Acknowledgements

This assessment was made possible by an unusually high level of collaboration in sharing stream and river monitoring data. We gathered data from state and federal agencies, city governments, university researchers and a watershed council to answer basic questions about the condition of Willamette basin rivers and streams.

The authors of this assessment thank the data contributors.

Robert Hughes, Oregon State University
Alan Herlihy, Oregon State University
Charles Hawkins, Utah State University
Ken Roley, City of Salem
Chris Prescott, City of Portland
Cindy Thieman, Long Tom Watershed Council

We received a tremendous amount of assistance over many years in sampling design, monitoring protocols and data analysis from people at the Environmental Protection Agency’s National Health and Environmental Effects Research Laboratory in Corvallis, Oregon, and from faculty at Oregon State University.

We thank the Oregon Department of Environmental Quality reviewers of earlier drafts of this report: Rick Hafele, Doug Drake, Avis Newell, and Jared Rubin. We also thank Shannon Hubler, DEQ, for help with the macroinvertebrate analysis.

We also thank Robert Hughes, Oregon State University; and Robert Danehy, Weyerhaeuser, for their review and comments.

Finally, we gratefully acknowledge the contribution of many unnamed field survey crew members whose careful, diligent work helps us better understand the health of the rivers and streams of the Willamette basin.
How to use this report

This report was written as a resource for water quality managers, watershed councils, municipalities and citizens to help understand the status of watershed conditions in the Willamette basin. Our interpretations are based on chemical, physical and biological indicators at three different spatial extents: basin, subbasin, and land use category. The data in this report were collected at randomly selected locations. Like a political poll, these locations represent the population of rivers and streams as a whole. It is not appropriate to interpret the information on an individual site basis. However, individual site data may be used for other purposes, such as indicating when water quality standards or other benchmarks are not met.

The bar charts in this report typically divide the information into “good”, “fair” and “poor” categories. These categories were chosen to maintain consistency with similar reports by Oregon Department of Environmental Quality (ODEQ) (Section B-1 of OWEB 2005, and, Mulvey and Borisenko 2008) and the US Environmental Protection Agency (US EPA) (Paulsen et al. 2008, and, Stoddard et al. 2005a). Where we have water quality standards, the categories were based on the standard. If a site did not meet the standard it was placed in the “poor” category. For other parameters, we evaluated the data based on the conditions found at hand-picked reference or least impaired sites with similar potential conditions. On each bar you will see a 95% confidence interval. The confidence intervals are based on the number of samples we had at each spatial extent. We included all available data that were collected using the random site selection process but for some parameter-spatial scale combinations the sample sizes were quite small. In these cases there is a risk that we have not adequately characterized the conditions. We flagged results based on fewer than 15 samples because caution is required when interpreting these findings.

The indicator groups – water quality, physical habitat structure, and biological - may be interpreted together to help understand the relationships among the parameters. This will provide insights into water body and watershed health that might otherwise be missed.

Introduction

Oregon’s Willamette basin is the hub of the state’s population and economy with 70% of the state’s population and 75% of the state’s employment in only 12% of the state’s land area. The basin contains some of the state’s most challenging water quality issues. Over the past 15 years more than a dozen stream and river surveys have monitored approximately 650 randomly selected sites on streams and rivers in the Willamette basin using US EPA’s Generalized Random Sampling Design (GRTS) and Environmental Monitoring and Assessment Program (EMAP) protocols. Monitoring was conducted by municipal, state and federal governments; university researchers, and local watershed councils. The Oregon Department of Environmental Quality has aggregated these various compatible data sets to evaluate stream and river status for the entire basin, for land use types and for 12 subbasins using a range of biological, water quality and physical habitat condition indicators.
Randomly selected sites are compared with least-human-impaired reference sites to evaluate the role of natural conditions and human activity to the current stream and river status.

The Oregon Department of Environment Quality (ODEQ) is required by law to develop a list of state waters that do not meet applicable water quality standards (Clean Water Act Section 303(d) (1) (A)). The standards are adopted to protect aquatic life, recreational uses, public water supplies and other identified beneficial uses. The 2004-2006 303d list submitted to the Environmental Protection Agency (EPA) identified water quality impairments for water temperature, bacteria and mercury in the Willamette basin (http://www.deq.state.or.us/WQ/TMDLs/TMDLs.htm). For each pollutant, DEQ identified the relative contributions of point sources and non-point sources to the impaired receiving waters and allocated the pollution reductions that were necessary to come into compliance with water quality standards (Total Maximum Daily Load or TMDL).

On September 12, 2006 DEQ issued the Willamette Basin TMDL as an order. The order covered 12 subbasins (4th field Hydrologic Units) in the Willamette. The Tualatin, Yamhill and Molalla/Pudding subbasins are also covered under separate TMDL’s which include additional pollutants such as pesticides, metals and low dissolved oxygen.

The TMDL’s are implemented through water quality permits and by designated management agencies (DMA’s) that include local government agencies and state and federal agencies. DMA’s are required to submit a Water Quality Management Plan (WQMP) outlining actions that will be taken to reduce pollutants to comply with the TMDL limits set forth ((OAR) 340-042-0080(3)). Over 40 WQMP’s have been reviewed and approved by DEQ basin coordinators in the Willamette basin. More than 20 additional plans have been submitted and are either pending approval or need minor changes to meet the implementation requirements. A few other DMA’s have not submitted plans and DEQ basin coordinators are assisting them in the planning process.

While plans are being written, finalized, reviewed and implemented, actions are being taken on the ground to improve water quality and watershed health conditions in the Willamette basin. DEQ’s Non-point Source Pollution Program (319) administers over one million dollars annually in grants aimed at reducing sources of non-point source pollution runoff to streams and rivers that have water quality impairments (TMDL’s), drinking water sources and groundwater management needs. DEQ also administers the Clean Water State Revolving Fund (CWSRF) loan program which loans money to cities, counties, sanitary districts, Soil and Water Conservation Districts (SWCD’s), and irrigation districts for water pollution control activities. In 2009, approximately $45 million will be loaned for water quality improvements.

In addition, the Oregon Watershed Enhancement Board (OWEB) provides funding for watershed councils, municipalities, landowners, SWCD’s and private parties to help improve habitat for threatened salmon runs in the Willamette basin and in other parts of Oregon. Many of the actions being implemented are directed at salmon recovery but should help to reduce stream temperatures, sediment runoff, nutrients, bacteria and mercury.
The ongoing commitment of Oregonians to maintaining and improving water quality and salmon habitat are essential for protecting the rivers and streams in the Willamette basin. It is also important that we strive to understand the effectiveness of the management practices, technologies and actions that are being used to protect and enhance our water quality so we can adapt to changing conditions and identify emerging issues. Monitoring of specific best management practices and best available technologies will help us understand what is working and what isn’t at the project scale. But perhaps even more important and challenging is trying to understand the cumulative effects of the various activities that are being taken at the basin, subbasin and land use scales.

This report provides a status assessment of the water quality, biological and physical habitat conditions at the basin, subbasin and land use spatial extents. These spatial scales are ecologically relevant and useful for understanding cumulative management effects. While this report does not address all the water quality parameters listed in the Willamette basin TMDL, it does include many parameters that are useful surrogates for understanding potential loading pathways for bacteria and mercury. It also includes a variety of parameters that are not listed in the Willamette TMDL that may warrant careful consideration for future management activities.

Executive Summary

- The biological health of 46% of the streams and river miles in the Willamette basin are in most disturbed condition as measured by the stream insect community and other macroinvertebrates.
- Agricultural land use is the largest source of most disturbed streams accounting for 62% of the most impaired stream miles while representing only about 30% of the total stream miles.
Biological Risk Factor: Fish

Biological Risk Factor: Macroinvertebrates

**Percent of Stream Miles Impaired**

*Figure 2. Extent of impairment and biological risk.*

- Warm water is the single most extensive impairment in the Willamette basin. Nearly 70% of the stream and river extent in the basin violates the temperature criteria for protecting sensitive cold water fish like salmon and trout. Streams with temperature violations were nearly twice as likely to have impaired macroinvertebrate biological condition and 14 times more likely to have impaired fish and amphibian biological condition.

- Riparian human disturbance, sparse canopy cover and degraded riparian vegetation are also extensive impairing between 30 and 44% of the stream extent.

- The extensive riparian vegetation impairment is most likely responsible for the extensive warm water impairment as well as the cause of impairment from low levels of large woody debris (25%), poor streambed stability (19%) and high fine sediment (24%).

- Impairment for random sites was significantly worse than for the least disturbed reference condition for the five most extensive stressors: water temperature, riparian human disturbance, canopy cover, riparian vegetation condition and large woody debris.

- Although impairment from very poor Oregon Water Quality Index scores and poor levels of total phosphorus were relatively rare (< 10%), these stressors were a significant risk to the biological condition of streams. Streams with very poor OWQI scores were over four times more likely to have impaired biological condition than streams with excellent water quality.
• The least impaired subbasins had a greater proportion of streams in forest land uses.

• In both agricultural and urban land uses more than 80% of the stream extent is in most disturbed biological condition.

• Forest has a comparatively low extent of disturbance with about 13% of the stream extent biologically impaired.

• The extent of disturbance in forest streams is significantly less than in urban and agricultural streams.

Project Scope and Design

*Randomly Selected Sites*

The Clean Water Act requires states to report on the condition of all waters in their state. There are only two ways to rigorously describe a large, extensive population like streams and rivers in a basin: take a complete census or conduct a probability survey.

![Map of locations](image.png)

*Figure 5. Locations of randomly selected stream and river sites in the Willamette basin.*

In a census, all river and stream segments would be visited and data on the stream condition collected. This would be a very expensive task in the Willamette with more than 11,000 miles of streams and rivers in the basin. A probability survey is like a public opinion poll where a relatively small, randomly selected sample is visited and analyzed. Compared to conducting a stream census, probability surveys are a cost effective and scientifically valid approach to describing all the water of the Willamette basin with a known level of statistical confidence (Olsen and Peck 2008).

*Site Weighting Factors*

In this assessment we are using 450 randomly selected sites compiled from a dozen probabilistic monitoring programs in the basin (Figure 5). Sites included the full range of water body size present in the Willamette basin from small headwater streams to large main stem rivers. Individually, these programs looked at streams in a variety of spatial sampling frames. These included looking at stream and river conditions by subbasin, within the borders of a city, ecoregion, size, land use, and salmon and steelhead habitat. These various sampling frames present some challenges in combining the data sources into a single probabilistic assessment.

One thing obvious in the map of randomly selected sites in Figure 5 is that there are three dense clusters of sites from surveys by the Long Tom Watershed Council and the cities of Portland and Salem. Another less obvious problem that affects the ‘randomness’ of the sample is our ability to gain permission to sample from some types of private land owners. Overall, we had less success in gaining access permission from rural, non-corporate landowners than from urban or corporate private landowners.

Fortunately, these potential sources of bias are easily addressed by differential site weighting factors. Site weights are the stream miles that each site in our poll represents in the basin as a whole. Site weights were calculated for each site by land use category and by monitoring project cluster. Sites that were part of a dense
cluster have a proportionally lower site weight than a similar site that is not part of a cluster. Differential site weighting allows us to easily combine projects of very different sampling frames and correct for biases introduced by landowner access problems.

**Reference Condition**

In addition to randomly selected sites used to describe regional conditions we used data from about 240 reference sites to evaluate natural background conditions. Reference sites represent the least-human-impaired sites we can find. We selected reference sites by identifying watersheds with lower levels of human activity on maps and then visiting candidate sites to conduct a human disturbance evaluation of the stream reach and watershed (Drake 2004).

The reference condition approach has long been used in ecological assessments to provide an unbiased estimate of attainable conditions (Hughes et al. 1986, Hughes 1995, Stoddard et al. 2006). The reference condition approach is an important component of this assessment. We use reference sites in two ways. First, we use reference sites to set good, fair, and poor benchmarks for habitat, water quality and biological condition indicators that do not yet have numeric water quality criteria. Second, we use the distribution of reference condition to estimate to what extent conditions are due to natural background conditions and what extent conditions are the results of human activity. Besides describing the extent of water quality and habitat stressors at randomly selected sites we also want to estimate what natural, relatively unimpaired conditions would look like. Comparing conditions at the random sites and estimated reference condition helps us to understand the effect of human activity on stream and river condition.

We feel it is important to use as many reference sites as possible to better represent the range and distribution of natural conditions, and to better incorporate the influence of natural disturbances. We have included reference sites outside of the Willamette basin but in regions of similar ecological potential with similar geology, soil, climate, topography, potential vegetation, in-stream habitat, water quality and biological condition (Figure 5). The ecoregions delineated in Figure 6 have been widely used in water quality assessments in Oregon (Thorsen, et al. 2003).

![Figure 6. Locations of ecoregional reference sites.](image)

The Willamette basin has three major (level three) ecoregions: the Coast Range, Willamette
Valley, and Cascades. We chose not to use reference sites that were in level four sub-ecoregions along the Pacific Ocean or south of 43.3° north latitude. We felt that these sites may be too strongly influenced by the Pacific Ocean or too far south to be representative of Willamette basin reference conditions.

Figure 6 shows clearly that reference site representation is not proportional across the three ecoregions in the basin. The Coast Range is a relatively small component of the basin compared to the Willamette Valley ecoregion yet the Valley ecoregion has far fewer reference sites. These differences reflect the pattern of human land use. Relatively unimpaired Willamette Valley stream reaches are far more difficult to locate than Cascade or Coast Range sites. The whole basin and 12 subbasins all have differing proportions of streams in the Coast Range, Willamette Valley and Cascade ecoregions. Estimating the reference conditions for each different spatial extent requires a different set of site weights. The site weights are the length of stream kilometers a site represents in the area being described. Ecoregional reference sites are weighted proportional to the extent of that ecoregion in each spatial scale to ensure a reasonable reference condition appropriate for each subbasin.

It is important to remember that reference sites are not pristine or unimpaired by human activity. While smaller streams at higher elevations may be in basins minimally impaired by human activity, larger streams and rivers, and streams at lower elevation will have considerable alteration from human activities. Often these reference streams represent local stream reaches in relatively better condition than most streams in the area. The reference condition is not intended to be a model of basin conditions at some historical time, such as pre-European-American settlement of Oregon. It estimates what the biological, water quality and habitat condition of the basin would look like if all streams were in the condition of the best streams we can find today (Whittier et al. 2007).

Appendix A of this assessment has more information on reference sites and benchmarks.

**Data Sources**

Between 1994 and 2007, 451 randomly selected sites and 238 hand-selected reference sites were surveyed between late June and late September (Figure 7). Forty-four random sites were also reference sites.

These sites were surveyed as part of more than a dozen different monitoring projects (Table 1, Figures 8-10).

**Figure 7. Data collection 1994-2007.**

Approximately half of the sites were surveyed by DEQ field crews in various random and reference site monitoring projects with about one third of the sites surveyed as part of the Oregon Plan for Salmon and Watersheds (Figure 8). Approximately one quarter of the sites were
surveyed in monitoring programs conducted by the EPA/OSU laboratory in Corvallis, Oregon, and one quarter were surveyed by watershed councils or municipalities.

Because not all monitoring projects collected all types of data the data sources by project graph looks a little different from the sites graph (Figure 9). About three quarters of the data sets come from DEQ monitoring projects with half coming from Oregon Plan monitoring. Approximately one quarter of the data sets come from sources outside of DEQ.

**Figure 8. Number of sites by project. See Table 1 for a project list.**

Figure 10 shows that macroinvertebrate samples represent the largest data set in the assessment with nearly 400 sites with data. Temperature data are the smallest data set with about 100 records.

With data from multiple sources being compiled into a single assessment, it was critical that standardized field and laboratory protocols were used by all the various monitoring programs to facilitate data sharing (Hughes and Peck 2008, IMST 2009). We have been very fortunate in this assessment that that the EPA’s Environmental Monitoring and Assessment Program’s methods for assessing streams and rivers have been so widely used in Oregon. Due to the cooperative approach of monitoring staff at the EPA’s laboratory in Corvallis, Oregon, DEQ’s Watershed Assessment Section, and others, there has been coordinated field crew training, methodology sharing and data analysis assistance for all of the monitoring programs that generated data used in this assessment.

Spatial Extents

In this assessment we examined the condition of Willamette basin rivers and streams for the entire basin and for a number of different land use categories and hydrologic areas (Tables 2 and 3, Figure 11).

Land Use

Using ArcGIS 9.2 geographic information system (GIS) software, Oregon zoning GIS data from the Department of Land Conservation and Development and land ownership layers (from Oregon Department of Forestry and the Oregon GIS Service Center) were combined with satellite imagery (US Geological Survey 2007) to create a land use layer for the Willamette basin with nine categories (Figure 11). The details of the GIS methods used to create the land use layer appear in the Technical Appendix.

This land use layer was used to classify our sites and the stream network within the basin. Sites were categorized according to the predominant land use within a 300 meter diameter circle centered on the site’s latitude and longitude; upstream land use beyond this circle was not considered when determining a site’s land use.

We felt that looking at stream conditions for different land uses was important because types of point source and non-point source stresses to water quality vary with human land use and activity. Management practices to address non-point source water quality problems are typically specific to the land use activity involved.

The predominant land use surrounding Willamette streams and rivers is forest which accounts for approximately 60% of the stream length. Public forest is the largest single land use class in the basin. Approximately a third of the stream miles are in agricultural land and 10% are in urban areas (Figure 12).

Subbasins

The 12 subbasins listed in Table 3 are the 4th field US Geological Survey Hydrologic Units. They are the spatial extent most often used by DEQ for conducting intensive water quality assessments and for determining waste load allocations for water quality limited water bodies as required by the Clean Water Act in the TMDL process. Not all of these units are true drainage basins; some are subsets or combinations of true basins.
Figure 12. Land use class stream length proportions.

Indicator Descriptions

In this assessment we looked at the overall ecological health or condition of Willamette basin rivers and streams. There is no single definition or indicator of stream ‘health’. By evaluating an array of biological, water quality and physical habitat indicators that are affected by human activity we get a picture of the overall stream condition.

In the following sections we list the various indicators, briefly describe why they are important, and provide a very brief description of the sample collection methods. More information on sample collection and analytical methods is provided in the Technical Appendix and in the cited references.

Indicators of Biological Condition

Using biological indicators of stream health is useful for a number of reasons. Because the aquatic organisms live in the water for extended periods of time, they are indicators of not just the current conditions but also the cumulative effect of a wide range of stressors over time. Organisms evolve to use habitats with specific characteristics. Changes in these characteristics as a result of human disturbance can result in changes in the species composition of a stream relative to what would be found under unimpaired conditions. This is something difficult to capture with a typical water quality “grab” sample that is collected at one time and analyzed for relatively few chemicals. The stressor that caused the impairment may not be present at the time of the sample collection, or the sample may not be analyzed for the appropriate stressor. Finally, the federal Clean Water Act (33 USC § 1251) sets the nation’s goal “to restore and maintain the chemical, physical, and biological integrity of the Nation’s waters.” Biological indicators of stream health are a direct measure of the extent to which waters achieve this goal.

In this assessment we look at two different biological assemblages: the macroinvertebrates that live on the stream bottom and the fish and
amphibians of the streams. There are benefits to looking at more than one group. Different groups respond to stressors differently. Macroinvertebrates live in all waters from the largest to the smallest, including some that naturally do not have fish. Macroinvertebrates are the foundation of the animal food chain in streams. They graze on algae, leaves and wood, and in turn are a source of food for fish. Fish are eaten by other wildlife and humans, and have a wider home ranges and longer lives thereby incorporating a wider range of conditions.

Aquatic Macroinvertebrates
Aquatic macroinvertebrates are a diverse group mostly made up of insects but also clams, mussels, crustaceans, worms and other types of creatures. They are animals that are large enough to see without a microscope and do not have an internal skeleton. A single stream sample can have dozens of different species, and the possible list of species a stream could have changes with locations and time.

In wadeable streams macroinvertebrate samples were collected using a fine mesh net from riffle habitat distributed throughout the survey reach (Figure 13). In wadeable streams without riffle habitat samples were collected in the fastest water habitat available. In non-wadeable rivers or from streams without fast water habitat macroinvertebrate samples were collected at transects evenly spaced throughout the survey reach (Oregon Department of Environmental Quality 2009a).

We evaluate the biological health of a stream’s macroinvertebrate assemblage using a species loss model. The list of species we observe (O) at a site is compared to the species expected (E) to be present at reference sites in the area at about the same time of year. The site macroinvertebrate score is a ratio of the observed to the expected species (O/E). O/E scores range from 0 meaning no species predicted in the reference condition model were found to 1.0 or more meaning that

Figure 13. Macroinvertebrate sampling.

all of the species predicted were found. An O/E score of 0.75 means that 25% of the species predicted for reference sites have been lost. O/E scores greater than 1.0 represent a species enriched condition. Species enrichment over what would be expected in reference condition streams may represent a slightly disturbed stream condition (Hubler 2008, Hawkins et al 2000).

Aquatic Vertebrates
The aquatic vertebrates are the second assemblage we used as an indicator of biological health. Typically, western streams have fewer than a dozen species of fish and amphibians although larger rivers have more species. As with aquatic macroinvertebrates, different vertebrate species have evolved to survive in differing habitats and conditions. Some are tolerant of poor water quality or habitat conditions while others are not.

Fish and amphibians were collected using a single pass with an electrofisher. Stunned individuals were collected in nets, identified, length measured and released (Figure 16). In wadeable streams the field crew used a backpack electrofisher (Figure 14). In non-wadeable rivers the field crew used a raft or
boat mounted electrofisher (Figure 15). Electrofishing was conducted over the entire survey reach. The goal of the electrofishing survey is to collect a representative sample of the most abundant species present and not conduct a census of all individuals or species present in the survey reach.

Figure 14. Backpack electrofishing.

Figure 15. Raft electrofishing.

To assess the condition of the aquatic vertebrates we used the vertebrate Assemblage Tolerance Index (ATI), an overall indicator of the species assemblage’s tolerance to a broad range of human disturbances. The index is a weighted average of individual taxon tolerance values created from habitat structure, water quality and species presence data from the western United States (Whittier et al. 2007).

Figure 16. Length measurement of a cutthroat trout.

Indicators of Water Quality Stress

Water quality and physical habitat conditions may have a range of values. Human activity and natural conditions both affect the values we measure in a stream or river. Since aquatic life has evolved to adapt to a range of stream conditions, the ecological health of streams can be impaired when those conditions are altered beyond the natural ranges. In this section we look at a relatively short list of water quality and habitat structure indicators that have been found to be important to the ecological health of aquatic systems and are affected by human activity (Table 4). It is not a complete list of all important stressors. For example, it does not include toxic chemicals in the water. Nor does it include water quality stressors that may be present during high stream flow conditions.

In this assessment a single set of water quality samples were collected at each site from a well mixed location in the mid channel of the stream near the downstream end of the survey reach. Samples were typically collected mid morning before any other survey work had been performed at the stream. Some analysis was performed in the field while other samples were returned to the laboratory for further analysis (Figure 17).

Table 4. Water quality indicators.
• Temperature
• Nitrogen
• Phosphorus
• Dissolved Oxygen
• Biochemical Oxygen Demand
• pH
• Total Solids
• Total Suspended Solids

Temperature was measured using a thermistor that recorded temperature at half hour intervals. Thermistor accuracy was checked with a reference thermometer of known accuracy before the devices were deployed and again after they were retrieved. Thermistors were deployed in a well mixed, mid channel location in the stream in the spring and retrieved in the fall in order to capture the warmest time period during the summer.

The highest 7 day average of daily maximum temperature (7DAM) was calculated for each site and compared to the water quality standard. The standard applicable at a particular site varies depending on the fish use at that location (see Appendix A of this assessment). In the categorical graphs the sites with 7DAM below the standard are ‘good’ and sites with 7DAM above the temperature standard are ‘poor’.

Nitrogen and Phosphorus
The biological productivity of streams depends on a combination of nutrients and energy. Nutrients can enter the stream dissolved in groundwater and surface water runoff. Nutrients can also enter the stream through the decomposition of solid material such as terrestrial plant leaves and wood falling into the stream and animal bodies, such as salmon carcasses. Human activity in a basin often increases nutrient input to a stream over the normal levels through fertilization of agricultural and residential land, animal and human wastes, and increased soil erosion. Conversely, human activity also leads to decreased stream nutrients in some areas, such as in higher elevation, forested streams, when there is a decrease in decomposing salmon.
carcasses resulting from reduced salmon populations.

The primary impact of nutrients is on the growth of aquatic plant and algal communities. Algae, like all plants, require nutrients for normal growth. Most of these nutrients are available in aquatic systems in excess of the algal nutritional requirements. Nitrogen and phosphorus are exceptions in that the availability of these nutrients frequently limits algal growth in lakes and streams. In most natural waters the availability of phosphorus limits algal growth. When extra phosphorus is added the next nutrient to become limiting is nitrogen. Algae feed some fish and macroinvertebrates that are eaten by fish and other organisms. Nutrient availability is a matter of balance. Too little nitrogen and phosphorus may mean a reduced food supply for juvenile salmonids and overall reduced stream productivity. Too much nitrogen and phosphorus leads to excess algal growth causing pH and dissolved oxygen problems unhealthy to salmonids and other species.

**Dissolved Oxygen**
Dissolved oxygen is essential to all life that depends on aerobic respiration, including fish, amphibians and aquatic macroinvertebrates. The amount of oxygen in water is determined by a number of factors. First, the solubility of oxygen in water decreases as water temperature increases. Second, the amount of oxygen dissolved in water decreases with decreasing barometric pressure. Barometric pressure decreases with increasing elevation and weather changes.

In many waters the biological activity in the water has a tremendous influence on the dissolved oxygen. Photosynthesis by algae and aquatic plants releases oxygen into the water and takes up carbon dioxide. In very productive, eutrophic systems photosynthesis temporarily creates super-saturated levels of oxygen over 100%. In a similar way, aerobic respiration can deplete the dissolved oxygen to lethally low levels in nutrient rich waters when photosynthesis stops at night. Also, high levels of un-decomposed organic material causing high levels of biochemical oxygen demand will deplete dissolved oxygen when the organic material is broken down by bacteria and fungi. Dissolved oxygen varies daily and seasonally as photosynthesis, respiration and water temperature vary. Turbulent, fast-moving water can restore depleted dissolved oxygen through aeration.

We measured dissolved oxygen in the field using a Winkler titration on a single sample typically collected during the mid-morning.

**Biochemical Oxygen Demand**
Biochemical oxygen demand (BOD) is the amount of dissolved oxygen consumed by microorganisms when breaking down the organic materials in the water under standardized laboratory conditions in 5 days. Waters polluted with untreated sewage or that have high levels of fine organic sediment from soil erosion will have high BOD. BOD can vary a lot naturally. Leaves and other organic material collect in depositional areas, contributing to the BOD of a stream. Anthropogenic influences include untreated manure and sewage, wood waste, leachate from landfills and sediments from erosion.

**pH**
pH is a measure of the acidity of waters and is an important and frequently measured water quality parameter critical to the growth and survival of aquatic life. It affects the toxicity of heavy metals and ammonia. Like dissolved oxygen and temperature, pH varies daily and seasonally with variations in photosynthesis and respiration resulting from changes in sunlight. In most waters pH is determined by dissolved
carbon dioxide gas, which forms carbonic acid, a weak acid. Algal photosynthesis and respiration in areas with abundant algal growth decrease dissolved carbon dioxide and increase the pH. At night pH in those same waters decreases as a result of carbon dioxide excretion during respiration. Such daily swings in pH can be very stressful to salmon and other aquatic life.

We measured pH in the field, typically around mid-morning, on freshly collected water samples using a meter with a glass pH electrode.

**Suspended Sediment: Total Solids and Turbidity**
The detrimental effects of excess fine sediment on juvenile salmon and other aquatic life are well known. Fine sediment can clog spaces between gravels and cobbles smothering salmon eggs and emerging fry. Excess fine sediment in the water column interferes with gill function and the ability of young fish to forage for food. Human activities near streams and rivers such as road building, construction, logging and agriculture that disturb the ground surface or remove stabilizing vegetation can lead to increased fine sediment in streams.

Fine sediment in the water is measured in two different ways in this assessment: total solids, total suspended solids and turbidity. Total solids and total suspended solids are determined by evaporating a known volume of water sample and then weighing the remaining residue for a filtered and unfiltered sample. Total and suspended solids have units of milligrams solid material per liter of water.

Like many other water quality parameters, these measures of water column sediment can vary widely depending on flow conditions. A single sample collected during summer low-flow conditions likely underestimates water quality sediment problems for many streams.

**Indicators of Physical Habitat Stress**
The habitat structure data used in this assessment were collected and analyzed using the EPA’s Environmental Monitoring and Assessment Program’s protocols for wadeable and non-wadeable streams (Peck et al. 2005 and Peck et al. 2006). Stream and river habitat data were collected from a length of stream that varied with size. Most wadeable streams had a sample length of 200 to 500 meters with a 150 meter minimum while larger rivers could have a sample length of more than a kilometer. Measurements of stream channel morphology, substrate, canopy cover, and riparian characteristics were conducted by the field crew at regularly spaced transects while other measurements were collected at intervals between transects (Table 5, Figures 18 and 19).

A field habitat crew of 2 people could usually conduct a habitat survey on a smaller wadeable site in 2 to 3 hours while a larger, more complex site might require several hours. Although the specific field method may have varied slightly for wadeable and non-wadeable water bodies, the habitat stressors assessed were the same. Non-wadeable water bodies were surveyed by raft or boat. Field crews complete about 40 pages of forms with raw physical habitat data at each site. Field crews re-sampled 10% of the sites for quality assurance.

The eight habitat indicators that we selected for this assessment were developed by the EPA and have been used in stream assessments in Oregon and across the country (Kaufmann et al. 1999). These indicators are important to fish and other aquatic life and are affected by human activity in the riparian area along the stream channel and in the drainage basin. Three stressors look at the condition of the streambed (streambed stability, percent fine
sediment, and percent sand and fine sediment), three stressors look at the condition of the riparian area (canopy cover, riparian vegetation condition, and riparian human disturbance) and two look at the condition of fish habitat (extent of fish cover and large woody debris habitat).

**Streambed Condition**

Many human activities affect the characteristics of streambeds, particularly the amount of small sized particles in the streambed. Frequently, excessive erosion increases in the amount of small sized sediment in streambeds. Excess fine sediment fills in the spaces between boulders and cobbles reducing habitat space for fish and macroinvertebrates. Accumulations of fine sediment in salmon spawning gravel can smother and kill salmon eggs and fry.

The evaluation of impairment from excess fine sediment needs to be done carefully. Simply measuring the amount of fine sediment in a streambed alone is not adequate to evaluate impairment. Not only is the amount of fine sediment affected by human disturbance but it also varies naturally with basin geology and soils, stream size, channel gradient, and streambed roughness. Larger, steeper streams in areas of erosion resistant soils and geology will naturally have less fine sediment than smaller, low gradient streams in areas with more erodible soils and geology.

The streambed stability indicator is a value that models the expected mean substrate size for a
stream reach based on the natural factors that affect streambed substrate size and compares it to the observed mean particle size. Expectations for good, fair and poor streambed stability were calibrated based on ecoregions that have soils and geology as a component.

We used two measures of fine sediment in this assessment. The first, percent fine sediment, is defined as silt, clay and muck material that feels slick between the fingers and not gritty (<0.06 mm diameter). The second, percent sand and fines, is the proportion of particles less than 2.0 mm in diameter. Both forms of fine sediment were included to be consistent with earlier DEQ reports. Substrate data were collected at evenly spaced transects along the survey reach.

**Riparian Condition**

The riparian area is a corridor of land along a stream or river. An intact, well-vegetated riparian area along streams and rivers will act like a buffer against human disturbance in the watershed. It can reduce nutrient and sediment runoff from nearby land, reduce erosion from unstable stream banks, provide shading vegetation to reduce stream temperature, provide fish and amphibian habitat in the form of large woody debris, and provide leaf litter food for aquatic life.

Canopy cover is a direct measure of the vegetation and topography over the stream channel. It was measured using a densiometer, a gridded spherical mirror that reflects the vegetation over the stream channel. Canopy cover measurements were taken at evenly spaced transects along the survey reach either at the center of the channel for wadeable streams or at the wet edge at the stream bank for non-wadeable streams.

Riparian vegetation condition was evaluated at 10 meter square plots on evenly spaced transects. Vegetation density estimates were made for the ground cover (<0.5 m high), mid layer (0.5 to 5.0 meters high) and canopy (>5 meters high). The riparian vegetation condition is the sum of the woody plant density in all three layers.

Field crews recorded the presence and proximity of eleven types of human land use or disturbance at riparian plots along the survey reach. Human disturbances were evaluated as occurring on the stream bank, within 10 meters, observable but beyond 10 meters or apparently absent. Riparian human disturbance score is a proximity-weighted indicator of general human stress on the stream.

**Fish Habitat Condition**

More diverse fish and amphibian assemblages are found in streams and rivers with complex habitat elements: boulders, undercut banks, large submerged logs. These structures provide spaces to rest, avoid strong currents, hide from predators, and wait for prey organisms. In-stream large wood is especially important because it creates complex habitat, such as pools and high water refugia, for juvenile salmonids. Habitat complexity also benefits macroinvertebrates, an important food source for salmonids, and wood provides habitat for some macroinvertebrate species. Human activity can simplify this habitat through channel straightening, loss of large woody debris from the riparian area and destabilization of stream banks.

The fish cover indicator is the sum of the areal presence of all types of fish cover observed in sections of stream at 11 evenly spaced transects. The large woody debris indicator is the volume of wood pieces within or above the active stream channel based on a tally by size category taken along the entire stream reach.

Condition Assessment

Spatial Extents

In the sections that follow we look at the biological, water quality and habitat condition of streams and rivers for the entire basin; for agricultural, forest and urban land use classes; and for the 12 subbasins in the Willamette. We also compare the condition at randomly selected sites with the modeled reference condition for the entire Willamette basin and for the 12 subbasins. Reference condition represents our estimate of natural background conditions and is based on the least-human-impaired sites we can find. A statistically significant difference between the random and reference extent of impairment indicates problems caused by human activity and natural conditions.

Confidence Intervals, Statistical Significance, and Sample Size

Data from probabilistic surveys are usually presented with information about the confidence of the estimates. The thin lines at the ends of the bars in the charts of this report are a measure of the statistical confidence or certainty of the information presented. The lines are the range of the 95% confidence interval, meaning that there is a 95% chance that the true value falls within that range and a 5% chance that the true value is outside that range. Two values are said to be statistically significantly different if their confidence intervals do not overlap. A small, narrow confidence interval is better than a wide confidence interval but more expensive to create since it involves sampling a larger number of sites.

The number of sites sampled is a major determinant of the confidence interval size. When the sample size is small the confidence interval will be big. For example, in the Willamette basin, with a sample size of 395 randomly selected sites for macroinvertebrates, 37.3% of the extent of streams and rivers has least-impaired biological condition for macroinvertebrates with a confidence interval of plus or minus (+) 5.4%. This means that we are 95% certain that the true value of the proportion of least-impaired stream extent is somewhere between 31.9% and 42.7%. In the Clackamas subbasin, with a sample size of only 23 randomly selected sites, the proportion of stream extent with least-disturbed macroinvertebrate communities was 47.4% ± 17.5%. We are 95% certain that the true proportion of least impaired Clackamas basin streams is between 29.9% and 64.9%.

For a number of geographic units and data sets presented in this assessment the sample sizes are small, resulting in confidence intervals that are larger than ideal. We have included warnings in the charts for using some of the results where the sample size was less than 15, causing very large confidence intervals. For example, the temperature data set was the smallest in this assessment and tended to have more geographic units with very low sample size warnings (Figure 20). The private non-industrial forest land use also had a rather small sample size. It is important for the reader to pay attention to the confidence intervals when interpreting these results and making decisions based on these data. Appendix B of this report has more information on sample sizes for the various spatial extents.

Percent of Stream Miles Impaired

Figure 20. Extent of impairment in Willamette basin rivers and streams.

Biological Condition

As summarized in Figure 21, the biological condition of the macroinvertebrate community was most disturbed at 46% of the Willamette basin streams and rivers, compared to only 23% for basin reference condition. The extent of streams with impaired aquatic vertebrate communities was about 30% of the stream extent. The extent of streams with impaired vertebrate communities was about 20% greater than reference conditions. These differences between random and reference conditions are statistically significant.

Water Quality

Warm water temperature was the single most extensive water quality stressor in the Willamette basin (Figures 20 and 22). More than 66% of the stream and river length exceeded the temperature standard to protect sensitive fish. Under modeled reference conditions only 39% of the streams and rivers were impaired by temperature over the standard.

Other water quality stressors were less extensive with less than 20% of the stream network impaired. All other water quality stressors a greater extent of impaired stream length than the estimated reference condition, but except for extent of total nitrogen and Oregon water Quality Index, the differences between random and reference condition were not statistically significant at the 95% confidence interval.

For streams in good or excellent condition, four water quality stressors showed statistically significant better conditions at reference sites compared to random sites: Oregon Water Quality Index, temperature, biochemical oxygen demand, and total nitrogen (Figure 22).
Figure 21. Biological and structural habitat conditions of Willamette basin rivers and streams.
Figure 22. Water quality conditions of Willamette basin rivers and streams.
Structural Habitat Structure

Human disturbance in the riparian area was the greatest source of structural habitat impairment in the basin (Figures 20 and 21). Reduced levels of canopy cover impaired 34% of the stream extent and sparse riparian vegetation impaired about 30% of the stream extent in the basin. Low levels of in-stream large woody debris impaired 25% of the stream extent. High levels of fine sediment impaired nearly 24% of the stream miles. More than 40% of the stream extent had high levels of human disturbance in the riparian area. The extent of impairment from most of these habitat stressors was significantly greater at the randomly selected sites than at the reference condition. The extensive riparian impairment was most likely the cause of the extensive warm water impairment in the basin.

Condition of Willamette Basin Rivers and Streams by Land Use

Although we had adequate sample sizes for the three major land use classes (agriculture, forest and urban), land use sub-class results should be interpreted with caution because the 95% confidence intervals tend to be large as a result of small sample sizes. While it appears that private non-industrial forest and higher intensity urban land use have streams with greater overall impairment, these differences are not significantly different than the larger general land use groups.

Biological Condition

The land use categories that showed the greatest impairment in the macroinvertebrate assemblages were agriculture with 89% of the stream miles most disturbed and urban with 81% of streams in most disturbed condition (Figure 23). Forest had streams with the least impaired macroinvertebrate assemblages with 12% of streams and rivers most disturbed, 19% moderately disturbed, and 61% least disturbed. Land use sub-classes are presented in Figure 24 but these results should be interpreted with caution since the 95% confidence intervals tend to be large because of small sample sizes. It appears that private non-industrial forest was in poorer biological condition than other forest types.

Water Quality

Figures 25, 26 and 27 summarize the water quality of the land use classes and sub-classes. Of the three major land use classes, both agricultural and urban land uses had high proportions of streams above the temperature standard (88% and 82% respectively). Forest overall had the lowest proportion of temperature impaired streams with 54% above the temperature standard. Public and private forest lands showed significantly different temperature patterns with 39% of public forest streams temperature impaired compared to more than 75% impaired on private forest land.

The continuous temperature data set was the smallest of the data sets used in this report. This resulted in very large 95% confidence intervals for the smaller, more specific land use sub-classes. The results for those classes are not summarized here but are presented in Figures 25, 26, and 27.

Low dissolved oxygen impaired about 30% of agricultural and urban stream extent but impaired less than 6% of all forest stream extent.

Nitrogen and phosphorus enrichment were more extensive in agricultural and urban streams than in forest streams. Less than 5% of forest streams had high levels of nitrogen and phosphorus while 36% of urban streams had high nitrogen levels.
and 22% had high phosphorus. In agricultural streams 16% had high nitrogen and 11% had high phosphorus levels.

**Habitat Structure**

Overall, urban streams had the greatest impairment from unstable streambeds and excess fine sediment with 61% of the urban stream extent impaired by unstable streambed compared to more than 30% of agricultural streams and only 9% of forest streams.

The riparian areas of urban and agricultural streams had greater extent of streams in poor condition compared to forest streams and rivers. About 82% of agricultural streams and 30% of urban streams had impaired canopy cover while the level of impairment of forest streams was about 12%.

**Condition of Willamette Basin Rivers and Streams by Subbasin**

In the previous section of this report we presented results for the entire Willamette basin and for basin-wide land use types. In this section we present results for the 12 subbasins in the Willamette basin. The results are presented in a similar format as before. Figure 31 compares the biological impairment of the macroinvertebrate community of the 12 subbasins with the estimated reference condition impairment. Figures 32 and 33 are graphs of the indicators of vertebrate and macroinvertebrate biological health, Figures 34 to 39 present the water quality conditions, and Figures 40 to 45 present the habitat structure conditions.

We have also presented the reference condition for each subbasin. The reference condition graphs are an estimate of what the subbasins would look like if all the stream miles were in as good a condition as the least impaired streams we can find today. The analysis we present in this section discusses the highlights of these results.

We remind the reader again to pay attention to the confidence intervals when interpreting these results. The temperature data set was the smallest data set in this assessment and often has a small sample size at most subbasin scales. In addition, land use sub-classes often have small sample sizes. See Appendix B in this assessment for more information on sample sizes used in this assessment.

Figure 31. Habitat conditions by land use classes: fish cover and large woody debris.
The most biologically impaired subbasins in the Willamette basin were the Mid Willamette, Upper Willamette and Lower Willamette with approximately 80% of the stream extent severely disturbed (Figure 31). The extent of disturbance was significantly worse at the random sites than at the reference sites.

The least impaired subbasins were the Middle Fork Willamette, McKenzie, Coast Fork Willamette and Clackamas with less than 20% of the stream extent severely disturbed. The randomly selected sites in these subbasins had a greater extent of biological disturbance than the estimated reference condition although the difference in disturbance extent between random and reference condition was not significant.

The most disturbed subbasins had greater proportions of streams in agricultural and urban land uses. The least impaired subbasins had their headwaters in the Cascade Range and had greater proportions of forest land use.

The Cascades Subbasins

There are four subbasins in the Willamette basin with headwaters on the west slope of the Cascades Range: Clackamas, North Santiam, McKenzie and the Middle Fork Willamette. In the Cascades summer stream flow is fed from snow melt at higher elevations. Most of these subbasins had extensive forests with public forest being the most extensive land use and agriculture and urban land use less extensive than in other subbasins in the Willamette basin (Table 6).

Clackamas Subbasin

The Clackamas subbasin had the highest proportion of stream length in good biological condition for aquatic vertebrates (74%) but the 7th highest proportion in good condition for macroinvertebrates (44%) among the 12 subbasins.

The extent of poor habitat structure conditions was fairly low for the stressors we evaluated and not significantly different than the reference condition. The riparian human disturbance (34% poor) and fine sediment (20% poor) were the most extensive stressors in the basin but were not significantly worse than reference condition.

The overall chemical water quality was generally good with 94% of the stream extent with excellent OWQI scores. The extent of streams with nitrogen and phosphorus enrichment was among the lowest of the 12 subbasins, however impairment from warm water temperature was fairly extensive with 50% of the stream length impaired with warm water compared to only 29% for the reference condition.

North Santiam Subbasin

The North Santiam subbasin had the third highest proportion of stream length in good biological condition for aquatic vertebrates (56%) and the 5th highest proportion in least disturbed condition for aquatic macroinvertebrates (57%) among the 12 subbasins.

Leading habitat stressors in the North Santiam subbasin were low levels of large woody debris, riparian human disturbance and sparse riparian vegetation condition (approximately one third of the stream length in poor condition for these indicators). Levels of fine sediment and streambed stability were good (approximately 6% or less in poor condition). The extent of stream length impaired by habitat stressors was
not significantly different than reference condition.

Overall water quality of the North Santiam subbasin was generally good with the highest proportion of streams with excellent OWQI scores of the 12 subbasins. The most extensive water quality stressor was warm water temperature (31%) although the extent of stream length impaired was not significantly different than reference condition.

**McKenzie Subbasin**

Among the Cascades subbasins, the McKenzie subbasin had a fairly large extent of streams with fair to poor biological condition for aquatic vertebrates (50%) compared to reference condition (27%). The subbasin had the 3rd highest proportion of stream length in good biological condition for aquatic macroinvertebrates (68%).

The leading habitat stressors were high levels of riparian human disturbance (21% of the stream length), low riparian canopy density (19%) and sparse riparian vegetation (15%), although the extent impaired was not significantly different from reference condition.

The overall water quality in the McKenzie subbasin was very good with 94% of the stream length with excellent OWQI scores, the second highest extent in excellent condition of the 12 subbasins. Surprisingly, the extent of stream length impaired by warm water temperature was high (66% of stream length failing the temperature criteria to protect salmon and bull trout). This was a significantly greater extent than the modeled reference condition for the McKenzie subbasin (27%).

**Middle Fork Willamette Subbasin**

The Middle Fork Willamette subbasin had the greatest proportion of stream length in good biological condition for aquatic macroinvertebrates (72%) and the 4th greatest extent of streams in good biological condition for aquatic vertebrates (54%) of the 12 subbasins.

</table>
The overall condition of stream habitat in the Middle Fork Willamette subbasin was good for all indicators and comparable to reference. The most extensive stressor was riparian human disturbance for approximately 30% of the stream extent. The Middle Fork Willamette subbasin had the 5th greatest extent of streams impaired by low levels of large woody debris (28%) and low levels of fish cover of all types (16%).

The overall water quality condition in the Middle Fork Willamette subbasin was good with 86% of the stream length having excellent OWQI scores. The leading water quality stressor in the subbasin was warm water temperature (50%).

**The Coast Range Subbasins**

There are four subbasins on the west side of the Willamette basin with headwaters in the Coast Range: Tualatin, Yamhill, Upper Willamette, and Coast Fork Willamette. Stream flow in these subbasins is fed more from rainfall than from snow melt as in the Cascade subbasins. The Tualatin, Yamhill and Upper Willamette subbasins have extensive areas of agricultural and urban land use and less extensive area in forest. The Coast Fork Willamette subbasin has more extensive forest land use than the other three subbasins.

**Tualatin Subbasin**

The Tualatin subbasin is the second most urbanized subbasin in the Willamette basin with nearly 27% of the stream length in urban land use (Table 7). The Tualatin subbasin contains a portion of the greater Portland metropolitan region including all or part of the cities of Beaverton, Hillsboro, Forest Grove, Tigard, Tualatin, and Lake Oswego.

The Tualatin subbasin had the 4th highest extent of stream length in disturbed biological condition for both aquatic vertebrates (37%) and aquatic macroinvertebrates (71%).

The overall stream habitat condition of the Tualatin subbasin indicated extensive stream length in undesirable condition for supporting aquatic life with undesirably high levels of fine sediment and low fish habitat complexity being the leading habitat stressors. The Tualatin subbasin ranked first among the 12 subbasins with the greatest extent of stream length disturbed by unstable streambeds (96%), excess fine sediment (81%) and riparian human disturbance (78%). The Tualatin subbasin also had the greatest extent of stream length impaired by low levels of large woody debris habitat (50%) and had the second greatest extent of streams with low quality fish cover (35%).

We also found extensive water quality impairment in the Tualatin subbasin. The Tualatin subbasin had the greatest extent of stream length with poor to very poor OWQI scores, indicating overall impaired water quality condition for the subbasin. Leading water quality stressors included high water temperature, nutrient enrichment, and high total solids. Of the 12 subbasins, the Tualatin subbasin had the highest proportion of stream length impaired by low dissolved oxygen in the basin (41%), and the second highest extent of impairment for high levels of total solids (46%) and nutrient enrichment (more than 35%).

**Yamhill Subbasin**

The Yamhill subbasin had a moderate level of stream extent with impaired biological condition for aquatic vertebrates (17% in poor
condition) and aquatic macroinvertebrates (63% in most disturbed condition).

Our survey indicated a moderately high level of habitat impairment. The Yamhill subbasin ranked second in greatest extent of stream length impaired by sparse riparian vegetation (53%) and third in impairment from unstable stream bottoms (49%) and low canopy (38%), and fourth for high levels of fine sediment (43%).

The Yamhill subbasin had a moderate level of water quality impairment compared to the 12 other subbasins with approximately 40% of the stream extent with excellent OWQI scores. High water temperature was the leading stressor impairing 37% of the stream extent in the subbasin. The Yamhill subbasin ranked third in the extent of streams that passed the water quality temperature standard.

**Upper Willamette Subbasin**
The Upper Willamette subbasin has extensive agricultural land use (57% of the stream miles). It also contains most of the Eugene-Springfield metropolitan area, Oregon’s third largest urban area (Proehl 2009).

The Upper Willamette subbasin had the second greatest extent of streams with most disturbed biological condition for both aquatic macroinvertebrates (78%) and aquatic vertebrates (50%), indicating a generally high level of stream overall impairment in the subbasin.

Sparse riparian vegetation and high levels of fine sediment were the leading habitat stressors in the subbasin. Poor riparian vegetation conditions and low levels of stream shading affected 47% of the stream extent. Unstable stream bottoms and high levels of fine sediment affected 44% of the stream extent. The Upper Willamette subbasin had the second highest extent of streams with poor levels of canopy cover of the 12 Willamette subbasins.

Nearly one quarter of the stream miles in the Upper Willamette subbasin had poor to very poor OWQI scores indicating generally extensive water quality impairment. The overall water quality of Upper Willamette subbasin ranked the fourth worse of the 12 subbasins. Leading water quality stressors were excessively high water temperature (65%), low dissolved oxygen (32%) and high total solids (19%). Among the 12 subbasins, the Upper Willamette ranked the third most impaired for low dissolved oxygen and phosphorus enrichment (16%) and fourth for total solids.

**Coast Fork Willamette Subbasin**
The overall biological condition of the Coast Fork Willamette subbasin streams was good in comparison to the 12 Willamette subbasins. The Coast Fork Willamette ranked second in extent of streams in least impaired biological condition for aquatic macroinvertebrates (70%) and aquatic vertebrates (64%).

The general structural habitat quality was good in the Coast Fork Willamette subbasin. Leading stressors were low levels of large woody debris (28%) and low fish habitat complexity (15%). Although undesirably low levels of large woody debris habitat were one of the leading habitat stressors, the Coast Fork Willamette ranked third in extent of streams with good levels of large woody debris among the 12 subbasins. The Coast Fork Willamette subbasin had the largest proportion of stream extent with good levels of streambed stability (93%), riparian vegetation (79%) and stream canopy (62%) of the 12 subbasins.

The Coast Fork Willamette subbasin had fairly good overall chemical water quality with 92% of the stream extent with excellent to good OWQI scores, ranking fifth among the subbasins in extent of stream length in excellent to good water quality condition. High levels of total solids were the leading water quality stressor with 78% of the stream extent with poor to fair condition for total solids.

Valley Floor Subbasins

The four valley floor subbasins are more heavily urbanized and have more extensive agriculture than the other subbasins (Table 8). Some of the largest cities in Oregon are in these subbasins. The subbasins are at lower elevation, and have lower overall stream gradients than most of the other subbasins in this assessment. Unlike the other Willamette subbasins the Lower and Mid Willamette subbasins are not true watersheds where all precipitation that falls in the basin has the potential to pass through a single confluence.

Lower Willamette Subbasin

The Lower Willamette subbasin is the most downstream portion of the Willamette basin. It is the most extensively urbanized subbasin in this assessment with 51% in urban land use. Most of the greater Portland metropolitan region is in this subbasin. Portland is the largest city in the state with 570,000 residents within city limits and 2.2 million people in the greater metropolitan area (Proehl 2009).

The Lower Willamette subbasin had the third highest proportion of stream extent in most disturbed condition for aquatic macroinvertebrates (77%) and aquatic vertebrates (41%). Only the Mid and Upper Willamette subbasins exceeded the Lower Willamette in the extent of biologically impaired streams.

High fine sediment and poor quality fish habitat were the leading habitat impairments in the subbasin. The Lower Willamette subbasin ranked second of the 12 subbasins for extent of streams with unstable streambeds (62%) and high fine sediment (50%). It ranked third for extent of streams with high riparian human
disturbance (60%) and highest for extent of stream length with low quality fish cover (39%).

The overall water quality in the Lower Willamette subbasin ranks second worse after the Tualatin subbasin in extent of stream length with poor to very poor OWQI scores. Temperature was the leading source of water quality impairment with 82% of the stream extent exceeded the temperature standard. Nutrient enrichment was also a major stressor in the subbasin with 50% of the stream extent with high total phosphorus and 22% with high total nitrogen. Impairment with high levels of total solids (24%) was also fairly extensive.

Mid Willamette Subbasin
The Mid Willamette subbasin is the most agricultural subbasin in the Willamette with 60% of the stream and river extent in agriculture, and the least forested with only 15% of the stream length in forested land use. The subbasin is the third most urban in the Willamette basin and contains Salem, the state capital and the second largest metropolitan area in the state.

The Mid Willamette subbasin had the highest proportion of most disturbed stream length for aquatic macroinvertebrate condition (86%) and aquatic vertebrate condition (77%), indicating generally unhealthy streams for this subbasin.

Leading habitat impairments in the subbasin included the highest proportion of stream extent impaired by sparse riparian vegetation (76%) and low stream canopy cover (65%). Low levels of large woody debris impaired about 40% of the stream length. The Mid Willamette subbasin had the second highest proportion of stream length with high levels of riparian human disturbance (63%) of the 12 subbasins.

The overall water quality in the Mid Willamette subbasin was the third worse in terms of extent of stream length with poor to very poor OWQI scores. No randomly selected sites were found to have OWQI scores in the excellent category, the only subbasin where that occurred. Impairment from high water temperature was extensive with all of the random sites surveyed in the subbasin exceeding the temperature standard. The Mid Willamette subbasin had the highest extent of stream length impaired by total solids (46%). Nutrient enrichment was
also a problem in the subbasin. Fair to poor levels of phosphorus occurred at 94% of the stream length and of nitrogen at 61% of the stream extent.

**Molalla/Pudding Subbasin**
The Molalla/Pudding subbasin ranked in the bottom half of the 12 subbasins for extent of streams with good biological condition for aquatic vertebrates (42%) and near the middle for extent of streams with good biological condition for aquatic macroinvertebrates (56%). The most extensive water quality stressors in the Molalla/Pudding subbasin were high water temperature (87% poor), nitrogen enrichment (71% poor) and low dissolved oxygen (33% poor). The extent of streams impaired by these three stressors was significantly greater than at the estimated reference condition for the subbasin and among the most extensive of the 12 subbasins. Overall water quality for the Molalla/Pudding subbasin ranked near the middle of the 12 subbasins with 52% of the stream length with excellent OWQI scores.

The overall extent of poor habitat conditions was fairly high in the Molalla/Pudding subbasin with 43% of the stream extent with poor riparian human disturbance. The most extensive impairment was from low levels of canopy cover (36%) and poor riparian vegetation condition (44%). Approximately 30% of the streams had high levels of fine sediment and 14% had poor streambed stability.

**South Santiam Subbasin**
The biological condition of the South Santiam subbasin ranked near the middle of the 12 subbasins with 46% of the stream extent in unimpaired condition for aquatic vertebrates and 50% in unimpaired condition for aquatic macroinvertebrates.

The most extensive stressors for habitat were low levels of large woody debris habitat (42%), low stream canopy cover (26%) and sparse riparian vegetation (17%). Human disturbance scores for the South Santiam subbasin indicate that 84% of the stream extent had moderate to high levels of human disturbed riparian areas.

Overall water quality conditions in the South Santiam subbasin ranked near the middle of the 12 Willamette subbasins with 95% of the stream extent with excellent or good OWQI scores. The most extensive water quality stressor in the subbasin was high water temperature impairing 46% of the extent of stream length.
Conclusions

The Condition of Willamette Basin Rivers and Streams

The Willamette basin is Oregon’s most populous basin with only 12% of the land area but 70% of the human population and 75% of the jobs in the state. Human activity has altered the health of rivers and streams in the basin. Basin-wide, 46% of the stream miles are in severely impaired biological condition relative to reference condition streams. Streams in forest land use are in relatively good condition compared to urban and agricultural land uses with only 18% of all impaired streams in forests. Urban land use, comprising only about 10% of the stream miles in the basin has 21% of the basin’s severely impaired stream miles. Similarly, agriculture with about 30% of the basin’s stream miles has 62% of the impaired stream miles. Within each land use category, 89% of agricultural streams, 81% of urban and 12% of forest streams have severe biological impairment.

Warm water temperature is the most extensive stressor we assessed impairing the ability of nearly 70% of the stream and river habitat to support salmon, trout and other sensitive aquatic species. Streams with poor water temperature conditions are 14 times more likely to have impaired fish and amphibian communities compared to streams with good temperature conditions. Human disturbance in the riparian area and poor condition riparian vegetation are also extensive stressors impairing 30 to 44% of the stream extent. Excessive streambed instability and high levels of fine sediment impairs 19 to 24% of stream extent.

In addition to these basin-wide impairments of extensive high temperature, impaired riparian condition, and high fine sediment, different land uses have differing impairment patterns. Impairment from nutrient enrichment is more extensive in urban streams than other land uses. Agricultural streams generally have more extensive impairment from sparse canopy cover and riparian vegetation impairment, riparian human disturbance and generally poor overall water quality. Poor levels of large woody debris and fish cover are among leading impairments in forest streams.

This assessment demonstrates the importance of trees, shrubs and ground cover along stream corridors for protecting the native fish, amphibians and aquatic insects that live in the rivers and streams. Healthy streamside vegetation is likely to help mitigate impacts from water quality stressors like warm water temperatures, excessive sediment and excessive nutrient inputs, while improving overall water quality conditions. In addition, mature streamside vegetation contributes woody debris to the stream channel, enhancing in-stream habitat and cover for organisms that live there.

Taken together, an interesting story emerges. The conditions on the stream bank are intertwined with water temperature, excessive stream sediment, a lack of large woody debris and water chemistry measurements that exceed standards and benchmarks. Healthy streamside vegetation provides shade to help reduce water temperature, provide stable bank conditions and keep out sediment and nutrients that can impair water quality.
Value of Probability Assessments and Standard Methods

In the Willamette Basin Rivers and Streams Assessment we use probability sampling approach to provide an unbiased, statistically valid assessment of regional conditions for a wide range of condition indicators with known confidence levels. The Willamette Basin Rivers and Streams Assessment is the first example that we know of where independent probabilistic surveys of streams and rivers are combined into a single, comprehensive assessment. This is possible only because of a common sampling frame and standardized data collection methods in all 15 studies we compiled. As a result of being able to use data collected by municipalities, university researchers, a watershed council and a federal agency in addition to our own data we were able to nearly double the number of sites available for analysis at a small fraction of the cost for DEQ to collect the data in the field. Since the vast majority of environmental monitoring is paid for by the taxpayer it makes sense for monitoring funders to require standard methods across projects where ever possible to facilitate the widest use of those data possible in order to make the most efficient use of limited monitoring resources.

Impacts of Population Growth and Economic Development.

When the Lewis and Clark expedition paddled their canoes past the mouth of the Willamette River in 1805 the basin was a very different place than it is today. The basin, home to Native Americans for thousands of years, had valley bottom lands with riparian hardwood forests, wet prairies, oak savannahs and woodlands. The Coast and Cascades Ranges were covered by mature coniferous forests. The rivers and streams flowed freely and salmon runs were abundant. The economic development and human population growth since then has brought agricultural production and the building of towns and cities to the valley bottom lands; logging for paper and other wood products to the Coast Range and Cascades; dam construction for flood control, irrigation, and power generation; waste water discharges from industry and cities; storm water runoff from paved lands, and extensive alteration of riparian corridors. It is these alterations that create the conditions of impairment we describe in this assessment.

The good news is that we are addressing the causes of impairment in the Willamette. DEQ controls waste discharges to surface waters from industry, waste water treatment plants, and urban storm water runoff through the discharge permit system (Oregon Department of Environmental Quality 2009b). The Clean Water Act directs DEQ to implement measures to restore water quality in waters that do not meet standards through the Total Maximum Daily Load program (Oregon Department of Environmental Quality 2009c). Water quality impairments from logging are addressed by the Forest Practices Act, administered by the Oregon Department of Forestry (Oregon Department of Forestry 2009). Water quality problems from farm and grazing lands are controlled through a voluntary program of Agricultural Water Quality Management Plans developed by local advisory councils (Oregon Department of Agriculture 2009). In addition, the Oregon Watershed Enhancement Board has awarded many millions of dollars in grants for voluntary stream restoration projects in the basin (Oregon Watershed Enhancement Board 2009).
Many of these Clean Water Act programs, Forest Practices Act requirements, restoration projects, and agricultural management plans include streamside vegetation and erosion control. The multiple functions of streamside vegetation suggest an elegant solution to mitigating biological stress factors. Many of the streamside restoration activities that are being funded are likely to have a positive impact on stream conditions and the aquatic organisms that live there.

But are these measures adequate? The fact that 46% of the stream and river miles are biologically impaired implies that there is still a lot of work to do. Much of the restoration activity being conducted today will take years before biological benefits can be measured. Concurrently, the future is likely to bring us more water quality challenges. If the population growth of the basin continues as it has in the past decades, the Portland-Eugene corridor will experience tremendous growth during the next century, due mostly to immigration (Lackey et al. 2006a). Predicted climate change could increase the average temperature in the basin by 2 to 7 °C during the next century, decrease the snowpack in the Cascades by 60%, and decrease summertime stream flows by 20 to 50% (Lackey et al. 2006b). The future will bring us even more demand for increasingly strained water resources. Current approaches to addressing water quality problems may be inadequate given the additional pressure of population growth and global warming. It will be more difficult to improve water quality and restore salmon populations in the future. We will have to work harder to maintain existing water quality and biological conditions, let alone make progress in restoring the health of water in the Willamette basin.

This information can be used by agricultural, municipal and forest land managers to help tailor more aggressive and comprehensive watershed protection, restoration activities, and controls of water quality impairment. In the future, this study will provide a foundation for interpreting the effectiveness of watershed restoration and protection actions at major land use scales and for understanding the cumulative effects of protection and restoration activities in the context of ongoing pressure from population growth, global warming, land use conversions and emerging water quality issues. The findings are even more crucial for planned development as population growth and global warming climate change creates potential for increased pressures on water quality and stream habitat crucial to survival of aquatic species and continuing quality of life in Oregon.

This assessment does point to opportunities for making significant improvements. Agricultural land use is both extensive in the Willamette basin and a significant source of water quality impairment. Agricultural Water Quality Management Plans are implemented by farmers on a largely voluntary basis. Other restoration activities to restore riparian areas on all lands are also diffuse and voluntary. Although these plans and restoration projects are focused on the right problems, they may not provide sufficient water quality and biological protection unless they are implemented in a more comprehensive way.

Appendix A: Setting Expectations: The Reference Condition Approach

Selecting Reference Sites:

To make an assessment of stream condition, one must define what constitutes acceptable conditions for each indicator. The reference condition approach has been widely used to identify least-disturbed conditions and set expected values or benchmarks for specific parameters, especially for parameters without clearly defined standards or criteria. Least-disturbed conditions represent “the best of what’s left” for any given region. In some parts of Oregon much of the landscape is relatively undisturbed, while in other regions the landscape has been altered more extensively by human activities. Our expectations of what constituted a natural range for an indicator of stress were based on regional reference sites within Level III Ecoregions (Thorsen et al. 2006). Ecoregions combine elements of geology, climate, elevation, and vegetative communities. Similar physiographic and biological characteristics make Level III Ecoregion a useful scale for deriving benchmarks based on reference condition.

To achieve an adequate sample size within each Level III Ecoregion, we aggregated reference sites across Oregon, Washington, and Idaho where ecoregions crossed state boundaries. Each state used slightly different protocols for selecting reference sites, however each protocol was based on a set of defined criteria for identifying the lowest levels of human disturbance in a region. ODEQ methods screen prospective reference sites at the local (reach) and watershed scales for the lowest levels of human activities (Drake 2004). USEPA methods employed aerial photos at the watershed scale, as well as including chemical and physical screens for reference identification (Stoddard et al. 2005a). Idaho DEQ (Grafe 2004) and Washington DOE (Plotnikoff 2001) combine reference selection procedures similar to both ODEQ and USEPA. Besides hand-picked reference sites, random W-EMAP sites that met reference site screening criteria were also used as reference sites. The hand-picked reference sites were not used in making population estimates.

A total of 319 reference sites were used to establish indicator benchmarks (Table 1A) for the assessment of perennial wadeable streams in Oregon. We aggregated some Level III Ecoregions as a result of the low number of available reference sites in the individual Ecoregions and the basic similarity of the aggregated Ecoregions. The Columbia Plateau, Snake River Plane and Northern Basin and Range Ecoregions were aggregated.

Setting Assessment Benchmarks:

Oregon and other states set water quality criteria to protect the beneficial uses of streams and rivers. For this assessment we used Oregon’s water quality standards to evaluate statewide conditions for those indicators with established numeric criteria (dissolved oxygen, temperature, and pH; Table 1A). When the standard was met, the water quality condition was considered “least disturbed”, and when the criteria
were not met, the water quality was considered “most disturbed”. For water quality and physical habitat indicators without numeric criteria, we used reference site values to establish three classes of stream condition. Where increasing indicator values were associated with a declining biological indicator response, the upper 75th and 95th percentiles of reference values were used to distinguish “least disturbed” (<75th), “moderately disturbed” (75th -95th), and “most disturbed” (>95th) classes. Where decreasing indicator values were associated with a declining biological indicator response, the lower 5th and 25th percentiles of reference values were used to distinguish “least disturbed” (>25th), “moderately disturbed” (5th -25th), and “most disturbed” (<5th) classes. The 5th /25th and 75th /95th benchmarks are consistent with the benchmarks used in USEPA’s EMAP-West report (Stoddard et al. 2005a).

**Note:** The table above includes various water quality benchmarks and standards for different ecoregions, along with additional data such as organic carbon standards and pH standards. The data is provided for different regions and includes various metrics such as conductivity, turbidity, total suspended solids, and dissolved oxygen. The benchmarks are based on Level 2 Ecoregions provided in Hubler, 2008, and include numeric standards for pH and temperature.

Appendix C: Relative Risk: evaluating stressor importance

The extent (% of stream miles) to which an indicator of stream condition exceeds certain benchmarks or criteria is one way to assess what parameters are degrading stream condition. Another way is to evaluate the risk a parameter poses to different biological assemblages, in this case macroinvertebrates or fish and amphibians. How can we assess the relative importance of the impairment created by a given stressor? To assess the risk a parameter poses to these assemblages, we have calculated the “relative risk” of specific habitat and chemistry parameters. It measures the likelihood that the biological condition will be impaired if the condition of an indicator is also poor.

Relative risk is an approach commonly used to communicate medical and health information such as the risk of smokers versus non-smokers of getting lung cancer. It is a useful tool for summarizing complex information and relationships in an easy to understand format. Relative risk can be defined as the probability of some poor outcome (getting a disease or degraded biological assemblage) when a poor stressor is present (smoking or poor streambed stability), divided by the probability of the poor outcome when the poor stressor condition is absent (Van Sickle et al., 2006).

In the following hypothetical example calculation of the risk of poor streambed stability to the macroinvertebrate community only the poor stressor condition is used. The fair stressor condition and moderately disturbed macroinvertebrate condition are not used.

<table>
<thead>
<tr>
<th>Estimated Stream Length (kilometers)</th>
<th>Stressor = Streambed Stability</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Good condition</td>
</tr>
<tr>
<td></td>
<td></td>
</tr>
<tr>
<td>Macr oinvertebrate Community Response</td>
<td>2,000</td>
</tr>
<tr>
<td>Most disturbed</td>
<td>9,000</td>
</tr>
<tr>
<td>Least Disturbed</td>
<td>Total</td>
</tr>
</tbody>
</table>

Relative Risk = \[
\frac{\text{Probability of Most Disturbed Biological Condition with Poor Streambed Stability}}{\text{Probability of Most Disturbed Biological Condition with Good Streambed Stability}}\]

\[
= \frac{8,000/9,000}{2,000/11,000} = \frac{0.89}{0.10} = 8.9
\]

This means that streams with poor streambed stability are nearly 9 times more likely to have most disturbed aquatic macroinvertebrates than streams with good streambed.

Large relative risk values for a parameter mean that the chances of having poor biotic condition are high when that parameter exceeds a certain threshold. For these analyses parameters with a relative risk value greater than 1.5, and where the 95% confidence interval is greater than 1.0, are considered significant. Relative risk values of 1.0 or less indicate insignificant parameter effect or risk.

Statistically significant risk factors are in bold type font and shaded blue. We consider a risk factor to be significant if the magnitude greater than 1.5 and 95% confidence interval (95%CI) greater than 1.0 are shaded blue and in bold type font.
