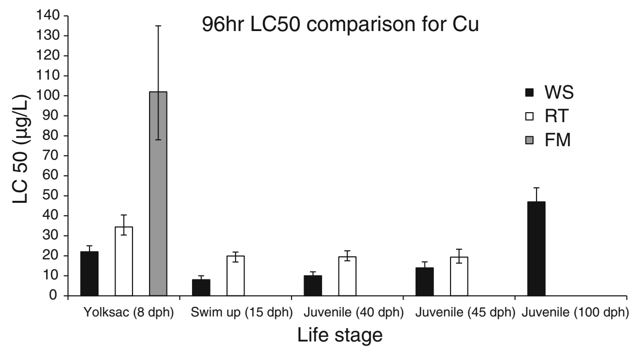

**Fig. 1** Comparison of median lethal concentrations ($LC_{50}$s) of white sturgeon (WS; *Acipenser transmontanus*), rainbow trout (RT; *Oncorhynchus mykiss*), and fathead minnow (FM; *Pimephales promelas*) life stages [days post-hatch(dph)] exposed to copper. *Error bars* represent confidence intervals for measured $LC_{50}$s

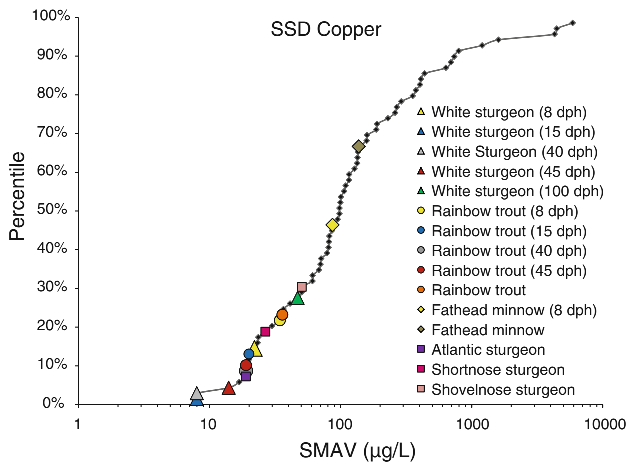

**Fig. 2** Species sensitivity distribution (SSDs) for copper. Values for species with life stages, expressed as days post-hatch (dph), are from experiments conducted at the University of Saskatchewan. Atlantic, shortnose, and shovelnose sturgeon values are from Dwyer et al. (2005), and all other species values are from the ECOTOX database (EPA 2007a). The Species Mean Acute Value (SMAV) is the geometrical mean $LC_{50}$ for a given species

calculated from the ECOTOX database, ranked in the 67th centile. The overall SMAV for fathead minnow, calculated from the ECOTOX database and the present study's findings, ranked in the 59th centile. Early life stage Atlantic (*Acipenser oxyrinchus*), shortnose (*Acipenser brevirostrum*), and shovelnose (*Scaphirhynchus platorynchus*) sturgeon based on data from Dwyer et al. (2005) ranked in the 7th, 19th, and 30th centile, respectively.

## Discussion

Based on findings of the present study, early life stage WS appear to be among the most sensitive fishes to acute Cu exposure, relative to other freshwater fishes. Three of the five life stages tested for WS were the most sensitive fishes in the SSD. The SMAV for WS was calculated and plotted in the SSD and WS were ranked the most sensitive species overall. Similarly, all other early life stage sturgeon incorporated in the same SSD, including Atlantic, shortnose, and shovelnose sturgeon, were relatively sensitive and ranked in the 23rd centile or less. In studies conducted by Dwyer et al. (2005), it was concluded that sturgeon in general should be considered a sensitive species in contaminant assessments, and results from the present study are consistent with these findings. Results of previous studies have shown that some standard test species, such as rainbow trout, are relatively sensitive to certain metals, whereas others, such as fathead minnow, are more tolerant (Besser et al. 2007; Dwyer et al. 2005; Taylor et al. 2000). LC values for the effects of Cu on rainbow trout and fathead minnow determined during the present study were slightly less, but generally consistent with previously reported SMAVs.

Post-hatch, early life stages of fish are generally considered more sensitive to contaminants than adults (Hutchinson et al. 1998; McKim 1977, McKim et al. 1978). In the present study, five early life stages of WS and four early life stages of rainbow trout were exposed to Cu to compare life stage specific sensitivity. For both species, the later larval/early juvenile life stages (15–45 dph) were more sensitive to the effects of Cu than was the yolksac (8 dph) life stage, and in the case of WS, the later juvenile life stage (100 dph). Greater sensitivity to Cu following the initial yolksac life stage and greater tolerance during the later juvenile life stage was observed for WS (Fig. 1). The observed differences in tolerance might be due to the fact that 8 dph larvae are still absorbing their yolksacs whereas at 15 dph larvae have begun to switch to exogenous feeding and are more physically active, leading to greater exposure since rates of respiration are increased and more water is forced over the gills. Rainbow trout, however, did not display a similar trend in sensitivity to Cu following 8 dph that was observed in WS. This might be due to differences in duration and timing of development of rainbow trout and WS, such that the observed sensitivities to Cu among the time periods (dph) tested might not be entirely comparable between species. Under culture conditions, rainbow trout embryos are typically incubated much longer than WS (4–14 weeks, depending on water temperatures, compared to 1 week for WS), and absorption of the yolksac can occur over a period twice as long. Therefore, longer development might result in less of a difference in sensitivity to Cu of post-yolksac larvae because rainbow trout are not transitioning through similar developmental stages as WS at comparable ages and at the same speed.

Significant differences in sensitivities among early life stages could have major implications in risk assessment and development of water quality guidelines and criteria. Risk assessments based on the assumption that younger fish tend to be more sensitive to contaminants than older fish could result in considerable underestimations of sensitivity if post-yolksac early life stages are not considered, as demonstrated in the present study, and lead to under-protection of certain species. Currently, in Canada and the United States, there is no requirement to evaluate differences in sensitivities among life stages when developing water quality guidelines and criteria. In the United States, differences in life stage sensitivity are taken into account but only if existing data demonstrates that there are differences of more than a factor of two (EPA 1985). If no toxicity data exist for various life stages of a species, then differences in sensitivities among life stages are not considered when calculating criteria or assessing potential for effects. To overlook these potential differences with a vulnerable population of fish could result in significant under-protection. Yolksac larvae of WS have greater tolerance to Cu toxicity compared to succeeding life stages, but since these earlier life stages might be in more intimate contact with biologically available metals in contaminated sediments, they might be more at risk than would be indicated solely by their tolerance to Cu concentrations. Greater exposure to Cu during the transition to exogenous feeding, however, is detrimental since previous studies have shown that WS are inherently sensitive during this period of development (Vardy et al. 2011). This poses an increased threat to early life stage juveniles that return to the bottom to feed and are at greater risk of exposure to sediment bound contaminants.

Early life stages of WS are sensitive to aqueous copper exposure and site-specific water quality guidelines and criteria should be evaluated closely to ensure adequate protection when sturgeons are of concern. The Canadian water quality guideline for the protection of aquatic life for Cu, adjusted to the present study's hardness of 57 mg/L $CaCO_3$, is 2 μg/L (CCME 2003). In the United States, criteria for protection of aquatic life for Cu are site-specific and freshwater criteria are calculated by use of the biotic ligand model (BLM; EPA 2007b). Based on the present study's water quality parameters for WS, the water quality acute criteria for Cu, recommended by the US EPA for protection of aquatic life (CMC; EPA 2007b, 2009), would be between 6.4 and 9.5 μg/L. In order to assess the degree of protection of WS in relation to water quality guidelines and criteria, one half the species mean acute value (½ SMAV) was calculated. This is similar, but on a species level, to EPA water quality criteria methods where one half final acute values (FAVs) are calculated. In the present study, ½ SMAV for WS is above the Canadian water quality guideline but falls within the calculated range for US criteria (Table 1). When half the $LC_{50}$ values for the individual life stages of WS are examined, some thresholds are less than US criteria. This merits further investigation, especially at the more sensitive life stages, to assess the level of protection in relation to water quality criteria for Cu.

This study provides a portion of much needed toxicity data for early life stage WS and identified significant differences in sensitivities among early life stages of fish. $LC_{50}$ values from the present study predicted similar trends in early life stage WS sensitivity when compared to chronic early life stage WS threshold values for Cu (chronic values: 19 dph = 9.9 μg/L and 58 dph = 12.4 μg/L; Vardy et al. 2011). When feasible, contaminant exposure studies should include different life stages to help elucidate possible differences in life stage sensitivities in order to develop more comprehensive water quality guidelines and criteria. WS are sensitive to Cu exposure and water quality guidelines and criteria may need to be evaluated on a site-by-site basis when WS early life stages are present in order to ensure protection. Other endpoints, such as effects of Cu exposure on olfaction, chemosensory, and/or behavior, for example, could also be investigated with WS because these endpoints have been shown to be the most sensitive endpoints in other fish species (Grosell 2012). In addition, alternate routes of exposure, such as from contaminated sediment or dietary uptake, warrant further investigation as water-only exposures may represent variable proportions of total exposure depending upon life stage.
