Health Evidence Review Commission's Value-based Benefits Subcommittee

Part 1

November 13, 2014

8:30 AM

Meridian Park Hospital
Community Health Education Center, Room 117B&C
19300 SW 65th Avenue, Tualatin, OR 97062

Section 1.0

Call to Order

Section 1.0

Staff Report

AGENDA
VALUE-BASED BENEFITS SUBCOMMITTEE
November 13, 2014
8:30am - 1:00pm
Meridian Park Room 117B&C
Community Health Education Center
Tualatin, OR 97062
A working lunch will be served at approximately 12:00 PM
All times are approximate

I. Call to Order, Roll Call, Approval of Minutes – Kevin Olson 8:30 AM

II. Staff report – Ariel Smits, Cat Livingston, Darren Coffman 8:35 AM
A. Update on the non-covered table

III. Biennial Review – Staff 8:40 AM
A. Report on the Back Pain Line Reorganization Task Force
B. Staff report on other biennial review updates/items

IV. Straightforward/Consent Agenda – Ariel Smits 8:50 AM
A. Straightforward table
B. Hip fracture treatment codes
C. Arthropod-borne viral fevers and viral hemorrhagic fevers
D. Determination of refraction
E. Diagnosis codes to be added to the Prioritized List from DMAP Excluded list review

V. 2015 CPT codes – Ariel Smits 9:00 AM
A. 2015 CPT codes
    A. Arthrocentesis
    B. 2015 CPT code issues
    C. Negative pressure wound therapy
    D. Genetic testing CPT codes
        1. High risk for breast cancer guideline
B. 2015 CDT codes
    A. Denture guideline

VI. New discussion items – Ariel Smits 11:00 AM
A. Unilateral tonsillar hypertrophy
B. Hemangiomas
C. Intraocular steroid implants

VII. Coverage Guidances for review – Ariel Smits 11:30 AM
A. Percutaneous interventions for cervical spine pain
B. Ablation for atrial fibrillation

C. Nuclear cardiac imaging

VIII. Previous Discussion Items – Cat Livingston, Ariel Smits 12:15 PM

A. Surgical treatment of sleep apnea in children with craniofacial anomalies

IX. Guidelines – Ariel Smits, Cat Livingston 12:25 PM

A. Adenoidectomy – revisions to the obstructive sleep apnea guideline and sinusitis surgery guideline
B. Retained tympanostomy tube guideline
C. Breastfeeding support and pumping supplies

X. Public comment 12:55 PM

XI. Adjournment – Kevin Olson 1:00 PM

Value-based Benefits Subcommittee Recommendations Summary
For Presentation to:
Health Evidence Review Commission in August 2014

For specific coding recommendations and guideline wording, please see the text of the 8-14-14 VbBS minutes.

RECOMMENDED CODE MOVEMENT (effective 10/1/14 unless otherwise noted)

- Make various straightforward coding changes
- Remove various nerve block procedure codes from lines on the Prioritized List and recommend they be returned to the Ancillary List
- Add diagnosis codes for diabetic retinopathy to the diabetic retinopathy line
- Add ICD-10 diagnosis codes for certain types of diabetes to the appropriate diabetes lines (effective 1/1/15)
- Remove diagnosis codes for chiropractic and osteopathic manipulation from the migraine headache line
- Add a new coding specification to the tension headache line specifying that chiropractic and osteopathic manipulation are on this line only for pairing with cervicogenic headache
- Move the diagnostic code for unspecified myopathy from the covered dysfunction lines to the new fibromyalgia line (effective 1/1/16)
- Add the diagnostic code for chronic fatigue syndrome to the new fibromyalgia line (effective 1/1/16)
- Remove diagnosis codes for osteomyelitis from the hyperbaric oxygen therapy line (to be reviewed by HERC in November, 2014)
- Add chemodenervation of the anal sphincter to the uncovered chronic anal fissure line
- Remove chemodenervation of extraocular muscles from the covered amblyopia line but leave on two covered strabismus lines
- Add various surgical codes for sex reassignment surgery to the gender dysphoria line (effective 1/1/15)

ITEMS CONSIDERED BUT NO RECOMMENDATIONS FOR CHANGES MADE

- Did not change the placement of tympanic membrane perforation diagnosis codes
- Leave diagnosis codes for unspecified rheumatism and fasciitis on a very low priority line rather than moving them to the new fibromyalgia line
- Did not change placement for botulinum toxin injections for treatment of neck or lower back pain or chronic daily headaches

RECOMMENDED GUIDELINE CHANGES (effective 10/1/14 unless otherwise noted)

- Eliminate the proposed guideline for treatments for Hepatitis C (which had been approved at the August 8, 2014 meeting)
- Modify the nerve block guideline to include the CPT codes for these procedures and make into an ancillary guideline

DRAFT

- Add a new guideline which specifies that removal of tympanostomy tubes is a covered service
- Modify the hyperbaric oxygen therapy guideline to add diabetic wounds as an indication, with specifics about when hyperbaric oxygen therapy would be appropriate (to be reviewed by HERC in November)
- Modify the spinal disorders guideline to require objective evidence of neurologic injury or radiculopathy
- Modify the rehabilitation guideline to limit the total number of therapy visits for all conditions to 30 per year, except for certain neurological conditions or when in an inpatient rehabilitation facility
- Modify the lymphedema guideline to specify that compression dressings/garments are covered for treatment of lymphedema even in the absence of complications
- Delete the Synagis guideline for RSV prophylaxis
- Add several new coding specifications regarding use of botulinum toxin and delete the guideline note regarding botulinum toxin use for bladder indications
- Modify the gender dysphoria guideline to add specifications for when cross-sex hormone therapy and sex reassignment surgery are appropriate (effective 1/1/15)

DRAFT

VAL□E-BASED BENEFITS S□BCOMMITTEE
Meridian Park Health
Community Health Education Center, Room 117B□C
Tualatin, OR
August 14, 2014
8:30 AM – 1:00 PM

Members Present: □evin Olson, MD, Chair; James Tyack, DMD; David Pollack, MD (left at 12:35 PM); Susan Williams, MD; Mark Gibson; Irene Croswell, RPh; Holly Jo Hodges, MD.

Members Absent: Laura Ocker, LAc.

Staff Present: Darren Coffman; Ariel Smits, MD, MPH; Cat Livingston, MD, MPH; Jason Gingerich; Denise Taray, RN; Daphne Peck.

Also Attending: Jesse Little, Actuarial Services Unit of DMAP; Laura Hill and Becky Reynolds, Abbvie; Sarah Schmidt, □oll; Camille □err and Deirdre Monroe, Allergan; Amy Burns and Mark Bradshaw, AllCare CCO; Josh Balloch, Pac/West Communications; Seth Adams, WVP Health Authority; □im Blood, WVCH; Jim Gardner, PhRMA; Bill Struyk, Johnson □Johnson; Paul Neilsen, Astra □eneca (Medimmune); Lisa Valaika, Genzyme; Rachel Seltzer, OHSU/OHA; Brian Neiubuurt, OHA; John Beckwith and Debbie Christensen, Sacred Heart Hospital; Aubrey Harrison, Danielle Askini, and Alex Lausen, Basic Rights Oregon; Megan Bird, MD, Legacy Health Systems; Ann Murray, BMS; Shannon Beatty, Medimmune; □athleen □lemann, FamilyCare; Lorren Sandt, Caring Ambassadors; Seth Johnstone and Jenn Burleton, TransActive; Eric Larsson, Lovaas Institute; Jim Murray, Hill-Ray; BJ Cavnor, One in Four Chronic Health; □ent Benner, MD, Oregon Clinic.

- **Roll Call□Minutes Approval□Staff Report**

  The meeting was called to order at 8:35 am and roll was called. Minutes from the June, 2014 VbBS meeting were previously reviewed and approved at the August 8th meeting. The minutes from the August 8th meeting are not yet available and will be reviewed and approved at the November, 2014 VBBS meeting.

  Coffman reviewed the timing of upcoming Prioritized Lists. The HERC retreat has been set for October 30, 2014. There was some discussion about whether this was a public meeting; staff will review the agenda and public meetings law and advise the commission.

  Note: line numbers referenced in these minutes are in the format of *October 1, 2014 line/January 1, 2015 line*

DRAFT

- **Topic: Straightforward Consent Agenda**

  Discussion: There was no discussion about the consent agenda items.

MOTION: To approve the consent agenda as presented CARRIES 7-0

Recommended Actions:

1) Add 40530 (Resection of lip, more than 1/4, without reconstruction) to line 292/279 CANCER OF S IN, E CLUDING MALIGNANT MELANOMA
2) Add 77418 (Intensity modulated treatment delivery, single or multiple fields/arcs, via narrow spatially and temporally modulated beams, binary, dynamic MLC, per treatment session) and 77421 (Stereoscopic -ray guidance for localization of target volume for the delivery of radiation therapy**)** to lines 252/242 CANCER OF OVAR and 459/439 CANCER OF GALLBLADDER AND OTHER BILIAR
3) Add 35606 (Bypass graft, with other than vein; carotid-subclavian) to line 440/419 TRANSIENT CEREBRAL ISCHEMIA; OCCLUSION/STENOSIS OF PRECEREBRAL ARTERIES WITHOUT OCCLUSION
4) Add 35452 (Transluminal balloon angioplasty, open; aortic) to line 472/452 ATHEROSCLEROSIS, AORTIC AND RENAL
5) Add 15120 (Split-thickness autograft, face, scalp, eyelids, mouth, neck, ears, orbits, genitalia, hands, feet, and/or multiple digits; first 100 sq cm or less, or 1% of body area of infants and children) and 15121 (each additional 100 sq cm, or each additional 1% of body area of infants and children, or part thereof) to line 448/427 COMPLICATIONS OF A PROCEDURE USUALL RE UIRING TREATMENT
6) Add 14040 (Adjacent tissue transfer or rearrangement, forehead, cheeks, chin, mouth, neck, axillae, genitalia, hands and/or feet; defect 10 sq cm or less) to line 459/438 H POSPADIAS AND EPISPADIAS
7) Add 62311 (Injection(s), of diagnostic or therapeutic substance(s),including anesthetic, antispasmodic, opioid, steroid, other solution, not including neurolytic substances, including needle or catheter placement, includes contrast for localization when performed, epidural or subarachnoid; lumbar or sacral) to lines 78/75 NEUROLOGICAL D SFUNCTION IN BREATHING, EATING, SWALLOWING, BOWEL, OR BLADDER CONTROL CAUSED B CHRONIC CONDITIONS; ATTENTION TO OSTOMIES and 318/297 NEUROLOGICAL D SFUNCTION IN POSTURE AND MOVEMENT CAUSED B CHRONIC CONDITIONS
8) Add 90670 (Pneumococcal conjugate vaccine, 13 valent) to line 3 PREVENTIVE SERVICES, BIRTH TO 10 EARS OF AGE and 4 PREVENTIVE SERVICES, OVER AGE OF 10 of the October 1, 2014 list and line 3 PREVENTION SERVICES WITH EVIDENCE OF EFFECTIVENESS of January 1, 2015 list
    a. Advise DMAP to remove 90670 from the Excluded List.

DRAFT

- **Topic: Nerve blocks**

  Discussion: Smits introduced the summary document regarding nerve blocks. The subcommittee felt that the return of these codes to the Ancillary List was the better of the two proposed staff recommendations. This will allow the nerve blocks to continue to be treated as anesthesia for the peri-operative uses. Additionally, HERC staff could not find previous discussion/rationale for moving these codes from Ancillary to the Prioritized List. The Subcommittee felt that this was likely a mistake and should be corrected. The guideline note is recommended to be changed to an Ancillary Guideline.

MOTION: To recommend the code and guideline note changes as presented CARRIES 7-0

Recommended Actions:

1) Remove all nerve block CPT codes (64400-64450) from lines on the Prioritized List
2) DMAP was advices to place CPT codes (64400-64450) on the Ancillary List
3) Make the current nerve block guideline into an Ancillary Guideline and modify to add the CPT codes. See Appendix A for final approved wording.
4) Note: The meeting materials mistakenly listed the code range as 64400-64550

- **Topic: Diabetic retinopathy codes**

  Discussion: Smits presented the staff summary for this topic. Allergan representatives informed staff that GN 116 needs to be considered for modification to allow pairing of intraocular steroids with the new FDA approved indication for limited use in diabetic retinopathy. Staff agreed to look into this possible GN change and bring back for further discussion at the November, 2014 VbBS meeting.

MOTION: To recommend the code changes as presented CARRIES 7-0

Recommended Actions:

1) Add the 362.0x codes (diabetic retinopathy, mild/moderate/severe, with or without proliferative retinopathy, and diabetic macular edema) to line 106/100 DIABETIC AND OTHER RETINOPATH
   a. Advise DMAP to remove the 362.0x codes from the Excluded List
   b. Note: there was a typographical error in the meeting materials. The correct ICD-9 code is 362.0x, not 367.0x
2) Add all codes in the E10.3xx family (Type 1 diabetes mellitus with ophthalmologic complications) to line 100 DIABETIC AND OTHER RETINOPATH for the January 1, 2015 Prioritized List

DRAFT

3) Add all codes in the E08.3xx family (diabetes due to underlying condition with retinopathy), E09.3xx family (drug or chemical induced diabetes with retinopathy), E11.3xx family (Type 2 diabetes mellitus with ophthalmologic complications), and E13.3xx family (other specified diabetes with retinopathy) to line 30 T□PE 2 DIABETES MELLITUS for the January 1, 2015 Prioritized List
4) Staff will review possible changes to GN116 for the November, 2014 VbBS meeting

- **Topic: Tympanostomy tube removal**

Discussion: Livingston reviewed the material in the packet for this topic. There was minimal discussion.

MOTION: To recommend the guideline note changes as presented□CARRIES 7-0□

Recommended Actions:
1) Make no changes to the placement of tympanic membrane perforation diagnosis codes
2) Add a new guideline specifying that retained tympanostomy tube removal is a covered procedure even if the underlying diagnosis for placement of these tubes was a non-covered diagnosis. See Appendix B for guideline wording.

- **Topic: Spinal manipulation for tension and migraine headaches**

Discussion: Smits reviewed the materials in the meeting packet for this topic. The subcommittee discussed that the evidence for treatment of migraine headache and tension headache showed moderate to good evidence of lack of effectiveness, which is generally a rationale for removing a service from a Prioritized List pairing. There was some discussion about adding a guideline note specifying what is meant by "cervicogenic headache." The group decided that such a guideline note could be added later if the health plans required assistance with this definition.

MOTION: To approve the code changes and coding specification as presented□ CARRIES 6-1 (Opposed: Hodges)□

Recommended Actions:
1) Remove osteopathic and chiropractic manipulation (CPT 98926- 98929, 98940-98943) from line 435/414 MIGRAINE HEADACHES
2) Add the following coding specifications to line 563/546 TENSION HEADACHES
    i. "OMT and CMT (CPT 98926- 98929, 98940-98943) pair on this line only with cervicogenic headache (R51)."

DRAFT

- **Topic: Wearable cardiac defibrillators**

  Discussion: Smits reviewed the packet materials regarding wearable cardiac defibrillators. Sarah Schmidt, representing □oll, the company which manufactures Life Vest, gave testimony that the purpose of this device is a temporary use until ICD placement or until the patient has his or her medications optimized and no longer will need an ICD. Ms. Schmidt noted that the studies regarding the effectiveness of Life Vest have difficulties in their methodology, although she was unsure what the issues with the methodology actually were. These methodology issues are the reason that no mortality benefit was seen in these studies. Ms. Schmidt stated that there are studies which show what the therapeutic shock rates were, and noted that she can provide these studies to HERC staff. She noted that in the □oll studies, 74% of patients who received a shock were alive 6 months later. She noted that the Life Vest allows discharge from hospital sooner. □oll is currently conducting an RCT of the Life Vest with planned release of the results in fall 2015.

  Subcommittee discussion centered around how successfully the vests stop ventricular fibrillation or ventricular tachycardia, and how often the shocks given by the vests are for these arrhythmias. It was noted that the lethal rhythms treated by this device generally have no symptoms other than sudden death, and so cannot be adequately treated by other means besides a bedside defibrillator. There is increasing numbers of requests for these devices. Hospitals and physicians are hesitant to discharge patients without these devices, as there is not another method in place to treat any fatal arrhythmias which might occur at home. Olson requested data on how often these devices are successfully converting serious arrhythmias. If was noted that the lack of evidence of effective reduction in mortality might stem from lack of patient compliance with wearing the device. Hodges noted that Life Vest use can be monitored, and that her health plan takes back the device if it is not being worn 21 or more hours a day.

  The decision was made to table this topic and have HERC staff find more information on the rate of successful shock of such lethal rhythms as ventricular fibrillation or ventricular tachycardia.

  Action:
  1) This topic was tabled until the November, 2014 VBBS meeting.

- **Topic: Fibromyalgia related diagnoses (general conditions and chronic fatigue syndrome)**

  Discussion: Smits reviewed the materials of general conditions related to fibromyalgia. The subcommittee felt that Rheumatism, unspecified and Fasciitis,

DRAFT

unspecified should not be moved to the fibromyalgia line as this would raise their priority on the Prioritized List.

Smits also reviewed the materials summarizing the research and recommendations regarding chronic fatigue syndrome. There was minimal discussion.

MOTION: To approve the code changes and line name change as amended CARRIES 7-0

Recommended Actions:

1) Move ICD-9 359.9 (Myopathy, unspecified) from lines 75,297,349,381 to the new fibromyalgia line
2) eep ICD-10 G72.9 (Myopathy, unspecified) on the Excluded List.
3) Add chronic fatigue syndrome (ICD-9 780.71/ICD-10 R53.82) to the new fibromyalgia line
    a. Advise DMAP to remove ICD-9 780.71/ICD-10 R53.82 from the Excluded List
4) Change line name to "Fibromyalgia, Chronic Fatigue Syndrome, and Related Disorders"

- **Topic: Coverage guidance—Hyperbaric Oxygen**

Discussion: Smits reviewed the packet materials regarding hyperbaric oxygen coverage. There was minimal discussion.

MOTION: To approve the code and guideline note change as presented CARRIES 7-0

Recommended Actions:

For the biennial review (to be reviewed by HERC later in the day)

1) Combine the two hyperbaric oxygen lines (lines 336 and 373) into one line placed at line 336 for the next biennial Prioritized List.

For review by HERC in November, along with the coverage guidance, for potential inclusion in January 1, 2015 list:

1) Add ICD-9 250.7, 250.8 and ICD-10 E11.5x,E11.621,E11.622,E11.628, S07.xxx,S17.xxx,S38.xxx, S57.xxx,S67.xxx, S77.xxx,S87.xxx,S97.xxx,and T79.Axx, to line 336 TO IC EFFECT OF GASES, FUMES, AND VAPORS RE UIRING H PERBARIC O GEN
2) Remove ICD-9 526.4, 686.00-686.09,709.3 and ICD-10 M46.20-M46.39 and M86.9 from line 336
3) Modify GN 107 as shown in Appendix A

DRAFT

- **Topic: Coverage guidance—percutaneous interventions for cervical spine pain**

  Discussion: The summary document was reviewed. A mistake in the recommendations was found: CPT 64490-64495 was proposed for exclusion as well as for addition to 3 lines on the Prioritized List. The proposed placement on the Excluded list was a mistake.

  Hodges cautioned that there would be a large demand for these types of procedures is coverage is added. Gibson expressed concern that the recommendations from HTAS to cover cervical epidural steroid injections and facet joint neurotomy were weak and based on a weak level of evidence. Shaffer commented that HTAS was led to recommend coverage based on the evidence plus clinical expertise and a desire to avoid more costly alternatives, such as spinal surgery. Gibson noted that the CCOs could elect to cover these procedures for cases in which they would help avoid a surgery, without adding these services to the Prioritized List and requiring coverage in all cases. He was concerned about adding these procedures to the Prioritized List based on weak evidence and provider testimony. The HTAS report was reviewed. The rational for recommending adding coverage for epidural spinal steroid injections was found to be "Though quality of evidence from trusted sources is very low, there is evidence from additional sources, namely a retrospective single cohort study, of some benefit when the recommended criteria are met. Additionally, other payer policies include a similar recommendation, namely Medicare and Washington State's payer policies." Williams expressed concern over using a retrospective cohort study as the basis for the decision. There was general concern over the low level of evidence and over using other payer policies as a deciding factor for adding a service to the Prioritized List. However, some members noted that these types of procedures may prevent surgery, reduce ER visits, lower narcotic use, and have other beneficial outcomes.

  HERC staff clarified that currently, epidural steroid injections are ancillary. This was felt to give these procedures the same status as procedures already included for coverage on the Prioritized List—such procedures must have evidence of ineffectiveness or evidence of harm or lower cost effectiveness compared to other procedures in order to be taken off the Prioritized List and therefore take away existing coverage. Procedures considered for initial addition to the list have a higher bar—they must have good evidence of effectiveness. The group initially felt that ancillary procedures should have the lower bar of evidence for inclusion on the List. However, this topic was readdressed later in the meeting, and several subcommittee members expressed concern with this policy. It was felt that many ancillary procedures were never formally reviewed and had a formal placement decision. Therefore, these procedures should be fully reviewed before addition to the List, just like new procedures. HERC staff agreed that this policy needed to be discussed further and placed it on the agenda for the VBBS/HERC retreat in October.

DRAFT

Hodges noted that clarification of when epidural steroids should be covered, such as in the proposed guideline, would be very helpful for the CCOs as these procedures are currently covered as ancillary. Shaffer noted that these injections are treatments and do not belong on the Ancillary List. Therefore, some placement decision needs to be made.

The subcommittee members noted that facet joint neurotomy was currently excluded. The evidence summary in the HTAS report stated that the recommendation for addition to coverage was based on the following: "Though quality of evidence from trusted sources is very low, the evidence shows there is some benefit when the recommended criteria are met. Coverage with these criteria was recommended by appointed expert." There was general agreement that expert opinion was not good enough evidence to justify coverage when the quality of evidence from trusted sources was very low. The group felt that facet joint neurotomy should not be added to the List.

Initially, the subcommittee voted to approve the addition of epidural steroid injections with the appropriate guideline and to not approve the addition of facet joint injections (Vote 6-0 with Pollack abstaining). However, this decision was reopened at a later point in the meeting and voided (Vote 7-0). The subcommittee wished to have this topic returned for further discussion to their November meeting.

Actions:
1) HERC staff will add a discussion about the level of evidence required for adding ancillary procedures to the Prioritized List to the VBBS/HERC agenda for the October retreat
2) This topic was tabled for further discussion in November.

- **Topic: Guideline Note 37, Disorders Of Spine With Neurologic Impairment**

Discussion: Smits introduced the summary document on this topic. There was no discussion.

MOTION: To approve the guideline note changes as presented CARRIES 7-0

Recommended Action:
1) GN 37 was modified as shown in Appendix A

- **Topic: Rehabilitation guideline**

Discussion: Smits reviewed the packet materials regarding suggested changes to the rehabilitation guideline. Olson expressed frustration with the medical directors requesting changes to VbBS decisions when they are not coming to

DRAFT

VbBS meetings. Smits noted that there has not been a medical director representative on the VbBS for over a year, since Chris □irk left. This meeting is the first official meeting for the new medical director representative, Holly Jo Hodges, who promised to bring the medical directors input to the VbBS meetings going forward.

The subcommittee felt that the staff recommended wording, including the suggesting additional wording, for the rehabilitation guideline was acceptable.

MOTION: To approve the guideline note changes as presented with additional optional language in the meeting materials□CARRIES 7-0□

Recommended Action:
1) Modify the rehabilitation guideline wording as shown in Appendix A

- **Topic: Lymphedema guideline**

Discussion: Smits presented the summary on proposed changes to the lymphedema guideline. John Beckwith, PT, testified that he was very concerned that the language in the guideline be very clear that compression dressings/garments were covered even when no complications were present. The subcommittee felt that the wording was sufficient. Hodges requested that clarification be made to the guideline to specify whether compression dressings included compression garments. Smits offered amended wording, adding in the term "garments." Beckwith requested that chronic venous insufficiency (CVI) be covered for compression dressings when appropriate. Smits reviewed her previous findings that CVI includes a range of conditions, from very mild to quite severe. It would be difficult to write a guideline specifying at what stage CVI was covered. The subcommittee requested that HERC staff work with experts to see if some coverage of compression dressings/garments should be done for CVI.

MOTION: To approve the guideline note changes as amended□CARRIES 7-0□

Recommended Actions:
1) GN 43 was modified as shown in Appendix A
2) HERC staff to evaluate potential coverage of compression dressings/garments for chronic venous insufficiency and bring back for subcommittee review at a future date

- **Topic: Denture guideline**

Discussion: This topic was tabled until the November, 2014 VbBS meeting.

DRAFT

- **Topic: Adenoidectomy—revisions to the obstructive sleep apnea guideline and sinusitis surgery guideline**

  Discussion: This topic was tabled until the November, 2014 VbBS meeting.

- **Topic: RSV guideline**

  Discussion: Livingston reviewed the summary document for proposed revisions to the RSV guideline. The CCO representatives testified that referring to P□T criteria would not be acceptable to them. The CCOs have their own committees and develop their own coverage criteria. They do not attend or participate in DMAP's P□T Committee meetings and do not feel that their preferences or opinions are taken into account in the P□T decision making process. If no guideline referring to P□T was adopted, then coverage of Synagis would revert to the individual CCO P□T committee decisions (or DMAP P□T coverage guidance for fee-for-service patients). This was felt to be the preferable alternative.

  There was also public comment received from Paul Nielson, Astra□eneca, who raised concerns about the quality of the new American Academy of Pediatrics guideline on RSV prophylaxis.

  The subcommittee decided to not adopt a new guideline referring to DMAP P□T criteria. However, it was recognized that the current Synagis guideline was out of compliance with national coverage recommendations by the American Academy of Pediatrics. Because DMAP and CCO P□T committee decisions can be much more timely than VbBS/HERC guideline note changes, the subcommittee decided to remove the Synagis guideline and similar drug related guidelines and not add any guidelines referring to DMAP P□T decisions.

MOTION: To approve the guideline note deletion but reject the proposed new guideline note□CARRIES 7-0□

Recommended Action:
1) Delete GN 69

- **Topic: Botulinum toxin**

  Discussion: Smits reviewed the summary document regarding Botox. The VbBS had previously indicated that they did not wish to have guidelines referring to the DMAP P&T coverage criteria (see "RSV guideline" discussion above). The proposed new guideline referring to P□T criteria was therefore not accepted.

MOTION: To approve the coding changes, coding specifications and guideline note deletion but not the proposed new guideline note□CARRIES 7-0□

DRAFT

Recommended Actions:

1) Add 46505 (Chemodenervation of internal anal sphincter) to line 506/532 CHRONIC ANAL FISSURE
2) Remove 67345 (Chemodenervation of extraocular muscle) from line 397/372 AMBL□OPIA
3) Do not add coverage for botulinum toxin injections for treatment of neck or lower back pain or chronic daily headaches
4) □eep the coding specification shown below on line 388/364 D□STONIA (UNCONTROLLABLE); LAR□NGEAL SPASM AND STENOSIS
   a. "Chemodenervation with botulinum toxin injection (CPT 64612, 64616) is included on this line only for treatment of blepharospasm (ICD-9 333.81/ICD-10-CM G24.5), spasmodic torticollis (ICD-9 333.83/ICD-10-CM G24.3), and other fragments of torsion dystonia (ICD-9 333.89/ICD-10-CM G24.9)."
5) Add the coding specification shown below to line 318/297 NEUROLOGICAL D□SFUNCTION IN POSTURE AND MOVEMENT CAUSED B□ CHRONIC CONDITIONS
   a. "Chemodenervation with botulinum toxin injection (CPT 64642-64647) is included on this line for treatment of upper and lower limb spasticity (ICD-9 333.6x, 333.7x, 340.xx, 341.0, 342.xx, 343.xx, 344.0x, 344.1, 344.2, 344.3x, 344.4x, 344.5, 344.89, 344.9, 359.0-359.2, 438.2x-438.5x/ICD-10 G24.02, G24.1, G35, G36.0, G71.xx, G80-G83, I69.03-I69.06).
6) Add the coding specification shown below to lines 452 STRABISMUS WITHOUT AMBL□OPIA AND OTHER DISORDERS OF BINOCULAR E□E MOVEMENTS; CONGENITAL ANOMALIES OF E□E/354 STRABISMUS DUE TO NEUROLOGIC DISORDER and 398 STRABISMUS WITHOUT AMBL□OPIA AND OTHER DISORDERS OF BINOCULAR E□E MOVEMENTS; CONGENITAL ANOMALIES OF E□E; LACRIMAL DUCT OBSTRUCTION IN CHILDREN
   a. "Chemodenervation with botulinum toxin injection (CPT 67345) is included on this line for the treatment of strabismus due to other neurological disorders (ICD-9 378.73 /ICD-10 H50.89)."
7) Add the coding specification shown below to line 421 ACHALASIA, NON-NEONATAL/382 ESOPHAGEAL STRICTURE; ACHALASIA
   a. "Chemodenervation with botulinum toxin injection (CPT 43201) is included on this line for treatment of achalasia (ICD-9 530.0/ICD-10 K22.0)."
8) Add the coding specification shown below to line 542/523 DISORDERS OF SWEAT GLANDS
   b. "Chemodenervation with botulinum toxin injection (CPT 64650, 64653) is included on this line for the treatment of axillary hyperhidrosis and palmar hyperhidrosis (ICD-9 705.2 and 780.8/ICD-10 L74.52, R61).
9) Delete GUIDELINE NOTE 103, CHEMODENERVATION OF THE BLADDER

DRAFT

➢ **Topic: Gender dysphoria**

Discussion: Smits reviewed the summary document in the meeting packet. There was considerable discussion regarding concerns for lack of an age restriction for surgical procedures. Smits reviewed that the Oregon age of consent for surgical procedures is age 15. Olson felt that these types of procedures should not be singled out for restriction until age 18 or even higher, as many other procedures which have life-long impact can be consented to at age 15. Expert testimony by Danielle Askini from Basic Rights Oregon and Jenn Burleton from TransActive indicated that youth are required to have extensive evaluations by qualified mental health professionals and that the year of hormone therapy required in the guideline acts as another safeguard against rash decisions by youth.

There was a minor edit to the proposed guideline to add in a missing word.

MOTION: To approve the line rescoring, updated treatment description, and the addition of cross-sex hormone therapy and various surgical procedures related to sex reassignment to the gender dysphoria line, and the new guideline as amended CARRIES 5-1 (Opposed: Tyack, Absent: Pollack)

Recommended Actions:

1) Change the treatment description of the gender dysphoria line to ~~MEDICAL/PS CHOTHERAP~~ MEDICAL AND SURGICAL TREATMENT; PS CHOTHERAP
2) Rescore the gender dysphoria line as shown below:
    a. Scoring proposal
    Category: 6
    HL: 6
    Suffering: 4
    Population effects: 0
    Vulnerable population: 0
    Tertiary prevention: 3
    Effectiveness: 2
    Need for service: 1
    Net cost: 2
    Score: 1040
    Approximate line placement: 312
3) Add cross-sex hormone therapy to the new gender dysphoria line
4) Add CPT 19301-19304, 53430, 54125, 54400-54417, 54520, 54660, 54690, 55175-55180, 55970, 55980, 56625, 56800, 56805, 56810, 57106-57107, 57110-57111, 57291-57292, 57335, 58150, 58180, 58260-58262, 58275-58291, 58541-58544, 58550-58554, 58570-58573, 58661, 58720 to the new gender dysphoria line
    a. Advise DMAP to remove CPT 55970 and 55980 from the Excluded List

DRAFT

5) Modify the guideline for the new gender dysphoria line as shown in Appendix A
6) Note that all of these recommended actions would take effect on January 1, 2015 when the new gender dysphoria line appears on the Prioritized List

- **Topic: Hepatitis C**

Discussion: Livingston reviewed the summary document regarding treatments for hepatitis C in the meeting packet. Written testimony from CCOs, legislators and concerned citizens was received.

The following public testimony was received verbally:

Amy Burns and Mark Bradshaw from AllCare presented a collaborative statement from 9 CCOs. The collective strongly discouraged a guideline note requiring CCOs to adhere to the P□T Committee's drug use criteria. They strongly felt that each CCO manages their own drug use and formularies and this drug class should be no different. They also had specific concerns about the criteria including:

1) Allowing off-label use of simeprevir and sofosburiv
2) Allowing for off-label use for patients who are post transplant. This goes against OARs that do not allow for investigational or experimental practices. There is no outcome data to support this. The liver transplant population has not been studied and is not recommended in the Sovaldi package insert.
3) Subjective language around who can prescribe
4) Important psychosocial and medical factors around treatment that aren't addressed

Jim Gardner, Oregon Council for PhMRA, a paid advocate, recommended not looking at single therapeutic products and raised legal concerns with this approach.

Ann Murray, Bristol Myers Squibb, stated that she thinks this would be the first time HERC would have taken this approach, in which a treatments for a condition appear both on a funded and unfunded line.

Subcommittee members made a request to PhRMA to decrease the cost of the drug, with the answer that they appreciated the comment.

□imberly Wyatt, Willamette Valley Community Health CCO and Dr. Seth Adams, pharmacist with WVCH, offered public comment. They stated they have their own pharmacy and therapeutics committee and have already created PA criteria for approval of these medications. It is important to the CCOS to have freedom to develop their own criteria. If there was going to be

DRAFT

accountability to another organization (DMAP's P□T Committee) then CCOs would have wanted to be responsible in the development of these criteria.

Subcommittee members asked about the CCOs concerns regarding criteria in the proposed guideline note for drug and alcohol testing. It was clarified that they felt 6 months sobriety was too short of a time. They also require a mental health evaluation to assess readiness to treat and ascertain whether patients are compliant with prescription drugs for other diseases, such as diabetes and hypertension.

Lorren Sandt, from Caring Ambassadors, and BJ Cavnor, 1 in 4 Chronic Disease, testified as well, both stating pharmaceutical funding for their organizations. Sandt requested hepatitis C drug treatments should remain above the funding line and that everyone with hepatitis C should be treated with these drugs. She also pointed to the AASLD/IDSA guideline not requiring abstinence or sobriety. Cavnor requested a workgroup that would follow national guidelines and demanded that all people be allowed to come to the table.

Dr. □ent Benner offered testimony with no current conflicts of interest. He spoke about the community standard that was developed by local hepatologists, and discussed the rationale for this.

Subcommitee members discussed the significant impact of these medications on the budget. There was a proposal to table the decision. Given the concerns CCOs have about the reference to P□T criteria, the need for ongoing dialogue, the new AASLD guidelines, it was felt that a final decision on this policy should be tabled until a future meeting.

It was clarified that there will be a pharmacoeconomic anlaysis available by the November meeting and that an updated DERP report and NICE guidelines may be available later this year or early next year as well.

MOTION: To reject the proposed new guideline regarding treatment of hepatitis C and table the topic until a future meeting□CARRIES 7-0□

Recommended Actions:

1) None

- **Topic: Proposed "Non covered" section of the Prioritized List**

Discussion: Smits introduced this topic and noted that the new "non-covered" table was presented for approval in concept only. There was minimal discussion.

DRAFT

Actions:

1) HERC staff will continue to work on developing the "non-covered" table and will publish it as a new portion of the January 1, 2015 Prioritized List.

- **Topic: Applied behavioral analysis for treatment of non-autistic self-injurious behavior**

  Discussion: This topic was tabled to the August HERC meeting.

  Actions: See minutes from the August HERC meeting.

- **Topic: Standardized assessment tools for evaluating progress for autism spectrum disorder**

  Discussion: This topic was tabled to the August HERC meeting.

  Actions: See minutes from the August HERC meeting.

- **Public Comment:**

  No additional public comment was received.

- **Issues for next meeting:**
  - Wearable cardiac defibrillators
  - Denture guideline
  - Adenoidectomy—revisions to the obstructive sleep apnea guideline and the sinusitis surgery guideline
  - Coverage guidance—percutaneous interventions for cervical spine pain
  - A new breastfeeding supplies guideline
  - Unilateral hearing loss in adults
  - OMT/CMT and the dysfunction lines
  - Tobacco cessation coverage
  - Tobacco smoking and procedures
  - PET scan for fever of unknown origin
  - Unilateral tonsillar hypertrophy
  - Various straightforward coding changes

- **Next meeting:**

  November 13, 2014 at Meridian Park Health Education Center, Tualatin, OR Room 117B□C.

DRAFT

- **Adjournment:**

  The meeting was adjourned at 1:30 PM.

DRAFT

Appendix A

Revised Guideline Notes

~~G□IDELINE NOTE 76~~ ANCILLARY G□IDELINE A3, NERVE BLOCKS *(Effective October 1, 2014)*

~~Lines 1,3,6,8,9,11,20,24,25,28,30,32,37-41,46-55,59-63,65,67,68,70-76,81-100,102-105,107,109-112,115-121,123-125,129-132,134-145,147,148,154,156-164,166-170,172-175,178,180,183-195,197-201,203,204,206,208,209,211-214,216-221,223,225-228,230,232-239,241-251,253-255,257-267,269,273-275,277-280,283-286,289-294,297-306,308-312,314-317,319-324,327,328,330-335,337-341,343,344,346,349,350,352,354-360,362-370,372,374-376,378-384,386,389,391,392,394,397-402,404-408,410,412,417,419-424,426-428,430-436,438-441,443-447,450,452,453,456,458,459,464-466,468-472,474,476,477,480-484,486,487,496,504,519,526,527,532,535,549,568,630~~

The Health Evidence Review Commission intends that single injection and continuous nerve blocks (CPT 64400-64550) should be covered services if they are required for successful completion of, perioperative pain control for, or post-operative recovery from a covered operative procedure when the diagnosis requiring the operative procedure is also covered. Additionally, nerve blocks are covered services for patients hospitalized with trauma, cancer, or intractable pain conditions, if the underlying condition is a covered diagnosis.

G□IDELINE NOTE 6, REHABILITATIVE THERAPIES *(Effective October 1, 2014)*

Lines 37,50-52,64,74-76,78,80,85,89,90,94,95,98-101, 108, 109, 115, 116, 122, 129, 139, 141-143,145,146,158,161,167,179,184,185,189, 190, 192, 194, 195, 201, 202, 208,209,216,226,237,239,270,271,273,274,279,288,289,293,297,302,304,307-309, 318, 336,342,349, 350, 363, 367, 369, 375,376,378, 382,384,385,387, 400,406, 407, 434, 441,443,448,455,467,478,489,493,507,516,535,549,562,580, 597,619,638

A total of 30 visits per year of rehabilitative therapy (physical, occupational and speech therapy, and cardiac and vascular rehabilitation) are included on these lines when medically appropriate. Additional visits, not to exceed 30 visits per year, may be authorized in exceptional circumstances, such as in cases of rapid growth/development. Physical, occupational and speech therapy, and cardiac and vascular rehabilitation are only included on these lines when the following criteria are met:

1) therapy is provided by a licensed physical therapist, occupational therapist, speech language pathologist, physician, or other practitioner licensed to provide the therapy,
2) there is objective, measurable documentation of clinically significant progress toward the therapy plan of care goals and objectives,
3) the therapy plan of care requires the skills of a ~~therapist~~ medical provider, and
4) the client and/or caregiver cannot be taught to carry out the therapy regimen independently.

DRAFT

Appendix A

No limits apply while in a skilled nursing facility for the primary purpose of rehabilitation, an inpatient hospital or an inpatient rehabilitation unit.

Spinal cord injuries, traumatic brain injuries, or cerebral vascular accidents are not subject to the visit limitations during the first year after an acute injury.

G□IDELINE NOTE 37, DISORDERS OF SPINE WITH NE□ROLOGIC IMPAIRMENT *(Effective October 1, 2014)*

Lines 374,545

Diagnoses are included on Line 374 when objective evidence of neurologic impairment or radiculopathy is present, as defined as:

A) Markedly abnormal reflexes
B) Segmental muscle weakness
C) Segmental sensory loss
D) EMG or NCV evidence of nerve root impingement
E) Cauda equina syndrome,
F) Neurogenic bowel or bladder
G) Long tract abnormalities

Otherwise, disorders of spine not meeting these criteria (e.g. pain alone) fall on Line 545.

G□IDELINE NOTE 43, LYMPHEDEMA *(Effective October 1, 2014)*

Lines 448,597,598

Lymphedema treatments are included on these lines when medically appropriate. These services are to be provided by a licensed practitioner who is certified by one of the accepted lymphedema training certifying organizations or a graduate of one of the National Lymphedema Network accepted training courses within the past two years. The only accepted certifying organization at this time is LANA (Lymphology Association of North America; http://www.clt-lana.org). Treatments for lymphedema are not subject to the visit number restrictions found in Guideline Note 6 REHABILITATIVE THERAPIES. It is the intent of the HERC that compression dressings/garments and other medical equipment needed for the treatment of lymphedema be covered even in the absence of ulcers or other complications.

G□IDELINE NOTE 43, LYMPHEDEMA *(Effective January 1, 2016)*

Line~~s 427,577,579~~ XXX (new lymphedema line ~427)

Lymphedema treatments are included on this line ~~these lines~~ when medically appropriate. These services are to be provided by a licensed practitioner who is certified by one of the accepted lymphedema training certifying organizations or a graduate of one of the National Lymphedema Network accepted training courses within the past two years. The only accepted certifying organization at this time is LANA (Lymphology

Association of North America; http://www.clt-lana.org). Treatments for lymphedema are not subject to the visit number restrictions found in Guideline Note 6 REHABILITATIVE THERAPIES.-It is the intent of the HERC that compression dressings/garments and other medical equipment needed for the treatment of lymphedema be covered even in the absence of ulcers or other complications.

G□IDELINE NOTE 107, HYPERBARIC O□YGEN *(Effective date pending HERC review of coverage guidance, not to be prior to January 1, 2015)*

Lines 336~~,373~~ (delete only for biennial review List)

Hyperbaric oxygen is a covered service only under the following circumstances:

- ~~when paired with ICD-9-CM code 526.4 for osteomyelitis of the jaw only~~
- when paired with ICD-9-CM codes 250.7x and 250.8x/ICD-10-CM E11.5x and E11.621,E11.622,E11.623 for diabetic wounds with gangrene OR diabetic wounds of the lower extremities in patients who meet the all of the following criteria:
    - Patient has Type 1 or Type 2 diabetes and has a lower extremity wound that is due to diabetes, AND
    - Patient has a wound classified as Wagner grade III or higher, AND
    - Patient has failed an adequate course of standard wound therapy including arterial assessment, with no measurable signs of healing after at least thirty days, AND
    - Wounds must be evaluated at least every 30 days during administration of hyperbaric oxygen therapy. Continued treatment with hyperbaric oxygen therapy is not covered if measurable signs of healing have not been demonstrated within any 30-day period of treatment.
- when paired with ICD-9-CM codes 526.89/ ICD-10--CM codes M27.8 for osteoradionecrosis of the jaw only
- when paired with ICD-9-CM codes 639.0, 670.02, and 670.04/ ICD-10--CM codes O08.0, M60.000-M60.09 only if the infection is a necrotizing soft-tissue infection
- ~~when paired with ICD-9-CM codes 730.10-730.99/ICD-10-CM M46.20-M46.39, M86.9 only for chronic refractory osteomyelitis unresponsive to conventional medical and surgical management~~
- when paired with ICD-9-CM codes 927-929/ICD-10 CM codes S07.xxx,S17.xxx,S38.xxx,S47.1xxA-S47.1xxD,S47.2xxA-S47.2xxD,S47.9xxA-S47.9xxD, S57.xxx,S67.xxx, S77.xxx,S87.xxx,S97.xxx, T79.Axx, only for posttraumatic crush injury of Gustilo type III B and C
- when paired with ICD-9-CM codes 990/ ICD-10--CM codes T66.xxxA only for osteoradionecrosis and soft tissue radiation injury
- when paired with ICD-9-CM codes 996.52, 996.7/ ICD-10--CM codes T86.820-T86.829,T82.898A, T82.898D, T82.9xxA, T82.9xxD, T83.89xA, T83.89xD, T83.9xxA, T83.9xxD, T84.89xA, T84.89xD, T84.9xxA, T84.9xxD, T85.89xA, T85.89xD, T859xxA, T859xxD only for compromised myocutaneous flaps.

DRAFT

Appendix A

G□IDELINE □□□ GENDER DYSPHORIA *(Effective January 1, 2015)*

Line 413

Hormone treatment is included on this line for use in delaying the onset of puberty and/or continued pubertal development with GnRH analogues for gender questioning children and adolescents. This therapy should be initiated at the first physical changes of puberty, confirmed by pubertal levels of estradiol or testosterone, but no earlier than Tanner stages 2-3. Prior to initiation of puberty suppression therapy, adolescents must fulfill eligibility and readiness criteria, and must have a comprehensive mental health evaluation. Ongoing psychological care is strongly encouraged for continued puberty suppression therapy.

Cross-sex hormone therapy is included on this line for treatment of adolescents and adults with gender dysphoria who meet appropriate eligibility and readiness criteria. To qualify for cross-sex hormone therapy, the patient must:

1) have persistent, well-documented gender dysphoria
2) have the capacity to make a fully informed decision and to give consent for treatment
3) have any significant medical or mental health concerns reasonably well controlled
4) have a thorough psychosocial assessment by a qualified mental health professional with experience in working with patients with gender dysphoria

Sex reassignment surgery is included for patients who are sufficiently physically fit and meet eligibility criteria. To qualify for surgery, the patient must:

1) have persistent, well documented gender dysphoria
2) have completed twelve months of continuous hormone therapy as appropriate to the member's gender goals unless hormones are not clinically indicated for the individual
3) have completed twelve months of living in a gender role that is congruent with their gender identity unless a medical and a mental health professional both determine that this requirement is not safe for the patient
4) have the capacity to make a fully informed decision and to give consent for treatment
5) have any significant medical or mental health concerns reasonably well controlled
6) have two referrals from qualified mental health professionals with experience in working with patients with gender dysphoria who have independently assessed the patient. Such an assessment should include the clinical rationale supporting the patient's request for surgery, as well as the rationale for the procedure(s)

Code	Code Description	Line(s) Involved	Issue	Recommendation(s)
26426	Repair of extensor tendon, central slip, secondary (eg, boutonniere deformity); using local tissue(s), including lateral band(s), each finger	**211** DEEP OPEN WOUND, WITH OR WITHOUT TENDON OR NERVE INVOLVEMENT **290** COMPLICATIONS OF A PROCEDURE ALWAYS REQUIRING TREATMENT **380** DISRUPTIONS OF THE LIGAMENTS AND TENDONS OF THE ARMS AND LEGS, EXCLUDING THE KNEE, RESULTING IN SIGNIFICANT INJURY/IMPAIRMENT **391** DEFORMITY/CLOSED DISLOCATION OF MINOR JOINT AND RECURRENT JOINT DISLOCATIONS	DMAP requested that 26426 pair with 736.21 (boutonniere deformity), which is on lines 381 (dysfunction line) and 391. 26426 is on lines 211,290,380. Boutonniere deformity is a condition of the finger. 26426 involves surgery on a finger, which is inappropriate for line 380	Remove 26426 from line 380 Add 26426 to line 391
64721	Neuroplasty and/or transposition; median nerve at carpal tunnel	**211** DEEP OPEN WOUND, WITH OR WITHOUT TENDON OR NERVE INVOLVEMENT	DMAP requested that 64721 pair with 955.1 (Injury to median nerve). 64721 is on lines 420,511,534,430.	Add 64721 to line 211
57287	Removal or revision of sling for stress incontinence (eg, fascia or synthetic)	290 COMPLICATIONS OF A PROCEDURE ALWAYS REQUIRING TREATMENT	DMAP requested that 57287 pair with 996.39 (Other mechanical complication of genitourinary device, implant, and graft). 57287 is currently on lines 331,459,471.	Add 57287 to line 290
34203	Embolectomy or thrombectomy, with or without catheter; popliteal-tibio-peroneal artery, by leg incision	**290** COMPLICATIONS OF A PROCEDURE ALWAYS REQUIRING TREATMENT	DMAP requested that 34203 pair with 996.74 (Other complications due to other vascular device, implant, and graft). 34203 is on lines 239,257,352.	Add 34203 to line 290

Straightforward Issues—November, 2014

Code	Code Description	Line(s) Involved	Issue	Recommendation(s)
10061	Incision and drainage of abscess (eg, carbuncle, suppurative hidradenitis, cutaneous or subcutaneous abscess, cyst, furuncle, or paronychia); complicated or multiple	**290** COMPLICATIONS OF A PROCEDURE ALWAYS REQUIRING TREATMENT	DMAP requested that 10061 pair with 998.59 (Other postoperative infection). 10061 is on lines 51, 209, 383, 405, 487, 528, 632, 377.	Add 10061 to line 290
43229	Esophagoscopy, flexible, transoral; with ablation of tumor(s), polyp(s), or other lesion(s) (includes pre- and post-dilation and guide wire passage, when performed)	**519** ESOPHAGITIS AND GERD; ESOPHAGEAL SPASM; ASYMPTOMATIC DIAPHRAGMATIC HERNIA	DMAP requested that 43229 pair with 530.82 (Barrett's esophagus). 43229 is on lines 319,382,600,647.	Add 43229 to line 519
		300 APLASTIC ANEMIAS	GN7 ERYTHROPOIESIS-STIMULATING AGENT (ESA) GUIDELINE is not referenced on line 300, which contains the diagnosis for anemia due to chronic kidney disease.	Add line 300 to GN7

Hip Fracture Treatment Codes

Issue: Hip fractures were consolidated on one line in May, 2014. All hip fracture diagnosis codes were moved to the new hip fracture line. HERC staff have identified certain CPT codes which related to hip fractures that need to be taken off other lines as the relevant paired diagnoses are no longer present on those lines.

CPT code	**Code description**	**Current Lines**	**Appropriate Lines**
27236	Open treatment of femoral fracture, proximal end, neck, internal fixation or prosthetic replacement	**85** FRACTURE OF HIP **290** COMPLICATIONS OF A PROCEDURE ALWAYS REQUIRING TREATMENT **358** CLOSED FRACTURE OF EXTREMITIES (EXCEPT MINOR TOES)	85, 290
27267	Closed treatment of femoral fracture, proximal end, head; without manipulation	**85, 358** **362** DEFORMITY/CLOSED DISLOCATION OF MAJOR JOINT AND RECURRENT JOINT DISLOCATIONS **391** DEFORMITY/CLOSED DISLOCATION OF MINOR JOINT AND RECURRENT JOINT DISLOCATIONS	85
27268	with manipulation	**85, 358, 362, 391**	85

HERC staff recommendations:

1) Remove 27236 from line 358
2) Remove 27267 and 27268 from lines 358, 362, and 391

Arthropod-borne Viral Fevers and Viral Hemorrhagic Fevers

Question: where should hemorrhagic fevers and certain arthropod borne diseases be located on the Prioritized List?

Question source: HERC staff

Issue: The ICD-10 codes for hemorrhagic fevers, such as Ebola, are currently located on one of two unfunded lines--623 OTHER VIRAL INFECTIONS or 660 INFECTIOUS DISEASES WITH NO OR MINIMALLY EFFECTIVE TREATMENTS OR NO TREATMENT NECESSARY. These infections require hospitalization and may require various intensive care treatments. The ICD-9 codes for these diseases are codes grouped with the arthropod borne diseases in the ICD-9 coding range, and are located on line 271 RICKETTSIAL AND OTHER ARTHROPOD-BORNE DISEASES. For example, Ebola is coded as 065.8 (Other specified arthropod-borne hemorrhagic fever). Line 271 will allow these diagnoses to have hospital and intensive care services. In the ICD-10 A98 family of codes, some diagnoses are arthropod-borne and some are not.

Dengue and yellow fever and West Nile are mosquito borne diseases which require medical care, and may require hospitalization and/or intensive care. The ICD-9 codes for these diagnoses are on line 271, but the ICD-10 code are inappropriately placed on line 660 INFECTIOUS DISEASES WITH NO OR MINIMALLY EFFECTIVE TREATMENTS OR NO TREATMENT NECESSARY.

HERC staff recommendation:

1) Move ICD-10 codes for arthropod-borne and hemorrhagic fever diagnoses as shown in the table below

ICD-10 Code	**Code description**	**Current Line**	**Recommended Line**
A90	Dengue fever	**660** INFECTIOUS DISEASES WITH NO OR MINIMALLY EFFECTIVE TREATMENTS OR NO TREATMENT NECESSARY	**271** RICKETTSIAL AND OTHER ARTHROPOD-BORNE DISEASES
A91	Dengue hemorrhagic fever	**660**	**271**
A92	Other mosquito-borne viral fevers	**660**	**271**
A93	Other arthropod-borne viral fevers, not elsewhere classified	**660**	**271**
A94	Unspecified arthropod-borne viral fever	**660**	**271**
A95	Yellow fever	**660**	**271**
A96	Arenaviral hemorrhagic fever	**623** OTHER VIRAL INFECTIONS	**196** SEPTICEMIA
A98.0	Crimean-Congo hemorrhagic fever	**660**	**271**
A98.1	Omsk hemorrhagic fever	**660**	**271**
A98.2	Kyasanur Forest disease	**660**	**271**
A98.3	Marburg virus disease	**623**	**196**
A98.4	Ebola virus disease	**623**	**196**
A98.5	Hemorrhagic fever with renal syndrome	**623**	**196**
A98.8	Other specified viral hemorrhagic fevers	**660**	**196**
A99	Unspecified viral hemorrhagic fever	**660**	**196**

Determination of Refraction Code 92015

Question: Where should eye exams for determination of refraction (CPT 92015) be located on the Prioritized List?

Question source: DMAP, HERC staff

Issue: 92015 (DETERMINATION OF REFRACTIVE STATE) is included on 55+ lines of the prioritized list. However, this service is intended to be used for the purpose of prescribing lenses/spectacles. While there is value and medical justification for an ophthalmological exam for medical conditions such as diabetes and MS, the medical conditions other than visual acuity disorders do not support the need for the determination of refractory state. The prioritized list has line 455 DISORDERS OF REFRACTION AND ACCOMODATION which includes 92015.

Despite the funded condition on line 455 for the treatment of disorders of refraction, the OHP benefit plan limits the coverage of lenses and spectacles as follows:

> Current OAR:
> 410-140-0140(4)(d)Visual services for the purpose of prescribing glasses/contact lenses, fitting fees, or glasses or contact lenses for:
> (A) Pregnant adult women are covered, and a complete examination and determination of refractive state is limited to once every 24 months;
> (B) Non-pregnant adults are not covered, except when the client:
> (i) Has a medical diagnoses of aphakia, pseudoaphakia, congenital aphakia, keratoconus; or
> (ii) Lacks the natural lenses of the eye due to surgical removal (e.g. cataract extraction) or congenital absence; or
> (iii) Has had a keratoplasty surgical procedure (e.g. corneal transplant) with limitations described in OAR 410-140-0160 Contact Lens Services and Supplies; and
> (iv) Is limited to one complete examination and determination of refractive state once every 24 months.

HERC staff recommendation:

1) Remove 92015 from all lines except line 455 DISORDERS OF REFRACTION AND ACCOMODATION

Diagnosis Codes on Current DMAP Excluded List Suggested for Placement on the Prioritized List

Question: Should certain codes now in the DMAP excluded file be placed on the Prioritized List?

Question source: DMAP and HERC staff

Issue: Coverage for services in OHP benefit plan is define by either prioritized funded or non-funded condition/ treatment pairs or non-prioritized conditions managed by DMAP Lists. HERC makes recommendations for placement of non-prioritized diagnosis codes into any one of the four DMAP Lists (Excluded, Exempt, Ancillary, Diagnostic Workup).

Historically, the DMAP lists have not been published, are poorly defined, and inconsistently utilized to the intent of the Oregon Administrative Rules. Those lists that include diagnosis codes have been revised in an effort to improve access to healthcare by making transparent the management of those diagnosis codes not included on the Prioritized List, provide more precise and useful information to providers about benefit coverage, and improve the accuracy of claims processing.

Old DMAP groups:
Excluded = never covered/ not eligible for exception
Exempt = Always covered
Ancillary = always covered when the CPT code is above the funded line (could not find any definition of an ancillary diagnosis code)
Diagnostic Workup File = always paid when paired with procedure codes above the funded line

The new DMAP lists replace the use of the Excluded, Exempt, and Ancillary lines for diagnosis codes and are defined as follows:

1. Conditions Not Covered (never covered/no exceptions) – This list is for the diagnosis codes that are specifically excluded by Oregon Administrative Rule and not eligible to be reviewed for coverage;
    a. Infertility
    b. Cosmetic
    c. Unrelated to improving health status
    d. Participation in experimental/ research programs

2. Undefined (usually not covered but eligible for review) – This list includes diagnosis codes that are unspecified. Some unspecified diagnosis codes are appropriately placed on the Prioritized List. Some unspecified codes may be used for both covered and uncovered diagnoses and are not placed on the List; these codes are eligible for review and for coverage if a more definitive diagnosis is not known. This list includes diagnosis codes that are

a. not definitive enough to determine line placement and ranking of the condition on the Prioritized List, or
b. other coding is available to more specifically define and support treatment.

3. Informational (not covered/informational only) – This list is for diagnosis codes that are not valid to determine reimbursement or benefit plan coverage and may include diagnosis codes that are
    a. External Causes of Mortality
    b. Personal/ Family History not relevant to covered preventative services
    c. Health status codes
    d. Health Care Encounter codes (non-specific or redundant)
    e. Not eligible as a primary diagnosis

4. Diagnostic Workup File (payable when paired with procedure codes)– Diagnosis codes included on this list are only reimbursable with non-prioritized procedure codes that are in the Diagnostic Procedure List. It is intended to allow for diagnostic services to more definitively diagnose
    a. Signs & symptoms
    b. Conditions requiring further evaluation to better define the primary diagnosis

In reviewing these lists, DMAP and HERC staff have identified ICD-9 diagnosis codes that can appropriately be placed on the Prioritized List.

HERC Staff Recommendations:

1) Add the ICD-9 diagnosis codes on the following spreadsheet to the indicated lines on the Prioritized List and advise DMAP to remove them from their current DMAP lists

ICD-9	Diagnosis Description	Current file	Recommended Placement
051.1	Pseudocowpox	EXCLUDED FILE	623 OTHER VIRAL INFECTIONS
051.2	Contagious pustular dermatitis	EXCLUDED FILE	623
051.9	Paravaccinia, unspecified	EXCLUDED FILE	623
173.00	Unspecified malignant neoplasm of skin of lip	EXCLUDED FILE	279 CANCER OF SKIN, EXCLUDING MALIGNANT MELANOMA
173.10	Unspecified malignant neoplasm of eyelid, including canthus	EXCLUDED FILE	279
173.20	Unspecified malignant neoplasm of skin of ear and external auditory canal	EXCLUDED FILE	279
173.30	Unspecified malignant neoplasm of skin of other and unspecified parts of face	EXCLUDED FILE	279
173.40	Unspecified malignant neoplasm of scalp and skin of neck	EXCLUDED FILE	279
173.50	Unspecified malignant neoplasm of skin of trunk, except scrotum	EXCLUDED FILE	279
173.60	Unspecified malignant neoplasm of skin of upper limb, including shoulder	EXCLUDED FILE	279
173.70	Unspecified malignant neoplasm of skin of lower limb, including hip	EXCLUDED FILE	279
173.80	Unspecified malignant neoplasm of other specified sites of skin	EXCLUDED FILE	279
173.90	Unspecified malignant neoplasm of skin, site unspecified	EXCLUDED FILE	279
228.09	Hemangioma of other sites	ANCILLARY CODES	636
278.02	Overweight	EXCLUDED FILE	661 ENDOCRINE AND METABOLIC CONDITIONS WITH NO OR MINIMALLY EFFECTIVE TREATMENTS OR NO TREATMENT NECESSARY

ICD-9	Diagnosis Description	Current file	Recommended Placement
278.8	Other hyperalimentation	EXCLUDED FILE	661
284.2	Myelophthisis	EXCLUDED FILE	118 APLASTIC ANEMIAS; AGRANULOCYTOSIS 300 APLASTIC ANEMIAS
300.20	Phobia, unspecified	EXCLUDED FILE	463 SIMPLE PHOBIAS AND SOCIAL ANXIETY DISORDER
300.89	Other somatoform disorders	EXCLUDED FILE	497 SOMATIZATION DISORDER, SOMATOFORM PAIN DISORDER, CONVERSION DISORDER
302.51	Trans-sexualism with asexual history	EXCLUDED FILE	413 GENDER DYSPHORIA
302.52	Trans-sexualism with homosexual history	EXCLUDED FILE	413
302.53	Trans-sexualism with heterosexual history	EXCLUDED FILE	413
302.81	Fetishism	EXCLUDED FILE	501 PARAPHILIAS AND OTHER PSYCHOSEXUAL DISORDERS
302.82	Voyeurism	EXCLUDED FILE	501
302.83	Sexual masochism	EXCLUDED FILE	501
302.84	Sexual sadism	EXCLUDED FILE	501
302.89	Other specified psychosexual disorders	EXCLUDED FILE	501
307.40	Nonorganic sleep disorder, unspecified	EXCLUDED FILE	614 DISORDERS OF SLEEP WITHOUT SLEEP APNEA
312.30	Impulse control disorder, unspecified	EXCLUDED FILE	467 OBSESSIVE-COMPULSIVE DISORDERS

ICD-9	Diagnosis Description	Current file	Recommended Placement
315.4	Developmental coordination disorder	EXCLUDED FILE	297 NEUROLOGICAL DYSFUNCTION IN POSTURE AND MOVEMENT CAUSED BY CHRONIC CONDITIONS 381 DYSFUNCTION RESULTING IN LOSS OF ABILITY TO MAXIMIZE LEVEL OF INDEPENDENCE IN SELF-DIRECTED CARE CAUSED BY CHRONIC CONDITIONS THAT CAUSE NEUROLOGICAL DYSFUNCTION
315.5	Mixed development disorder	EXCLUDED FILE	297,381
315.8	Other specified delays in development	EXCLUDED FILE	297,381
315.9	Unspecified delay in development	EXCLUDED FILE	297,381
321.0	Cryptococcal meningitis	EXCLUDED FILE	113 SUBACUTE MENINGITIS (EG. TUBERCULOSIS, CRYPTOCOCCOSIS)
321.1	Meningitis in other fungal diseases	EXCLUDED FILE	113
321.2	Meningitis due to viruses not elsewhere classified	EXCLUDED FILE	554 ASEPTIC MENINGITIS
321.3	Meningitis due to trypanosomiasis	EXCLUDED FILE	113
321.4	Meningitis in sarcoidosis	EXCLUDED FILE	113
321.8	Meningitis due to other nonbacterial organisms classified elsewhere	EXCLUDED FILE	113,554
323.01	Encephalitis and encephalomyelitis in viral diseases classified elsewhere	EXCLUDED FILE	540 VIRAL, SELF-LIMITING ENCEPHALITIS, MYELITIS AND ENCEPHALOMYELITIS
323.02	Myelitis in viral diseases classified elsewhere	EXCLUDED FILE	540

ICD-9	Diagnosis Description	Current file	Recommended Placement
323.1	Encephalitis, myelitis, and encephalomyelitis in rickettsial diseases classified elsewhere	EXCLUDED FILE	540
323.2	Encephalitis, myelitis, and encephalomyelitis in protozoal diseases classified elsewhere	EXCLUDED FILE	540
323.41	Other encephalitis and encephalomyelitis due to other infections classified elsewhere	EXCLUDED FILE	540
323.42	Other myelitis due to other infections classified elsewhere	EXCLUDED FILE	540
323.61	Infectious acute disseminated encephalomyelitis (ADEM)	EXCLUDED FILE	540
323.62	Other postinfectious encephalitis and encephalomyelitis	EXCLUDED FILE	540
323.63	Postinfectious myelitis	EXCLUDED FILE	540
323.71	Toxic encephalitis and encephalomyelitis	EXCLUDED FILE	540
323.72	Toxic myelitis	EXCLUDED FILE	540
327.01	Insomnia due to medical condition classified elsewhere	EXCLUDED FILE	614
327.02	Insomnia due to mental disorder	EXCLUDED FILE	614
327.14	Hypersomnia due to medical condition classified elsewhere	EXCLUDED FILE	614
327.15	Hypersomnia due to mental disorder	EXCLUDED FILE	614
330.2	Cerebral degeneration in generalized lipidoses	EXCLUDED FILE	75,297,349,381

ICD-9	Diagnosis Description	Current file	Recommended Placement
330.3	Cerebral degeneration of childhood in other diseases classified elsewhere	EXCLUDED FILE	75,297,349,381
336.2	Subacute combined degeneration of spinal cord in diseases classified elsewhere	EXCLUDED FILE	75,297,349,381
336.3	Myelopathy in other diseases classified elsewhere	EXCLUDED FILE	75,297,349,381
337.1	Peripheral autonomic neuropathy in disorders classified elsewhere	EXCLUDED FILE	75,297,349,381
347.10	Narcolepsy in conditions classified elsewhere, without cataplexy	EXCLUDED FILE	614
347.11	Narcolepsy in conditions classified elsewhere, with cataplexy	EXCLUDED FILE	614
357.1	Polyneuropathy in collagen vascular disease	EXCLUDED FILE	515 PERIPHERAL NERVE DISORDERS
357.3	Polyneuropathy in malignant disease	EXCLUDED FILE	515
357.4	Polyneuropathy in other diseases classified elsewhere	EXCLUDED FILE	515
366.41	Diabetic cataract	EXCLUDED FILE	301 CATARACT
366.42	Tetanic cataract	EXCLUDED FILE	301
366.43	Myotonic cataract	EXCLUDED FILE	301
366.44	Cataract associated with other syndromes	EXCLUDED FILE	301
372.15	Parasitic conjunctivitis	EXCLUDED FILE	508 CHRONIC CONJUNCTIVITIS, BLEPHAROCONJUNCTIVITIS
373.4	Infective dermatitis of eyelid of types resulting in deformity	EXCLUDED FILE	575 BLEPHARITIS

ICD-9	Diagnosis Description	Current file	Recommended Placement
373.5	Other infective dermatitis of eyelid	EXCLUDED FILE	575
373.6	Parasitic infestation of eyelid	EXCLUDED FILE	575
377.00	Papilledema, unspecified	ANCILLARY CODES	659 INTRACRANIAL CONDITIONS WITH NO OR MINIMALLY EFFECTIVE TREATMENTS OR NO TREATMENT NECESSARY
377.9	Unspecified disorder of optic nerve and visual pathways	EXCLUDED FILE	659
378.9	Unspecified disorder of eye movements	EXCLUDED FILE	398 STRABISMUS WITHOUT AMBLYOPIA AND OTHER DISORDERS OF BINOCULAR EYE MOVEMENTS; CONGENITAL ANOMALIES OF EYE; LACRIMAL DUCT OBSTRUCTION IN CHILDREN
420.0	Acute pericarditis in diseases classified elsewhere	EXCLUDED FILE	86 MYOCARDITIS, PERICARDITIS, AND ENDOCARDITIS
421.1	Acute and subacute infective endocarditis in diseases classified elsewhere	EXCLUDED FILE	86
484.1	Pneumonia in cytomegalic inclusion disease	EXCLUDED FILE	208 PNEUMOCOCCAL PNEUMONIA, OTHER BACTERIAL PNEUMONIA, BRONCHOPNEUMONIA
484.3	Pneumonia in whooping cough	EXCLUDED FILE	208
484.5	Pneumonia in anthrax	EXCLUDED FILE	208
484.6	Pneumonia in aspergillosis	EXCLUDED FILE	208
484.7	Pneumonia in other systemic mycoses	EXCLUDED FILE	208
484.8	Pneumonia in other infectious diseases classified elsewhere	EXCLUDED FILE	208

ICD-9	Diagnosis Description	Current file	Recommended Placement
521.40	Pathological resorption, unspecified	ANCILLARY CODES	654 DENTAL CONDITIONS WHERE TREATMENT IS CHOSEN PRIMARILY FOR AESTHETIC CONSIDERATIONS
521.41	Pathological resorption, internal	EXCLUDED FILE	654
521.42	Pathological resorption, external	EXCLUDED FILE	654
521.49	Other pathological resorption	EXCLUDED FILE	654
521.5	Hypercementosis	ANCILLARY CODES	654
523.00	Acute gingivitis, plaque induced	ANCILLARY CODES	222 DENTAL CONDITIONS (EG. PERIODONTAL DISEASE)
523.01	Acute gingivitis, non-plaque induced	ANCILLARY CODES	222
523.10	Chronic gingivitis, plaque induced	ANCILLARY CODES	222
523.11	Chronic gingivitis, non-plaque induced	ANCILLARY CODES	222
523.20	Gingival recession, unspecified	ANCILLARY CODES	222
523.21	Gingival recession, minimal	ANCILLARY CODES	222
523.22	Gingival recession, moderate	ANCILLARY CODES	222
523.23	Gingival recession, severe	ANCILLARY CODES	222
523.24	Gingival recession, localized	ANCILLARY CODES	222
523.25	Gingival recession, generalized	ANCILLARY CODES	222

ICD-9	Diagnosis Description	Current file	Recommended Placement
523.30	Aggressive periodontitis, unspecified	ANCILLARY CODES	222
523.31	Aggressive periodontitis, localized	ANCILLARY CODES	222
523.32	Aggressive periodontitis, generalized	ANCILLARY CODES	222
523.33	Acute periodontitis	ANCILLARY CODES	222
523.40	Chronic periodontitis, unspecified	ANCILLARY CODES	222
523.41	Chronic periodontitis, localized	ANCILLARY CODES	222
523.42	Chronic periodontitis, generalized	ANCILLARY CODES	222
523.5	Periodontosis	ANCILLARY CODES	222
523.6	Accretions on teeth	ANCILLARY CODES	654
523.8	Other specified periodontal diseases	ANCILLARY CODES	222
523.9	Unspecified gingival and periodontal disease	ANCILLARY CODES	222
524.32	Excessive spacing of teeth	ANCILLARY CODES	655 DENTAL CONDITIONS WHERE TREATMENT RESULTS IN MARGINAL IMPROVEMENT
525.0	Exfoliation of teeth due to systemic causes	ANCILLARY CODES	655
525.10	Acquired absence of teeth, unspecified	EXCLUDED FILE	457 DENTAL CONDITIONS (EG. MISSING TEETH, PROSTHESIS FAILURE)
525.11	Loss of teeth due to trauma	EXCLUDED FILE	457

ICD-9	Diagnosis Description	Current file	Recommended Placement
525.12	Loss of teeth due to periodontal disease	EXCLUDED FILE	457
525.13	Loss of teeth due to caries	EXCLUDED FILE	457
525.19	Other loss of teeth	EXCLUDED FILE	457
525.61	Open restoration margins	EXCLUDED FILE	655
525.62	Unrepairable overhanging of dental restorative materials	EXCLUDED FILE	655
525.63	Fractured dental restorative material without loss of material	EXCLUDED FILE	347 DENTAL CONDITIONS (EG. CARIES, FRACTURED TOOTH)
525.64	Fractured dental restorative material with loss of material	EXCLUDED FILE	347
525.65	Contour of existing restoration of tooth biologically incompatible with oral health	EXCLUDED FILE	655
525.66	Allergy to existing dental restorative material	EXCLUDED FILE	57 PREVENTIVE DENTAL SERVICES
525.8	Other specified disorders of the teeth and supporting structures	ANCILLARY CODES	655
526.61	Perforation of root canal space	EXCLUDED FILE	625 ANOMALIES OF RELATIONSHIP OF JAW TO CRANIAL BASE, MAJOR ANOMALIES OF JAW SIZE, OTHER SPECIFIED AND UNSPECIFIED DENTOFACIAL ANOMALIES
526.62	Endodontic overfill	EXCLUDED FILE	625
526.63	Endodontic underfill	EXCLUDED FILE	625
526.69	Other periradicular pathology associated with previous endodontic treatment	EXCLUDED FILE	625

ICD-9	Diagnosis Description	Current file	Recommended Placement
573.1	Hepatitis in viral diseases classified elsewhere	EXCLUDED FILE	202 CHRONIC HEPATITIS; VIRAL HEPATITIS
573.2	Hepatitis in other infectious diseases classified elsewhere	EXCLUDED FILE	202
595.4	Cystitis in diseases classified elsewhere	EXCLUDED FILE	278 UROLOGIC INFECTIONS
601.4	Prostatitis in diseases classified elsewhere	EXCLUDED FILE	521 CHRONIC PROSTATITIS, OTHER DISORDERS OF PROSTATE
604.91	Orchitis and epididymitis in diseases classified elsewhere	EXCLUDED FILE	278
608.81	Disorders of male genital organs in diseases classified elsewhere	EXCLUDED FILE	667 GENITOURINARY CONDITIONS WITH NO OR MINIMALLY EFFECTIVE TREATMENTS OR NO TREATMENT NECESSARY
608.85	Stricture of male genital organs	ANCILLARY CODES	667
608.86	Edema of male genital organs	EXCLUDED FILE	667
608.89	Other specified disorders of male genital organs	EXCLUDED FILE	667
629.0	Hematocele, female, not elsewhere classified	EXCLUDED FILE	536 CHRONIC PELVIC INFLAMMATORY DISEASE, PELVIC PAIN SYNDROME, DYSPAREUNIA
629.9	Unspecified disorder of female genital organs	EXCLUDED FILE	667
711.10	Arthropathy associated with Reiter's disease and nonspecific urethritis, site unspecified	EXCLUDED FILE	668 MUSCULOSKELETAL CONDITIONS WITH NO OR MINIMALLY EFFECTIVE TREATMENTS OR NO TREATMENT NECESSARY
711.11	Arthropathy associated with Reiter's disease and nonspecific urethritis, shoulder region	EXCLUDED FILE	668

ICD-9	Diagnosis Description	Current file	Recommended Placement
711.12	Arthropathy associated with Reiter's disease and nonspecific urethritis, upper arm	EXCLUDED FILE	668
711.13	Arthropathy associated with Reiter's disease and nonspecific urethritis, forearm	EXCLUDED FILE	668
711.14	Arthropathy associated with Reiter's disease and nonspecific urethritis, hand	EXCLUDED FILE	668
711.15	Arthropathy associated with Reiter's disease and nonspecific urethritis, pelvic region and thigh	EXCLUDED FILE	668
711.16	Arthropathy associated with Reiter's disease and nonspecific urethritis, lower leg	EXCLUDED FILE	668
711.17	Arthropathy associated with Reiter's disease and nonspecific urethritis, ankle and foot	EXCLUDED FILE	668
711.18	Arthropathy associated with Reiter's disease and nonspecific urethritis, other specified sites	EXCLUDED FILE	668
711.19	Arthropathy associated with Reiter's disease and nonspecific urethritis, multiple sites	EXCLUDED FILE	668
711.20	Arthropathy in Behcet's syndrome, site unspecified	EXCLUDED FILE	668
711.21	Arthropathy in Behcet's syndrome, shoulder region	EXCLUDED FILE	668
711.22	Arthropathy in Behcet's syndrome, upper arm	EXCLUDED FILE	668
711.23	Arthropathy in Behcet's syndrome, forearm	EXCLUDED FILE	668

ICD-9	Diagnosis Description	Current file	Recommended Placement
711.24	Arthropathy in Behcet's syndrome, hand	EXCLUDED FILE	668
711.25	Arthropathy in Behcet's syndrome, pelvic region and thigh	EXCLUDED FILE	668
711.26	Arthropathy in Behcet's syndrome, lower leg	EXCLUDED FILE	668
711.27	Arthropathy in Behcet's syndrome, ankle and foot	EXCLUDED FILE	668
711.28	Arthropathy in Behcet's syndrome, other specified sites	EXCLUDED FILE	668
711.29	Arthropathy in Behcet's syndrome, multiple sites	EXCLUDED FILE	668
711.30	Postdysenteric arthropathy, site unspecified	EXCLUDED FILE	668
711.31	Postdysenteric arthropathy, shoulder region	EXCLUDED FILE	668
711.32	Postdysenteric arthropathy, upper arm	EXCLUDED FILE	668
711.33	Postdysenteric arthropathy, forearm	EXCLUDED FILE	668
711.34	Postdysenteric arthropathy, hand	EXCLUDED FILE	668
711.35	Postdysenteric arthropathy, pelvic region and thigh	EXCLUDED FILE	668
711.36	Postdysenteric arthropathy, lower leg	EXCLUDED FILE	668
711.38	Postdysenteric arthropathy, other specified sites	ANCILLARY CODES	668
711.39	Postdysenteric arthropathy, multiple sites	ANCILLARY CODES	668

ICD-9	Diagnosis Description	Current file	Recommended Placement
711.40	Arthropathy associated with other bacterial diseases, site unspecified	ANCILLARY CODES	668
711.41	Arthropathy associated with other bacterial diseases, shoulder region	ANCILLARY CODES	668
711.42	Arthropathy associated with other bacterial diseases, upper arm	ANCILLARY CODES	668
711.43	Arthropathy associated with other bacterial diseases, forearm	ANCILLARY CODES	668
711.44	Arthropathy associated with other bacterial diseases, hand	ANCILLARY CODES	668
711.45	Arthropathy associated with other bacterial diseases, pelvic region and thigh	ANCILLARY CODES	668
711.46	Arthropathy associated with other bacterial diseases, lower leg	ANCILLARY CODES	668
711.47	Arthropathy associated with other bacterial diseases, ankle and foot	ANCILLARY CODES	668
711.48	Arthropathy associated with other bacterial diseases, other specified sites	ANCILLARY CODES	668
711.49	Arthropathy associated with other bacterial diseases, multiple sites	ANCILLARY CODES	668
711.50	Arthropathy associated with other viral diseases, site unspecified	ANCILLARY CODES	668
711.51	Arthropathy associated with other viral diseases, shoulder region	ANCILLARY CODES	668
711.52	Arthropathy associated with other viral diseases, upper arm	ANCILLARY CODES	668
711.53	Arthropathy associated with other viral diseases, forearm	ANCILLARY CODES	668
711.54	Arthropathy associated with other viral diseases, hand	ANCILLARY CODES	668

ICD-9	Diagnosis Description	Current file	Recommended Placement
711.55	Arthropathy associated with other viral diseases, pelvic region and thigh	ANCILLARY CODES	668
711.56	Arthropathy associated with other viral diseases, lower leg	ANCILLARY CODES	668
711.57	Arthropathy associated with other viral diseases, ankle and foot	ANCILLARY CODES	668
711.58	Arthropathy associated with other viral diseases, other specified sites	ANCILLARY CODES	668
711.59	Arthropathy associated with other viral diseases, multiple sites	ANCILLARY CODES	668
711.60	Arthropathy associated with mycoses, site unspecified	ANCILLARY CODES	668
711.61	Arthropathy associated with mycoses, shoulder region	ANCILLARY CODES	668
711.62	Arthropathy associated with mycoses, upper arm	ANCILLARY CODES	668
711.63	Arthropathy associated with mycoses, forearm	ANCILLARY CODES	668
711.64	Arthropathy associated with mycoses, hand	ANCILLARY CODES	668
711.65	Arthropathy associated with mycoses, pelvic region and thigh	ANCILLARY CODES	668
711.66	Arthropathy associated with mycoses, lower leg	ANCILLARY CODES	668
711.67	Arthropathy associated with mycoses, ankle and foot	ANCILLARY CODES	668
711.68	Arthropathy associated with mycoses, other specified sites	ANCILLARY CODES	668
711.69	Arthropathy associated with mycoses, involving multiple sites	ANCILLARY CODES	668

ICD-9	Diagnosis Description	Current file	Recommended Placement
711.70	Arthropathy associated with helminthiasis, site unspecified	ANCILLARY CODES	668
711.71	Arthropathy associated with helminthiasis, shoulder region	ANCILLARY CODES	668
711.72	Arthropathy associated with helminthiasis, upper arm	ANCILLARY CODES	668
711.73	Arthropathy associated with helminthiasis, forearm	ANCILLARY CODES	668
711.74	Arthropathy associated with helminthiasis, hand	ANCILLARY CODES	668
711.75	Arthropathy associated with helminthiasis, pelvic region and thigh	ANCILLARY CODES	668
711.76	Arthropathy associated with helminthiasis, lower leg	ANCILLARY CODES	668
711.77	Arthropathy associated with helminthiasis, ankle and foot	ANCILLARY CODES	668
711.78	Arthropathy associated with helminthiasis, other specified sites	ANCILLARY CODES	668
711.79	Arthropathy associated with helminthiasis, multiple sites	ANCILLARY CODES	668
711.80	Arthropathy associated with other infectious and parasitic diseases, site unspecified	ANCILLARY CODES	668
711.81	Arthropathy associated with other infectious and parasitic diseases, shoulder region	ANCILLARY CODES	668
711.82	Arthropathy associated with other infectious and parasitic diseases, upper arm	ANCILLARY CODES	668

ICD-9	Diagnosis Description	Current file	Recommended Placement
711.83	Arthropathy associated with other infectious and parasitic diseases, forearm	ANCILLARY CODES	668
711.84	Arthropathy associated with other infectious and parasitic diseases, hand	ANCILLARY CODES	668
711.85	Arthropathy associated with other infectious and parasitic diseases, pelvic region and thigh	ANCILLARY CODES	668
711.86	Arthropathy associated with other infectious and parasitic diseases, lower leg	ANCILLARY CODES	668
711.87	Arthropathy associated with other infectious and parasitic diseases, ankle and foot	ANCILLARY CODES	668
711.88	Arthropathy associated with other infectious and parasitic diseases, other specified sites	ANCILLARY CODES	668
711.89	Arthropathy associated with other infectious and parasitic diseases, multiple sites	ANCILLARY CODES	668
713.0	Arthropathy associated with other endocrine and metabolic disorders	ANCILLARY CODES	668
713.1	Arthropathy associated with gastrointestinal conditions other than infections	ANCILLARY CODES	668
713.2	Arthropathy associated with hematological disorders	ANCILLARY CODES	668
713.3	Arthropathy associated with dermatological disorders	ANCILLARY CODES	668
713.4	Arthropathy associated with respiratory disorders	ANCILLARY CODES	668

ICD-9	Diagnosis Description	Current file	Recommended Placement
713.6	Arthropathy associated with hypersensitivity reaction	ANCILLARY CODES	668
713.7	Other general diseases with articular involvement	ANCILLARY CODES	668
713.8	Arthropathy associated with other conditions classifiable elsewhere	ANCILLARY CODES	668
718.70	Developmental dislocation of joint, site unspecified	ANCILLARY CODES	668
718.70	Developmental dislocation of joint, site unspecified	ANCILLARY CODES	668
718.88	Other joint derangement, not elsewhere classified, other specified sites	ANCILLARY CODES	668
718.88	Other joint derangement, not elsewhere classified, other specified sites	ANCILLARY CODES	668
720.81	Inflammatory spondylopathies in diseases classified elsewhere	EXCLUDED FILE	545 ACUTE AND CHRONIC DISORDERS OF SPINE WITHOUT NEUROLOGIC IMPAIRMENT
727.01	Synovitis and tenosynovitis in diseases classified elsewhere	EXCLUDED FILE	612 DISORDERS OF SOFT TISSUE
730.70	Osteopathy resulting from poliomyelitis, site unspecified	ANCILLARY CODES	297 NEUROLOGICAL DYSFUNCTION IN POSTURE AND MOVEMENT CAUSED BY CHRONIC CONDITIONS 381 DYSFUNCTION RESULTING IN LOSS OF ABILITY TO MAXIMIZE LEVEL OF INDEPENDENCE IN SELF-DIRECTED CARE CAUSED BY CHRONIC CONDITIONS THAT CAUSE NEUROLOGICAL DYSFUNCTION
730.71	Osteopathy resulting from poliomyelitis, shoulder region	ANCILLARY CODES	297,381
730.72	Osteopathy resulting from poliomyelitis, upper arm	ANCILLARY CODES	297,381

ICD-9	Diagnosis Description	Current file	Recommended Placement
730.73	Osteopathy resulting from poliomyelitis, forearm	ANCILLARY CODES	297,381
730.74	Osteopathy resulting from poliomyelitis, hand	ANCILLARY CODES	297,381
730.75	Osteopathy resulting from poliomyelitis, pelvic region and thigh	ANCILLARY CODES	297,381
730.76	Osteopathy resulting from poliomyelitis, lower leg	ANCILLARY CODES	297,381
730.77	Osteopathy resulting from poliomyelitis, ankle and foot	ANCILLARY CODES	297,381
730.78	Osteopathy resulting from poliomyelitis, other specified sites	ANCILLARY CODES	297,381
730.79	Osteopathy resulting from poliomyelitis, multiple sites	ANCILLARY CODES	297,381
730.80	Other infections involving bone in diseases classified elsewhere, site unspecified	ANCILLARY CODES	258 CHRONIC OSTEOMYELITIS
730.81	Other infections involving bone in diseases classified elsewhere, shoulder region	ANCILLARY CODES	258
730.82	Other infections involving bone in diseases classified elsewhere, upper arm	ANCILLARY CODES	258
730.83	Other infections involving bone in diseases classified elsewhere, forearm	ANCILLARY CODES	258
730.84	Other infections involving bone in diseases classified elsewhere, hand	ANCILLARY CODES	258
730.85	Other infections involving bone in diseases classified elsewhere, pelvic region and thigh	ANCILLARY CODES	258
730.86	Other infections involving bone in diseases classified elsewhere, lower leg	ANCILLARY CODES	258

ICD-9	Diagnosis Description	Current file	Recommended Placement
730.87	Other infections involving bone in diseases classified elsewhere, ankle and foot	ANCILLARY CODES	258
730.88	Other infections involving bone in diseases classified elsewhere, other specified sites	ANCILLARY CODES	258
730.89	Other infections involving bone in diseases classified elsewhere, multiple sites	DIAGNOSTIC WORKUP FILE	258
731.3	Major osseous defects	DIAGNOSTIC WORKUP FILE	534 DEFORMITIES OF UPPER BODY AND ALL LIMBS
731.8	Other bone involvement in diseases classified elsewhere	DIAGNOSTIC WORKUP FILE	668
733.99	Other disorders of bone and cartilage	EXCLUDED FILE	668
737.40	Curvature of spine, unspecified, associated with other conditions	DIAGNOSTIC WORKUP FILE	412 SPINAL DEFORMITY, CLINICALLY SIGNIFICANT 588 SPINAL DEFORMITY, NOT CLINICALLY SIGNIFICANT
737.41	Kyphosis associated with other conditions	DIAGNOSTIC WORKUP FILE	412,588
737.42	Lordosis associated with other conditions	DIAGNOSTIC WORKUP FILE	412,588
737.43	Scoliosis associated with other conditions	DIAGNOSTIC WORKUP FILE	412,588
756.81	Absence of muscle and tendon	EXCLUDED FILE	668

ICD-9	Diagnosis Description	Current file	Recommended Placement
759.3	Situs inversus	EXCLUDED FILE	662 CARDIOVASCULAR CONDITIONS WITH NO OR MINIMALLY EFFECTIVE TREATMENTS OR NO TREATMENT NECESSARY
774.5	Perinatal jaundice from other causes	DIAGNOSTIC WORKUP FILE	106 HEMOLYTIC DISEASE DUE TO ISOIMMUNIZATION, ANEMIA DUE TO TRANSPLACENTAL HEMORRHAGE, AND FETAL AND NEONATAL JAUNDICE
779.31	Feeding problems in newborn	EXEMPT FILE	19 FEEDING PROBLEMS IN NEWBORNS
779.32	Bilious vomiting in newborn	DIAGNOSTIC WORKUP FILE	2 BIRTH OF INFANT
779.34	Failure to thrive in newborn	EXEMPT FILE	19
848.0	Sprain of septal cartilage of nose	EXCLUDED FILE	616 SPRAINS AND STRAINS OF ADJACENT MUSCLES AND JOINTS, MINOR
848.2	Sprain of thyroid region	EXCLUDED FILE	616

Section 3.0

New Codes

Code	Code Descriptions	Proposed Placement	Notes
20604	Arthrocentesis, aspiration and/or injection, small joint or bursa (eg, fingers, toes); with ultrasound guidance, with permanent recording and reporting	**50** RHEUMATOID ARTHRITIS AND OTHER INFLAMMATORY POLYARTHROPATHIES **157** PYOGENIC ARTHRITIS **290** COMPLICATIONS OF A PROCEDURE ALWAYS REQUIRING TREATMENT **306** GOUT **468** OSTEOARTHRITIS AND ALLIED DISORDERS **511** PERIPHERAL ENTHESOPATHIES **533** BENIGN NEOPLASM OF BONE AND ARTICULAR CARTILAGE INCLUDING OSTEOID OSTEOMAS; BENIGN NEOPLASM OF CONNECTIVE AND OTHER SOFT TISSUE **597** SYNOVITIS AND TENOSYNOVITIS	See arthrocentesis document
20606	Arthrocentesis, aspiration and/or injection, intermediate joint or bursa (eg, temporomandibular, acromioclavicular, wrist, elbow or ankle, olecranon bursa); with ultrasound guidance, with permanent recording and reporting	**50, 157, 290, 306, 468, 511, 533, 597**	See arthrocentesis document
20611	Arthrocentesis, aspiration and/or injection, major joint or bursa (eg, shoulder, hip, knee, subacromial bursa); with ultrasound guidance, with permanent recording and reporting	**50, 157, 290, 306, 422, 468, 511, 533, 597** **435** INTERNAL DERANGEMENT OF KNEE AND LIGAMENTOUS DISRUPTIONS OF THE KNEE, RESULTING IN SIGNIFICANT INJURY/IMPAIRMENT	See arthrocentesis document
20983	Ablation therapy for reduction or eradication of 1 or more bone tumors (eg, metastasis) including adjacent soft tissue when involved by tumor extension, percutaneous, including imaging guidance when performed; cryoablation	**Non-Covered List**	See Issues document
21811	Open treatment of rib fracture(s) with internal fixation, includes thoracoscopic visualization when performed, unilateral; 1-3 ribs	**112** FRACTURE OF RIBS AND STERNUM, OPEN	
21812	Open treatment of rib fracture(s) with internal fixation, includes thoracoscopic visualization when performed, unilateral; 4-6 ribs	**112** FRACTURE OF RIBS AND STERNUM, OPEN	
21813	Open treatment of rib fracture(s) with internal fixation, includes thoracoscopic visualization when performed, unilateral; 7 or more ribs	**112** FRACTURE OF RIBS AND STERNUM, OPEN	
22510	Percutaneous vertebroplasty (bone biopsy included when performed), 1 vertebral body, unilateral or bilateral injection, inclusive of all imaging guidance; cervicothoracic	**484** CLOSED DISLOCATIONS/FRACTURES OF NON-CERVICAL VERTEBRAL COLUMN WITHOUT SPINAL CORD INJURY	22520-22522 (Percutaneous vertebroplasty (bone biopsy included when performed), 1 vertebral body,unilateral or bilateral injection;...) were on line 507 (became line 484). These codes were deleted with 2015 CPT codes. The new codes include the radiologic supervision which were previously separate codes
22511	Percutaneous vertebroplasty (bone biopsy included when performed), 1 vertebral body, unilateral or bilateral injection, inclusive of all imaging guidance; lumbosacral	**484** CLOSED DISLOCATIONS/FRACTURES OF NON-CERVICAL VERTEBRAL COLUMN WITHOUT SPINAL CORD INJURY	See 22510
22512	Percutaneous vertebroplasty (bone biopsy included when performed), 1 vertebral body, unilateral or bilateral injection, inclusive of all imaging guidance; each additional cervicothoracic or lumbosacral vertebral body (List separately in addition to code f	**484** CLOSED DISLOCATIONS/FRACTURES OF NON-CERVICAL VERTEBRAL COLUMN WITHOUT SPINAL CORD INJURY	See 22510
22513	Percutaneous vertebral augmentation, including cavity creation (fracture reduction and bone biopsy included when performed) using mechanical device (eg, kyphoplasty), 1 vertebral body, unilateral or bilateral cannulation, inclusive of all imaging guidance; thoracic	**484** CLOSED DISLOCATIONS/FRACTURES OF NON-CERVICAL VERTEBRAL COLUMN WITHOUT SPINAL CORD INJURY	22523-22525 (Percutaneous vertebral augmentation, including cavity creation (fracture reduction and bone biopsy included when performed) using mechanical device, 1 vertebral body, unilateral or bilateral cannulation (eg, kyphoplasty)...) were on line 507 (became line 484). Previous separate radiologic interpretation CPT codes are now included in these codes.
22514	Percutaneous vertebral augmentation, including cavity creation (fracture reduction and bone biopsy included when performed) using mechanical device (eg, kyphoplasty), 1 vertebral body, unilateral or bilateral cannulation, inclusive of all imaging guidance; lumbar	**484** CLOSED DISLOCATIONS/FRACTURES OF NON-CERVICAL VERTEBRAL COLUMN WITHOUT SPINAL CORD INJURY	See 22513 above

Code	Code Descriptions	Proposed Placement	Notes
22515	Percutaneous vertebral augmentation, including cavity creation (fracture reduction and bone biopsy included when performed) using mechanical device (eg, kyphoplasty), 1 vertebral body, unilateral or bilateral cannulation, inclusive of all imaging guidance; each additional vertebral body	**484** CLOSED DISLOCATIONS/FRACTURES OF NON-CERVICAL VERTEBRAL COLUMN WITHOUT SPINAL CORD INJURY	See 22513 above
22858	Total disc arthroplasty (artificial disc), anterior approach, including discectomy with end plate preparation (includes osteophytectomy for nerve root or spinal cord decompression and microdissection); second level, cervical	**374** DISORDERS OF SPINE WITH NEUROLOGIC IMPAIRMENT **545** ACUTE AND CHRONIC DISORDERS OF SPINE WITHOUT NEUROLOGIC IMPAIRMENT	22856 (Total disc arthroplasty (artificial disc), anterior approach, including discectomy with end plate preparation (includes osteophytectomy for nerve root or spinal cord decompression and microdissection); single interspace, cervical) is on lines 374,545
27279	Arthrodesis, sacroiliac joint, percutaneous or minimally invasive (indirect visualization), with image guidance, includes obtaining bone graft when performed, and placement of transfixing device	**187** FRACTURE OF PELVIS, OPEN AND CLOSED	27280 (Arthrodesis, sacroiliac joint (including obtaining graft)) was on line 189 (became 187), deleted with 2015 CPT codes
33270	Insertion or replacement of permanent subcutaneous implantable defibrillator system, with subcutaneous electrode, including defibrillation threshold evaluation, induction of arrhythmia, evaluation of sensing for arrhythmia termination, and programming or	**103** CARDIOMYOPATHY **115** CONGENITAL HEART BLOCK; OTHER OBSTRUCTIVE ANOMALIES OF HEART **286** LIFE-THREATENING CARDIAC ARRHYTHMIAS **290** COMPLICATIONS OF A PROCEDURE ALWAYS REQUIRING TREATMENT	Other implantable defibrillator systems on 103, 115, 286, 290
33271	Insertion of subcutaneous implantable defibrillator electrode	**103, 115, 286, 290**	See 33270
33272	Removal of subcutaneous implantable defibrillator electrode	**103, 115, 286, 290**	See 33270
33273	Repositioning of previously implanted subcutaneous implantable defibrillator electrode	**103, 115, 286, 290**	See 33270
33418	Transcatheter mitral valve repair, percutaneous approach, including transseptal puncture when performed; initial prosthesis	**73** ACUTE AND SUBACUTE ISCHEMIC HEART DISEASE, MYOCARDIAL INFARCTION **86** MYOCARDITIS, PERICARDITIS, AND ENDOCARDITIS 93 DISCORDANT CARDIOVASCULAR CONNECTIONS **94** CONGENITAL MITRAL VALVE STENOSIS/INSUFFICIENCY **115** CONGENITAL HEART BLOCK; OTHER OBSTRUCTIVE ANOMALIES OF HEART **190** RHEUMATIC MULTIPLE VALVULAR DISEASE **193** CHRONIC ISCHEMIC HEART DISEASE **261** DISEASES OF MITRAL, TRICUSPID, AND PULMONARY VALVES **290** COMPLICATIONS OF A PROCEDURE ALWAYS REQUIRING TREATMENT **368** ALLERGIC BRONCHOPULMONARY ASPERGILLOSIS	mitral valve repair open procedures are on lines 73, 86, 94, 115, 190, 193, 261, 290, 368
33419	Transcatheter mitral valve repair, percutaneous approach, including transseptal puncture when performed; additional prosthesis(es) during same session (List separately in addition to code for primary procedure)	**73, 86, 94, 115, 190, 193, 261, 290, 368**	See 33418 above
33946	Extracorporeal membrane oxygenation (ECMO)/extracorporeal life support (ECLS) provided by physician; initiation, veno-venous	**11** RESPIRATORY CONDITIONS OF FETUS AND NEWBORN **48** COARCTATION OF THE AORTA **71** VENTRICULAR SEPTAL DEFECT **73** ACUTE AND SUBACUTE ISCHEMIC HEART DISEASE, MYOCARDIAL INFARCTION **74** CONGENITAL PULMONARY VALVE ANOMALIES **81** PATENT DUCTUS ARTERIOSUS; AORTIC PULMONARY FISTULA/WINDOW **86** MYOCARDITIS, PERICARDITIS, AND ENDOCARDITIS **89** ENDOCARDIAL CUSHION DEFECTS **90** CONGENITAL PULMONARY VALVE ATRESIA **93** DISCORDANT CARDIOVASCULAR CONNECTIONS **94** CONGENITAL MITRAL VALVE STENOSIS/INSUFFICIENCY **102** HEART FAILURE **109** TETRALOGY OF FALLOT (TOF); CONGENITAL VENOUS ABNORMALITIES **110** CONGENITAL STENOSIS AND INSUFFICIENCY OF AORTIC VALVE **115** CONGENITAL HEART BLOCK; OTHER OBSTRUCTIVE ANOMALIES OF HEART **123** ATRIAL SEPTAL DEFECT, SECUNDUM **132** COMMON TRUNCUS **134** TOTAL ANOMALOUS PULMONARY VENOUS CONNECTION **138** INTERRUPTED AORTIC ARCH **142** EBSTEIN'S ANOMALY **180** COMMON VENTRICLE **186** SEPTICEMIA **192** CONGENITAL TRICUSPID ATRESIA AND STENOSIS **236** HYPOPLASTIC LEFT HEART SYNDROME	Lines with diagnoses of respiratory failure (11, 237), cardiac failure lines with treatments including VAD procedures (86, 102), cardiogenic shock (73), septic shock (186), persistant fetal circulation (81), congenital heart disease (48, 71, 74, 89, 90, 93, 94, 109, 110, 115, 123, 132, 134, 138, 142, 180, 192, 236), cardiac transplant and complications thereof (244, 267) Current CPT codes 33960, 33961 (Prolonged extracorporeal circulation for cardiopulmonary insufficiency) are Exempt (always covered). These codes are deleted with 2015 CPT code set. Exempt (always covered) would be another option; however, virtually all diagnoses for which ECMO is used should be on these lines.

Code	Code Descriptions	Proposed Placement	Notes
33947	Extracorporeal membrane oxygenation (ECMO)/extracorporeal life support (ECLS) provided by physician; initiation, veno-arterial	**11, 48, 71, 73, 74, 81, 86, 89, 90, 93, 94, 102, 109, 110, 115, 123, 132, 134, 138, 142, 180, 186, 192, 236, 237, 244, 267**	See 33946 above
33948	Extracorporeal membrane oxygenation (ECMO)/extracorporeal life support (ECLS) provided by physician; daily management, each day, veno-venous	**11, 48, 71, 73, 74, 81, 86, 89, 90, 93, 94, 102, 109, 110, 115, 123, 132, 134, 138, 142, 180, 186, 192, 236, 237, 244, 267**	See 33946 above
33949	Extracorporeal membrane oxygenation (ECMO)/extracorporeal life support (ECLS) provided by physician; daily management, each day, veno-arterial	**11, 48, 71, 73, 74, 81, 86, 89, 90, 93, 94, 102, 109, 110, 115, 123, 132, 134, 138, 142, 180, 186, 192, 236, 237, 244, 267**	See 33946 above
33951	Extracorporeal membrane oxygenation (ECMO)/extracorporeal life support (ECLS) provided by physician; insertion of peripheral (arterial and/or venous) cannula(e), percutaneous, birth through 5 years of age (includes fluoroscopic guidance, when performed)	**11, 48, 71, 73, 74, 81, 86, 89, 90, 93, 94, 102, 109, 110, 115, 123, 132, 134, 138, 142, 180, 186, 192, 236, 237, 244, 267**	See 33946 above
33952	Extracorporeal membrane oxygenation (ECMO)/extracorporeal life support (ECLS) provided by physician; insertion of peripheral (arterial and/or venous) cannula(e), percutaneous, 6 years and older (includes fluoroscopic guidance, when performed)	**11, 48, 71, 73, 74, 81, 86, 89, 90, 93, 94, 102, 109, 110, 115, 123, 132, 134, 138, 142, 180, 186, 192, 236, 237, 244, 267**	See 33946 above
33953	Extracorporeal membrane oxygenation (ECMO)/extracorporeal life support (ECLS) provided by physician; insertion of peripheral (arterial and/or venous) cannula(e), open, birth through 5 years of age	**11, 48, 71, 73, 74, 81, 86, 89, 90, 93, 94, 102, 109, 110, 115, 123, 132, 134, 138, 142, 180, 186, 192, 236, 237, 244, 267**	See 33946 above
33954	Extracorporeal membrane oxygenation (ECMO)/extracorporeal life support (ECLS) provided by physician; insertion of peripheral (arterial and/or venous) cannula(e), open, 6 years and older	**11, 48, 71, 73, 74, 81, 86, 89, 90, 93, 94, 102, 109, 110, 115, 123, 132, 134, 138, 142, 180, 186, 192, 236, 237, 244, 267**	See 33946 above
33955	Extracorporeal membrane oxygenation (ECMO)/extracorporeal life support (ECLS) provided by physician; insertion of central cannula(e) by sternotomy or thoracotomy, birth through 5 years of age	**11, 48, 71, 73, 74, 81, 86, 89, 90, 93, 94, 102, 109, 110, 115, 123, 132, 134, 138, 142, 180, 186, 192, 236, 237, 244, 267**	See 33946 above
33956	Extracorporeal membrane oxygenation (ECMO)/extracorporeal life support (ECLS) provided by physician; insertion of central cannula(e) by sternotomy or thoracotomy, 6 years and older	**11, 48, 71, 73, 74, 81, 86, 89, 90, 93, 94, 102, 109, 110, 115, 123, 132, 134, 138, 142, 180, 186, 192, 236, 237, 244, 267**	See 33946 above
33957	Extracorporeal membrane oxygenation (ECMO)/extracorporeal life support (ECLS) provided by physician; reposition peripheral (arterial and/or venous) cannula(e), percutaneous, birth through 5 years of age (includes fluoroscopic guidance, when performed)	**11, 48, 71, 73, 74, 81, 86, 89, 90, 93, 94, 102, 109, 110, 115, 123, 132, 134, 138, 142, 180, 186, 192, 236, 237, 244, 267**	See 33946 above
33958	Extracorporeal membrane oxygenation (ECMO)/extracorporeal life support (ECLS) provided by physician; reposition peripheral (arterial and/or venous) cannula(e), percutaneous, 6 years and older (includes fluoroscopic guidance, when performed)	**11, 48, 71, 73, 74, 81, 86, 89, 90, 93, 94, 102, 109, 110, 115, 123, 132, 134, 138, 142, 180, 186, 192, 236, 237, 244, 267**	See 33946 above
33959	Extracorporeal membrane oxygenation (ECMO)/extracorporeal life support (ECLS) provided by physician; reposition peripheral (arterial and/or venous) cannula(e), open, birth through 5 years of age (includes fluoroscopic guidance, when performed)	**11, 48, 71, 73, 74, 81, 86, 89, 90, 93, 94, 102, 109, 110, 115, 123, 132, 134, 138, 142, 180, 186, 192, 236, 237, 244, 267**	See 33946 above
33962	Extracorporeal membrane oxygenation (ECMO)/extracorporeal life support (ECLS) provided by physician; reposition peripheral (arterial and/or venous) cannula(e), open, 6 years and older (includes fluoroscopic guidance, when performed)	**11, 48, 71, 73, 74, 81, 86, 89, 90, 93, 94, 102, 109, 110, 115, 123, 132, 134, 138, 142, 180, 186, 192, 236, 237, 244, 267**	See 33946 above
33963	Extracorporeal membrane oxygenation (ECMO)/extracorporeal life support (ECLS) provided by physician; reposition of central cannula(e) by sternotomy or thoracotomy, birth through 5 years of age (includes fluoroscopic guidance, when performed)	**11, 48, 71, 73, 74, 81, 86, 89, 90, 93, 94, 102, 109, 110, 115, 123, 132, 134, 138, 142, 180, 186, 192, 236, 237, 244, 267**	See 33946 above
33964	Extracorporeal membrane oxygenation (ECMO)/extracorporeal life support (ECLS) provided by physician; reposition central cannula(e) by sternotomy or thoracotomy, 6 years and older (includes fluoroscopic guidance, when performed)	**11, 48, 71, 73, 74, 81, 86, 89, 90, 93, 94, 102, 109, 110, 115, 123, 132, 134, 138, 142, 180, 186, 192, 236, 237, 244, 267**	See 33946 above
33965	Extracorporeal membrane oxygenation (ECMO)/extracorporeal life support (ECLS) provided by physician; removal of peripheral (arterial and/or venous) cannula(e), percutaneous, birth through 5 years of age	**11, 48, 71, 73, 74, 81, 86, 89, 90, 93, 94, 102, 109, 110, 115, 123, 132, 134, 138, 142, 180, 186, 192, 236, 237, 244, 267**	See 33946 above
33966	Extracorporeal membrane oxygenation (ECMO)/extracorporeal life support (ECLS) provided by physician; removal of peripheral (arterial and/or venous) cannula(e), percutaneous, 6 years and older	**11, 48, 71, 73, 74, 81, 86, 89, 90, 93, 94, 102, 109, 110, 115, 123, 132, 134, 138, 142, 180, 186, 192, 236, 237, 244, 267**	See 33946 above

Code	Code Descriptions	Proposed Placement	Notes
33969	Extracorporeal membrane oxygenation (ECMO)/extracorporeal life support (ECLS) provided by physician; removal of peripheral (arterial and/or venous) cannula(e), open, birth through 5 years of age	**11, 48, 71, 73, 74, 81, 86, 89, 90, 93, 94, 102, 109, 110, 115, 123, 132, 134, 138, 142, 180, 186, 192, 236, 237, 244, 267**	See 33946 above
33984	Extracorporeal membrane oxygenation (ECMO)/extracorporeal life support (ECLS) provided by physician; removal of peripheral (arterial and/or venous) cannula(e), open, 6 years and older	**11, 48, 71, 73, 74, 81, 86, 89, 90, 93, 94, 102, 109, 110, 115, 123, 132, 134, 138, 142, 180, 186, 192, 236, 237, 244, 267**	See 33946 above
33985	Extracorporeal membrane oxygenation (ECMO)/extracorporeal life support (ECLS) provided by physician; removal of central cannula(e) by sternotomy or thoracotomy, birth through 5 years of age	**11, 48, 71, 73, 74, 81, 86, 89, 90, 93, 94, 102, 109, 110, 115, 123, 132, 134, 138, 142, 180, 186, 192, 236, 237, 244, 267**	See 33946 above
33986	Extracorporeal membrane oxygenation (ECMO)/extracorporeal life support (ECLS) provided by physician; removal of central cannula(e) by sternotomy or thoracotomy, 6 years and older	**11, 48, 71, 73, 74, 81, 86, 89, 90, 93, 94, 102, 109, 110, 115, 123, 132, 134, 138, 142, 180, 186, 192, 236, 237, 244, 267**	See 33946 above
33987	Arterial exposure with creation of graft conduit (eg, chimney graft) to facilitate arterial perfusion for ECMO/ECLS (List separately in addition to code for primary procedure)	**11, 48, 71, 73, 74, 81, 86, 89, 90, 93, 94, 102, 109, 110, 115, 123, 132, 134, 138, 142, 180, 186, 192, 236, 237, 244, 267**	See 33946 above
33988	Insertion of left heart vent by thoracic incision (eg, sternotomy, thoracotomy) for ECMO/ECLS	**11, 48, 71, 73, 74, 81, 86, 89, 90, 93, 94, 102, 109, 110, 115, 123, 132, 134, 138, 142, 180, 186, 192, 236, 237, 244, 267**	See 33946 above
33989	Removal of left heart vent by thoracic incision (eg, sternotomy, thoracotomy) for ECMO/ECLS	**11, 48, 71, 73, 74, 81, 86, 89, 90, 93, 94, 102, 109, 110, 115, 123, 132, 134, 138, 142, 180, 186, 192, 236, 237, 244, 267**	See 33946 above
34839	Physician planning of a patient-specific fenestrated visceral aortic endograft requiring a minimum of 90 minutes of physician time	**84** INJURY TO INTERNAL ORGANS **257** ARTERIAL EMBOLISM/THROMBOSIS: ABDOMINAL AORTA, THORACIC AORTA **280** INJURY TO BLOOD VESSELS OF THE THORACIC CAVITY **289** DISSECTING OR RUPTURED AORTIC ANEURYSM **330** NON-DISSECTING ANEURYSM WITHOUT RUPTURE	Endovascular aortic graft procedures (CPT 34841-34848) are on line 84,257,280,289,330
37218	Transcatheter placement of intravascular stent(s), intrathoracic common carotid artery or innominate artery, open or percutaneous antegrade approach, including angioplasty, when performed, and radiological supervision and interpretation	**322** STROKE **419** TRANSIENT CEREBRAL ISCHEMIA; OCCLUSION/STENOSIS OF PRECEREBRAL ARTERIES WITHOUT OCCLUSION	Similar code 37217 (Transcatheter placement of intravascular stent(s), intrathoracic common carotid artery or innominate artery by retrograde treatment, open ipsilateral cervical carotid artery exposure) is on lines 322, 419
43180	Esophagoscopy, rigid, transoral with diverticulectomy of hypopharynx or cervical esophagus (eg, Zenker's diverticulum), with cricopharyngeal myotomy, includes use of telescope or operating microscope and repair, when performed	**384** ESOPHAGITIS; ESOPHAGEAL AND INTRAESOPHAGEAL HERNIAS **519** ESOPHAGITIS AND GERD; ESOPHAGEAL SPASM; ASYMPTOMATIC DIAPHRAGMATIC HERNIA	530.6 (Diverticulum of esophagus, acquired) is on lines 384,519
44381	Ileoscopy, through stoma; with transendoscopic balloon dilation	**32** REGIONAL ENTERITIS, IDIOPATHIC PROCTOCOLITIS, ULCERATION OF INTESTINE **46** INTUSSCEPTION, VOLVULUS, INTESTINAL OBSTRUCTION, HAZARDOUS FOREIGN BODY IN GI TRACT WITH RISK OF PERFORATION OR OBSTRUCTION **105** CONGENITAL ANOMALIES OF DIGESTIVE SYSTEM AND ABDOMINAL WALL EXCLUDING NECROSIS; CHRONIC INTESTINAL PSEUDO-OBSTRUCTION **161** CANCER OF COLON, RECTUM, SMALL INTESTINE AND ANUS **647** BENIGN NEOPLASMS OF DIGESTIVE SYSTEM	Similar code 44379 (Small intestinal endoscopy, enteroscopy beyond second portion of duodenum, including ileum; with transendoscopic stent) is on lines 46,105 Add 44379 to lines 32, 161, and 647
44384	Ileoscopy, through stoma; with placement of endoscopic stent (includes pre- and post-dilation and guide wire passage, when performed)	**32** REGIONAL ENTERITIS, IDIOPATHIC PROCTOCOLITIS, ULCERATION OF INTESTINE **46** INTUSSCEPTION, VOLVULUS, INTESTINAL OBSTRUCTION, HAZARDOUS FOREIGN BODY IN GI TRACT WITH RISK OF PERFORATION OR OBSTRUCTION **105** CONGENITAL ANOMALIES OF DIGESTIVE SYSTEM AND ABDOMINAL WALL EXCLUDING NECROSIS; CHRONIC INTESTINAL PSEUDO-OBSTRUCTION **161** CANCER OF COLON, RECTUM, SMALL INTESTINE AND ANUS **647** BENIGN NEOPLASMS OF DIGESTIVE SYSTEM	See 44381 above
44401	Colonoscopy through stoma; with ablation of tumor(s), polyp(s), or other lesion(s) (includes pre-and post-dilation and guide wire passage, when performed)	**46** INTUSSCEPTION, VOLVULUS, INTESTINAL OBSTRUCTION, HAZARDOUS FOREIGN BODY IN GI TRACT WITH RISK OF PERFORATION OR OBSTRUCTION **60** ULCERS, GASTRITIS, DUODENITIS, AND GI HEMORRHAGE **105** CONGENITAL ANOMALIES OF DIGESTIVE SYSTEM AND ABDOMINAL WALL EXCLUDING NECROSIS; CHRONIC INTESTINAL PSEUDO-OBSTRUCTION **161** CANCER OF COLON, RECTUM, SMALL INTESTINE AND ANUS **170** ANAL, RECTAL AND COLONIC POLYPS **647** BENIGN NEOPLASMS OF DIGESTIVE SYSTEM	Simlar code 44394 (Colonoscopy through stoma; with removal of tumor(s), polyp(s), or other lesion(s) by snare technique) is on lines 46,105,161,170,647 Similar code 45384 (Colonoscopy, flexible; with removal of tumor(s), polyp(s), or other lesion(s) by hot biopsy forceps) is on lines 46,60,105,161,170,647

Code	Code Descriptions	Proposed Placement	Notes
44402	Colonoscopy through stoma; with endoscopic stent placement (including pre- and post-dilation and guide wire passage, when performed)	**32** REGIONAL ENTERITIS, IDIOPATHIC PROCTOCOLITIS, ULCERATION OF INTESTINE **46** INTUSSCEPTION, VOLVULUS, INTESTINAL OBSTRUCTION, HAZARDOUS FOREIGN BODY IN GI TRACT WITH RISK OF PERFORATION OR OBSTRUCTION **105** CONGENITAL ANOMALIES OF DIGESTIVE SYSTEM AND ABDOMINAL WALL EXCLUDING NECROSIS; CHRONIC INTESTINAL PSEUDO-OBSTRUCTION **161** CANCER OF COLON, RECTUM, SMALL INTESTINE AND ANUS **647** BENIGN NEOPLASMS OF DIGESTIVE SYSTEM	45327 (Proctosigmoidoscopy, rigid; with transendoscopic stent placement (includes predilation)) is on lines 46,105,647 Lines 32, 161 are also appropriate Add 45327 to lines 32 and 161
44403	Colonoscopy through stoma; with endoscopic mucosal resection	**Diagnostic Procedures List**	Similar code 43254 is Diagnostic
44404	Colonoscopy through stoma; with directed submucosal injection(s), any substance	**32** REGIONAL ENTERITIS, IDIOPATHIC PROCTOCOLITIS, ULCERATION OF INTESTINE **46** INTUSSCEPTION, VOLVULUS, INTESTINAL OBSTRUCTION, HAZARDOUS FOREIGN BODY IN GI TRACT WITH RISK OF PERFORATION OR OBSTRUCTION **60** ULCERS, GASTRITIS, DUODENITIS, AND GI HEMORRHAGE **105** CONGENITAL ANOMALIES OF DIGESTIVE SYSTEM AND ABDOMINAL WALL EXCLUDING NECROSIS; CHRONIC INTESTINAL PSEUDO-OBSTRUCTION **161** CANCER OF COLON, RECTUM, SMALL INTESTINE AND ANUS **170** ANAL, RECTAL AND COLONIC POLYPS **189** DIVERTICULITIS OF COLON **647** BENIGN NEOPLASMS OF DIGESTIVE SYSTEM	45381 (Colonoscopy, flexible; with directed submucosal injection(s), any substance) is on lines 32,46,60,105,161,170,189,480,647,629 480 and 629 are not appropriate for colonoscopy through stoma
44405	Colonoscopy through stoma; with transendoscopic balloon dilation	**32** REGIONAL ENTERITIS, IDIOPATHIC PROCTOCOLITIS, ULCERATION OF INTESTINE **46** INTUSSCEPTION, VOLVULUS, INTESTINAL OBSTRUCTION, HAZARDOUS FOREIGN BODY IN GI TRACT WITH RISK OF PERFORATION OR OBSTRUCTION **105** CONGENITAL ANOMALIES OF DIGESTIVE SYSTEM AND ABDOMINAL WALL EXCLUDING NECROSIS; CHRONIC INTESTINAL PSEUDO-OBSTRUCTION **161** CANCER OF COLON, RECTUM, SMALL INTESTINE AND ANUS **647** BENIGN NEOPLASMS OF DIGESTIVE SYSTEM	Similar code 45386 (Colonoscopy, flexible; with transendoscopic balloon dilation) is on lines 32,46,105,161 Add 45386 to line 647
44406	Colonoscopy through stoma; with endoscopic ultrasound examination, limited to the sigmoid, descending, transverse, or ascending colon and cecum and adjacent structures	**Diagnostic Procedures List**	
44407	Colonoscopy through stoma; with transendoscopic ultrasound guided intramural or transmural fine needle aspiration/biopsy(s), includes endoscopic ultrasound examination limited to the sigmoid, descending, transverse, or ascending colon and cecum and adjace	**Diagnostic Procedures List**	
44408	Colonoscopy through stoma; with decompression (for pathologic distention) (eg, volvulus, megacolon), including placement of decompression tube, when performed	**46** INTUSSCEPTION, VOLVULUS, INTESTINAL OBSTRUCTION, HAZARDOUS FOREIGN BODY IN GI TRACT WITH RISK OF PERFORATION OR OBSTRUCTION **105** CONGENITAL ANOMALIES OF DIGESTIVE SYSTEM AND ABDOMINAL WALL EXCLUDING NECROSIS; CHRONIC INTESTINAL PSEUDO-OBSTRUCTION	Megacolon and volvulus diagnoses are on line 46 Hirschsprung's disease is on line 105
45346	Sigmoidoscopy, flexible; with ablation of tumor(s), polyp(s), or other lesion(s) (includes pre- and post-dilation and guide wire passage, when performed)	**46** INTUSSCEPTION, VOLVULUS, INTESTINAL OBSTRUCTION, HAZARDOUS FOREIGN BODY IN GI TRACT WITH RISK OF PERFORATION OR OBSTRUCTION **60** ULCERS, GASTRITIS, DUODENITIS, AND GI HEMORRHAGE **105** CONGENITAL ANOMALIES OF DIGESTIVE SYSTEM AND ABDOMINAL WALL EXCLUDING NECROSIS; CHRONIC INTESTINAL PSEUDO-OBSTRUCTION **161** CANCER OF COLON, RECTUM, SMALL INTESTINE AND ANUS **170** ANAL, RECTAL AND COLONIC POLYPS **647** BENIGN NEOPLASMS OF DIGESTIVE SYSTEM	Simlar code 44394 (Colonoscopy through stoma; with removal of tumor(s), polyp(s), or other lesion(s) by snare technique) is on lines 46,105,161,170,647 Similar code 45384 (Colonoscopy, flexible; with removal of tumor(s), polyp(s), or other lesion(s) by hot biopsy forceps) is on lines 46,60,105,161,170,647
45347	Sigmoidoscopy, flexible; with placement of endoscopic stent (includes pre- and post-dilation and guide wire passage, when performed)	**32** REGIONAL ENTERITIS, IDIOPATHIC PROCTOCOLITIS, ULCERATION OF INTESTINE **46** INTUSSCEPTION, VOLVULUS, INTESTINAL OBSTRUCTION, HAZARDOUS FOREIGN BODY IN GI TRACT WITH RISK OF PERFORATION OR OBSTRUCTION **105** CONGENITAL ANOMALIES OF DIGESTIVE SYSTEM AND ABDOMINAL WALL EXCLUDING NECROSIS; CHRONIC INTESTINAL PSEUDO-OBSTRUCTION **161** CANCER OF COLON, RECTUM, SMALL INTESTINE AND ANUS **647** BENIGN NEOPLASMS OF DIGESTIVE SYSTEM	45327 (Proctosigmoidoscopy, rigid; with transendoscopic stent placement (includes predilation)) is on lines 46,105,647 Lines 32, 161 are also appropriate
45349	Sigmoidoscopy, flexible; with endoscopic mucosal resection	**Diagnostic Procedures List**	
45350	Sigmoidoscopy, flexible; with band ligation(s) (eg, hemorrhoids)	**480** THROMBOSED AND COMPLICATED HEMORRHOIDS **629** UNCOMPLICATED HEMORRHOIDS	Similar code 46947 (Hemorrhoidopexy) is on lines 480, 629

Code	Code Descriptions	Proposed Placement	Notes
45388	Colonoscopy, flexible; with ablation of tumor(s), polyp(s), or other lesion(s) (includes pre- and post-dilation and guide wire passage, when performed)	**46** INTUSSCEPTION, VOLVULUS, INTESTINAL OBSTRUCTION, HAZARDOUS FOREIGN BODY IN GI TRACT WITH RISK OF PERFORATION OR OBSTRUCTION **60** ULCERS, GASTRITIS, DUODENITIS, AND GI HEMORRHAGE **105** CONGENITAL ANOMALIES OF DIGESTIVE SYSTEM AND ABDOMINAL WALL EXCLUDING NECROSIS; CHRONIC INTESTINAL PSEUDO-OBSTRUCTION **161** CANCER OF COLON, RECTUM, SMALL INTESTINE AND ANUS **170** ANAL, RECTAL AND COLONIC POLYPS **647** BENIGN NEOPLASMS OF DIGESTIVE SYSTEM	Similar code 45384 (Colonoscopy, flexible; with removal of tumor(s), polyp(s), or other lesion(s) by hot biopsy forceps) is on lines 46,60,105,161,170,647
45389	Colonoscopy, flexible; with endoscopic stent placement (includes pre- and post-dilation and guide wire passage, when performed)	**32** REGIONAL ENTERITIS, IDIOPATHIC PROCTOCOLITIS, ULCERATION OF INTESTINE **46** INTUSSCEPTION, VOLVULUS, INTESTINAL OBSTRUCTION, HAZARDOUS FOREIGN BODY IN GI TRACT WITH RISK OF PERFORATION OR OBSTRUCTION **105** CONGENITAL ANOMALIES OF DIGESTIVE SYSTEM AND ABDOMINAL WALL EXCLUDING NECROSIS; CHRONIC INTESTINAL PSEUDO-OBSTRUCTION **161** CANCER OF COLON, RECTUM, SMALL INTESTINE AND ANUS **647** BENIGN NEOPLASMS OF DIGESTIVE SYSTEM	45327 (Proctosigmoidoscopy, rigid; with transendoscopic stent placement (includes predilation)) is on lines 46,105,647 Lines 32, 161 are also appropriate
45390	Colonoscopy, flexible; with endoscopic mucosal resection	**Diagnostic Procedures List**	
45393	Colonoscopy, flexible; with decompression (for pathologic distention) (eg, volvulus, megacolon), including placement of decompression tube, when performed	**46** INTUSSCEPTION, VOLVULUS, INTESTINAL OBSTRUCTION, HAZARDOUS FOREIGN BODY IN GI TRACT WITH RISK OF PERFORATION OR OBSTRUCTION **105** CONGENITAL ANOMALIES OF DIGESTIVE SYSTEM AND ABDOMINAL WALL EXCLUDING NECROSIS; CHRONIC INTESTINAL PSEUDO-OBSTRUCTION	Megacolon and volvulus are on line 46 Hirschsprung's disease is on line 105
45398	Colonoscopy, flexible; with band ligation(s) (eg, hemorrhoids)	**480** THROMBOSED AND COMPLICATED HEMORRHOIDS **629** UNCOMPLICATED HEMORRHOIDS	Similar code 46947 (Hemorrhoidopexy) is on lines 480, 629
45399	Unlisted procedure, colon	**Ancillary Codes File**	Will require manual review
46601	Anoscopy; diagnostic, with high-resolution magnification (HRA) (eg, colposcope, operating microscope) and chemical agent enhancement, including collection of specimen(s) by brushing or washing, when performed	**Diagnostic Procedures List**	
46607	Anoscopy; with high-resolution magnification (HRA) (eg, colposcope, operating microscope) and chemical agent enhancement, with biopsy, single or multiple	**Diagnostic Procedures List**	
47383	Ablation, 1 or more liver tumor(s), percutaneous, cryoablation	**Non-Covered List**	See Issues document
52441	Cystourethroscopy, with insertion of permanent adjustable transprostatic implant; single implant	**331** FUNCTIONAL AND MECHANICAL DISORDERS OF THE GENITOURINARY SYSTEM INCLUDING BLADDER OUTLET OBSTRUCTION	Similar HCPCS codes C9739-C9740 (Cystourethroscopy with transprostatic implant; 1 to 3 implants or 4 or more implants) care on line 331 **NICE 2014**: Current evidence on the efficacy and safety of insertion of prostatic urethral lift implants to treat lower urinary tract symptoms secondary to benign prostatic hyperplasia is adequate to support the use of this procedure
52442	Cystourethroscopy, with insertion of permanent adjustable transprostatic implant; each additional permanent adjustable transprostatic implant (List separately in addition to code for primary procedure)	**331** FUNCTIONAL AND MECHANICAL DISORDERS OF THE GENITOURINARY SYSTEM INCLUDING BLADDER OUTLET OBSTRUCTION	See 52441
62302	Myelography via lumbar injection, including radiological supervision and interpretation; cervical	**Diagnostic Procedures List**	Other myelography codes (62284, 72240, 72255, etc.) are Diagnostic
62303	Myelography via lumbar injection, including radiological supervision and interpretation; thoracic	**Diagnostic Procedures List**	
62304	Myelography via lumbar injection, including radiological supervision and interpretation; lumbosacral	**Diagnostic Procedures List**	
62305	Myelography via lumbar injection, including radiological supervision and interpretation; 2 or more regions (eg, lumbar/thoracic, cervical/thoracic, lumbar/cervical, lumbar/thoracic/cervical)	**Diagnostic Procedures List**	
64486	Transversus abdominis plane (TAP) block (abdominal plane block, rectus sheath block) unilateral; by injection(s) (includes imaging guidance, when performed)	**Ancillary Codes File**	See Issues document
64487	Transversus abdominis plane (TAP) block (abdominal plane block, rectus sheath block) unilateral; by continuous infusion(s) (includes imaging guidance, when performed)	**Ancillary Codes File**	See Issues document
64488	Transversus abdominis plane (TAP) block (abdominal plane block, rectus sheath block) bilateral; by injections (includes imaging guidance, when performed)	**Ancillary Codes File**	See Issues document

Code	Code Descriptions	Proposed Placement	Notes
64489	Transversus abdominis plane (TAP) block (abdominal plane block, rectus sheath block) bilateral; by continuous infusions (includes imaging guidance, when performed)	**Ancillary Codes File**	See Issues document
66179	Aqueous shunt to extraocular equatorial plate reservoir, external approach; without graft	**143** GLAUCOMA, OTHER THAN PRIMARY ANGLE-CLOSURE **247** PRIMARY ANGLE-CLOSURE GLAUCOMA	66180 (with graft) is on lines 143,247
66184	Revision of aqueous shunt to extraocular equatorial plate reservoir; without graft	**143** GLAUCOMA, OTHER THAN PRIMARY ANGLE-CLOSURE **247** PRIMARY ANGLE-CLOSURE GLAUCOMA	66185 (with graft) is on line 143 Add 66185 to line 247
76641	Ultrasound, breast, unilateral, real time with image documentation, including axilla when performed; complete	**Diagnostic Procedures List**	
76642	Ultrasound, breast, unilateral, real time with image documentation, including axilla when performed; limited	**Diagnostic Procedures List**	
77061	Digital breast tomosynthesis; unilateral	**Non-Covered List**	See Issues document
77062	Digital breast tomosynthesis; bilateral	**Non-Covered List**	See Issues document
77063	Screening digital breast tomosynthesis, bilateral (List separately in addition to code for primary procedure)	**Non-Covered List**	See Issues document
77085	Dual-energy X-ray absorptiometry (DXA), bone density study, 1 or more sites; axial skeleton (eg, hips, pelvis, spine), including vertebral fracture assessment	**Diagnostic Procedures List**	Similar code 77080 and 77081 are diagnostic
77086	Vertebral fracture assessment via dual-energy X-ray absorptiometry (DXA)	**Diagnostic Procedures List**	Similar code 77080 and 77081 are diagnostic
77306	Teletherapy isodose plan; simple (1 or 2 unmodified ports directed to a single area of interest), includes basic dosimetry calculation(s)	**97,116,117,119,129,130,133,137,139,161,195,199,203,204,212,214,162, 218,219,233,238,241,242,262,263,265,266,274,279,291,292,299,319,320 ,321,333,359,376, 401, 402, 424, 439,533,600,611**	Current teletherapy CPT codes (77305, 77310, 77315) have been deleted and replaced with 77306 and 77307. The old CPT codes for teletherapy planning where on the radiation therapy lines.
77307	Teletherapy isodose plan; complex (multiple treatment areas, tangential ports, the use of wedges, blocking, rotational beam, or special beam considerations), includes basic dosimetry calculation(s)	**97,116,117,119,129,130,133,137,139,161,195,199,203,204,212,214,162, 218,219,233,238,241,242,262,263,265,266,274,279,291,292,299,319,320 ,321,333,359,376, 401, 402, 424, 439,533,600,611**	See 77306
77316	Brachytherapy isodose plan; simple (calculation[s] made from 1 to 4 sources, or remote afterloading brachytherapy, 1 channel), includes basic dosimetry calculation(s)	**117, 137, 161, 195, 203, 212, 262, 265, 266, 274, 291, 292, 299, 320, 333, 376, 439, 465, 600**	Current brachytherapy CPT codes (77326, 77327, 77328) have been deleted and replaced with CPT 77316-77318. The old CPT codes for brachytherapy were on these 19 radiation therapy lines
77317	Brachytherapy isodose plan; intermediate (calculation[s] made from 5 to 10 sources, or remote afterloading brachytherapy, 2-12 channels), includes basic dosimetry calculation(s)	**117, 137, 161, 195, 203, 212, 262, 265, 266, 274, 291, 292, 299, 320, 333, 376, 439, 465, 600**	See 77316
77318	Brachytherapy isodose plan; complex (calculation[s] made from over 10 sources, or remote afterloading brachytherapy, over 12 channels), includes basic dosimetry calculation(s)	**117, 137, 161, 195, 203, 212, 262, 265, 266, 274, 291, 292, 299, 320, 333, 376, 439, 465, 600**	See 77316
77385	Intensity modulated radiation treatment delivery (IMRT), includes guidance and tracking, when performed; simple	**97,116,117,119,129,130,133,137,139,161,195,199,203,204,212,214,162, 218,219,233,238,241,242,262,263,265,266,274,279,291,292,299,319,320 ,321,333,359,376, 401, 402, 424, 439,533,600,611**	These codes replace CPT 77418 (Intensity modulated treatment delivery, single or multiple fields/arcs, via narrow spatially and temporally modulated beams, binary, dynamic MLC, per treatment session) which was on the radiation therapy lines
77386	Intensity modulated radiation treatment delivery (IMRT), includes guidance and tracking, when performed; complex	**97,116,117,119,129,130,133,137,139,161,195,199,203,204,212,214,162, 218,219,233,238,241,242,262,263,265,266,274,279,291,292,299,319,320 ,321,333,359,376, 401, 402, 424, 439,533,600,611**	See 77385
77387	Guidance for localization of target volume for delivery of radiation treatment delivery, includes intrafraction tracking, when performed	**41,75,85,97,116,117,119,129,130,133,137,139,161,195,199,203,204,212, 214,162,218,219,233,238,241,242,262,263,265,266,274,279,291,292,299 ,319,320,321,333,359,376, 401, 402, 424, 439,533,600,611**	Radiation therapy lines
80163	Digoxin; free	**Diagnostic Procedures List**	
80165	Valproic acid (dipropylacetic acid); free	**Diagnostic Procedures List**	
80300	Drug screen, any number of drug classes from Drug Class List A; any number of non-TLC devices or procedures, (eg, immunoassay) capable of being read by direct optical observation, including instrumented-assisted when performed (eg, dipsticks, cups, cards,	**Diagnostic Procedures List**	
80301	Drug screen, any number of drug classes from Drug Class List A; single drug class method, by instrumented test systems (eg, discrete multichannel chemistry analyzers utilizing immunoassay or enzyme assay), per date of service	**Diagnostic Procedures List**	
80302	Drug screen, presumptive, single drug class from Drug Class List B, by immunoassay (eg, ELISA) or non-TLC chromatography without mass spectrometry (eg, GC, HPLC), each procedure	**Diagnostic Procedures List**	

Code	Code Descriptions	Proposed Placement	Notes
80303	Drug screen, any number of drug classes, presumptive, single or multiple drug class method; thin layer chromatography procedure(s) (TLC) (eg, acid, neutral, alkaloid plate), per date of service	**Diagnostic Procedures List**	
80304	Drug screen, any number of drug classes, presumptive, single or multiple drug class method; not otherwise specified presumptive procedure (eg, TOF, MALDI, LDTD, DESI, DART), each procedure	**Diagnostic Procedures List**	
80320	Alcohols	**Diagnostic Procedures List**	
80321	Alcohol biomarkers; 1 or 2	**Diagnostic Procedures List**	
80322	Alcohol biomarkers; 3 or more	**Diagnostic Procedures List**	
80323	Alkaloids, not otherwise specified	**Diagnostic Procedures List**	
80324	Amphetamines; 1 or 2	**Diagnostic Procedures List**	
80325	Amphetamines; 3 or 4	**Diagnostic Procedures List**	
80326	Amphetamines; 5 or more	**Diagnostic Procedures List**	
80327	Anabolic steroids; 1 or 2	**Diagnostic Procedures List**	
80328	Anabolic steroids; 3 or more	**Diagnostic Procedures List**	
80329	Analgesics, non-opioid; 1 or 2	**Diagnostic Procedures List**	
80330	Analgesics, non-opioid; 3-5	**Diagnostic Procedures List**	
80331	Analgesics, non-opioid; 6 or more	**Diagnostic Procedures List**	
80332	Antidepressants, serotonergic class; 1 or 2	**Diagnostic Procedures List**	
80333	Antidepressants, serotonergic class; 3-5	**Diagnostic Procedures List**	
80334	Antidepressants, serotonergic class; 6 or more	**Diagnostic Procedures List**	
80335	Antidepressants, tricyclic and other cyclicals; 1 or 2	**Diagnostic Procedures List**	
80336	Antidepressants, tricyclic and other cyclicals; 3-5	**Diagnostic Procedures List**	
80337	Antidepressants, tricyclic and other cyclicals; 6 or more	**Diagnostic Procedures List**	
80338	Antidepressants, not otherwise specified	**Diagnostic Procedures List**	
80339	Antiepileptics, not otherwise specified; 1-3	**Diagnostic Procedures List**	
80340	Antiepileptics, not otherwise specified; 4-6	**Diagnostic Procedures List**	
80341	Antiepileptics, not otherwise specified; 7 or more	**Diagnostic Procedures List**	
80342	Antipsychotics, not otherwise specified; 1-3	**Diagnostic Procedures List**	
80343	Antipsychotics, not otherwise specified; 4-6	**Diagnostic Procedures List**	
80344	Antipsychotics, not otherwise specified; 7 or more	**Diagnostic Procedures List**	
80345	Barbiturates	**Diagnostic Procedures List**	
80346	Benzodiazepines; 1-12	**Diagnostic Procedures List**	
80347	Benzodiazepines; 13 or more	**Diagnostic Procedures List**	
80348	Buprenorphine	**Diagnostic Procedures List**	
80349	Cannabinoids, natural	**Diagnostic Procedures List**	
80350	Cannabinoids, synthetic; 1-3	**Diagnostic Procedures List**	
80351	Cannabinoids, synthetic; 4-6	**Diagnostic Procedures List**	
80352	Cannabinoids, synthetic; 7 or more	**Diagnostic Procedures List**	
80353	Cocaine	**Diagnostic Procedures List**	
80354	Fentanyl	**Diagnostic Procedures List**	
80355	Gabapentin, non-blood	**Diagnostic Procedures List**	
80356	Heroin metabolite	**Diagnostic Procedures List**	
80357	Ketamine and norketamine	**Diagnostic Procedures List**	
80358	Methadone	**Diagnostic Procedures List**	
80359	Methylenedioxyamphetamines (MDA, MDEA, MDMA)	**Diagnostic Procedures List**	
80360	Methylphenidate	**Diagnostic Procedures List**	
80361	Opiates, 1 or more	**Diagnostic Procedures List**	
80362	Opioids and opiate analogs; 1 or 2	**Diagnostic Procedures List**	
80363	Opioids and Opiate analogs; 3 or 4	**Diagnostic Procedures List**	
80364	Opioids and Opiate analogs; 5 or more	**Diagnostic Procedures List**	
80365	Oxycodone	**Diagnostic Procedures List**	
80366	Pregabalin	**Diagnostic Procedures List**	
80367	Propoxyphene	**Diagnostic Procedures List**	
80368	Sedative hypnotics (non-benzodiazepines)	**Diagnostic Procedures List**	
80369	Skeletal muscle relaxants; 1 or 2	**Diagnostic Procedures List**	
80370	Skeletal muscle relaxants; 3 or more	**Diagnostic Procedures List**	
80371	Stimulants, synthetic	**Diagnostic Procedures List**	
80372	Tapentadol	**Diagnostic Procedures List**	
80373	Tramadol	**Diagnostic Procedures List**	
80374	Stereoisomer (enantiomer) analysis, single drug class	**Diagnostic Procedures List**	
80375	Drug(s) or substance(s), definitive, qualitative or quantitative, not otherwise specified; 1-3	**Diagnostic Procedures List**	
80376	Drug(s) or substance(s), definitive, qualitative or quantitative, not otherwise specified; 4-6	**Diagnostic Procedures List**	
80377	Drug(s) or substance(s), definitive, qualitative or quantitative, not otherwise specified; 7 or more	**Diagnostic Procedures List**	
81246	FLT3 (fms-related tyrosine kinase 3) (eg, acute myeloid leukemia), gene analysis; tyrosine kinase domain (TKD) variants (eg, D835, I836)	**97** CHILDHOOD LEUKEMIAS **401** ACUTE PROMYELOCYTIC LEUKEMIA **402** ACUTE MYELOID LEUKEMIA Treatment: BONE MARROW TRANSPLANT **241** MYELOID DISORDERS	See Issues document

Code	Code Descriptions	Proposed Placement	Notes
81288	MLH1 (mutL homolog 1, colon cancer, nonpolyposis type 2) (eg, hereditary non-polyposis colorectal cancer, Lynch syndrome) gene analysis; promoter methylation analysis	**161** CANCER OF COLON, RECTUM, SMALL INTESTINE AND ANUS	Test done on a tumor , may affect treatment or surveillance
81313	PCA3/KLK3 (prostate cancer antigen 3 [non-protein coding]/kallikrein-related peptidase 3 [prostate specific antigen]) ratio (eg, prostate cancer)	**Non-Covered List**	See Issues document
81410	Aortic dysfunction or dilation (eg, Marfan syndrome, Loeys Dietz syndrome, Ehler Danlos syndrome type IV, arterial tortuosity syndrome); genomic sequence analysis panel, must include sequencing of at least 9 genes, including FBN1, TGFBR1, TGFBR2, COL3A1,	**Diagnostic List**	Genetics review
81411	Aortic dysfunction or dilation (eg, Marfan syndrome, Loeys Dietz syndrome, Ehler Danlos syndrome type IV, arterial tortuosity syndrome); duplication/deletion analysis panel, must include analyses for TGFBR1, TGFBR2, MYH11, and COL3A1	**Diagnostic List**	Genetics review
81415	Exome (eg, unexplained constitutional or heritable disorder or syndrome); sequence analysis	**Diagnostic List**	Genetics review
81416	Exome (eg, unexplained constitutional or heritable disorder or syndrome); sequence analysis, each comparator exome (eg, parents, siblings) (List separately in addition to code for primary procedure)	**Diagnostic List**	Genetics review
81417	Exome (eg, unexplained constitutional or heritable disorder or syndrome); re-evaluation of previously obtained exome sequence (eg, updated knowledge or unrelated condition/syndrome)	**Non-Covered List**	Genetics review
81420	Fetal chromosomal aneuploidy (eg, trisomy 21, monosomy X) genomic sequence analysis panel, circulating cell-free fetal DNA in maternal blood, must include analysis of chromosomes 13, 18, and 21	**1** PREGNANCY	Prenatal testing guideline applies
81425	Genome (eg, unexplained constitutional or heritable disorder or syndrome); sequence analysis	**Non-Covered List**	Genetics review
81426	Genome (eg, unexplained constitutional or heritable disorder or syndrome); sequence analysis, each comparator genome (eg, parents, siblings) (List separately in addition to code for primary procedure)	**Non-Covered List**	Genetics review
81427	Genome (eg, unexplained constitutional or heritable disorder or syndrome); re-evaluation of previously obtained genome sequence (eg, updated knowledge or unrelated condition/syndrome)	**Non-Covered List**	Genetics review
81430	Hearing loss (eg, nonsyndromic hearing loss, Usher syndrome, Pendred syndrome); genomic sequence analysis panel, must include sequencing of at least 60 genes, including CDH23, CLRN1, GJB2, GPR98, MTRNR1, MYO7A, MYO15A, PCDH15, OTOF, SLC26A4, TMC1, TMPRSS3	**Diagnostic List**	Genetics review
81431	Hearing loss (eg, nonsyndromic hearing loss, Usher syndrome, Pendred syndrome); duplication/deletion analysis panel, must include copy number analyses for STRC and DFNB1 deletions in GJB2 and GJB6 genes	**Diagnostic List**	Genetics review
81435	Hereditary colon cancer syndromes (eg, Lynch syndrome, familial adenomatosis polyposis); genomic sequence analysis panel, must include analysis of at least 7 genes, including APC, CHEK2, MLH1, MSH2, MSH6, MUTYH, and PMS2	**Diagnostic List**	Genetics review
81436	Hereditary colon cancer syndromes (eg, Lynch syndrome, familial adenomatosis polyposis); duplication/deletion gene analysis panel, must include analysis of at least 8 genes, including APC, MLH1, MSH2, MSH6, PMS2, EPCAM, CHEK2, and MUTYH	**Diagnostic List**	Genetics review
81440	Nuclear encoded mitochondrial genes (eg, neurologic or myopathic phenotypes), genomic sequence panel, must include analysis of at least 100 genes, including BCS1L, C10orf2, COQ2, COX10, DGUOK, MPV17, OPA1, PDSS2, POLG, POLG2, RRM2B, SCO1, SCO2, SLC25A4, S	**Diagnostic List**	Genetics review
81445	Targeted genomic sequence analysis panel, solid organ neoplasm, DNA analysis, 5-50 genes (eg, ALK, BRAF, CDKN2A, EGFR, ERBB2, KIT, KRAS, NRAS, MET, PDGFRA, PDGFRB, PGR, PIK3CA, PTEN, RET), interrogation for sequence variants and copy number variants or re	**Diagnostic List**	ALK, BRAF, KRAS, EGFR, PTEN appear to be standard testing
81450	Targeted genomic sequence analysis panel, hematolymphoid neoplasm or disorder, DNA and RNA analysis when performed, 5-50 genes (eg, BRAF, CEBPA, DNMT3A, EZH2, FLT3, IDH1, IDH2, JAK2, KRAS, KIT, MLL, NRAS, NPM1, NOTCH1), interrogation for sequence variants	**Diagnostic List**	NPMI, BRAF, IDH, KRAS, FTL3 appear to be standard testing

Code	Code Descriptions	Proposed Placement	Notes
81455	Targeted genomic sequence analysis panel, solid organ or hematolymphoid neoplasm, DNA and RNA analysis when performed, 51 or greater genes (eg, ALK, BRAF, CDKN2A, CEBPA, DNMT3A, EGFR, ERBB2, EZH2, FLT3, IDH1, IDH2, JAK2, KIT, KRAS, MLL, NPM1, NRAS, MET, N	**Diagnostic List**	ALK, BRAF, KRAS, EGFR, NPM1, FTL3 appear to be standard testing
81460	Whole mitochondrial genome (eg, Leigh syndrome, mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes [MELAS], myoclonic epilepsy with ragged-red fibers [MERFF], neuropathy, ataxia, and retinitis pigmentosa [NARP], Leber hereditary op	**Diagnostic List**	Genetics review
81465	Whole mitochondrial genome large deletion analysis panel (eg, Kearns-Sayre syndrome, chronic progressive external ophthalmoplegia), including heteroplasmy detection, if performed	**Diagnostic List**	Genetics review
81470	X-linked intellectual disability (XLID) (eg, syndromic and non-syndromic XLID); genomic sequence analysis panel, must include sequencing of at least 60 genes, including ARX, ATRX, CDKL5, FGD1, FMR1, HUWE1, IL1RAPL, KDM5C, L1CAM, MECP2, MED12, MID1, OCRL,	**Non-Covered List**	Genetics review
81471	X-linked intellectual disability (XLID) (eg, syndromic and non-syndromic XLID); duplication/deletion gene analysis, must include analysis of at least 60 genes, including ARX, ATRX, CDKL5, FGD1, FMR1, HUWE1, IL1RAPL, KDM5C, L1CAM, MECP2, MED12, MID1, OCRL,	**Non-Covered List**	Genetics review
81519	Oncology (breast), mRNA, gene expression profiling by real-time RT-PCR of 21 genes, utilizing formalin-fixed paraffin embedded tissue, algorithm reported as recurrence score	**195** CANCER OF BREAST; AT HIGH RISK OF BREAST CANCER	See issues document
83006	Growth stimulation expressed gene 2 (ST2, Interleukin 1 receptor like-1)	**Non-Covered List**	See issues document
87505	Infectious agent detection by nucleic acid (DNA or RNA); gastrointestinal pathogen (eg, Clostridium difficile, E. coli, Salmonella, Shigella, norovirus, Giardia), includes multiplex reverse transcription, when performed, and multiplex amplified probe tech, 3-5 targets	**Diagnostic Procedures List**	
87506	Infectious agent detection by nucleic acid (DNA or RNA); gastrointestinal pathogen (eg, Clostridium difficile, E. coli, Salmonella, Shigella, norovirus, Giardia), includes multiplex reverse transcription, when performed, and multiplex amplified probe tech, 6-11 targets	**Diagnostic Procedures List**	
87507	Infectious agent detection by nucleic acid (DNA or RNA); gastrointestinal pathogen (eg, Clostridium difficile, E. coli, Salmonella, Shigella, norovirus, Giardia), includes multiplex reverse transcription, when performed, and multiplex amplified probe tech, 12-25 targets	**Diagnostic Procedures List**	
87623	Infectious agent detection by nucleic acid (DNA or RNA); Human Papillomavirus (HPV), low-risk types (eg, 6, 11, 42, 43, 44)	**Diagnostic Procedures List**	Non-oncogenic, or low-risk HPV types, such as HPV 6 or 11, can cause (1) benign or low-grade abnormalities of cervical cells, (2) anogenital warts, and (3) a disease of the respiratory tract called recurrent respiratory papillomatosis (RRP).
87624	Infectious agent detection by nucleic acid (DNA or RNA); Human Papillomavirus (HPV), high-risk types (eg, 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 68)	**Diagnostic Procedures List**	G0123 (pap smear) is diagnostic
87625	Infectious agent detection by nucleic acid (DNA or RNA); Human Papillomavirus (HPV), types 16 and 18 only, includes type 45, if performed	**Diagnostic Procedures List**	G0123 (pap smear) is diagnostic
87806	Infectious agent antigen detection by immunoassay with direct optical observation; HIV-1 antigen(s), with HIV-1 and HIV-2 antibodies	**Diagnostic Procedures List**	
88341	Immunohistochemistry or immunocytochemistry, per specimen; each additional single antibody stain procedure (List separately in addition to code for primary procedure)	**Diagnostic Procedures List**	
88344	Immunohistochemistry or immunocytochemistry, per specimen; each multiplex antibody stain procedure	**Diagnostic Procedures List**	
88364	In situ hybridization (eg, FISH), per specimen; each additional single probe stain procedure (List separately in addition to code for primary procedure)	**Diagnostic Procedures List**	FISH is often used for finding specific features in DNA for use in genetic counseling, medicine, and species identification.[2] FISH can also be used to detect and localize specific RNA targets (mRNA, lncRNA and miRNA) in cells, circulating tumor cells, and tissue samples.
88366	In situ hybridization (eg, FISH), per specimen; each multiplex probe stain procedure	**Diagnostic Procedures List**	

Code	Code Descriptions	Proposed Placement	Notes
88369	Morphometric analysis, in situ hybridization (quantitative or semi-quantitative), manual, per specimen; each additional single probe stain procedure (List separately in addition to code for primary procedure)	**Diagnostic Procedures List**	In situ hybridization (ISH) is a type of hybridization that uses a labeled complementary DNA or RNA strand (i.e., probe) to localize a specific DNA or RNA sequence in a portion or section of tissue
88373	Morphometric analysis, in situ hybridization (quantitative or semi-quantitative), using computer-assisted technology, per specimen; each additional single probe stain procedure (List separately in addition to code for primary procedure)	**Diagnostic Procedures List**	
88374	Morphometric analysis, in situ hybridization (quantitative or semi-quantitative), using computer-assisted technology, per specimen; each multiplex probe stain procedure	**Diagnostic Procedures List**	
88377	Morphometric analysis, in situ hybridization (quantitative or semi-quantitative), manual, per specimen; each multiplex probe stain procedure	**Diagnostic Procedures List**	
89337	Cryopreservation, mature oocyte(s)	**Non-Covered List**	In vitro fertilization is an excluded procedures
90630	Influenza virus vaccine, quadrivalent (IIV4), split virus, preservative free, for intradermal use	**3** PREVENTION SERVICES WITH EVIDENCE OF EFFECTIVENESS	
90651	Human Papillomavirus vaccine types 6, 11, 16, 18, 31, 33, 45, 52, 58, nonavalent (HPV), 3 dose schedule, for intramuscular use	**3** PREVENTION SERVICES WITH EVIDENCE OF EFFECTIVENESS	
91200	Liver elastography, mechanically induced shear wave (eg, vibration), without imaging, with interpretation and report	**Non-Covered List**	See Issues document
92145	Corneal hysteresis determination, by air impulse stimulation, unilateral or bilateral, with interpretation and report	**Non-Covered List**	See Issues document
93260	Programming device evaluation (in person) with iterative adjustment of the implantable device to test the function of the device and select optimal permanent programmed values with analysis, review and report by a physician or other qualified health care	**Ancillary Codes File**	DMAP will need to manually review
93261	Interrogation device evaluation (in person) with analysis, review and report by a physician or other qualified health care professional, includes connection, recording and disconnection per patient encounter; implantable subcutaneous lead defibrillator sy	**Ancillary Codes File**	DMAP will need to manually review
93355	Echocardiography, transesophageal (TEE) for guidance of a transcatheter intracardiac or great vessel(s) structural intervention(s) (eg,TAVR, transcathether pulmonary valve replacement, mitral valve repair, paravalvular regurgitation repair, left atrial ap	**48** COARCTATION OF THE AORTA **71** VENTRICULAR SEPTAL DEFECT **73** ACUTE AND SUBACUTE ISCHEMIC HEART DISEASE, MYOCARDIAL INFARCTION **74** CONGENITAL PULMONARY VALVE ANOMALIES **81** PATENT DUCTUS ARTERIOSUS; AORTIC PULMONARY FISTULA/WINDOW **86** MYOCARDITIS, PERICARDITIS, AND ENDOCARDITIS **89** ENDOCARDIAL CUSHION DEFECTS **90** CONGENITAL PULMONARY VALVE ATRESIA **93** DISCORDANT CARDIOVASCULAR CONNECTIONS **94** CONGENITAL MITRAL VALVE STENOSIS/INSUFFICIENCY **102** HEART FAILURE **109** TETRALOGY OF FALLOT (TOF); CONGENITAL VENOUS ABNORMALITIES **110** CONGENITAL STENOSIS AND INSUFFICIENCY OF AORTIC VALVE **115** CONGENITAL HEART BLOCK; OTHER OBSTRUCTIVE ANOMALIES OF HEART **123** ATRIAL SEPTAL DEFECT, SECUNDUM **132** COMMON TRUNCUS **134** TOTAL ANOMALOUS PULMONARY VENOUS CONNECTION **138** INTERRUPTED AORTIC ARCH **142** EBSTEIN'S ANOMALY **180** COMMON VENTRICLE **190** RHEUMATIC MULTIPLE VALVULAR DISEASE **192** CONGENITAL TRICUSPID ATRESIA AND STENOSIS **193** CHRONIC ISCHEMIC HEART DISEASE **227** DISEASES AND DISORDERS OF AORTIC VALVE	All congenital heart defect lines, valvular disorder lines and major heart structural defect lines Alternative: Diagnostic Procedures File
93644	Electrophysiologic evaluation of subcutaneous implantable defibrillator (includes defibrillation threshold evaluation, induction of arrhythmia, evaluation of sensing for arrhythmia termination, and programming or reprogramming of sensing or therapeutic pa	**103** CARDIOMYOPATHY **115** CONGENITAL HEART BLOCK; OTHER OBSTRUCTIVE ANOMALIES OF HEART **286** LIFE-THREATENING CARDIAC ARRHYTHMIAS **290** COMPLICATIONS OF A PROCEDURE ALWAYS REQUIRING TREATMENT	Implantable defibrillator systems on 103, 115, 286, 290
93702	Bioimpedance spectroscopy (BIS), extracellular fluid analysis for lymphedema assessment(s)	**Non-Covered List**	See Issues document

Code	Code Descriptions	Proposed Placement	Notes
93895	Quantitative carotid intima media thickness and carotid atheroma evaluation, bilateral	**Non-Covered List**	See Issues document
96127	Brief emotional/behavioral assessment (eg, depression inventory, attention-deficit/hyperactivity disorder [ADHD] scale), with scoring and documentation, per standardized instrument	**Inpatient and outpatient medical lines**	Alcohol/drug use assessment tools (SBIRT; CPT 99408, 99409) are on all inpatient and outpatient medical lines

Policy

1. Aetna considers any of the following serum tumor markers for the stated indication medically necessary:
    1. Prostate-specific antigen (PSA) for prostate cancer screening (see CPB 0521 - Prostate Cancer Screening), staging, monitoring response to therapy, and detecting disease recurrence.
    2. Carcinoembryonic antigen (CEA) for any of the following:
        1. As a preoperative prognostic indicator in members with known colorectal carcinoma or mucinous appendiceal carcinoma when it will assist in staging and surgical treatment planning; *or*
        2. To detect asymptomatic recurrence of colorectal cancer after surgical and/or medical treatment for the diagnosis of colorectal cancer (not as a screening test for colorectal cancer); *or*
        3. To monitor response to treatment for metastatic cancer.
    3. 1p19q codeletion molecular cytogenetic analysis for astrocytoma and gliomas
    4. ALK gene fusion as a molecular biomarker in non-small cell lung cancer
    5. ALK gene rearrangement for diffuse large B cell lymphoma, peripheral T-cell lymphoma, and post-transplant lymphoproliferative disorder
    6. ALK translocations for selecting candidates for crizotinib (Xalkori) in inflammatory myofibroblastic tumor
    7. APC for familial adenomatous polyposis when criteria are met in CPB 140 - Genetic Testing; and for desmoid fibromatosis; experimental for other indications.
    8. Afirma Thyroid FNA analysis for assessing fine needle aspiration samples from thyroid nodules that are indeterminate; experimental for other indications.
    9. BCR/ABL fluorescent in situ hybridization (FISH) for lymphoblastic lymphoma, acute myeloid leukemia, acute lymphocytic leukemia and chronic myelogenous leukemia; experimental for other indications.
    10. BRAF V600 mutation for hairy cell leukemia; gastrointestinal stromal tumors; Lynch syndrome testing for persons meeting criteria in CPB 140 - Genetic Testing; melamoma for vemurafenib, dabrafenib, and trametinib (see CPB 743 - Pharmacogenomic and Pharmacodynamic Testing; and colorectal cancer if KRAS nonmutated; experimental for other indications.
    11. Cancer antigen 125 (CA 125) levels for any of the following:

1. As a preoperative diagnostic aid in women with ovarian masses that are suspected to be malignant, such that arrangements can be made for intraoperative availability of a gynecological oncologist if the CA 125 is increased; *or*
2. As a screening test for ovarian cancer when there is a history of hereditary cancer syndrome (a pattern of clusters of ovarian cancer within two or more generations); *or*
3. Diagnosis of ovarian cancer in women with new symptoms (bloating, pelvic or abdominal pain, difficulty eating or feeling full quickly, or urinary frequency and urgency) that have persisted for three or more weeks, where the clinician has performed a pelvic and rectal examination and suspects ovarian cancer; *or*
4. In members with adenocarcinoma of unknown primary, to rule out ovarian cancer; *or*
5. In members with known ovarian cancer, as an aid in the monitoring of disease, response to treatment, detection of recurrent disease, or assessing value of performing second-look surgery.

12. CA 19-9 to monitor the clinical response to therapy or detect early recurrence of disease in members with known gastric cancer, pancreatic cancer, gallbladder cancer, cholangiocarcinoma or adenocarcinoma of the ampulla of Vater.
13. CA 19-9 to rule out cholangiocarcinoma in persons with primary sclerosing cholangitis undergoing liver transplantation.
14. CA 19-9 as a tumor marker for mucinous appendiceal carcinoma.
15. CD 20, for determining eligibility for anti-CD20 treatment (rituximab) -- see CPB 0314 - Rituximab (Rituxan).
16. CD 25, for determining eligibility for denileukin diftitox (Ontak) treatment.
17. CD 31 immunostaining, for diagnosis of angiosarcoma.
18. CD 33, for determining eligibility for anti-CD33 (gemtuzumab, Mylotarg) treatment.
19. CD 52, for determining eligibility for anti-CD52 (alemtuzumab, Campath) treatment.
20. CD117 (c-kit), for determining eligibility for treatment with imatinib mesylate (Gleevec).
21. Cyclin D1, for diagnosis and predicting disease recurrence of mantle cell lymphoma.
22. Epidermal growth factor receptor (EGFR) testingfor tyrosine kinase inhibitors (erlotinib (Tarceva), gefitinib (Iressa), afatinib (Gilotrif)) in non-small cell lung cancer.
23. Human epidermal growth factor receptor 2 (HER2) evaluation in breast, gastric and esophageal cancer - see CPB 0313 - Trastuzumab (Herceptin), Ado-Trastuzumab (Kadcyla) and Pertuzumab (Perjeta).
24. IGH@ (Immunoglobulin heavy chain locus), gene rearrangement analysis to detect abnormal clonal population(s) in non-Hodgkin's lymphomas,hairy cell leukemia, and post-transplant lymphoproliferative disorder.
25. IGK@ (Immunoglobulin kappa light chain locus), gene rearrangement analysis, evaluation to detect abnormal clonal population(s) for non-Hodgkin's lymphoma, systemic light chain amyloidosis
26. IDH mutation for glioma
27. K-ras (KRAS) mutation analysis, with BRAF reflex testing, to predict non-response to cetuximab (Erbitux) and panitumumab (Vectibix) in the treatment of anal adenocarcinoma, metastatic colorectal cancer and small bowel adenocarcinoma; K-ras (KRAS) mutation analysis to predict non-response to erlotinib (Tarceva) in the treatment of non-small cell lung cancer; experimental for all other indications.
28. Measurement of estrogen and progesterone receptors on primary breast cancers, and on metastatic lesions if the results would influence treatment planning.
29. MLH1, MSH2, MSH6 for persons meeting HNPCC/Lynch Syndrome testing criteria in CPB 140 - Genetic Testing; colorectal cancer in persons under age 50; and all

persons with Stage II colon cancer; experimental for all other indications,

30. Mycosis fungoides, diagnosis: polymerase chain reaction (PCR) for T-cell receptor gamma chain gene rearrangement as an adjunct to the histopathologic diagnosis of mycosis fungoides.
31. Myeloperoxidase (MPO) immunostaining, FLT3-ITD, CEBPA mutation, NPM1 mutation, and KIT mutation for diagnosis of acute myeloid leukemia.
32. NPM1 in acute myeloid leukemia; experimental for other indications.
33. PML/RARA for acute promyelocytic leukemia; experimental for all other indications.
34. PTEN for persons meeting Cowden syndrome testing criteria in CPB 140 - Genetic Testing; experimental for all other indications.
35. Placental alkaline phosphatase (PLAP), to diagnose germ cell seminoma and non-seminoma germ cell tumors in unknown primary cancers.
36. ROS-1 to predict response to crizotinib (Xalkori) for the treatment of non-small cell lung cancer (NSCLC).
37. Serial measurements of alpha fetoprotein (AFP) to diagnose germ cell tumors in members with adenocarcinoma, or carcinoma not otherwise specified, involving mediastinal nodes; or the diagnosis and monitoring of hepatocellular carcinoma (e.g., before considering liver transplantation).
38. Serial measurements of CA 15-3 (also known as CA 27-29 or Truquant RIA) in following the course of treatment in women diagnosed with breast cancer, especially advanced metastatic breast cancer (an increasing CA 15-3 level may suggest treatment failure).
39. Serial measurements of human chorionic gonadotropin (HCG) to diagnose germ cell tumors in members with adenocarcinoma, or carcinoma not otherwise specified, involving mediastinal nodes, or to monitor treatment in members with known trophoblastic tumors (invasive hydatidiform moles and choriocarcinomas) and germinal cell tumors (teratocarcinoma and embryonal cell carcinoma) of the ovaries or testes, or to monitor for relapse after remission is achieved.
40. Serial measurements of AFP and HCG together to diagnose and monitor testicular cancer.
41. Steroid hormone receptor status in both pre-menopausal and post-menopausal members to identify individuals most likely to benefit from endocrine forms of adjuvant therapy and therapy for recurrent or metastatic breast cancer.
42. TCB@ (T cell antigen receptor, beta), gene rearrangement analysis to detect abnormal clonal population(s); for T-cell prolymphocytic leukemia
43. TCG@ (T cell receptor, gamma), gene rearrangement analysis for T-cell prolymphocytic leukemia
44. Oncotype Dx (also known as 21 gene RT-PCR test) to assess necessity of adjuvant chemotherapy in females or males with recently diagnosed breast tumors, where all of the following criteria are met:

    1. Breast cancer is nonmetastatic (node negative[1]); *and*
    2. Breast tumor is estrogen receptor positive; *and*
    3. Breast tumor is HER2 receptor negative or breast tumor is HER2 receptor positive and less than 1 cm in diameter. (Rationale: adjuvant chemotherapy with trastuzumab (Herceptin) is considered to be medically necessary regardless of an Oncotype Dx score for HER2 receptor positive lesions 1 cm or more in diameter); *and*
    4. Adjuvant chemotherapy is not precluded due to any other factor (e.g., advanced age and/or significant co-morbidities); *and*
    5. Member and physician (prior to testing) have discussed the potential results of the test and agree to use the results to guide therapy (i.e., member will forgo adjuvant chemotherapy if Oncotype Dx score is low).

45. Urokinase plasminogen activator (uPA) and plasminogen activator inhibitor 1 (PAI-

1) for the determination of prognosis in patients with newly diagnosed, node negative breast cancer.

46. ZAP-70, for assessing prognosis and need for aggressive therapy in persons with chronic lymphocytic leukemia.

[1] Either standard node dissection negative by hematoxylin and eosin (H&E) staining or sentinel node negative by H&E staining (if sentinel node is negative by H&E, but immunoassay is positive, then still considered node negative for this purpose). In addition, women with isolated tumor cells in lymph nodes (micrometastases) are considered node negative.

More than one Oncotype Dx test may be medically necessary for persons with breast cancer who have two or more histologically distinct tumors that meet medical necessity criteria. Repeat Oncotype Dx testing or testing of multiple tumor sites in the same person has no proven value for other indications. Oncotype Dx is considered experimental and investigational for node positive breast cancer, ductal carcinoma in situ (OncotypeDx DCIS), colon cancer (OncotypeDx Colon), prostate cancer (OncotypeDx Prostate) and all other indications.

2. Aetna considers the bladder tumor antigen (BTA) Stat test, the nuclear matrix protein (NMP22) test, the fibrin/fibrinogen degradation products (Aura-Tek FDfP) test, or the UroVysion fluorescent in situ hybridization (FISH) test medically necessary in any of the following conditions:

    1. Follow-up of treatment for bladder cancer; *or*
    2. Monitoring for eradication of bladder cancer; *or*
    3. Recurrences after eradication.

    Aetna considers the BTA Stat test, the NMP22 test, the Aura-Tek FDP test, or the UroVysion fluorescent in situ hybridization (FISH) test experimental and investigational for screening of bladder cancer, evaluation of hematuria, and all other indications.

3. Aetna considers the use of the ImmunoCyte immunohistochemistry test medically necessary as an adjunct to cystoscopy or cytology in the monitoring of persons with bladder cancer.

    Aetna considers the ImmunoCyte immunohistochemistry test experimental and investigational in the diagnosis of bladder cancer or for screening for bladder cancer in asymptomatic persons.

4. Aetna considers genetic testing for Janus Kinase 2 (JAK2) mutations in persons with chronic myeloproliferative disorders (CMPDs) medically necessary for the following indications: 1) qualitative assessment of JAK2-V617F sequence variant using methods with detection thresholds of up to 5% for initial diagnostic assessment of adult patients presenting with symptoms of CMPD; 2) diagnostic assessment of polycythemia vera in adults; and 3) differential diagnosis of essential thrombocytosis and primary myelofibrosis from reactive conditions in adults.

    Aetna considers genetic testing for Janus Kinase 2 (JAK2) mutations in persons with chronic myeloproliferative disorders (CMPDs) experimental and investigational for any other indication including: 1) diagnostic assessment of myeloproliferative disorders in children; 2) quantitative assessment of JAK2-V617F allele burden subsequent to qualitative detection of JAK2-V617F.

5. Aetna considers each of the following experimental and investigational. The peer reviewed medical literature does not support these tests as having sufficient sensitivity or specificity necessary to define their clinical role:

1. CEA used for all other indications including any of the following:

    1. As a screening test for colorectal cancer; or
    2. As a sole determinant to treat a colorectal cancer member with adjuvant therapy or systemic therapy for presumed metastatic disease; or
    3. For diagnosis, prognosis, or monitoring of treatment in members with lung cancer; or
    4. For routine use of CEA alone for monitoring response to treatment of colorectal when there are other simple tests available to indicate a response; or
    5. For screening, diagnosis, staging or routine surveillance of breast cancer.

2. AFP for the diagnosis of trophoblastic tumors and other oncologic indications.
3. Assaying for loss of heterozygosity (LOH) on the long arm of chromosome 18 (18q) or deleted in colon cancer (DCC) protein (18q-LOH/DCC) for colorectal cancer.
4. Biomarker Translation (BT) test for breast cancer and other indications.
5. BluePrint molecular subtyping profile for breast cancer
6. BRAF mutation analysis in lung cancer, thyroid cancer.
7. Breast Cancer Gene Expression Ratio (HOXB13:IL17BR).
8. BreastNext Next-Gen Cancer Panel
9. CA 125 for all other indications including use as a screening test for colorectal cancer or ovarian cancer (other than as indicated above) or for differential diagnosis of members with symptoms of colonic disease.
10. CA 19-9 for all other indications including breast, colorectal, esophageal, gastro-esophageal, liver, or uterine cancer; pancreatic pseudocyst; screening persons with primary sclerosing cholangiitis without signs or symptoms of cholangiocarcinoma; or screening persons with primary sclerosing cholangitis for development of cholangiocarcinoma.
11. CancerNext Next-Gen Cancer Panel
12. Carcinoembryonic antigen cell adhesion molecule 6 (CEACAM6) for predicting the risk of breast cancer.
13. Carcinoembryonic antigen cellular adhesion molecule-7 (CEACAM-7) expression as a predictive marker for rectal cancer recurrence.
14. Caris Target Now Molecular Profiling Test.
15. CellSearch assay (for all cancers).
16. CK5, CK14, p63, and Racemase P504S testing for prostate cancer.
17. c-Met expression for predicting prognosis in persons with advanced NSCLC and colorectal cancer, and other indications.
18. Cofilin (CFL1) as a prognostic and drug resistance marker in non-small cell lung cancer.
19. ColonSentry test for screening of colorectal cancer.
20. Colonext Next-Gen Cancer Panel
21. ColoPrint, CIMP, LINE-1 hypomethylation, and Immune cells for colon cancer.
22. Colorectal Cancer DSA (Almac Diagnostics, Craigavon, UK)
23. CxBladder Test
24. Cyclin D1 and FADD (Fas-associated protein with death domain) for head and neck squamous cell carcinoma
25. DecisionDx-UM (uveal melanoma) (Castle Biosciences, Phoenix, AZ)
26. DCIS Recurrence Score.
27. Des-gamma-carboxy prothrombin (DCP) (also known as "prothrombin produced by vitamin K absence or antagonism II" [PIVKA II]) for diagnosing and monitoring hepatocellular carcinoma and other indications.
28. *Early*CDT-Lung test.
29. EGFR gene expression analysis for transitional (urothelial) cell cancer
30. EGFRVIII for glioblastoma multiforme
31. EML4-ALK as a diagnostic tool for stage IV non-small-cell lung cancer.
32. Estrogen and progesterone receptors when used alone to assign a member with breast

cancer to prognostic groupings since they are relatively weak predictors of long-term relapse and breast cancer related mortality rates.

33. Excision repair cross-complementation group 1 protein (ERCC1) for persons with NSCLC, colon or with gastric cancer who are being considered for treatment with platinum-based chemotherapy, and other indications.
34. FoundationOne and FoundationOne Heme
35. Gene hypermethylation for prostate cancer
36. GeneKey (GeneKey Corp., Boston, MA)
37. GeneSearch Breast Lymph Node (BLN) assay.
38. Glutathione-S-transferase P1 (GSTP1) for screening, detection and management of prostate cancer.
39. HE4 for ovarian cancer and other indications.
40. HERmark testing for breast cancer and other indications.
41. Insight DX Breast Cancer Profile
42. Mammaprint.
43. Mammostrat
44. Microarray-based gene expression profile testing using the MyPRS test for multiple myeloma.
45. Micro-RNAs (miRNAs) miRview mets and miRview mets2 (Rosetta Genomics Laboratories, Philadelphia, PA; Rosetta Genomics Ltd., Rehovot, Israel)
46. Mirinform Thyroid Cancer Test
47. Mucin 4 expression as a predictor of survival in colorectal cancer.
48. My Prognostic Risk Signature (MyPRS) (Signal Genetics LLC, New York, NY)
49. NRAS mutation for selecting persons with metastatic colorectal cancer who may benefit from (i) EGFR-targeted monoclonal antibody therapies cetuximab and panitumumab or (ii) anti-VEGF antibody bevacizumab; to predict disease prognosis and select persons with melanoma who may benefit from tyrosine kinase inhibitor therapies, and other indications.
50. OVA1 test.
51. OvaCheck test
52. Ovanext Next-Gen Cancer Panel.
53. OvaSure.
54. OncInsights (Intervention Insights, Grand Rapids, MI)
55. Panexia test
56. Pathwork Tissue of Origin test.
57. Phosphatidylinositol-4,5-bisphosphonate 3-kinase, catalytic subunit alpha polypeptide gene (PIK3CA) for predicting disease prognosis and selecting individuals with metastatic colorectal cancer who are being considered for treatment with EGFR antagonists cetuximab and panitumumab, and other indications.
58. PreOvar test for the KRAS-variant to determine ovarian cancer risk.
59. Previstage GCC for colorectal cancer
60. Prolaris for prostate cancer
61. ProOnc TumorSourceDx test (Prometheus Laboratories, San Diego, CA) to identify tissue or origin for metastatic tumor.
62. Prostate core mitotic test
63. Prostate Px and Post-Op Px for predicting recurence of prostate cancer.
64. Proveri prostate cancer assay (PPCA)
65. PTEN gene expression for non-small cell lung cancer
66. Ras oncogenes (except KRAS and BRAF).
67. ResponseDx Colon
68. Ribonucleotide reductase subunit M1 (RRM1) for persons with NSCLC who are being considered for treatment with gemcitabine-based chemotherapy, and other indications.
69. ROS1 re-arrangements for persons with lung cancer who may benefit from crizotinib therapy, and other indications.
70. Rotterdam Signature 76-gene panel.

71. Serum amyloid A as a biomarker for endometrial endometrioid carcinoma to monitor disease recurrence and rtargetesponse to therapy.
72. Single nucleotide polymorphisms for breast cancer (Oncovue, Brevagen)
73. TargetPrint gene expression test for evaluation of estrogen receptor, progesterone receptor, and HER2receptor status in breast cancer.
74. The 41-gene signature assay
75. Theros Breast Cancer Index.
76. Theros CancerType ID (bioTheranostics Inc., San Diego, CA)
77. Thymidylate synthase..
78. TMPRSS fusion genes for prostate cancer.
79. Topographic genotyping (PathFinderTG).
80. Total (whole) gene sequencing for cancer.
81. UroCor cytology panels (DD23 and P53) for bladder cancer
82. Vascular Endothelial Growth Factor (VEGF).
83. Vascular endothelial growth factor receptor 2 (VEGFR2) expression for identifying persons with colorectal cancer that is likely to respond to VEGF inhibition, and other indications.
84. Veristrat.
85. WT1 mutation, RUNX1 mutation, MLL-PTD, IDH1 mutation, IDH2 R172, IDH2 codon 140 mutation.
86. Any of the following circulating tumor markers also is considered experimental and investigational for screening asymptomatic subjects for cancer, diagnosis, staging, routine surveillance of cancer and monitoring the response to treatment:

a2-PAG	CA-SCC	MAM-6	TAG12
AMACR	Cathepsin-D, Cathepsin-L	Motility-related protein (MRP)	TAG72
Bcl-2	Cyclin E (fragments or whole length)	Multidrug resistance glycoprotein (Mdr1)	TAG72.3
BCM	DU-PAN-2	Murine double minute 2 (MDM2)	TAG72.5
CA195	Early prostate cancer antigen (EPCA)	NSE	TATI
CA242	Guanylyl cyclase C (Previstage GCC molecular test)	p53 (TP53)	Thrombospondin-1 (THBS-1)
CA50	Hepsin	PCA3 (DD3) / UpM3	Thymosin B15
CA549	Human kallikrein 2 (HK2)	PNA/ELLA	TNF-a
CA72-4	LASA	Prostate stem cell antigen (PSCA)	Topoisomerase II Alpha (TOP2A)

CAM17-1	LPA	SCC	TPA
CAM26	M 26	SLEX	Thymosin B15
CAM29	M 29	SPAN-1	Nuclear Matrix Protein 66 (NMP66)
CAR-3	MSA	SLX	Anti-malignin antibody screen (AMAS) test
CYFRA21-1	MCA	ST-439	

Background

Tumor markers are substances normally produced in low quantities by cells in the body. Detection of a higher-than-normal serum level by radioimmunoassay or immunohistochemical techniques usually indicates the presence of a certain type of cancer. Currently, the main use of tumor mfarkers is to assess a cancer's response to treatment and to check for recurrence. In some types of cancer, tumor marker levels may reflect the extent or stage of the disease and can be useful in predicting how well the disease will respond to treatment. A decrease or return to normal in the level of a tumor marker may indicate that the cancer has responded favorably to therapy. If the tumor marker level rises, it may indicate that the cancer is spreading. Finally, measurements of tumor marker levels may be used after treatment has ended as a part of follow-up care to check for recurrence.

However, in many cases the literature states that measurements of tumor marker levels alone are insufficient to diagnose cancer for the following reasons: (1) tumor marker levels can be elevated in people with benign conditions; (2) tumor marker levels are not elevated in every person with cancer, especially in the early stages of the disease; and (3) many tumor markers are not specific to a particular type of cancer; and (4) the level of a tumor marker can be elevated by more than one type of cancer.

Elevated levels of Prostate-Specific Antigen (PSA) may be found in the blood of men with benign prostate conditions, such as prostatitis and benign prostatic hyperplasia (BPH), or with a malignant growth in the prostate. While PSA does not allow distinction between benign prostate conditions and cancer, an elevated PSA level may indicate that other tests are necessary to determine whether cancer is present. PSA levels have been shown to be useful in monitoring the effectiveness of prostate cancer treatment, and in checking for recurrence after treatment has ended. Use of PSA for screening remains very controversial. Although researchers are in the process of studying the value of PSA along with digital rectal exams for routine screening of men ages 55 to 74 for prostate cancer; and the literature does not show at this time whether using PSA to screen for prostate cancer actually does reduce the number of deaths caused by this cancer. The American Cancer Society recommends annual screening with PSA and digital rectal exam for African American men and men with familial tendency age 40 or older and all men age 50 or older.

In a review on biomarkers for prostate cancer detection, Parekh, et al. (2007) stated that prostate stem cell antigen, alpha-methyl coenzyme-A racemase, PCA3, early prostate cancer antigen, hepsin and human kallikrein 2 are promising markers that are currently undergoing validation. An assessment of PCA3 prepared for the Agency for Healthcare Research and Quality (2013) concluded: "For diagnostic accuracy, there was a low strength of evidence that PCA3 had better diagnostic accuracy for positive biopsy results than tPSA elevations, but insufficient evidence that this led to improved intermediate or long-term health outcomes. For all other settings, comparators, and outcomes, there was insufficient evidence."

Hutchinson et al (2005) stated that in tissue-based assays, thymosin beta15 (B15) has been shown to correlate with prostate cancer and with recurrence of malignancy. To be clinically effective, it must be shown that thymosin B15 is released by the tumor into body fluids in detectable concentrations. These researchers developed a quantitative assay that can measure clinically relevant levels of thymosin B15 in human urine. Sixteen antibodies were raised against recombinant thymosin B15 and/or peptide conjugates. One antibody, having stable characteristics over the wide range of pH and salt concentrations found in urine and minimal cross-reactivity with other beta thymosins, was used to develop a competitive enzyme-linked immunosorbent assay (ELISA). Urinary thymosin B15 concentration was determined for control groups; normal (n = 52), prostate intraepithelial neoplasia (PIN, n = 36), and patients with prostate cancer; untreated (n = 7) with subsequent biochemical failure, radiation therapy (n = 17) at risk of biochemical recurrence. The operating range of the competition ELISA fell between 2.5 and 625 ng/ml. Recoveries exceeded 75%, and the intra- and inter-assay coefficients of variability were 3.3% and 12.9%, respectively. No cross-reactivity with other urine proteins was observed. A stable thymosin B15 signal was recovered from urine specimens stored at -20 degrees C for up to 1 year. At a threshold of 40 (ng/dl)/microg protein/mg creatinine), the assay had a sensitivity of 58% and a specificity of 94%. Relative to the control groups, thymosin B15 levels were greater than this threshold in a significant fraction of patients with prostate cancer ($p < 0.001$), including 5 of the 7 patients who later experienced PSA recurrence. The authors concluded that an ELISA that is able to detect thymosin B15 at clinically relevant concentrations in urine from patients with prostate cancer has been established. They noted that the assay will provide a tool for future clinical studies to validate urinary thymosin B15 as a predictive marker for recurrent prostate cancer.

Carcinoembryonic antigen (CEA) is a normal cell product that is over-expressed by adenocarcinomas, primarily of the colon, rectum, breast, and lung. It is normally found in small amounts in the blood of most healthy people, but may become elevated in people who have cancer or some benign conditions. According to the available literature, the primary use of CEA is in monitoring colorectal cancer, especially when the disease has metastasized. CEA is also used after treatment to check for recurrence of colorectal cancer. However, the literature indicates a wide variety of other cancers can produce elevated levels of this tumor marker, including melanoma; lymphoma; and cancers of the breast, lung, pancreas, stomach, cervix, bladder, kidney, thyroid, liver, and ovary. Elevated CEA levels can also occur in patients with non-cancerous conditions, including inflammatory bowel disease, pancreatitis, and liver disease.

The American Society of Clinical Oncology (ASCO)'s update of recommendations for the use of tumor markers in gastrointestinal cancer (Gershon, et al., 2006) stated that post-operative CEA levels should be performed every 3 months for stage II and III disease for at least 3 years if the patient is a potential candidate for surgery or chemotherapy of metastatic disease.

The Gynecologic Cancer Foundation, the Society of Gynecologic Oncologists, and the American Cancer Society have issued a consensus statement to promote early detection of ovarian cancer, which recommends that women who have symptoms, including bloating, pelvic or abdominal pain, difficulty eating or feeling full quickly, and urinary frequency and urgency, are urged to see a gynecologist if symptoms are new and persist for more than three weeks (ACS, 2007; SGO, 2007). Ovarian cancer is among the deadliest types of cancer because diagnosis usually comes very late, after the cancer has spread. If the cancer is found and surgically removed before it spreads outside the ovary, the five year survival rate is 93%. However, only 19% of cases are

detected early enough for that kind of successful intervention. It is estimated that 22,430 new cases and 15,280 deaths will be reported in 2007 (ACS, 2007). The consensus statement recommendations are based on studies that show the above symptoms appeared in women with ovarian cancer more than in other women (Goff, et al., 2004; Daly & Ozols, 2004). The recommendations acknowledge that there is not consensus on what physicians should do when patients present with these symptoms. According to a consensus statement issued by the Gynecologic Cancer Foundation, pelvic and rectal examination in women with the symptoms is one first step. If there is a suspicion of cancer, the next step may be a transvaginal ultrasound to check the ovaries for abnormal growths, enlargement, or telltale pockets of fluid that can indicate cancer. Testing for CA-125 levels should also be considered.

There is no evidence available that measurement of CA-125 can be effectively used for widespread screening to reduce mortality from ovarian cancer, nor that the use of this test would result in decreased rather than increased morbidity and mortality. According to the available literature, not all women with elevated CA 125 levels have ovarian cancer. CA 125 levels may also be elevated by cancers of the uterus, cervix, pancreas, liver, colon, breast, lung, and digestive tract. Non-cancerous conditions that can cause elevated CA 125 levels include endometriosis, pelvic inflammatory disease, peritonitis, pancreatitis, liver disease, and any condition that inflames the pleura. Menstruation and pregnancy can also cause an increase in CA 125. However, according to the available literature, changes in CA 125 levels can be effectively used in the management of treatment for ovarian cancer. In women with ovarian cancer being treated with chemotherapy, the literature suggests a falling CA 125 level generally indicates that the cancer is responding to treatment and increased survival is expected. Increasing CA 125 levels during or after treatment, on the other hand, may suggest that the cancer is not responding to therapy or that residual cancer remains. According to the available literature, failure of the CA 125 level to return to normal after three cycles of chemotherapy indicates residual tumor, early treatment failure and decreased survival. Under accepted guidelines, CA 125 levels can also be used to monitor patients for recurrence of ovarian cancer. Although an elevated CA 125 level is highly correlated with the presence of ovarian cancer, the literature suggests a normal value does not exclude residual or recurrent disease.

Aetna's preventive services guidelines are based on the recommendations of leading primary care medical professional organizations and federal public health agencies. None of these organizations recommend routine screening of average-risk, asymptomatic women with serum CA-125 levels for ovarian cancer. These organizations have concluded that serum CA-125 levels are not sufficiently sensitive or specific for use as a screening test for ovarian cancer, and that the harms of such screening outweigh the benefits.

The American College of Obstetricians and Gynecologists (2002) has stated that "[u]nfortunately, there is no screening test for ovarian cancer that has proved effective in screening low-risk asymptomatic women. Measurement of CA 125 levels and completion of pelvic ultrasonography (both abdominal and transvaginal) have been the two tests most thoroughly evaluated.... Data suggest that currently available tests do not appear to be beneficial for screening low-risk, asymptomatic women because their sensitivity, specificity, positive predictive value, and negative predictive value have all been modest at best. Because of the low incidence of disease, reported to be approximately one case per 2,500 women per year, it has been estimated that a test with even 100% sensitivity and 99% specificity would have a positive predictive value of only 4.8%, meaning 20 of 21 women undergoing surgery would not have primary ovarian cancer. Unfortunately, no test available approaches this level of sensitivity or specificity."

The National Cancer Institute (2004) has stated: "There is insufficient evidence to establish that screening for ovarian cancer with serum markers such as CA 125 levels, transvaginal ultrasound, or pelvic examinations would result in a decrease in mortality from ovarian cancer. A serious potential harm is the false-positive test result, which may lead to anxiety and invasive diagnostic procedures. There is good evidence that screening for ovarian cancer with the tests above would result in more diagnostic laparoscopies and laparotomies than new ovarian cancers found. Unnecessary oophorectomies may also result."

The U.S. Preventive Services Task Force (2004) recommends against routine screening with serum CA-125 level for ovarian cancer. The Task Force concluded that the potential harms of such screening outweigh the potential benefits.

A variety of other tumor markers have been investigated for early detection of ovarian cancer as well as different combinations of tumor markers complementary to CA 125 that could potentially offer greater sensitivity and specificity than CA 125 alone. Preliminary studies on HE4 (human epididymis protein 4), a relatively new marker for ovarian cancer, reported similar sensitivity to CA 125 when comparing ovarian cancer cases to healthy controls, and a higher sensitivity when comparing ovarian cancer cases to benign gynecologic disease (Hellstrom, et al., 2003 & 2008; Moore, et al., 2008;) However, an assessment on genomic tests for ovarian cancer prepared by Duke University for the Agency for Healthcare Research and Quality (AHRQ, 2006) stated, "Although research remains promising, adaptation of genomic tests into clinical practice must await appropriately designed and powered studies in relevant clinical settings." Further studies are needed to determine if HE4 significantly adds to the sensitivity of CA 125 while maintaining a high specificity.

CA 15-3 is a serum cancer antigen that has been used in the management of patients with breast cancer. According to the available literature, its low detection rate in early stage disease indicates that CA 15-3 cannot be used to screen or diagnose patients with breast cancer. It has been widely used to monitor the effectiveness of treatment for metastatic cancer. Cancers of the ovary, lung, and prostate may also raise CA 15-3 levels. The literature indicates elevated levels of CA 15-3 may be associated with non-cancerous conditions, such as benign breast or ovarian disease, endometriosis, pelvic inflammatory disease, and hepatitis.

Similar to the CA 15-3 antigen, CA 27-29 is found in the blood of most breast cancer patients. The literature indicates CA 27-29 levels may be used in conjunction with other procedures (such as mammograms and measurements of other tumor marker levels) to check for recurrence in women previously treated for stage II and stage III breast cancer. CA 27-29 levels can also be elevated by cancers of the colon, stomach, kidney, lung, ovary, pancreas, uterus, and liver. First trimester pregnancy, endometriosis, ovarian cysts, benign breast disease, kidney disease, and liver disease are non-cancerous conditions that can also elevate CA 27-29 levels.

Initially found in colorectal cancer patients, CA 19-9 has also been identified in patients with pancreatic, stomach, hepatocellular cancer, and bile duct cancer. In those who have pancreatic cancer, the literature indicates higher levels of CA 19-9 tend to be associated with more advanced disease. Although the sensitivity of the CA 19-9 level in patients with pancreatic cancer is relatively high, the specificity is lowered by elevations that occur in patients with benign pancreatic or liver disease. Non-cancerous conditions that may elevate CA 19-9 levels include gallstones, pancreatitis, cirrhosis of the liver, and cholecystitis. Although excellent correlations have been reported between CA 19-9 measurements and relapse in patients with pancreatic cancer who are followed after surgical resection, no patient has been salvaged by the earlier diagnosis of relapse, a fact that reflects the lack of effective therapy.

Guidelines from the National Comprehensive Cancer Network (NCCN, 2010) state that measurement of CA 19-9 should be considered in evaluating patients with intrahepatic or extrahepatic cholangiocarcinoma and gallbladder cancer. The guidelines note that CA 19-9 is often elevated in persons with cholangiocarcinoma or gallbladder cancer, although this marker is not specific for these cancers. Nehls, et al. (2004) considered CA19-9 as one of the several new potential tumor markers for the diagnosis of cholangiocarcinoma. Levy, et al. (2005) aimed to characterize the test properties of CA 19-9 and of a change in CA 19-9 over time in predicting cholangiocarcinoma in patients with primary sclerosing cholangitis. Charts of 208 patients were reviewed. Fourteen patients had cholangiocarcinoma. Median CA 19-9 was higher with cholangiocarcinoma (15 versus 290 U/ml, $p < 0.0001$). A cutoff of 129 U/ml provided: sensitivity 78.6%, specificity 98.5%, adjusted positive predictive value 56.6% and negative predictive value 99.4%. The median change over time was 664 U/ml in cholangiocarcinoma

compared to 6.7 U/ml in primary sclerosing cholangitis alone ($p < 0.0001$). A cutoff of 63.2 U/ml for change in CA 19-9 provided: sensitivity 90%, specificity 98% and positive predictive value 42%.

CA 19-9 is produced by adenocarcinomas of the pancreas, stomach, gall-bladder, colon, ovary, and lung, and it is shed into the circulation. Although numerous studies have addressed the potential utility of CA 19-9 in adenocarcinoma of the colon and rectum, the sensitivity of CA 19-9 was always less than that of the CEA test for all stages of disease. Its use for screening asymptomatic populations has been hampered by a false-positive rate of 15% to 30% in patients with non-neoplastic diseases of the pancreas, liver, and biliary tract. Only a few studies have addressed the use of CA 19-9 in monitoring patients' post-primary therapy. Significant postsurgical decreases are observed for CA 19-9, but these decreases have not been correlated with survival or disease-free interval. In monitoring response to treatment, decreases in CEA have been found to more accurately reflect response to therapy than did decreases of CA 19-9. Progressive increases of the marker may signal disease progression in 25% of the patients who express the CA 19-9 marker, but this monitoring provides only a minimal lead time of 1 to 3 months. Monitoring with CA 19-9 has not been shown to improve the management of patients with colorectal cancer. The serum CA 19-9 level does not add significant information to that provided by CEA, which is currently regarded as the marker of choice for this neoplasm.

Sinakos and colleagues (2011) evaluated the long-term outcomes in Mayo Clinic patients presenting with primary sclerosing cholangitis (PSC) between 2000 and 2010 (n= 73) for incidence of cholagiocarcinoma (CCA). The results showed initial levels of CA 19-9 in patients without CCA were significantly lower than those from patients with CCA ($p < 0.0001$). No factors known to affect CA 19-9 levels were identified in 33% of the patients without CCA; endoscopic treatment and recurrent bacterial cholangitis were associated with levels of CA 19-9 in 26% and 22% of these patients, respectively.

Juntermanns (2011) prospectively analyzed a bile duct tumor database and retrieved records of 238 patinets who underwent surgery between 1999 and 2008. Their findings included that pre-operative CA19-9 serum levels did not show a statically reliable differentiation between benign or malignant dignity. The authors concluded that current diagnostics cannot differentiate malignant from benign tumor masses in the hepatic hilum with required reliability. The authors further concluded that administration of CIK cells, thymus factor, IL-2 and IFN-alpha after AHSCT could improve the immunologic function of patients, and TH1/TH2 ratio may virtually reflect the immune status of patients, but that more information is required to make prognostic assessments of immune reconstruction and the long-term survival rate.

Sarbia et al (1993) investigated 69 adenocarcinomas of the esophagogastric junction and found high rates of antigen expression were found for the “intestinal” markers CA 19-9 (between 55.5% and 100%) and BW 494 (between 42.9 and 86.7%). The authors concluded that these data, in combination with CK-20 expression, PGII, and 2B5 indicate that the distribution of adenocarcinomas with gastric and.or intestinal differentiation at the esophagogastric junction forms a continuum with out clear-cut borders. This study has not been replicated and NCCN guidelines for Esophageal and Esophagogastric Junction Cancers does not include recommendations for CA 19-9 testing for these indications (NCCN, 2011).

The American Society of Clinical Oncology (ASCO)'s update of recommendations for the use of tumor markers in gastrointestinal cancer (Gershon, et al., 2006) stated that for pancreatic cancer, CA 19-9 can be measured every 1 to 3 months for patients with locally advanced or metastatic disease receiving active therapy.

Mucinous carcinoma of the appendix is a rare entity most commonly associated with primary tumors of the appendix and colon, and for which spread is generally confined to the abdominal cavity (Andreopoulou et al, 2007). Imaging assessment of these mucinous lesions is difficult, and recent studies have explored the use of tumor markers as clinical tools in evaluation of mucinous carcinoma of the appendix.

Carmignani et al (2004) evaluated patients with synchronous systemic and intraperitoneal dissemination of appendix cancer greated with cytoreductive surgery and perioperative regional chemotherapy with a mean follow up time of 42.6 months. Results of this study indicated that patients with elevated CEA and CA 19-9 levels had a shorter median survival time (p=0.0083 and p = 0.0193, respectively). In a subsequent study, Carmingnani et al (2004) prospectively recorded tumor markers CEA and CA19-9 within 1 week prior to definitive treatment. The investigators found CEA elevated in 56% of 532 patients and CA19-9 elevated in 67.1% of those patients. They reported that "although the absolute level of tumor marker did not correlate with prognosis, a normal value indicated an improved survival." Their findings included an elevated CEA in 35.2% of 110 patients determined to have recurrent disease and an elevated CA 19-9 in 62.9%, while 68.2% of patients had at least one of the tumor markers elevated.

Current guidelines indicate that for liver transplantation for primary sclerosing cholangitis, stringent efforts should be made to detect superadded cholangiocarcinoma, including measurement of CA 19-9 (Devlin & O'Grady, 1999).

Human chorionic gonadotropin (HCG) is normally produced in increasing quantities by the placenta during pregnancy. Accepted guidelines provide that HCG levels can be used to screen for choriocarcinoma in women who are at high risk for the disease, and to monitor the treatment of trophoblastic disease. The literature states that elevated HCG levels may also indicate the presence of cancers of the testis, ovary, liver, stomach, pancreas, and lung.

Accepted guidelines provide that alpha fetoprotein (AFP) and b-HCG measurements are valuable for determining prognosis and monitoring therapy in patients with non-seminomatous germ cell cancer. Because of the low incidence of elevated AFP and b-HCG levels in early-stage cancer, the literature suggests these markers have no value in screening for testicular cancer. However, the specificity of these markers is such that when determined simultaneously, at least one marker will be positive in 85% of patients with active cancer. The value of AFP and b-HCG as markers is enhanced by a low frequency of false-positive results and by the chemoresponsiveness of testicular cancer. The literature states that only rarely do patients with other types of cancer have elevated levels of AFP. Non-cancerous conditions that can cause elevated AFP levels include benign liver conditions, such as cirrhosis or hepatitis, ataxia telangiectasia, Wiscott-Aldrich syndrome, and pregnancy.

Alpha-fetoprotein is normally produced by a developing fetus. Alpha fetoprotein levels begin to decrease soon after birth and are usually undetectable in the blood of healthy adults, except during pregnancy. According to accepted guidelines, an elevated level of AFP strongly suggests the presence of either primary liver cancer or germ cell cancer of the ovary or testicle. As AFP is an established test for the diagnosis and monitoring of hepatoma, it is used as a screening tool to rule out the presence of a liver neoplasm before considering liver transplantation. This is especially pertinent in cases (e.g., cirrhosis) where there is an increased risk of developing a primary liver tumor.

The estrogen receptor and progesterone receptor are intracellular receptors that are measured directly in tumor tissue. These receptors are polypeptides that bind their respective hormones, translocate to the nucleus, and induce specific gene expression. Most oncologists have used the estrogen receptor and also the progesterone receptor not only to predict the probability of response to hormonal therapy at the time of metastatic disease, but also to predict the likelihood of recurrent disease, and to predict the need for adjuvant hormonal therapy or chemotherapy. Although these latter uses for estrogen and progesterone receptors are commonly accepted by most oncologists, the data on which these conclusions are based are quite controversial.

Neuron-specific enolase (NSE) has been detected in patients with neuroblastoma, small cell lung cancer, Wilms' tumor, melanoma, and cancers of the thyroid, kidney, testicle, and pancreas. However, studies of NSE as a tumor marker have concentrated primarily on patients with neuroblastoma and small cell lung cancer. According to the available literature, measurement of

NSE level in patients with these diseases cannot be correlated to the extent of the disease, the patient's prognosis, or the patient's response to treatment because of the poor sensitivity of this marker.

LASA is a complex marker that measures the amount of sialic acid in serum and can be elevated in serum from patients with any number of different neoplasms. This serum cancer marker has not been widely accepted for use in the detection or prognosis of colorectal carcinoma. There is no practical information concerning outcome and the use of LASA in the medical literature. Although several articles describe the use of LASA in the diagnosis of colorectal cancer and its association with tumor-node-metastasis (TNM) stage, it has been shown that patients with colorectal polyps and colorectal carcinoma both have elevated LASA levels, and that the levels returned to baseline after removal of either polyps or carcinomas.

p53 is a tumor suppressor gene on the short arm of chromosome 17 that encodes a protein that is important in the regulation of cell division. Although the full role of p53 in the normal and neoplastic cell is unknown, there is evidence that the gene product is important in preventing the division of cells containing damaged DNA. p53 gene deletion or mutation is a frequent event along with other molecular abnormalities in colorectal carcinogenesis. The literature on p53 abnormality and prognosis in colorectal cancer suffers from a paucity of reported data and the use of a variety of techniques in assay and statistical analysis in the small numbers of cases analyzed. For these reasons, the literature generally does not recommend p53 analysis as a routine approach to assisting in the management of patients with colorectal cancer.

The ras proto-oncogenes are normal cellular components, which are thought to be important for transduction of signals required for proliferation and differentiation. The ras oncogene family has 3 members: H-ras, K-ras, and N-ras. Ras gene mutations can be found in a variety of tumor types, although the incidence varies greatly. The highest incidences are found in adenocarcinomas of the pancreas (90%), colon (50%), and lung (30%); thyroid tumors (50%), and myeloid leukemia (30%).

Investigators have established an association between some genotypes of K-ras (KRAS) oncogenes and response to treatment with cetuximab or panitumumab (Lievre et al, 2006 and 2008; Di Fiore et al, 2007; Gonçalves et al, 2008; De Roock et al, 2008). Patients whose tumors express specific forms of the KRAS gene exhibit considerably decreased responses to cetuximab and panitumumab. It has been theorized that cetuximab and panitumumab do not target epidermal growth factor receptor (EGFR) associated with these specific KRAS mutations and thus are unable to block their activation. It has been suggested that KRAS genotype be considered as a selection factor for cancer patients who are candidates for treatment with cetuximab or panitumumab.

Karapetis and colleagues (2008) stated that treatment with cetuximab improves overall survival (OS) and progression-free survival (PFS) and preserves the quality of life in patients with colorectal cancer that has not responded to chemotherapy. The mutation status of the K-ras gene in the tumor may affect the response to cetuximab and have treatment-independent prognostic value. These investigators analyzed tumor samples, obtained from 394 of 572 patients (68.9 %) with colorectal cancer who were randomly assigned to receive cetuximab plus best supportive care or best supportive care alone, to look for activating mutations in exon 2 of the K-ras gene. They evaluated if the mutation status of the K-ras gene was associated with survival in the cetuximab and supportive-care groups. Of the tumors evaluated for K-ras mutations, 42.3 % had at least one mutation in exon 2 of the gene. The effectiveness of cetuximab was significantly associated with K-ras mutation status ($p = 0.01$ and $p < 0.001$ for the interaction of K-ras mutation status with OS and PFS, respectively). In patients with wild-type K-ras tumors, treatment with cetuximab as compared with supportive care alone significantly improved OS (median of 9.5 versus 4.8 months; hazard ratio for death, 0.55; 95 % confidence interval [CI], 0.41 to 0.74; $p < 0.001$) and PFS (median of 3.7 months versus 1.9 months; hazard ratio for progression or death, 0.40; 95 % CI, 0.30 to 0.54; $p < 0.001$). Among patients with mutated K-ras tumors, there was no significant difference between those who were treated with cetuximab

and those who received supportive care alone with respect to OS (hazard ratio, 0.98; p = 0.89) or PFS (hazard ratio, 0.99; p = 0.96). In the group of patients receiving best supportive care alone, the mutation status of the K-ras gene was not significantly associated with OS (hazard ratio for death, 1.01; p = 0.97). The authors concluded that patients with a colorectal tumor bearing mutated K-ras did not benefit from cetuximab, whereas patients with a tumor bearing wild-type K-ras did benefit from cetuximab. The mutation status of the K-ras gene had no influence on survival among patients treated with best supportive care alone.

The ASCO's provisional clinical opinion on testing for KRAS gene mutations in patients with metastatic colorectal carcinoma to predict response to anti-EGFR monoclonal antibody therapy (Allegra et al, 2009) stated that based on systematic reviews of the relevant literature, all patients with metastatic colorectal carcinoma who are candidates for anti-EGFR antibody therapy should have their tumor tested for KRAS mutations in a CLIA-accredited laboratory. If KRAS mutation in codon 12 or 13 is detected, then patients with metastatic colorectal carcinoma should not receive anti-EGFR antibody therapy as part of their treatment.

The KRAS oncogene mutation tests are intended to aid in the formulation of treatment decisions for patients who may be candidates for treatment of metastatic epithelial cancers with anti-EGFR therapies such as cetuximab or panitumumab. Several tests for KRAS mutation are currently available in the United States; however, at this time, no KRAS genotype test kits have been approved by the FDA.

At the 2008 Annual Meeting of the American Society of Clinical Oncology (ASCO), data on 540 patients with metastatic colorectal cancer in the randomized, phase III CRYSTAL trial were presented. Among 192 patients with KRAS mutations, there was no improvement in overall responses or PFS from the addition of cetuximab to standard chemotherapy. In the patients with normal KRAS, the 1-year PFS rate was 43% for patients receiving cetuximab versus 25% for those receiving only standard chemotherapy, and the overall response rate was 59% versus 43%, respectively (van Cutsem, 2008). Also at the 2008 ASCO meeting, data from 233 metastatic colorectal cancer patients were presented that confirmed the correlation of KRAS status with patient response to anti-EGFR therapy. No benefit was found after addition of cetuximab to standard chemotherapy with FOLFOX (the combination of fluorouracil, leucovorin, and oxaliplatin) in patients with a mutated KRAS; however, addition of cetuximab to FOLFOX increased both response rate and PFS in patients with a wild-type (i.e., un-mutated) KRAS gene (Bokemeyer, 2008). Response to panitumumab was correlated to KRAS status in a published phase III trial. A total of 427 patients with metastatic colorectal cancer received either panitumumab or best supportive care. Panitumumab exhibited a 17% response rate among patients with normal KRAS, but 0% response among patients with KRAS mutations (Amado, 2008).

A meta-analysis of results from 8 studies involving 817 patients with colorectal cancer found that the presence of KRAS mutation predicted lack of response to treatment with anti-EGFR monoclonal antibodies (e.g., panitumumab or cetuximab), whether as stand-alone therapy or in combination with chemotherapy (Linardou, et al., 2008). This analysis also provided empirical evidence that k-RAS mutations are highly specific negative predictors of response (de-novo resistance) to single-agent EGFR tyrosine-kinase inhibitors in advanced non-small cell lung cancer; and similarly to anti-EGFR monoclonal antibodies alone or in combination with chemotherapy in patients with metastatic colorectal cancer.

The Blue Cross and Blue Shield Association (BCBSA, 2008) Technology Evaluation Center Medical Advisory Panel concluded that use of KRAS mutation analysis meets TEC criteria to predict non-response to anti-EGFR monoclonal antibodies cetuximab and panitumumab to treat metastatic colorectal cancer. The TEC assessment found that the evidence is sufficient to conclude that patients with mutated KRAS tumors in the setting of metastatic colorectal cancer do not respond to anti-EGFR monoclonal antibody therapy. The assessment explained that the data show that the clinical benefit of using EGFR inhibitors in treating metastatic colorectal cancer, either as monotherapy or in combination with other treatment regimens, is not seen in

patients with KRAS-mutated tumors. The assessment found: "This data supports knowing a patient's tumor mutation status before consideration of use of an EGFR inhibitor in the treatment regimen. Identifying patients whose tumors express mutated KRAS will avoid exposing patients to ineffective drugs, avoid exposure to unnecessary drug toxicities, and expedite the use of the best available alternative therapy."

Colorectal cancer guidelines from the National Comprehensive Cancer Network (NCCN, 2010) recommend consideration of reflex BRAF testing in patients with wild type KRAS. The NCCN guidelines explain that several small studies suggest that patients with wild-type KRAS and a BRAF mutation are unlikely to respond to anti-EGFR therapies such as cetuximab and panitumumab. The guidelines explain that patients with a known BRAF mutation are unlikely to respond to anti-EGFR antibodies, although the data are somewhat inconsistent. Studies demonstrate that in patients with metastatic colorectal cancer, about 8 percent have mutations in the BRAF gene. Testing for the BRAF V600E mutation is performed by PCR amplification and direct DNA sequence analysis.

In the United States, bladder malignancy is the 4th commonest cancer in men and the 8th commonest in women. Patients usually present with urinary tract symptoms (e.g., gross or microscopic hematuria or irritative voiding symptoms such as frequency, dysuria, and urgency). Evaluations of these patients usually entail voided-urine cytology, cystoscopy, and upper urinary tract imaging such as intravenous pyelography, renal sonography, or retrograde pyelography. Most newly diagnosed bladder cancers are superficial (i.e., not invading beyond the lamina propria on histological examination), and are known as transitional cell carcinoma (TCC). These superficial bladder cancers are usually managed by transurethral resection. However, the literature shows that approximately 50 - 75% of treated TCC recur. Furthermore, 10 – 15% of TCC progress to muscle-invasive bladder cancer. According to the literature, the prevalence of recurrence after initial treatment as well as the natural history of TCC necessitates long-term follow-up. Following treatment, accepted guidelines provide that patients who have previously been diagnosed with TCC should usually undergo urine cytology/cystoscopy every 3 months in the 1st year, every 6 months in the 2nd year, and once-yearly afterwards.

Currently, urine cytology with confirmatory cystoscopy represents the cornerstone for the identification of bladder tumors. However, the subjectivity and low sensitivity of cytology led to the development of several urine-based tests as adjuncts to cytology/cystoscopy for the diagnosis and follow-up of patients with TCC. These tests include the BTA Stat test (Bard Diagnostic, Redmond, WA), the NMP22 test (Matritech, Newton, MA), the Aura-Tek FDP test (PerImmune, Rockville, MD), and the Vysis UroVysion FISH Test (Vysis, Inc., Downers Grove, IL). They are usually objective, qualitative (BTA Stat and Aura-Tek FDP), or quantitative (NMP22, UroVysion), and have higher sensitivity than cytology, but some have lower specificity. So far, no single bladder tumor marker has emerged as the generally accepted test of choice, and none has been established as a screening tool for bladder malignancy.

Although urine cytology has been shown to be less accurate than urinary biomarker tests, familiarity with the method as well as ease of performance justify the continued routine use of the former by primary care physicians, especially in patients who have no history of bladder malignancy. The urine-based biomarker tests have been shown to be accurate in detecting low-grade bladder tumors. In particular, these tests may be of help in deciding the need for further diagnostic assessment of patients with a history of bladder cancer and negative results on urine cytology. For example, elevated levels of urinary bladder tumor markers in patients with a history of TCC may warrant earlier, rather than delayed, cystoscopic examination. On the other hand, consideration may be given to lengthening the intervals between cystoscopic investigations when values of these tumor markers are normal.

In summary, urine-based bladder tumor marker tests have been shown to be useful as an adjunct to urine cytology and cystoscopy in monitoring for recurrences of bladder cancer, but according to the available literature should not be used as a screening tool for bladder malignancy. The U.S. Preventive Services Task Force (USPSTF, 2004) has concluded that the potential harms of

screening for bladder cancer using available tests, such as microscopic urinalysis, urine dipstick, urine cytology, or such new tests as bladder tumor antigen (BTA) or nuclear matrix protein (NMP22) immunoassay, outweigh any potential benefits.

Svatek et al (2008) examined the role of urinary cathepsin B and L in the detection of bladder urothelial cell carcinoma. These investigators concluded that urinary cathepsin L is an independent predictor of bladder cancer presence and invasiveness in patients with a history of urothelial carcinoma of the bladder. They stated that further evaluation of this marker is necessary before its use as an adjunct to cystoscopy for urothelial carcinoma of the bladder.

Oncotype Dx (Genomic Health, Inc., Redwood City, CA) is a diagnostic laboratory-developed assay that quantifies the likelihood of breast cancer recurrence in women with newly diagnosed, stage I or II, node negative, estrogen receptor positive breast cancer, who will be treated with tamoxifen. The assay analyzes the expression of a panel of 21 genes, and is intended for use in conjunction with other conventional methods of breast cancer analysis. Together with staging, grading, and other tumor marker analyses, Oncotype Dx is intended to provide greater insight into the likelihood of systemic disease recurrence. Clinical studies have evaluated the prognostic significance of the Oncotype Dx multigene assay in breast cancer (Paik, et al., 2004; Esteva, et al., 2003).

There currently is a lack of evidence from prospective clinical studies of the impact of this test on the management of women with breast cancer demonstrating improvements in clinical outcomes, Bast & Hortobagyi (2004) commented that "[b]efore use of the recurrence score [from the Oncotype Dx multigene assay] is applied to general patient care, however, additional studies are needed." The National Cancer Institute is sponsoring a prospective, randomized controlled clinical study, the TAILORx study, using the Oncotype Dx assay to help identify a group of patients with a mid-range risk of recurrence to determine whether treating patients with hormonal therapy only is equivalent to treating them with hormonal therapy in combination with adjuvant chemotherapy.

However, there is indirect evidence of the clinical utility of the Oncotype Dx. Paik et al (2006) used banked tumor samples from previous clinical studies of tamoxifen and adjuvant chemotherapy in early breast cancer to assess the performance of the Oncotype Dx multigene assay in predicting response to adjuvant chemotherapy. These investigators examined tumor samples from subjects enrolled in the National Surgical Adjuvant Breast and Bowel Project (NSABP) B20 trial to determine whether there is a correlation between the recurrence score (RS) determined by Oncotype Dx in tumor samples and subsequent response to adjuvant chemotherapy. A total of 651 patients were assessable (227 randomly assigned to tamoxifen and 424 randomly assigned to tamoxifen plus chemotherapy). The test for interaction between chemotherapy treatment and RS was statistically significant ($p = 0.038$). Patients with high-RS (RS greater than or equal to 31) tumors (ie, high risk of recurrence) had a large benefit from chemotherapy (relative risk, 0.26; 95% confidence interval 0.13 to 0.53; absolute decrease in 10-year distant recurrence rate: mean, 27.6%; standard error, 8.0%). Patients with low-RS (less than 18) tumors derived minimal, if any, benefit from chemotherapy treatment (relative risk, 1.31; 95% confidence interval, 0.46 to 3.78; absolute decrease in distant recurrence rate at 10 years: mean, -1.1%; standard error, 2.2%). The investigators found that patients with intermediate-RS tumors did not appear to have a large benefit, but the investigators concluded that the uncertainty in the estimate cannot exclude a clinically important benefit.

One limitation of the study by Paik et al (2006) is that the NASBP B20 trial was conducted before the advent of important advances in breast cancer chemotherapy, including the introduction of trastuzumab (Herceptin), which has been demonstrated to improve overall and disease-free survival in breast cancer patients with HER2 positive tumors. Current guidelines recommend the use of trastuzumab adjuvant chemotherapy in women with metastatic HER2 positive breast cancer, and women with HER2 positive nonmetastatic breast cancers 1 cm or more in diameter. Thus, the Oncotype Dx score would not influence the decision to use adjuvant trastuzumab in women with HER2 positive tumors 1 cm or more in diameter.

Commenting on an early report of this study by Paik et al, of the Oncotype Dx presented in abstract form, the BlueCross BlueShield Association Technology Evaluation Center assessment stated that “additional studies in different populations are needed to confirm whether risk prediction is sufficiently accurate for physicians and patients to choose with confidence whether to withhold adjuvant chemotherapy.”

The selection criteria for the TailorRx prospective trial of OncotypeDx state that candidates should have negative axillary nodes as determined by a sentinel lymph node biopsy and/or axillary dissection as defined by the American Joint Committee on Cancer 6th Edition Staging System (NCI, 2009). The AJCC 6th Edition criteria redefined isolated tumor cells as node negative (the prior version of the criteria, AJCC 5th Edition, classified isolated tumor cells as node positive). "Isolated tumor cells (single cells or cell deposits) will now be defined as tumor cell deposits no larger than 0.2 mm in diameter that may or may not (but usually do not) show histologic evidence of malignant activity. Pending further information, isolated tumor cells will be classified as node-negative, because it is believed that the unknown benefits of providing treatment for these small lesions would not outweigh the morbidity caused by the treatment itself." (Singletary, et al., 2002). However, the banked tumor samples used in the study by Paik, et al. (2006) to validate the OncotypeDx were classified based on AJCC 5th Ed. criteria. In addition, there is new evidence demonstrating that women with isolated tumor cells are at a significantly increased risk of breast cancer. Investigators from the Netherlands found an association between isolated tumor cells and micrometastases in regional lymph nodes and clinical outcome of breast cancer (de Boer, et al., 2009). These investigators identified all patients in the Netherlands who underwent a sentinel-node biopsy for breast cancer before 2006 and had breast cancer with favorable primary-tumor characteristics and isolated tumor cells or micrometastases in the regional lymph nodes. Patients with node-negative disease were randomly selected from the years 2000 and 2001. The primary end point was disease-free survival. The investigators identified 856 patients with node-negative disease who had not received systemic adjuvant therapy (the node-negative, no-adjuvant-therapy cohort), 856 patients with isolated tumor cells or micrometastases who had not received systemic adjuvant therapy (the node-positive, no-adjuvant-therapy cohort), and 995 patients with isolated tumor cells or micrometastases who had received such treatment (the node-positive, adjuvant-therapy cohort). The median follow-up was 5.1 years. The adjusted hazard ratio for disease events among patients with isolated tumor cells who did not receive systemic therapy, as compared with women with node-negative disease, was 1.50 (95% confidence interval [CI], 1.15 to 1.94); among patients with micrometastases, the adjusted hazard ratio was 1.56 (95% CI, 1.15 to 2.13). Among patients with isolated tumor cells or micrometastases, the adjusted hazard ratio was 0.57 (95% CI, 0.45 to 0.73) in the node-positive, adjuvant-therapy cohort, as compared with the node-positive, no-adjuvant-therapy cohort. The investigators concluded that isolated tumor cells or micrometastases in regional lymph nodes were associated with a reduced 5-year rate of disease-free survival among women with favorable early-stage breast cancer who did not receive adjuvant therapy. In patients with isolated tumor cells or micrometastases who received adjuvant therapy, disease-free survival was improved.

The Medical Advisory Panel of the BlueCross BlueShield Association Technology Evaluation Center (BCBCA, 2014) concluded that use of Oncotype DX to determine recurrence risk for deciding whether to undergo adjuvant chemotherapy in women with unilateral, nonfixed, hormone receptorâ€’positive, lymph nodeâ€’negative breast cancer who will receive hormonal therapy meets the Blue Cross and Blue Shield Association Technology Evaluation Center (TEC) criteria.

The Oncotype Dx has also been promoted for use in women with node-positive, ER-positive breast cancer. An assessment by the BlueCross BlueShield Association (2010) concluded that it has not yet been demonstrated whether use of the Oncotype Dx for selecting adjuvant chemotherapy in patients with lymph-node-positive breast cancer improves health outcomes. The report explained that the evidence for not selecting chemotherapy for women with low RS values is based on low event rates and wide confidence intervals that include the possibility of benefit

from chemotherapy. Because the data allow for a possible benefit of chemotherapy in patients with low RS results, it is unknown if health outcomes would be improved, the same, or worse, if chemotherapy was withheld in these women. The report stated that, due to the lack of clear and sufficient information, there is a need for a second, confirmatory study. The report stated that the Fred Hutchinson Cancer Research Center will conduct a nationwide, NCI-sponsored, Phase III clinical trial to determine the predictive ability of the Oncotype Dx to identify which patients with lymph-node-positive breast cancer will benefit from chemotherapy.

Acceptance of 21-gene recurrence score assays as tools for clinical decision making in women or men with early stage breast cancer is controversial due to the lack of prospective validation studies, nevertheless, 2007 guidelines from an expert panel convened by ASCO on tumor markers in breast cancer concluded that multiparameter gene expression analysis (i.e., Oncotype Dx assay) can be used to predict the risk of recurrence in women with newly diagnosed, node-negative, ER-positive breast cancer. Although it is reasonable to consider the use of a 21-gene recurrence score assay in males, none of the data generated to date have been in men with breast cancer (Gradishar, 2010).

A 2009 abstract that looked at cases of male breast cancer (BC) with Oncotype Dx, concluded, "This large genomic study of male BC reveals a heterogeneous biology as measured by the standardized quantitative oncotype Dx breast cancer assay, similar to that observed in female BC. Some differences, which may reflect the differences in hormone biology between males and females, were noted and deserve further study." (Shak et al, 2009).

The Oncotype Dx has also been promoted for use in colorectal cancer. However, there is a lack of evidence establishing the clinical utility of this test in colorectal cancer.

The results of the Quick and Simple and Reliable Study (QUASAR) were published by Gray et al (2011). The purpose of the QUASAR study was develop quantitative gene expression assays to assess recurrence risk and benefits from chemotherapy in patients with stage II colon cancer. Recurrence score (RS) and treatment score (TS) were calculated from gene expression levels of 13 cancer-related genes and from five reference genes. The results of the study showed risk of recurrence to be significantly associated with RS (95% confidence interval, 1.11 to 1.74; p = 0.004). Recurrence risks at 3 years were 12%, 18%, and 22% for predefined low, intermediate, and high recurrence risk groups, respectively. Continuous RS was associated with risk of recurrence (p=0.006), but there was no trend for increased benefit from chemotherapy at higher TS (p=0.95). The continuous 12-gene RS has been validated in a prospective study for assessment of recurrence risk in patients with stage II colon cancer after surgery. RS was also found to provide prognostic value that complements T stage and mismatch repair.

In February 2007, the Food and Drug Administration (FDA) approved Mammaprint (Agendia, Amsterdam), a DNA microarray-based test used to predict whether women with early breast cancer might face the disease again. The test measures the activity of 70 genes, providing information about the likelihood that cancer will recur. It measures each of these genes in a sample of a woman's breast-cancer tumor and then uses a specific formula to produce a score that determines if the patient is deemed low-risk or high-risk for metastasis. In clinical trials, 1 in 4 women found to be at high risk by Mammaprint had recurrence of their cancer within 5 years. However, there are questions regarding the accuracy of this test. The positive predictive values at 5 and 10 years were 23% and 29%, respectively, while the corresponding negative predictive values were 95% and 90%, respectively.

Mammaprint was tested on 307 patients under the age of 61 years who underwent surgery for stage I or stage II breast cancer, and who have tumor size equal to or less than 5 cm, and lymph node-negative. The study found that Mammaprint more than doubled physicians' ability to predict breast cancer recurrence. Furthermore, a major clinical study is now underway to determine if the test really helps patients avoid needless chemotherapy. The European study will recruit 6,000 patients with early-stage breast cancer.

In reviewing gene expression profiling as a guide for the management of early stage breast cancer, the California Technology Assessment Forum (CTAF, 2007) stated that the Oncotype Dx recurrence score meets CTAF Technology Assessment Criteria 1 through 5 for safety, effectiveness and improvement in health outcomes when used with other tools to inform the decision to use chemotherapy in patients recently diagnosed with invasive breast cancer meeting the following criteria:

- Estrogen or progesterone receptor positive
- Lymph node negative
- Tumor size less than 5 cm.

On the other hand, the CTAF stated that the use of other forms of gene expression profiling, including the 70-gene prognostic signature (Mammaprint), do not meet CTAF Technology Assessment Criteria 3 through 5 for safety, effectiveness and improvement in health outcomes.

More recently, the California Technology Assessment Forum (CTAF) reassessed the Mammaprint, and concluded that it did not meet CTAF criteria (Tice, 2010). The report concluded that "it remains unclear how the 70-gene prognostic signature should be used in managing patients with early stage breast cancer." The report noted that a large, randomized clinical trial (MINDACT) enrolling 6000 patients in Europe will test the hypothesis that use of the 70-gene prognostic score can improve outcomes for women with early stage breast cancer.

Other technology assessments (e.g., CvZ, 2010; Smartt, 2009) and guidelines (e.g., Harris, et al., 2007; NCCN, 2011) have also found insufficient evidence for use of the Mammaprint. ASCO's 2006 update of the breast cancer follow-up and management guidelines in the adjuvant setting stated that the use of CBCs, chemistry panels, bone scans, chest radiographs, liver ultrasounds, computed tomography scans, [18F]fluorodeoxyglucose-positron emission tomography scanning, magnetic resonance imaging, or tumor markers (CEA, CA 15-3, and CA 27.29) is not recommended for routine breast cancer follow-up in an otherwise asymptomatic patient with no specific findings on clinical examination. It stated that careful history taking, physical examination, and regular mammography are appropriate for detecting breast cancer recurrence. Currently, there is a lack of evidence that the use of Mammaprint would influence the decisions that women and their physicians make with regard to adjuvant therapy. The clinical value of this test has yet to be established.

On February 19, 2014, the BlueCross BlueShield Association Technology Evaluation Center Medical Advisory Panel voted that the Mammaprint to determine recurrence risk in women with early stage breast cancer does not meet the TEC criteria (BCBSA, 2014).

A report prepared by the Evaluation of Genomic Applications in Practice and Prevention (EGAPP) Working Group evaluated the evidence for three gene expression assays on the market; Oncotype Dx, MammaPrint and the Breast Cancer Profiling (BCP or H/I ratio) test, and for gene expression signatures underlying the assays. The report found that, for clinical validity, studies differed according to whether they examined the actual test that is currently being offered to patients or the underlying gene signature. The report found that almost all of the Oncotype Dx evidence was for the marketed test, the strongest validation study being from one arm of a randomized controlled trial (NSABP-14) with a clinically homogeneous population. This study showed that the test, added in a clinically meaningful manner to standard prognostic indices. The MammaPrint signature and test itself was examined in studies with clinically heterogeneous populations (e.g., mix of ER positivity and tamoxifen treatment) and showed a clinically relevant separation of patients into risk categories, but it was not clear exactly how many predictions would be shifted across decision thresholds if this were used in combination with traditional indices.The BCP test itself was examined in one study, and the signature was tested in a variety of formulations in several studies. The report identified one randomized controlled trial that provided high quality retrospective evidence of the clinical utility of Oncotype Dx to predict chemotherapy treatment benefit, but evidence for clinical utility was not found for MammaPrint or the H/I ratio. The report concluded that Oncotype Dx is furthest along the validation pathway,

with strong retrospective evidence that it predicts distant spread and chemotherapy benefit to a clinically relevant extent over standard predictors, in a well-defined clinical subgroup with clear treatment implications. The report concluded that the evidence for clinical implications of using MammaPrint was not as clear as with Oncotype Dx, and the ability to predict chemotherapy benefit does not yet exist. The report concluded that the H/I ratio test requires further validation. For all tests, the relationship of predicted to observed risk in different populations still needs further study, as does their incremental contribution, optimal implementation, and relevance to patients on current therapies.

The EGAPP Working Group (2009) reported that they found adequate evidence regarding the association of the Oncotype Dx Recurrence Score with disease recurrence and adequate evidence for response to chemotherapy. The EWG found adequate evidence to characterize the association of MammaPrint with future metastases, but inadequate evidence to assess the added value to standard risk stratification, and could not determine the population to which the test would best apply. The evidence was inadequate to characterize the clinical validity of the Quest H:I Test. The EGAPP Working Group reported that they found no evidence regarding the clinical utility of the MammaPrint and Quest H:I Ratio tests, and inadequate evidence regarding Oncotype Dx. The EGAPP Working Group noted that these technologies have potential for both benefit and harm.

The Rotterdam Signature 76-gene panel (Veridex, LLC) is a multivariate index assay that is intended to assist in assessing a patient's risk of systemic recurrence of cancer following successful initial treatment of localized node-negative breast cancer with surgery and tamoxifen alone. This multigene assay is intended for use in lymph-node negative breast cancer patients. The Rotterdam Signature panel uses microarray processing to measure cellular concentrations of mRNA in fresh tissue samples. The Rotterdam Signature panel uses the Human Genome U133a GeneChip (Affymetrix, Inc.) to identify patients that have gene expression signatures associated with either a low or high risk of developing metastatic disease. A multicenter study investigated the ability of the Rotterdam 76-gene signature to identify patients at risk of distant metastases within 5 and 10 years of first diagnosis, using frozen tissue samples from 180 patients with node-negative breast cancer who had not received systemic chemotherapy (Foekens, et al., 2006). The Rotterdam 76-gene signature correctly identified 27 out of 30 cases of relapse within 5 years (90% sensitivity) and 75 out of 150 patients who did not relapse (50% specificity). An earlier summary of the same study (Foekens, et al., 2005) reported a hazard ratio for distant metastasis-free survival comparing favorable versus unfavorable signature = 7.41 (95% confidence interval 2.63-20.9); p = 8.5 x 10-6). The hazard ratio of overall survival comparing favorable versus unfavorable signature = 5.45 (95% confidence interval 1.62-18.3); p = .002. There are no published studies that have assessed the clinical utility of the Rotterdam 76-gene signature by monitoring the long-term outcomes of the patients selected and not selected for chemotherapy on the basis of assay results.

The Breast Cancer Gene Expression Ratio (HOXB13:IL17BR, also known as H/I) (AviaraDx, Inc., Carlsbad, CA) is intended to predict the risk of disease recurrence in women with estrogen receptor (ER)-positive, lymph node-negative breast cancer. The Breast Cancer Gene Expression Ratio is based on the ratio of the expression of two genes: the homeobox gene-B13 (HOXB13) and the interleukin- 17B receptor gene (IL17BR). In breast cancers that are more likely to recur, the HOXB13 gene tends to be over-expressed, while the IL-17BR gene tends to be under-expressed. In an 852-patient retrospective study, Ma, et al. (2006) found that the HOXB13:IL17BR ratio (H:I expression ratio) independently predicted breast cancer recurrence in patients with ER-positive, lymph-node negative cancer. The H:I expression ratio was found to be predictive in patients who received tamoxifen therapy as well as in those who did not. Expression of HOXB13, IL17BR, CHDH, estrogen receptor (ER) and progesterone receptor (PR) were quantified by real-time polymerase chain reaction (PCR) in 852 formalin-fixed, paraffin-embedded primary breast cancers from 566 untreated and 286 tamoxifen-treated breast cancer patients. Gene expression and clinical variables were analyzed for association with relapse-free survival (RFS) by Cox proportional hazards regression models. The investigators reported that, in the entire cohort, expression of HOXB13 was associated with shorter RFS (p = .008), and

expression of IL17BR and CHDH was associated with longer RFS ($p < .0001$ for IL17BR and $p = .0002$ for CHDH). In ER-positive patients, the HOXB13:IL17BR index predicted clinical outcome independently of treatment, but more strongly in node-negative patients. In multivariate analysis of the ER-positive node-negative subgroup including age, PR status, tumor size, S phase fraction, and tamoxifen treatment, the two-gene index remained a significant predictor of RFS (hazard ratio = 3.9; 95% confidence interval 1.5 to 10.3; $p = .007$). The clinical value of the Breast Cancer Gene Expression Ratio was also evaluated in a study by Goetz, et al. (2006). That study found that a high H:I expression ratio is associated with an increased rate of relapse and mortality in ER-positive, lymph node-negative cancer patients treated with surgery and tamoxifen. Goetz, et al. (2006) examined the association between the ratio of the HOXB13 to IL17BR expression and the clinical outcomes of relapse and survival in women with ER-positive breast cancer enrolled onto a North Central Cancer Treatment Group adjuvant tamoxifen trial (NCCTG 89-30-52). Tumor blocks were obtained from 211 of 256 eligible patients, and quantitative reverse transcription-PCR profiles for HOXB13 and IL-17BR were obtained from 206 patients. In the node-positive cohort (n = 86), the HOXB13/IL-17BR ratio was not associated with relapse or survival. In contrast, in the node-negative cohort (n = 130), a high HOXB13/IL-17BR ratio was associated with significantly worse RFS [hazard ratio (HR), 1.98; $p = 0.031$], DFS (HR, 2.03; $p = 0.015$), and OS (HR, 2.4; $p = 0.014$), independent of standard prognostic markers.

The Blue Cross and Blue Shield Association Technology Evaluation Center (BCBSA, 2007) announced that its Medical Advisory Panel (MAP) concluded that the use of the Breast Cancer Gene Expression Ratio gene expression profiling does not meet the TEC criteria. The Evaluation of Genomic Applications in Practice and Prevention (EGAPP) Working Group is currently preparing an evaluation of the H:I ratio test.

In a systematic review on gene expression profiling assays in early-stage breast cancer, Marchionni, et al. (2008) summarized evidence on the validity and utility of 3 gene expression-based prognostic breast cancer tests: Oncotype Dx, MammaPrint, and H/I. The authors concluded that gene expression technologies show great promise to improve predictions of prognosis and treatment benefit for women with early-stage breast cancer. However, more information is needed on the extent of improvement in prediction, characteristics of women in whom the tests should be used, and how best to incorporate test results into decision making about breast cancer treatment.

Guidelines from the American Society for Clinical Oncology (Harris, et al., 2007) found that, in newly diagnosed patients with node-negative, estrogen-receptor positive breast cancer, the Oncotype Dx assay can be used to predict the risk of recurrence in patients treated with tamoxifen. The ASCO guidelines concluded that Oncotype Dx may be used to identify patients who are predicted to obtain the most therapeutic benefit from adjuvant tamoxifen and may not require adjuvant chemotherapy. The ASCO guidelines found, in addition, that patients with high recurrence scores appear to achieve relatively more benefit from adjuvant chemotherapy than from tamoxifen. ASCO found that there are insufficient data at present to comment on whether these conclusions generalize to hormonal therapies other than tamoxifen, or whether this assay applies to other chemotherapy regimens. Guidelines from the American Society for Clinical Oncology (Harris, et al., 2007) concluded that the precise clinical utility and appropriate application for other multiparameter assays, such as the MammaPrint assay, the Rotterdam Signature, and the Breast Cancer Gene Expression Ratio are under investigation. ASCO also found insufficient data to recommend use of proteomic patterns for management of patients with breast cancer.

TargetPrint is a microarray-based gene expression test which offers a quantitative assessment of the patient's level of estrogen receptor (ER), progesterone receptor (PR) and HER2/neu overexpression in breast cancer. The manufacturer states that TargetPrint is offered in conjunction with MammaPrint gene expression profiling to provide the physician an even more complete basis for treatment decisions. The manufacturer states that, as compared to Immunohistochemistry (IHC), TargetPrint provides additional information. Whereas IHC

provides a semi-quantitative positive or negative result, the gene expression result provided by TargetPrint provides data on the absolute level of ER, PR and HER2 gene expression. Published information on the TargetPrint is limited to studies examining its correlation with measurements of ER, PR, and HER2 receptors (Gunven et al, 2011; Gevensleben et al, 2010; Roepman et al, 2009). There is a lack of evidence from published prospective clinical studies that demonstrates that quantification of ER, PR, and HER2 gene expression by TargetPrint alters management such that clinical outcomes are improved.

The Mammostrat is a prognostic immunohistochemistry (IHC) test that measures the risk of breast cancer recurrence in post-menopausal, node-negative, estrogen receptor-expressing breast cancer patients who will receive hormonal therapy and are considering adjuvant chemotherapy. The test analyzes five monoclonal antibody biomarkers and applies a diagnostic algorithm to assess whether patients have a high, moderate, or low risk of recurrence after they have had their breast cancer tumor surgically removed and have been treated with tamoxifen.

Bartlett et al (2010) tested the efficacy of the Mammostrat in a mixed population of cases treated in a single center with breast-conserving surgery and long-term follow-up. Tissue microarrays from a consecutive series of 1,812 women managed by wide local excision and post-operative radiotherapy were collected. Of 1,390 cases stained, 197 received no adjuvant hormonal or chemotherapy, 1,044 received tamoxifen only, and 149 received a combination of hormonal therapy and chemotherapy. Median age at diagnosis was 57 years, 71% were post-menopausal, 23.9% were node-positive and median tumor size was 1.5 cm. Samples were stained using triplicate 0.6 mm2 tissue microarray cores, and positivity for p53, HTF9C, CEACAM5, NDRG1 and SLC7A5 was assessed. Each case was assigned a Mammostrat risk score, and distant recurrence-free survival (DRFS), relapse-free survival (RFS) and overall survival (OS) were analyzed by marker positivity and risk score. Increased Mammostrat scores were significantly associated with reduced DRFS, RFS and OS in ER-positive breast cancer ($p < 0.00001$). In multivariate analyses the risk score was independent of conventional risk factors for DRFS, RFS and OS ($p < 0.05$). In node-negative, tamoxifen-treated patients, 10-year recurrence rates were 7.6 +/- 1.5% in the low-risk group versus 20.0 +/- 4.4% in the high-risk group. Further, exploratory analyses revealed associations with outcome in both ER-negative and un-treated patients. The authors concluded that the Mammostrat can act as an independent prognostic tool for ER-positive, tamoxifen-treated breast cancer and the results of the study revealed a possible association with outcome regardless of node status and ER-negative tumors.

There is insufficient evidence to determine whether the Mammostrat test is better than conventional risk assessment tools in predicting the recurrence of breast cancer. Furthermore, neither NCCN or ASCO have incorporated the test into their guidelines as a diagnostic tool.

The OvaCheck™ (Correlogic Systems, Inc.) is a proteomic analysis of blood for the early detection of ovarian cancer. A similar test, which involved a different molecular pattern, was the subject of a 2002 study of 216 women with ovarian cancer. That study showed that the proteomic test had a specificity of 100% and a sensitivity of 95%, with a positive predictive value of 94% (Petricoin, et al., 2002). While this study showed that a proteomic test detected ovarian cancers even where CA-125 levels were normal, this study included only women who had been detected with ovarian cancer by other means. There is inadequate evidence that this test will be effective for screening women with undetected ovarian cancer.

In addition, there is concern, given the low prevalence of ovarian cancer, that this test is not sufficiently specific for use in screening. The National Cancer Institute explains that even an ovarian cancer test with a specificity of 99% means that 1% of those who did not have cancer would test positive, which is “far too high a rate for commercial use” (NCI, 2004). For a rare disease such as ovarian cancer, which has an approximate prevalence of 1 in 2,500 in the general population, a 99% specificity and 100% sensitivity translates into 25 women falsely identified for every one true cancer found.

The OvaCheck™ test employs electrospray ionization (ESI) type of mass spectrometry using

highly diluted denatured blood samples. This method differs from a matrix-assisted laser desorption ionization (MALDI) analysis of undiluted native sera samples that was used in the Lancet study and is currently under investigation by the National Cancer Institute and Food and Drug Administration (NCI, 2004). The NCI notes that "[t]he class of molecules analyzed by these two approaches, and thus the molecules that constitute the diagnostic patterns, would be expected to be entirely different." Neither the NCI nor FDA has been involved in the design or validation of OvaCheck™ methodology.

As the Ovacheck test is performed as a "home-brewed" test by two national laboratories instead of as a commercially available kit, FDA approval of the OvaCheck test may not be required. The Society for Gynecologic Oncologists (SGO, 2004) has reviewed the literature regarding OvaCheck and concluded that "more research is needed to validate the test's effectiveness before offering it to the public." Similarly, the American College of Obstetricians and Gynecologists (2004) has stated that "more research is needed to validate the test's effectiveness before recommending it to the public."

An assessment of the Ovacheck test and other genomic tests for ovarian cancer prepared for the Agency for Healthcare Research and Quality by the Duke Evidence-Based Practice Center (Myers, et al., 2006) reached the following conclusions: "Genomic test sensitivity/specificity estimates are limited by small sample sizes, spectrum bias, and unrealistically large prevalences of ovarian cancer; in particular, estimates of positive predictive values derived from most of the studies are substantially higher than would be expected in most screening or diagnostic settings. We found no evidence relevant to the question of the impact of genomic tests on health outcomes in asymptomatic women. Although there is a relatively large literature on the association of test results and various clinical outcomes, the clinical utility of changing management based on these results has not been evaluated." Specifically regarding Ovacheck and other proteomic tests for ovarian cancer, the assessment found that, "[a] lthough all studies reported good discrimination for the particular protein profile studied, there were several recurrent issues that limit the ability to draw inferences about potential clinical applicability," in particular technical issues with the assays themselves, variations in analytic methods used among studies, and an unrealistically high prevalence of ovarian cancer in the datasets compared to what would be expected in a normal screening population.

OvaSure is an ovarian cancer screening test that entails the use of 6 biomarkers (leptin, prolactin, osteopontin, insulin-like growth factor II, macrophage inhibitory factor and CA-125) to assess the presence of early stage ovarian cancer in high-risk women. Visintin et al (2008) characterized and validated the OvaSure for discriminating between disease-free and ovarian cancer patients. These researchers analyzed 362 healthy controls and 156 newly diagnosed ovarian cancer patients. Concentrations of leptin, prolactin, osteopontin, insulin-like growth factor II, macrophage inhibitory factor, and CA-125 were determined using a multiplex, bead-based, immunoassay system. All 6 markers were evaluated in a training set (181 samples from the control group and 113 samples from ovarian cancer patients) and a test set (181 sample control group and 43 ovarian cancer). Multiplex and ELISA exhibited the same pattern of expression for all the biomarkers. None of the biomarkers by themselves was good enough to differentiate healthy versus cancer cells. However, the combination of the 6 markers provided a better differentiation than CA-125. Four models with less than 2% classification error in training sets all had significant improvement (sensitivity 84 % to 98% at specificity 95%) over CA-125 (sensitivity 72% at specificity 95%) in the test set. The chosen model correctly classified 221 out of 224 specimens in the test set, with a classification accuracy of 98.7%. The authors noted that the OvaSure is the first blood biomarker test with a sensitivity of 95.3% and a specificity of 99.4% for the detection of ovarian cancer. Six markers provided a significant improvement over CA-125 alone for ovarian cancer detection. Validation was performed with a blinded cohort. They stated that this novel multiplex platform has the potential for efficient screening in patients who are at high risk for ovarian cancer.

However, the Society of Gynecologic Oncologists (SGO, 2008) released an opinion regarding OvaSure, which stated that additional research is needed before the test should be offered to

women outside the context of a research study. Moreover, SGO stated that it will "await the results of further clinical validation of OvaSure with great interest".

Furthermore, according to the FDA's web site, the FDA sent the Laboratory Corporation of America a warning letter stating that it is illegally marketing OvaSure to detect ovarian cancer. According to the FDA warning letter, their review indicates that this product is a device under section 201(h) of the Food, Drug, and Cosmetic Act (FDCA or Act), 21 U.S.C. 321(h), because it is intended for use in the diagnosis of disease or other conditions, or in the cure, treatment, prevention, or mitigation of disease. The Act requires that manufacturers of devices that are not exempt obtain marketing approval or clearance for their products from the FDA before they may offer them for sale. This helps protect the public health by ensuring that new devices are shown to be both safe and effective or substantially equivalent to other devices already legally marketed in this country for which approval is not required. According to the FDA warning letter, no such determination has been made for OvaSure.

Thrombospondin-1 (THBS-1), an angiogenesis inhibitor, has been identified as a potential monitoring marker in gynecologic malignancies. In a randomized phase III study on the co-expression of angiogenic markers and their associations with prognosis in advanced epithelial ovarian cancer, Secord, et al. (2007) reported that high THBS-1 may be an independent predictor of worse progression-free and overall survival in women with advanced-stage EOC. However, the authors stated, "A larger prospective study is warranted for validation of these findings."

Guanyl cyclase C (GCC) is a receptor protein normally expressed in high concentrations on the luminal surface of the gastrointestinal epithelium. Expression of GCC persists on mucosal cells that have undergone malignant transformation. Thus, GCC has potential use as a marker to determine spread of colorectal cancer to lymph nodes. A retrospective study of 21 patients post surgical resection of colorectal cancer found that all 11 of 21 patients who were free of cancer for 5 years or more were negative for GCC in lymph nodes, whereas all 10 of 21 patients whose cancer returned within 3 years of surgery were positive for GCC. However, the value of the GCC marker test in the management of colorectal cancer needs to be evaluated in prospective clinical outcome studies. A large prospective study is currently being conducted to compare standard histological examination of lymph nodes to the GCC marker test.

Thymidylate synthase is a DNA synthesis related gene. According to Compton (2008), the prognostic value of this promising and potentially clinically applicable molecular marker has been studied in colorectal cancer. Compton found that the independent influence of this marker on prognosis remains unproven. Compton explained that "[v]ariability in assay methodology, conflicting results from various studies examining the same factor, and the prevalence of multiple small studies that lack statistically robust, multivariate analyses all contribute to the lack of conclusive data." Compton concluded that before this marker can be incorporated into clinically meaningful prognostic stratification systems, more studies are required using multivariate analysis, well-characterized patient populations, reproducible and current methodology, and standardized reagents.

In a special report on pharmacogenomics of cancer, the BlueCross and BlueShield Association's Technology Evaluation Center (TEC) (2007) described the results of a meta-analysis on thymidylate synthase protein expression and survival in colorectal cancer that stated low thymidylate synthase expression was significantly associated with better survival, but heterogeneity and possible bias prevented firm conclusions.

Current guidelines from the American Society for Colon and Rectal Surgeons (2004) stated: "In the future, DNA analysis and the intratumoral expression of specific chemical substances", including thymidylate synthase, "may be used routinely to further assess prognosis or response to therapy." In addition, Shankaran, et al. (2008) stated in a review on the role of molecular markers in predicting response to therapy in patients with colorectal cancer, "Although to date no molecular characteristics have emerged as consistent predictors of response to therapy, retrospective studies have investigated the role of a variety of biomarkers, including

microsatellite instability, loss of heterozygosity of 18q, type II transforming growth factor beta receptor, thymidylate synthase, epidermal growth factor receptor, and Kirsten-ras (KRAS)."

Tumour angiogenesis is associated with invasiveness and the metastatic potential of various cancers. Vascular endothelial growth factor (VEGF), the most potent and specific angiogenic factor identified to date, regulates normal and pathologic angiogenesis. An evidence report from Cancer Care Ontario (Welch, et al., 2008) on the use of the VEGF inhibitor bevacizumab in colorectal cancer explained that the increased expression of VEGF has been correlated with metastasis, recurrence, and poor prognosis in many cancers, including colorectal cancer. Guidelines from the National Institute for Health and Clinical Excellence (NICE, 2007) explained that bevacizumab (Avastin) is a recombinant humanised monoclonal IgG1 antibody that acts as an angiogenesis inhibitor. It targets the biological activity of VEGF, which stimulates new blood vessel formation in the tumour. However, neither the FDA approved labeling of bevacizumab or evidence-based guidelines recommend measurement of VEGF to diagnose colorectal cancer or to select patients for treatment. In a special report on pharmacogenomics of cancer, the BlueCross and BlueShield Association's Technology Evaluation Center (TEC) (2007) stated that pre-treatment VEGF levels do not appear to be predictive of response to anti-angiogenic therapy.

PCA3 (DD3) is a gene that has been found to be highly overexpressed in prostate cancer. This gene has been investigated as a potential diagnostic marker for prostate cancer. However, there are no published clinical outcome studies of the effectiveness of the PCA3 gene in screening, diagnosis or management of prostate cancer.

Prostate cancer antigen 3 (PCA3) (Progensa, Gene-Probe, Inc.) encodes a prostate-specific mRNA. It is one of the most prostate cancer-specific genes identified, with over-expression in about 95% of cancers tested. The PCA3 urine assay is an amplified nucleic acid assay, which uses transcription-mediated amplification (TMA) to quantify PCA3 and PSA mRNA in prostate cells found in urine samples. The PCA3 score is calculated as the ratio between PCA3 and PSA mRNA. The main target population of this non-invasive test is men with raised PSA but a negative prostate biopsy. Other target groups include men with a slightly raised PSA, as well as men with signs and symptoms suggestive of prostate cancer.

van Gils and colleagues (2007) stated that the recently discovered PCA3 is a promising prostate cancer marker. These investigators performed a multi-center study to validate the diagnostic performance of the PCA3 urine test established in an earlier single-institution study. The first voided urine after DRE was collected from a total of 583 men with serum PSA levels between 3 and 15 ng/ml who were to undergo prostate biopsies. These researchers determined the PCA3 score in these samples and correlated the results with the results of the prostate biopsies. A total of 534 men (92%) had an informative sample. The area under the receiver-operating characteristic curve, a measure of the diagnostic accuracy of a test, was 0.66 for the PCA3 urine test and 0.57 for serum PSA. The sensitivity for the PCA3 urine test was 65%, the specificity was 66% (versus 47% for serum PSA), and the negative predictive value was 80%. The authors concluded that the findings of this multi-center study validated the diagnostic performance of the PCA3 urine test in the largest group studied thus far using a PCA3 gene-based test.

Marks and associates (2007) examined the potential utility of the investigational PCA3 urine assay to predict the repeat biopsy outcome. Urine was collected after DRE (3 strokes per lobe) from 233 men with serum PSA levels persistently 2.5 ng/ml or greater and at least one previous negative biopsy. The PCA3 scores were determined using a highly sensitive quantitative assay with TMA. The ability of the PCA3 score to predict the biopsy outcome was assessed and compared with the serum PSA levels. The RNA yield was adequate for analysis in the urine samples from 226 of 233 men (i.e., the informative specimen rate was 97%). Repeat biopsy revealed prostate cancer in 60 (27%) of the 226 remaining subjects. Receiver operating characteristic curve analysis yielded an area under the curve of 0.68 for the PCA3 score. In contrast, the area under the curve for serum PSA was 0.52. Using a PCA3 score cutoff of 35, the assay sensitivity was 58% and specificity 72%, with an odds ratio of 3.6. At PCA3 scores of less

than 5, only 12% of men had prostate cancer on repeat biopsy; at PCA3 scores of greater than 100, the risk of positive biopsy was 50%. The authors concluded that in men undergoing repeat prostate biopsy to rule out cancer, the urinary PCA3 score was superior to serum PSA determination for predicting the biopsy outcome. The high specificity and informative rate suggest that the PCA3 assay could have an important role in prostate cancer diagnosis.

Groskopf et al (2007) reported that the PCA3 score is independent of prostate volume and was highly correlated with the risk of positive biopsy. The PCA3 test was performed on 529 men scheduled for prostate biopsy. Overall, the PCA3 score had a sensitivity of 54% and a specificity of 74%. A PCA3 score of less than 5 was associated with a 14% risk of positive biopsy, while a PCA3 score of greater than 100 was associated with a 69% risk of positive biopsy.

Haese et al (2007) presented preliminary results from a European multicenter study of PCA3. Enrolled patients had a PSA level of less than or equal to 2.5 ng/mL, had 1 or 2 previous negative biopsies, and were scheduled for repeat biopsy. The specificity of the PCA3 score (cutoff 35) was found to be 78%, and the sensitivity was 67%. Patients with a PCA3 score of greater than or equal to 35 had a 33% probability of a positive repeat biopsy, compared to a 6% probability for those with a PCA3 score of less than 35.

An assessment by the BlueCross BlueShield Association Technology Evaluation Center (BCBSA, 2008) found that, in general, PCA3 assay results to date are preliminary; interpretation of results has not been standardized and clinical utility studies of decision-making for initial biopsy, repeat biopsy or treatment have not been reported.

Tosoian et al (2010) evaluated the relationship between PCA3 and prostate biopsy results in men in a surveillance program. Urine specimens were obtained from 294 men with prostate cancer enrolled in the Johns Hopkins surveillance program. The follow-up protocol included semi-annual free and total PSA measurements, digital rectal examination and annual surveillance prostate biopsy. Cox proportional hazards regression was used to evaluate the association between PCA3 results and progression on surveillance biopsy (defined as Gleason pattern 4 or 5, more than 2 positive biopsy cores or more than 50% involvement of any core with cancer). Patients with progression on biopsy (12.9%) had a mean PCA3 score similar to that of those without progression (60.0 versus 50.8, $p = 0.131$). Receiver operating characteristics analysis suggested that PCA3 alone could not be used to identify men with progression on biopsy (area under the curve = 0.589, 95% CI 0.496 to 0.683, $p = 0.076$). After adjustment for age and date of diagnosis PCA3 was not significantly associated with progression on biopsy ($p = 0.15$). The authors concluded that in men with low risk prostate cancer who were carefully selected for surveillance the PCA3 score was not significantly associated with short-term biopsy progression. They stated that further analysis is necessary to assess the usefulness of PCA3 in combination with other biomarkers or in selected subsets of patients undergoing surveillance.

While there are studies examining the positive and negative predictive values of the PCA3 urine assay, there is currently a lack of evidence of the effect of this test on management of individuals with or suspected of prostate cancer. The PCA3 urine assay shows promise as a prostate cancer diagnostic tool, however, more research is needed to ascertain the clinical value of this assay for screening and diagnostic purposes.

Donovan et al (2008) from Aureon, the manufacturer of Prostate Px, reported on the development and validation of their systems pathology model for predicting prostate cancer recurrence after prostatectomy. The clinical utility of defining high risk for failure after radical prostatectomy is to decide whether patients require closer follow-up than average or whether adjuvant radiotherapy, hormone therapy, or chemotherapy would be of benefit. In this analysis, the concordance index for the systems pathology approach used by Aureon was 0.83, but was only slightly better than a 10-variable model that used only the usual clinical parameters, with a concordance index of 0.80. The corresponding hazard ratios for clinical failure were 6.37 for the 10-variable clinical model, and 9.11 for the systems pathology approach. In an accompanying editorial, Klein, et al. (2009) questioned the clinical significance of these differences. They noted

that "[a]lthough the difference in concordance indices was statistically significant, the question is whether there is sufficient clinical relevance to justify the extra effort, expense, and clinical expertise needed for the systems approach ... In contemporary clinical practice, a patient with a hazard ratio of 6.37 generated by the model using easily derived, routinely reported clinical and pathological parameters is just as likely to be a candidate for closer monitoring or adjuvant therapy than one with a hazard ratio of 9.11 generated by the systems approach".

Sutcliffe et al (2009) provided an evidence-based perspective on the prognostic value of novel markers in localized prostate cancer and identified the best prognostic model including the 3 classical markers and investigated if models incorporating novel markers are better. Eight electronic bibliographic databases were searched. The reference lists of relevant articles were checked and various health services research-related resources consulted via the internet. The search was restricted to publications from 1970 onwards in the English language. Selected studies were assessed, data extracted using a standard template, and quality assessed using an adaptation of published criteria. Because of the heterogeneity regarding populations, outcomes and study type, meta-analyses were not undertaken and the results are presented in tabulated format with a narrative synthesis of the results. A total of 30 papers met the inclusion criteria, of which 28 reported on prognostic novel markers and 5 on prognostic models. A total of 21 novel markers were identified from the 28 novel marker studies. There was considerable variability in the results reported, the quality of the studies was generally poor and there was a shortage of studies in some categories. The marker with the strongest evidence for its prognostic significance was PSA velocity (or doubling time). There was a particularly strong association between PSA velocity and prostate cancer death in both clinical and pathological models. In the clinical model the hazard ratio for death from prostate cancer was 9.8 (95 % CI 2.8 to 34.3, $p < 0.001$) in men with an annual PSA velocity of more than 2 ng/ml versus an annual PSA velocity of 2 ng/ml or less; similarly, the hazard ratio was 12.8 (95 % CI 3.7 to 43.7, $p < 0.001$) in the pathological model. The quality of the prognostic model studies was adequate and overall better than the quality of the prognostic marker studies. Two issues were poorly dealt with in most or all of the prognostic model studies: (i) inclusion of established markers, and (ii) consideration of the possible biases from study attrition. Given the heterogeneity of the models, they can not be considered comparable. Only 2 models did not include a novel marker, and 1 of these included several demographical and co-morbidity variables to predict all-cause mortality. Only 2 models reported a measure of model performance, the C-statistic, and for neither was it calculated in an external data set. It was not possible to assess whether the models that included novel markers performed better than those without. This review highlighted the poor quality and heterogeneity of studies, which render much of the results inconclusive. It also pinpointed the small proportion of models reported in the literature that are based on patient cohorts with a mean or median follow-up of at least 5 years, thus making long-term predictions unreliable. Prostate-specific antigen velocity, however, stood out in terms of the strength of the evidence supporting its prognostic value and the relatively high hazard ratios. There is great interest in PSA velocity as a monitoring tool for active surveillance but there is as yet no consensus on how it should be used and, in particular, what threshold should indicate the need for radical treatment.

In an editorial on clinically relevant prognostic markers for prostate cancer, Gelmann and Henshall (2009) stated that "[u]ntil we have sufficiently discriminating markers to inform treatment decisions, the problem of whom to treat will continue to grow exponentially as the number of cases of screening-detected low-risk cancer increases".

The CellSearch™ Epithelial Cell Kit, along with the CellSpotter™ Analyzer (Veridex, LLC, Warren, NJ) is a device designed to automate the detection and enumeration of circulating tumor cells (CTCs) of epithelial origin (CD45-, EpCAM+, and cytokeratins 8, 18+ and/or 19+) in whole blood in patients with advanced breast cancer. It is intended for use in adjunctively monitoring and predicting cancer disease progression and response to therapy.

The CellSearch Epithelial Cell Kit received FDA 510(k) clearance on January 21, 2004. The FDA concluded that the device is substantially equivalent to immunomagnetic circulating cancer cell selection and enumeration systems. These devices consist of biological probes,

fluorochromes and other reagents, preservation and preparation devices and semi-automated analytical instruments to select and count circulating cancer cells in a prepared sample of whole blood.

The CellSearch Epithelial Cell Kit quantifies CTCs by marking cancerous cells with tiny, protein-coated magnetic balls in whole blood. These cells are stained with fluorescent markers for identification and then dispensed into a cartridge for analysis where a strong magnetic field is applied to the mixture causing the magnetically marked cells to move to the cartridge surface. The cartridge is then analyzed by the CellSpotter Analyzer. A medical professional rechecks the CTCs and the CellSpotter Analyzer tallies the final CTC count.

In a prospective, multicenter study, Cristofanilli et al (2004) used the CellSearch System on 177 patients with measurable metastatic breast cancer for levels of CTCs both before the patients started a new line of therapy and at follow-up. The progression of the disease or the response to treatment was determined with the use of standard imaging studies at the participating centers every nine to twelve weeks. Outcomes were assessed according to levels of CTCs at baseline, before the patients started a new therapy. In the first test, patients with 5 or more CTCs per 7.5 ml of blood compared to a group with fewer than 5 CTCs had a shorter median progression-free survival (2.7 months vs. 7.0 months) and shorter overall survival (10.1 months vs. greater than 18 months). At the follow-up visit, approximately three to four weeks after the initiation of therapy, the percentage of patients with more than 5 CTC was reduced from 49 percent to 30 percent, suggesting a benefit from therapy. The difference in progression-free survival between the two groups remained consistent (2.1 months for women with 5 or more CTCs vs. 7 months for women with less than 5 CTCs). Overall, survival in the women with more than 5 CTCs was 8.2 months compared to greater than 18 months in the cohort with less than 5 CTCs. Cristofanilli concluded that the number of CTCs before treatment was an independent predictor of progression-free survival and overall survival in patients with metastatic breast cancer. However, Cristofanilli also concluded that the results may not be valid for patients who do not have measurable disease or for those starting a new regimen of hormone therapy, immunotherapy, or both. He states, “The prognostic implications of an elevated level of circulating tumor cells for patients with metastatic disease who are starting a new treatment may be an opportunity to stratify these patients in investigational studies”. Furthermore, the study did not address whether patients with an elevated number of circulating tumor cells might benefit from other therapies. Thus, this minimally invasive assay requires further evaluation as a prognostic marker of disease progression and response to therapy.

The clinical application of quantifying CTCs in the peripheral blood of breast cancer patients remains unclear. Published data in the peer-reviewed medical literature are needed to determine how such measurements would guide treatment decisions and whether these decisions would result in beneficial patient outcomes (Kahn, et al., 2004; Abeloff, et al., 2004). An assessment of CellSearch by AETSA (2006) concluded "In the current stage of development of this technology, there is no evidence that it provides any advantage over existing technology for CTC identification or indeed any additional clinical use." Guidelines from the American Society for Clinical Oncology (Harris, et al., 2007) found: "The measurement of circulating tumor cells (CTCs) should not be used to make the diagnosis of breast cancer or to influence any treatment decisions in patients with breast cancer. Similarly, the use of the recently U.S. Food and Drug Administration (FDA)-cleared test for CTC (CellSearch Assay) in patients with metastatic breast cancer cannot be recommended until further validation confirms the clinical value of this test."

Although studies relate circulating tumor cells to prognostic indicators (see, e.g., Cohen, et al., 2008; De Giorgi, et al., 2009), there are a lack of published prospective clinical studies demonstrating that measurement of CTCs alters management such that clinical outcomes are improved. Such clinical outcome studies are currently ongoing. Current guidelines from the National Comprehensive Cancer Network (NCCN) and the American Society for Clinical Oncology (ASCO) make no recommendation for use of circulating tumor cells.

Estrogen and progestin receptors are important prognostic markers in breast cancer, and the

higher the percentage of overall cells positive as well as the greater the intensity, the better the prognosis. Estrogen and progesterone receptor positivity in breast cancer cells is an indication the patient may be a good candidate for hormone therapy. HER-2/neu is an oncogene. Its gene product, a protein, is over-expressed in approximately 20 to 30% of breast cancers. The over-expressed protein is present in unusually high concentration on the surface of some malignant breast cancer cells, causing these cells to rapidly proliferate. It is important because these tumors are susceptible to treatment with Herceptin (trastuzumab), which specifically binds to this over-expressed protein. Herceptin blocks these protein receptors, inhibiting continued replication and tumor growth.

There are additional tests that may be used in breast cancer cases, such as DNA ploidy, Ki-67 or other proliferation markers. However, most authorities believe that HER-2/neu, estrogen and progesterone receptor status are the most important to evaluate first. The other tests do not have therapeutic implications and, when compared with grade and stage of the disease, are not independently significant with respect to prognosis.

Harris et al (2007) updated ASCO's recommendations for the use of tumor marker tests in the prevention, screening, treatment, and surveillance of breast cancer. Thirteen categories of breast tumor markers were considered, 6 of which were new for the guideline. The following categories showed evidence of clinical utility and were recommended for use in practice: CA 15-3, CA 27.29, CEA, estrogen receptor, progesterone receptor, human epidermal growth factor receptor 2, urokinase plasminogen activator, plasminogen activator inhibitor 1, and certain multi-parameter gene expression assays. Not all applications for these markers were supported, however. The following categories demonstrated insufficient evidence to support routine use in clinical practice: DNA/ploidy by flow cytometry, p53, cathepsin D, cyclin E (fragments or whole length), proteomics, certain multi-parameter assays, detection of bone marrow micrometastases, and circulating tumor cells (e.g., CellSearch assay). These guidelines found present data insufficient to recommend measurement of Ki67, cyclin D, cyclin E, p27, p21, thymidine kinase, topoisomerase II, or other markers of proliferation to assign patients to prognostic groups. The guidelines also found insufficient data to recommend assessment of bone marrow micrometastases for management of patients with breast cancer.

The PathFinderTG (RedPath Integrated Pathology, Pittsburgh, PA), also known as topographic genotyping, is described by the manufacturer as a quantitative genetic mutational analysis platform for resolving “indeterminate, atypical, suspicious, equivocal and non-diagnostic specimen” diagnoses from pathology specimens (RedPath, 2007). The manufacturer states that PathFinder TG "focuses on acquired mutational damage rather than inherited genetic predisposition for certain diseases, although there are certain NIH recommended inherited conditions for which we do test." The manufacturer states that the temporal sequence of acquired mutational damage revealed by the PathFinderTG test is an earlier demonstration of tumor biological aggressiveness than current staging systems that rely on the depth of invasion already achieved by the tumor. Available published evidence for topographic genotyping focuses on retrospective analyses of pathology specimens examining correlations of test results with tumor characteristics (e.g., Saad, et al., 2008; Lin, et al., 2008; Finkelstein, et al., 2003; Pollack, et al., 2001; Riberio, et al., 1998; Kounelis, et al., 1998; Finkelstein, et al., 1998; Holst, et al., 1998; Jones, et al., 1997; Holst, et al., 1997; Pricolo, et al., 1997; Przygodzki, et al., 1997; Finkelstein, et al., 1996; Kanbour-shakir, et al., 1996; Ribeiro, et al., 1996; Pryzgodzki, et al., 1996; Safatle-Ribeiro, et al., 1996; Papadaki, et al., 1996; Przygodzki, et al., 1996; Pricolo, et al., 1996; Finkelstein, et al., 1994). There are no prospective clinical outcome studies on the use of topographic genotyping in guiding patient management. Current evidence-based guidelines from leading medical professional organizations and public health agencies do not include recommendations for topographic genotyping. In a review on molecular analysis of pancreatic cyst fluid, Shen and colleagues (2009) stated that a large study with validation of PathFinderTG molecular testing of pancreatic fluid will be needed before a firm conclusion can be drawn.

A systematic evidence review of the PathFinderTG prepared for the Agency for Healthcare Research and Quality (Trikalinos, et al., 2010) found that most studies on loss-of-heterozygosity

based topographic genotyping with PathfinderTG were excluded because they only described the molecular profile of different tumors, without assessing the ability of the method to help make diagnosis, prognosis or treatment guidance. The review found no studies that directly measured whether using loss-of-heterozygosity based topographic genotyping with PathfinderTG improves patient-relevant clinical outcomes. The review reported that eligible studies on the diagnostic and prognostic ability of loss-of-heterozygosity based topographic genotyping with PathfinderTG were small in sample sizes and had overt methodological limitations. The review reported that important characteristics of their designs were not clearly reported. The report noted that loss-of-heterozygosity based topographic genotyping with PathfinderTG is claimed to be particularly useful in cases where conventional pathology is unable to provide a conclusive diagnosis. However, the included studies were not designed to address this question. Therefore, it is unclear if the findings of the reviewed studies are directly applicable to patients with the same cancers but with inconclusive diagnosis.

Carcinoma of unknown primary (CUP) is a biopsy-proven metastatic solid tumor with no primary tumor identified and represents approximately 2% to 4% of all cancer cases. The diagnosis of CUP is made following inconclusive results from standard tests (e.g., biopsy, immunochemistry and other blood work, chest x-rays, and occult blood stool test). The absence of a known primary tumor presents challenges to the selection of appropriate treatment strategies. As a result, patients have a poor prognosis, and fewer than 25% survive 1 year from the time of diagnosis. A variety of tissue-biopsy testing techniques currently are used to determine the origin of the CUP, including immunochemistry; histological examination of specimens stained with eosin and hematoxylin, and electron microscopy. These techniques definitively identify the type of carcinoma in less than 20% to 30% of CUP.

Gene expression profiling is a technique used to identify the genetic makeup of a tissue sample by characterizing the patterns of mRNA transcribed, or "expressed", by its DNA. Specific patterns of gene expression, reflected in unique configurations of mRNA, are associated with different tumor types. By comparing the gene expression profile (GEP) of an unknown tumor to the profiles of known primary cancers ("referent" profiles), it may be possible to determine the type of tumor from which the CUP originated.

In July 2008, the FDA cleared for marketing the Pathwork Tissue of Origin test (Pathwork Diagnostics, Sunnyvale, CA), a gene expression profiling test that uses microarray processing to determine the type of cancer cells present in a tumor of unknown origin. The test uses the PathChip (Affymetrix Inc., Santa Clara, CA), a custom-designed gene expression array, to measure the expression from 1,668 probe sets to quantify the similarity of tumor specimens to 15 common malignant tumor types, including: bladder, breast, colorectal, gastric, germ cell, hepatocellular, kidney, non-small cell lung, non-Hodgkin's lymphoma, melanoma, ovarian, pancreatic, prostate, soft tissue sarcoma, and thyroid. The degree of correspondence between the tissue sample's GEP and a referent profile is quantified and expressed as a probability-based score.

A multi-center, clinical validation study reported on comparisons of diagnoses based on GEP from 477 banked tissue samples of undifferentiated and poorly differentiated metastases versus standard of care pathology based diagnoses. Comparison of the GEP based diagnoses versus pathology based diagnoses yielded an 89% agreement and the concurrence was greater than 92% for 8 out of 15 types of primary tumors. The overall accuracy of the test was approximately 95% and 98% for positive and negative determinations, respectively (Monzon, et al., 2007).

Gene expression profiling is a promising technology in the management of CUP; however, there is insufficient evidence of its clinical utility compared to that achieved by expert pathologists using current standards of practice. A draft clinical guideline on metastatic malignant disease of unknown origin by the National Institute for Clinical Excellence (NICE, 2010) recommends against using gene expression profiling (e.g., Pathwork TOT, CupPrint, Theros CancerTypeID, miRview Mets) to identify primary tumors in patients with CUP. The guideline explained that currently there is no evidence that gene-expression based profiling improves the management or

changes the outcomes for patients with CUP. Guidelines on occult primary from the National Comprehensive Cancer Network (NCCN, 2010) state that, while gene expression profiling looks promising, "prospective clinical trials are necessary to confirm whether this approach can be used in choosing treatment options which would improve the prognosis of patients with occult primary cancers."

A technology assessment prepared for the Agency for Healthcare Research and Quality (Meleth, et al., 2013) found that the clinical accuracy of the PathworkDx, miRview, and CancerTypeID are similar, ranging from 85 percent to 88 percent, and that the evidence that the tests contribute to identifying a tumor of unknown origin was moderate. The assessment concluded that we do not have sufficient evidence to assess the effect of the tests on treatment decisions and outcomes. The assessment noted that most studies of these tests were funded wholly or partially by the manufacturers of these tests, and that the most urgent need in the literature is to have the clinical utility of the tests evaluated by research groups that have no evidence conflict of interest.

The presence of breast tumor cells in axillary lymph nodes is a key prognostic indicator in breast cancer. During surgery to remove breast tumors, patients often undergo biopsy of the sentinel (i.e., first) node(s) that receive lymphatic fluid from the breast. Excised sentinel lymph nodes are currently evaluated post-operatively by formalin-fixed paraffin-embedded Hematoxylin and Eosin (H&E) histology and IHC. GeneSearch™ Breast Lymph Node (BLN) assay (Veridex, LLC, Warren, NJ) is a novel method to examine the extracted sentinel lymph nodes for metastases and can provide information during surgery within 30 to 40 minutes from the time the sentinel node is removed, potentially avoiding a second operation for some patients. The GeneSearch BLN assay received FDA pre-market approval on July 16, 2007 as a qualitative in vitro diagnostic test for the rapid detection of metastases larger than 0.2 mm in nodal tissue removed from sentinel lymph node biopsies of breast cancer patients. GeneSearch BLN assay uses real time reverse transcriptase polymerase chain reaction (RT-PCR) to detect the gene expression markers, mammaglobin (MG) and cytokeratin 10 (CI19), which are abundant in breast tissue but scarce in lymph node cells. In the clinical trial conducted by Veridex, which was submitted to the FDA, the sensitivity of the GeneSearch BLN Assay was reported to be 87.6% and the specificity was 94.2% (Julian, et al., 2008). According to the product labeling,"The GeneSearch™ Breast Lymph Node (BLN) assay may be used in conjunction with sentinel lymph node biopsy for a patient who has been counseled on use of this test and has been informed of its performance. False positive results may be associated with increased morbidity. False negative and inconclusive test results may be associated with delayed axillary node dissection. Clinical studies so far are inconclusive about a benefit from treatment based on findings of breast cancer micro-metastases in sentinel lymph nodes."

Blumencranz et al (2007) compared the GeneSearch BLN assay with results from conventional histologic evaluation from 416 patients at 11 clinical sites and reported that the GeneSearch BLN assay detected 98% of metastases greater than 2 mm in size and 57% of metastasis less than 0.2 mm. False positives were reported in 4% of the cases. However, there were several limitations of this study, including the lack of a description of patient recruitment, inadequate descriptions of several analyses performed, substantial variations in test performance across sites, and ad hoc comparison of the assay to other intra-operative techniques.

Viale et al (2008) analyzed 293 lymph nodes from 293 patients utilizing the GeneSearch BLN assay. Using histopathology as the reference standard, the authors reported that the BLN assay correctly identified 51 of 52 macro-metastatic and 5 of 20 micro-metastatic sentinel lymph nodes (SLNs), with a sensitivity of 98.1% to detect metastases larger than 2 mm, 94.7% for metastases larger than 1 mm, and 77.8% for metastases larger than 0.2 mm. The overall concordance with histopathology was 90.8%, with a specificity of 95.0%, a positive predictive value of 83.6%, and a negative predictive value of 92.9%. When the results were evaluated according to the occurrence of additional metastases to non-SLN in patients with histologically positive SLNs, the assay was positive in 33 (91.7%) of the 36 patients with additional metastases and in 22 (66.6%) of the 33 patients without further echelon involvement. The authors concluded that the sensitivity of the GeneSearch BLN assay is comparable to that of the histopathologic

examination of the entire SLN by serial sectioning at 1.5 to 2 mm.

Although treatment for metastases larger than 2.0 mm is widely accepted as beneficial, clinical studies have not yet provided data for a consensus on benefit from treatment based on very small breast cancer metastases (between 0.2 mm and 2.0 mm) in SLNs. False positive results may be associated with increased morbidity, usually due to effects of axillary node dissection surgery. Patients who undergo axillary lymph node dissection (ALND) have significantly higher rates of increased swelling in the upper arm and forearm (lymphedema), pain, numbness, and motion restriction about the shoulder when compared with patients who undergo only sentinel lymph node dissection (SLND). False negative and inconclusive test results may be associated with delayed axillary node dissection. Clinical studies so far are inconclusive regarding a benefit from treatment based on findings of breast cancer micro-metastases in SLNs. Preliminary data suggest that the GeneSearch BLN assay has high specificity and moderate sensitivity when only macro-metastases are included in the analysis. The clinical significance of micro-metastases is still being debated in the literature, thus, the failure of the GeneSearch BLN assay to perform adequately in the detection of micro-metastases is of unknown significance.

A systematic evidence review by the BlueCross BlueShield Association Technology Evaluation Center (BCBSA, 2007) determined that the use of the GeneSearch BLN assay to detect sentinel node metastases in early stage breast cancer does not meet the TEC criteria. The assessment stated, "There are several operational issues that add difficulty to the use of the GeneSearch assay, including the need for fresh specimens (rather than putting them in formalin for permanent fixation), the learning curve involved in reducing both the percentage of invalid results (from about 15% initially to 4 - 8% for more experienced technicians) and the time to perform the test compared to alternative intra-operative techniques (which take less than 15 minutes)." Furthermore, the assessment stated "The GeneSearch assay also provides less information for staging than other intra-operative procedures, since it cannot distinguish between micro- and macro-metases. Nor can it indicate the location of the metastasis (inside or outside the node). Post-operative histology is therefore required in all cases. It is less crucial when frozen section histology is performed, since pathologists can judge the size of the metastasis and its location from this test, although distortion is possible. To summarize, the data available is inadequate to assess the clinical utility of the GeneSearch assay compared to either post-operative histology alone or to the alternative intra-operative tests such as imprint cytology and frozen section histology. In addition, the balance of benefits versus harms may require higher specificity to avoid unnecessary ALNDs and their sequelae, whereas the GeneSearch design emphasizes sensitivity."

Thus, there is insufficient evidence to make a conclusion about the effectiveness of the GeneSearch BLN assay. The FDA is requiring the manufacturer to conduct two post-approval studies. The primary objective of the first study is to estimate the positive predictive concordance between the GeneSearch BLN assay and histology as routinely practiced and the objectives of the second clinical study are (i) determine the assay turn-around-time from the time of node removal to the report of the assay result to the surgeon and (ii) determine whether the assay result was or was not received in time to make an intra-operative decision and (iii) collect data in relation to other surgical procedures during the sentinel lymph node dissection/breast surgery to determine if the assay turn-around-time resulted in longer surgery time.

Provista Life Sciences (Phoenix, AZ) has developed a laboratory test called the Biomarker Translation Test, or the BT Test, which is a test score based on a multi-protein biomarker analysis (i.e., IL-2, -6,-8,-12, TNFa, EGF, FGF, HGF, VEGF) and medical profile of an individual's risk factors for breast cancer. It is intended to be used as an adjunctive test along with other breast cancer detection modalities, however, there are no published studies of the effectiveness of this test.

Bcl-2 (B-cell CLL/lymphoma 2; BCL2) is a proto-oncogene whose protein product, bcl-2, suppresses programmed cell death (apoptosis), resulting in prolonged cellular survival without increasing cellular proliferation. Dysregulation of programmed cell death mechanisms plays a

role in the pathogenesis and progression of cancer as well as in the responses of tumors to therapeutic interventions. Many members of the Bcl-2 family of apoptosis-related genes have been found to be differentially expressed in various malignancies (Reed, 1997).

Salgia (2008) reviewed the evidence for detection of Bcl-2 in lung cancer. The author observed that Bcl-2 over-expression has been reported in 22 to 56% of lung cancers with a higher expression in squamous cell carcinoma as compared to adenocarcinoma histology. The author concluded, however, that the association of Bcl-2 expression and prognosis in non-small cell lung cancer is unclear. Multiple reports have demonstrated that Bcl-2-positive lung cancers are associated with a superior prognosis compared to those that are Bcl-2 negative. However, other studies have failed to demonstrate any survival impact with bcl-2 positivity, while over-expression has also been associated with a poorer outcome. A meta-analysis that included 28 studies examining the prognostic influence of Bcl-2 in non-small cell lung cancer concluded that over-expression of Bcl-2 was associated with a significantly better prognosis in surgically resected (hazard ratio 0.5, 95% CI 0.39-0.65).

Compton (2008) recently reviewed the evidence on the Bcl-2 oncogene and other tumor markers in colon cancer. Compton explained that Bcl-2 is a gene related to aptosis/cell suicide. Bcl-2 over-expression leading to inhibition of cell death signaling has been observed as a relatively early event in colorectal cancer development. The author concluded that the independent influence of the Bcl-2 oncogene on prognosis remains unproven, and explained that the variability in assay methodology, conflicting results from various studies examining the same factor, and the prevalence of multiple small studies that lack statistically robust, multivariate analyses all contribute to the lack of conclusive data. Compton concluded that before the Bcl-2 oncogene and certain other tumor markers can be incorporated into clinically meaningful prognostic stratification systems,"more studies are required using multivariate analysis, well-characterized patient populations, reproducible and current methodology, and standardized reagents."

Compton (2008) reviewed the evidence for intratumor microvessel density (MVD) and antibodies against CD31 in colorectal cancer. The author explained that intratumoral MVD is a reflection of tumor-induced angiogenesis. Microvessel density has been independently associated with shorter survival in some, but not all studies. A meta-analysis of all studies relating MVD expression to prognosis concluded that at least some of the variability could be explained by the different methods of MVD assessment. The author noted that there was a significant inverse correlation between immunohistochemical expression and survival when MVD was assessed using antibodies against CD31 or CD34, but not factor VIII. The author concluded, however, that there is a need for evaluation of MVD in large studies of prognostic factors using multivariate analysis; however, standard guidelines for staining, evaluation, and interpretation of MVD are lacking.

In a review, Hayes (2008) reviewed the evidence for assessing angiogenesis factors in breast cancer. The author noted that, in an early report, MVD count (as indicated by IHC staining for endothelial cells, such as factor VIII-related antigen or CD31) was a statistically significant independent predictor of both disease-free and overall survival in women with both node-negative and node-positive breast cancer. The author noted, however, that subsequent data are conflicting, with some studies confirming and others refuting the initial findings. The author stated that, "As with many of the other tumor marker studies, evaluation of angiogenesis is complicated by technical variation, reader inconsistency, and potential interaction with therapy."

Burgdorf (2006) reviewed the use of CD31 in acquired progressive lymphangioma. The author stated that special staining techniques reveal that the cells are variably positive for CD31, but that the staining patterns are too variable to be of diagnostic importance.

Some authorities have stated that CD31 staining may be useful for diagnosing angiosarcomas (Schwartz, 2008; Carsi & Sim, 2008; Fernandez & Schwartz, 2007; McMains & Gourin, 2007). CD31 immunostaining can help confirm that the tumor originates from blood vessels.

The topoisomerase II alpha gene (TOP2A) is located adjacent to the HER-2 oncogene at the chromosome location 17q12-q21 and is either amplified or deleted (with equal frequency) in a great majority of HER-2 amplified primary breast tumors and also in tumors without HER-2 amplification. Recent experimental as well as numerous, large, multi-center trials suggest that amplification (and/or deletion) of TOP2A may account for both sensitivity or resistance to commonly used cytotoxic drugs (e.g., anthracyclines) depending on the specific genetic defect at the TOP2A locus. An analysis of TOP2A aberrations in the Danish Breast Cancer Cooperative Group trial 89D (Nielsen, et al., 2008) suggested a differential benefit of adjuvant chemotherapy in patients with primary breast cancer, favoring treatment with epirubicin in patients with TOP2A amplifications, and perhaps deletions; however, the authors concluded that, "Additional studies are needed to clarify the exact importance of TOP2A deletions on outcome, but deletions have proven to be associated with a very poor prognosis."

The National Comprehensive Cancer Network (NCCN, 2008) guideline on breast cancer does not address the use of TOP2A testing.

Ghoneim et al (2008) explained that thrombospondin-1 (TSP-1) is a member of a family of five structurally related extracellular glycoproteins that plays a major role in cell-matrix and cell to cell interactions. Due to its multifunctional nature and its ability to bind to a variety of cell surface receptors and matrix proteins, TSP-1 has been identified as a potential regulator of angiogenesis and tumor progression. Data collected by Secord, et al. (2007) suggested that high THBS-1 levels may be an independent predictor of worse progression-free and overall survival in women with advanced-stage epithelial ovarian cancer. However, a phase II clinical trail (Garcia, et al., 2008) of bevacizumab and low-dose metronomic oral cyclophosphamide in recurrent ovarian cancer reported that levels of TSP-1 were not associated with clinical outcome.

In a review on multidrug resistance in acute leukemia, List and Spier (1992) explained that the mdr1 gene or its glycoprotein product, P-glycoprotein, is detected with high frequency in secondary acute myeloid leukemia (AML) and poor-risk subsets of acute lymphoblastic leukemia. Investigations of mdr1 regulation in normal hematopoietic elements have shown a pattern that corresponds to its regulation in acute leukemia, explaining the linkage of mdr1 to specific cellular phenotypes. Therapeutic trials are now in progress to test the ability of various MDR-reversal agents to restore chemotherapy sensitivity in high-risk acute leukemias.

In a phase III multi-center randomized study to determine whether quinine would improve the survival of adult patients with de novo AML, Soary, et al. (2003) reported that neither mdr1 gene or P-glycoprotein expression influenced clinical outcome.

A phase I/II study of the MDR modulator Valspodar (PSC 833, Novartis Pharma) combined with daunorubicin and cytarabine in patients with relapsed and primary refractory acute myeloid leukemia (Gruber, et al., 2003) reported that P-glycoprotein did not give an obvious improvement to the treatment results.

Motility-related protein (MRP-1) is a glycoprotein with a sequence identical to that of CD9, a white blood cell differentiation antigen. The level of MRP-1/CD9 expression has been found in investigational studies to inhibit cell motility and low MRP-1/CD9 expression may be associated with the metastatic potential of breast cancer (Miyake, et al., 1995). CD9 immuno-expression is also being investigated as a potential new predictor of tumor behavior in patients with squamous cell carcinoma of the head and neck (Mhawech, et al., 2004) as well as other tumors (e.g., urothelial bladder carcinoma, colon cancer, lung cancer); however, prospective studies are needed to determine the clinical role of MRP-1/CD9 expression in tumors.

The National Comprehensive Cancer Network's guideline on occult primary tumors includes placental alkaline phosphatase (PLAP) as a useful marker to assist in identifying germ cell seminoma and non-seminoma germ cell tumors in unknown primary cancer (NCCN, 2009).

Myeloperoxidase (MPO), a blood protein, is a major component of azurophilic granules of

neutrophils. Myeloperoxidase analysis has been used to distinguish between the immature cells in acute myeloblastic leukemia (cells stain positive) and those in acute lymphoblastic leukemia (cells stain negative). The National Comprehensive Cancer Network guidelines on acute myeloid leukemia (AML) include MPO analysis in the classification of AML (NCCN, 2008).

Matsuo et al (2003) examined the prognostic factor of the percentage of MPO-positive blast cells for AML. Cytochemical analysis of MPO was performed in 491 patients who were registered to the Japan Adult Leukemia Study Group (AML92 study). Patients were divided into two groups using the percentage of MPO-positive blast (high [> or = 50%] and low [< 50%]). Complete remission rates were 85.4% in the former and 64.1% in the latter (p = 0.001). The OS and the disease-free survival (DFS) were significantly better in the high MPO group (48.3 versus 18.7% for OS, and 36.3 versus 20.1% for DFS, p < 0.001, respectively). Multi-variate analysis showed that both karyotype and the percentage of MPO-positive blast cells were equally important prognostic factors. The high MPO group still showed a better survival even when restricted to the intermediate chromosomal risk group or the patients with normal karyotype (p < 0.001). The OS of patients with normal karyotype in the high MPO group was almost equal to that of the favorable chromosomal risk group. The authors concluded that the percentage of MPO-positive blast cells is a simple and highly significant prognostic factor for AML patients, and especially useful to stratify patients with normal karyotype.

The most commonly used marker for hepatocellular carcinoma (HCC) is the AFP level. Des-gamma-carboxy prothrombin (DCP) (also known as "prothrombin produced by vitamin K absence or antagonism II" [PIVKA II]) has also shown promise in the diagnosis of HCC (Toyoda, et al., 2006; Ikoma, et al., 2002; Nomura, et al., 1996; Liebman, et al., 1984). In one series of 76 patients with HCC, this marker was elevated in 69 patients with a mean serum concentration of 900 mcg/L. Much lower mean values were seen in patients with chronic active hepatitis, metastatic disease to the liver, and normal subjects (10 and 42 mcg/L and undetectable, respectively) (Liebman, et al., 1984). Elevations in serum levels of DCP are less frequent in tumors less than 3 cm in size (Nakamura, et al., 2006; Weitz & Liebman, 1993;). Aoyagi, et al. (1996) and Weitz & Liebman (1993) reported that abnormal prothrombin levels do not correlate well with serum AFP.

Toyoda at al (2006) measured AFP, lens culinaris agglutinin A-reactive fraction of AFP (AFP-L3), and DCP for the evaluation of tumor progression and prognosis of patients with HCC (n = 685) at the time of initial diagnosis. Positivity for AFP > 20 ng/dL, AFP-L3 > 10% of total AFP, and/or DCP > 40 mAU/mL was determined. In addition, tumor markers were measured after treatment of HCC. Of the 685 patients, 337 (55.8%) were positive for AFP, 206 (34.1%) were positive for AFP-L3, and 371 (54.2%) were positive for DCP. In a comparison of patients positive for only 1 tumor marker, patients positive for AFP-L3 alone had a greater number of tumors, whereas patients positive for DCP alone had larger tumors and a higher prevalence of portal vein invasion. When patients were compared according to the number of tumor markers present, the number of markers present clearly reflected the extent of HCC and patient outcomes. The number of markers present significantly decreased after treatment. The authors concluded that tumor markers AFP-L3 and DCP appeared to represent different features of tumor progression in patients with HCC and that the number of tumor markers present could be useful for the evaluation of tumor progression, prediction of patient outcome, and treatment efficacy.

The National Comprehensive Cancer Network's guideline on HCC (NCCN, 2008) does not include measurement of DCP among the surveillance test options for HCC. According to NCCN guidelines, proposed surveillance for the early detection of HCC among high-risk populations (e.g., chronic hepatitis C virus-infected patients) includes liver ultrasonography every 3 to 6 months and evaluation of alkaline phosphatase, albumin, and AFP. The guidelines stated, "It is not yet clear if early detection of hepatocellular cancer with routine screening improves the percentage of patients detected with disease at a potentially curative stage, but high-risk chronic hepatitis C virus - infected patients should be considered for ongoing recurrent screening until these issues have been resolved. The level of des-gamma-carboxy-prothrombin protein induced by vitamin K absence (PIVKA-II) is also increased in many patients with hepatocellular

carcinoma. However, as is true with AFP, PIVKA-II may be elevated in patients with chronic hepatitis." Furthermore, according to Sherman (2008), DCP has not been adequately studied as a screening test for HCC and cannot be recommended at this time.

Researchers at Matritech (Newton, MA) have detected the presence of nuclear matrix protein (NMP) in the blood of women at the early stage of breast cancer, which is absent in the blood of healthy women, as well as those with fibroadenoma. NMP66 has been selected as a marker for further development and clinical trials of a test for use in the detection and monitoring of women with, or at risk for, breast cancer have been initiated (Wright and McGechan, 2003). However, there are no published studies on the effectiveness of NMP66 testing at this time.

HERmark testing has been proposed for a number of indications, including use to predict response to trastuzumab in the treatment of metastatic breast cancer. Monogram, the manufacturer of the HERmark test, claims that the test can provide a more precise and quantitative measurement of the HER2 gene than IHC and fluorescent in-situ hybridization (FISH) tests. The HERmark provides a quantitative measurement of HER2 total protein and HER2 homodimer levels, while conventional methods are an indirect measure of the HER2 gene, the manufacturer claims. The HERmark test will be offered as a CLIA-validated assay through Monogram's CAP-certified clinical laboratory. Other proposed indications for HERmark include determining the prognosis for breast cancer, and predicting treatment results in cancers other than breast cancer (e.g., ovarian prostate, head and neck, etc.). There are no current recommendations from leading medical professional organizations for the use of HERmark testing for breast cancer.

Noon et al (2010) stated that renal cell carcinoma (RCC) is the ype of kidney cancer and f ollows an unpredictable disease cours searchers reviewed 2 critical genes associated with disease p op53 and murine double minute 2 (MDM2) -- and provided a comp and critical analysis of th e literature regarding these Information was compiled by searching the PubMed databas ere published or e-published up to April 1, 2009. Search te renal cancer, renal cell carcinoma, p53, and MDM2. Full articles and dary data were examined; and, when appropriate, references we re chitional material. All studies that described assessment of p53 in renal cancer were i ncluded. The authors concluded that inpression, but not p53 mutation, is associated with redu ced ovemore rapid disease progression in RCC. There also was evidence regulation is associated with decreased disease-specific survival. of RCC stood out as unusual and will requi re further inves increased p53 expression is tightly linked with increased ion; and (ii) p atients who have tumors that display increaDM2 expression may have the poorest overall survival. Becausevidence to support the conclusion that p53 mutation is associatsurvival, it seemed clear that increased p53 expression in Rpendent of mutation. The authors stated that further investigation of the mechanisms leading to increased p53/MDM2 expression in RCC may lead to improved prognostication and to the identification of novel therapeutic interventions.

The OVA1 Test (Vermillion Inc. and Quest Diagnostics) is a serum test that is intended to help physicians determine if a woman is at risk for a malignant pelvic mass prior to biopsy or exploratory surgery, when the physician’s independent clinical and radiological evaluation does not indicate malignancy. The OVA1 Test employs an in vitro diagnostic multivariate index (IVDMIA) that combines the results of five immunoassays to produce a numerical score indicating a women's likelihood of malignancy. The OVA1 Test is intended to help physicians assess if a pelvic mass is benign or malignant in order to help determine whether to refer a woman to a gynecologic oncologist for surgery. The OVA1 Test was cleared by the FDA for use in women who meet the following criteria: over age 18, ovarian adnexal mass present for which surgery is planned, and not yet referred to an oncologist. The intended use of the OVA1 Test is an aid to further assess the likelihood that malignancy is present when the physician’s independent clinical and radiological evaluation does not indicate malignancy. According to the product labeling, the OVA1 Test is not intended as a screening or stand-alone diagnostic assay. There is a lack of evidence in the peer-reviewed published medical literature on the OVA1 Test.

In an editorial on the OVA1 Test, Muller (2010) stated that the role of OVA1 in a generalized

practice setting and cost-benefit ratio has yet to be determined. Furthermore, the ACOG Committee Opinion on the role of the obstetrician-gynecologist in the early detection of epithelial ovarian cancer (2011) noted that the clinical utility of the OVA1 Test "is not yet established".

The ColonSentry test (GeneNews, Toronto, Canada) measures the expression of seven genes, which serve as biomarkers to detect colorectal cancer. Interpretation of the status of these seven biomarkers is intended to assist physicians in identifying patients who have an increased current risk. According to the manufacturer, individuals assessed as having an increased current risk of colorectal cancer should consider having a colonoscopy. Individuals assessed as having a decreased current risk of colorectal cancer should discuss with their doctor further screening, including repeating ColonSentry at regular intervals. There is a lack of evidence in the peer-reviewed published medical literature on the effectiveness of colorectal cancer screening with ColonSentry. No current evidence-based guidelines from medical professional organizations or public health agencies recommend ColonSentry for colorectal cancer screening.

Prostate Px (Aureon) uses a prostate cancer patient's biopsy tissue to provide an assessment of disease severity and disease recurrence. Clinical data is integrated with an analysis of each patient's cancer using tissue histology and molecular biomarkers, such as androgen receptor, associated with disease progression. Although the manufacturer states that the results of the Prostate Px can be used in decision-making, there is a lack of evidence of the clinical utility of this test in altering the management of patients such that clinical outcomes are improved.

Post-Op Px is a prognostic test that utilizes a patented systems pathology approach to analyze prostatectomy tissue by combining cellular, molecular and clinical information to provide a thorough and more accurate picture of each patient's individual risk of prostate cancer recurrence. (Aureon, 2010). Donovan et al (2011) evaluated the performance of a systems-based risk assessment tool with standard defined risk groups and the 10 year postoperative normogram for predicting disease progression. The systems model was found to be more accurate than standard risk groups both to predict significant disease progression ($p < 0.001$) and for predicting prostate-specific antigen recurrence ($p < 0.001$). However, this study has not been replicated in the peer-reviewed literature.

An assessment by the BlueCross BlueShield Association Technology Evaluation Center (2010) concluded that tumor-cell epidermal growth factor receptor (EGFR) mutation analysis to predict response to erlotinib (Tarceva) in patients with advanced non-small cell lung cancer (NSCLC) meets the Blue Cross and Blue Shield Association Technology Evaluation Center (TEC) criteria. Furthermore, guidelines from the National Comprehensive Cancer Network (NCCN, 2010) recommend EGFR testing for the following histologic subtypes of NSCLC: (i) adenocarcinoma, (ii) large cell, and (iii) NSCLC not otherwise specified. Epidermal growth factor receptor testing is not recommended for squamous cell carcinoma.

Messick et al (2010) evaluated carcinoembryonic antigen cellular adhesion molecule-7 (CEACAM-7) expression in rectal cancer as a predictive recurrence factor. A single-institution colorectal cancer database and a frozen tissue biobank were queried for rectal cancer patients. CEACAM-7 messenger RNA (mRNA) expression from normal rectal mucosa and rectal cancers was analyzed using quantitative real-time polymerase chain reaction (PCR). Expression-level differences among normal tissue, disease-free survivors, and those that developed recurrence were analyzed. A total of 84 patients were included in the study, which consisted of 37 patients with non-recurrent disease (median follow-up of 170 months), 29 patients with recurrent disease, and 18 patients with stage IV disease. CEACAM-7 expression was decreased 21-fold in rectal cancers compared with normal mucosa ($p = 0.002$). The expression levels of CEACAM-7 were relatively decreased in tumors that developed recurrence compared with non-recurrence, significantly for stage II patients (14-fold relative decrease, $p = 0.002$). For stages I-III, disease-free survival segregates were based on relative CEACAM-7 expression values ($p = 0.036$), specifically for stage II ($p = 0.018$). The authors concluded that CEACAM-7 expression is significantly decreased in rectal cancer. Expression differences between long-term survivors and

those with recurrent disease introduce a potential tumor marker to define a subset of patients who benefit most from adjuvant therapy. Moreover, they stated that additional study and validation are needed before CEACAM-7 can be applied in clinical settings.

Castro et al (2010) assessed the potential value of cofilin (CFL1) gene (main member of the invasion/metastasis pathway) as a prognostic and predictive NSCLC biomarker. Meta-analysis of tumor tissue microarray was applied to examine expression of CFL1 in archival lung cancer samples from 111 patients, and its clinicopathologic significance was investigated. The robustness of the finding was validated using another independent data set. Finally, the authors assayed in vitro the role of CFL1 levels in tumor invasiveness and drug resistance using 6 human NSCLC cell lines with different basal degrees of CFL1 gene expression. Cofilin levels in biopsies discriminated between good and bad prognosis at early tumor stages (IA, IB, and IIA/B), where high CFL1 levels are correlated with lower overall survival rate ($p < 0.0001$). Biomarker performance was further analyzed by IHC, hazard ratio ($p < 0.001$), and receiver-operating characteristic curve (area = 0.787; $p < 0.001$). High CFL1 mRNA levels and protein content are positively correlated with cellular invasiveness (determined by Matrigel Invasion Chamber System) and resistance (2-fold increase in drug 50 % growth inhibition dose) against a list of 22 alkylating agents. Hierarchical clustering analysis of the CFL1 gene network had the same robustness for stratified NSCLC patients. The authors concluded that these findings indicated that the CFL1 gene and its functional gene network can be used as prognostic biomarkers for NSCLC and could also guide chemotherapeutic interventions. Moreover, prospective, large-scale, randomized clinical trials are needed to establish the role of CFL1 as a prognostic and drug resistance marker for NSCLC.

The *Early*CDT-Lung (Oncimmune, De Soto, KS) test measures antibodies to 6 tumor-associated antigens: p53, NY-ESO-1, CAGE, GBU4-5, Annexin 1, and SOX2. Elevation of any one of the panel of immuno-biomarkers above a predetermined cut-off value suggests that a tumor might be present. The test is designed to be used in conjunction with diagnostic imaging. High-risk individuals with a positive *Early*CDT-Lung would have additional testing such as a CT scan or the test would be used as a follow-up test for indeterminate lung nodules identified by CT.

Deeb et al (2004) stated that E-cadherin (E-cad) and epidermal growth factor receptor (EGFR) are important cell adhesion and signaling pathway mediators. Theyr reported the results of a study which aimed to assess their expression in lung adenocarcinoma (AdC) and squamous cell carcinoma (SCC) and their association with clinicopathologic variables. Two to three cores from 130 resectable lung cancers (stages I-IIIA) were arrayed into three blocks using a Beecher system. Markers expression and coexpression were analyzed against clinicopathologic variables (age, gender, smoking status, performance status, weight loss, histology, grade, stage, and lymph node involvement) and patient survival. For E-cad, 65 cases (55%) were positive (+), 53 (45%) were negative (-); and for EGRF, 43 cases (34%) were (+), and 83 (66%) were (-). There was no significant association between E-cad or EGFR, and any of the clinicopathologic variables except for an association between EGFR(+) and SCC histologic type. Both negative and cytoplasmic staining of E-cad correlated with shorter patient survival with P=0.008 and 0.002, respectively. EGFR expression did not correlate with patient survival, but, patients with E-cad(-)/EGFR(+) phenotype had poorer survival than those with E-cad(+)/EGFR(-) (P=0.026). The authors concluded that lung AdC and SCC may be stratified based on expression of E-cad and EGFR with the E-cad(-)/EGFR(+) expression having a worse disease outcome.

Yoshida et al (2011) report that a subset of lung cancers harbors an EML4-ALK (echinoderm microtubule-associated protein-like 4-anaplastic lymphoma kinase) gene fusion, and they examined 15 lung adenocarcinomas with reverse-transcriptase polymerase chain reaction-proven EML4-ALK fusion transcripts and 30 ALK-negative cases. Positive rearrangement signals (splits or isolated 3' signals) were identified in 13 to 78% (mean ± SD, 41% ± 19%) of tumor cells in the ALK-positive cohort and in 0 to 15% (mean ± SD, 6% ± 4%) of cells in the ALK-negative cohort. Sensitivity was at 93% and specificity at 100%. The only false-negative tumor having only 13% CISH-positive cells displayed predominantly (76%) isolated 5' signals unaccompanied by 3' signals. FISH showed largely similar signal profiles, and the results were completely

concordant with CISH.The authors stated that they have successfully introduced CISH for diagnosing EML4-ALK-positive lung adenocarcinoma. This method allows simultaneous visualization of genetics and tumor cytomorphology and facilitates the molecular evaluation and could be applicable in clinical practice to detect lung cancer that may be responsive to ALK inhibitors.

Ellis et al (2011) conducted a systematic review and a consensus meeting of Canadian lung cancer oncologists and pathologists to make recommendations on the use of biomarkers in NSCLC. The articles were reviewed by pairs of oncologists and pathologists to determine eligibility for inclusion. Ten oncologists and pathologists reviewed and summarized the literature at a meeting attended by 37 individuals. The findings included that there is some evidence that histology is prognostic for survival as well as evidence from multiple randomized clinical trials to recommend the following: histologic subtype is predictive of treatment efficacy and for some agents toxicity. Immunohistochemistry testing should be performed on NSCLC specimens that cannot be classified accurately with conventional H&E staining. As EGFR mutations are predictive of benefit from tyrosine kinase inhibitors, diagnostic NSCLC samples should be routinely tested for EGFR-activating mutations. Clinical data on K-RAS mutations are inconsistent, therefore testing is not recommended. There is insufficient evidence to recommend other biomarker testing. No biomarkers to date reliably predict improved efficacy for anti-VEGF therapy. The authors concluded that outine assessment for EML4/ALK mutations is not recommended at present, although emerging data suggest that it may become valuable in the near future.

Boyle et al (2011) reported the sensitivity and specificity of an panel of 6 tumor-related antigens (p53, NY-ESO-1, CAGE, GBU4-5, Annexin) in patients with lung cancer. Three cohorts of patients with newly diagnosed lung cancer were identified: group 1 (n = 145), group 2 (n = 241) and group 3 (n = 269). Patients were individually matched by gender, age and smoking history to a control individual with no history of malignant disease. Serum samples were obtained after diagnosis but before any anticancer treatment. Autoantibody levels were measured against the panel of 6 tumor-related antigens (p53, NY-ESO-1, CAGE, GBU4-5, Annexin 1 and SOX2). Assay sensitivity was tested in relation to demographic variables and cancer type/stage. The autoantibody panel demonstrated a sensitivity/specificity of 36 %/91 %, 39 %/89 % and 37 %/90 % in groups 1, 2 and 3, respectively, with good reproducibility. There was no significant difference between different lung cancer stages, indicating that the antigens included covered the different types of lung cancer well. The authors concluded that the assay confirms the value of an autoantibody panel as a diagnostic tool and offers a potential system for monitoring patients at high-risk of lung cancer.

There is insufficient evidence of the effectiveness of the *Early*CDT-Lung as a screening test for the early detection of lung cancer. Systematic screening for lung cancer is not unequivocally recommended by any major professional organization. The USPSTF (2004) concluded that current evidence was insufficient to recommend for, or against, screening for lung cancer. Whether earlier detection of lung cancer will translate to a mortality benefit remains unclear.

Shanmugan and co-workers (2010) stated that mucin 4 (MUC4) is aberrantly expressed in colorectal adenocarcinomas (CRCs) but its prognostic value is unknown. Archival tissue specimens collected from 132 CRC patients who underwent surgical resection without pre-surgery or pos-tsurgery therapy were evaluated for expression of MUC4 by using a mouse monoclonal antibody and horseradish peroxidase. MUC4 expression levels were correlated with clinicopathologic features and patient survival. Survival was estimated by both uni-variate Kaplan-Meier and multi-variate Cox regression methods. In both normal colonic epithelium and CRCs, MUC4 staining was localized primarily in the cytoplasm. The optimal immunostaining cut-off value (greater than or equal to 75 % positive cells and an immunostaining score greater than or equal to 2.0), which was derived by using the bootstrap method, was used to categorize CRCs into groups of high expression (33 of 132 patients; 25 %) or low expression (99 of 132 patients; 75 %). Patients who had early stage tumors (stages I and II) with high MUC4

expression had a shorter disease-specific survival (log-rank; p = 0.007) than patients who had with low expression. Patients who had advanced-stage CRCs (stages III and IV) did not demonstrate such a difference (log-rank; p = 0.108). Multi-variate regression models that were generated separately for patients with early stage and advanced-stage CRC confirmed that increased expression of MUC4 was an independent indicator of a poor prognosis only for patients who had early stage CRCs (HR 3.77; 95 % CI: 1.46 to 9.73). The authors stated that aftr validating these findings in larger retrospective and prospective studies, a stage-based anayses could establish the utility of MUC4 as a prognostic molecular marker of early stage CRC.

Ratner et al (2010) stated that ovarian cancer (OC) is the single most deadly form of women's cancer, typically presenting as an advanced disease at diagnosis in part due to a lack of known risk factors or genetic markers of risk. The KRAS oncogene and altered levels of the microRNA (miRNA) let-7 are associated with an increased risk of developing solid tumors. In this study, these researchers investigated a hypothesized association between an increased risk of OC and a variant allele of KRAS at rs61764370, referred to as the KRAS-variant, which disrupts a let-7 miRNA binding site in this oncogene. Specimens obtained were tested for the presence of the KRAS-variant from non-selected OC patients in 3 independent cohorts, 2 independent ovarian case-control studies, and OC patients with hereditary breast and ovarian cancer syndrome (HBOC) as well as their family members. The results indicated that the KRAS-variant is associated with more than 25 % of non-selected OC cases. Furthermore, these researchers found that it is a marker for a significant increased risk of developing OC, as confirmed by 2 independent case-control analyses. Lastly, they determined that the KRAS-variant was present in 61 % of HBOC patients without BRCA1 or BRCA2 mutations, previously considered uninformative, as well as in their family members with cancer. These findings supported the hypothesis that the KRAS-variant is a genetic marker for increased risk of developing OC, and they suggested that the KRAS-variant may be a new genetic marker of cancer risk for HBOC families without other known genetic abnormalities.

Hollestelle et al (2011) noted that recently, a variant allele in the 3'UTR of the KRAS gene (rs61764370 T>G) was shown to be associated with an increased risk for developing non-small cell lung cancer, as well as OC, and was most enriched in OC patients from HBOC families. This functional variant has been shown to disrupt a let-7 miRNA binding site leading to increased expression of KRAS in vitro. In the current study, these investigators genotyped this KRAS-variant in breast cancer index cases from 268 BRCA1 families, 89 BRCA2 families, 685 non-BRCA1/BRCA2 families, and 797 geographically matched controls. The allele frequency of the KRAS-variant was found to be increased among patients with breast cancer from BRCA1, but not BRCA2 or non-BRCA1/BRCA2 families as compared to controls. As BRCA1 carriers mostly develop ER-negative breast cancers, these researchers also examined the variant allele frequency among indexes from non-BRCA1/BRCA2 families with ER-negative breast cancer. The prevalence of the KRAS-variant was, however, not significantly increased as compared to controls, suggesting that the variant allele not just simply associates with ER-negative breast cancer. Subsequent expansion of the number of BRCA1 carriers with breast cancer by including other family members in addition to the index cases resulted in loss of significance for the association between the variant allele and mutant BRCA1 breast cancer. In this same cohort, the KRAS-variant did not appear to modify breast cancer risk for BRCA1 carriers. More importantly, results from the current study suggested that KRAS-variant frequencies might be increased among BRCA1 carriers, but solid proof requires confirmation in a larger cohort of BRCA1 carriers.

ProOnc TumorSourceDx test is designed to identify tissue or origin for metastastic tumor. It identifies 25 possible classes of tissue origin corresponding to 17 distinct tissues and organs. It requires only 48 microRNAs to identify tissue of origin based on microRNA expression levels. However, there is insufficient evidence regarding its clinical value as tumor markers.

Cocco and associates (2010) examined the expression of serum amyloid A (SAA) in endometrial endometrioid carcinoma and evaluated its potential as a serum biomarker. SAA gene and protein expression levels were evaluated in endometrial endometrioid carcinoma and normal endometrial

tissues, by real-time PCR, IHC, and flow cytometry. SAA concentration in 194 serum samples from 50 healthy women, 42 women with benign diseases, and 102 patients including 49 grade 1, 38 grade 2, and 15 grade 3 endometrial endometrioid carcinoma was also studied by a sensitive bead-based immunoassay. SAA gene expression levels were significantly higher in endometrial endometrioid carcinoma when compared with normal endometrial tissues (mean copy number by real-time PCR = 182 versus 1.9; p = 0.001). IHC revealed diffuse cytoplasmic SAA protein staining in poorly differentiated endometrial endometrioid carcinoma tissues. High intra-cellular levels of SAA were identified in primary endometrial endometrioid carcinoma cell lines evaluated by flow cytometry, and SAA was found to be actively secreted in vitro. SAA concentrations (microg/ml) had medians of 6.0 in normal healthy women and 6.0 in patients with benign disease (p = 0.92). In contrast, SAA values in the serum of endometrial endometrioid carcinoma patients had a median of 23.7, significantly higher than those of the healthy group (p = 0.001) and benign group (p = 0.001). Patients harboring G3 endometrial endometrioid carcinoma were found to have SAA concentrations significantly higher than those of G1/G2 patients. The authors concluded that SAA is not only a liver-secreted protein, but is also an endometrial endometrioid carcinoma cell product. SAA is expressed and actively secreted by G3 endometrial endometrioid carcinoma, and it is present in high concentration in the serum of endometrial endometrioid carcinoma patients. SAA may represent a novel biomarker for endometrial endometrioid carcinoma to monitor disease recurrence and response to therapy. They stated that additional studies are needed to validate these findings.

Monzon et al (2009) stated that malignancies found in unexpected locations or with poorly differentiated morphologies can pose a significant challenge for tissue of origin determination. Current histologic and imaging techniques fail to yield definitive identification of the tissue of origin in a significant number of cases. The aim of this study was to validate a predefined 1,550-gene expression profile for this purpose. Four institutions processed 547 frozen specimens representing 15 tissues of origin using oligonucleotide microarrays were used in this study. Half of the specimens were metastatic tumors, with the remainder being poorly differentiated and undifferentiated primary cancers chosen to resemble those that present as a clinical challenge. In this blinded multi-center validation study the 1,550-gene expression profile was highly informative in tissue determination. The study found overall sensitivity (positive percent agreement with reference diagnosis) of 87.8 % (95 % CI: 84.7 % to 90.4 %) and overall specificity (negative percent agreement with reference diagnosis) of 99.4 % (95 % CI: 98.3 % to 99.9 %). Performance within the subgroup of metastatic tumors (n = 258) was found to be slightly lower than that of the poorly differentiated and undifferentiated primary tumor subgroup, 84.5 % and 90.7 %, respectively (p = 0.04). Differences between individual laboratories were not statistically significant. The authors concluded that this study represents the first adequately sized, multi-center validation of a gene-expression profile for tissue of origin determination restricted to poorly differentiated and undifferentiated primary cancers and metastatic tumors. These results indicate that this profile should be a valuable addition or alternative to currently available diagnostic methods for the evaluation of uncertain primary cancers.

Monzon and Koen (2010) stated that tumors of uncertain or unknown origin are estimated to constitute 3 % to 5 % of all metastatic cancer cases. Patients with these types of tumors show worse outcomes when compared to patients in which a primary tumor is identified. New molecular tests that identify molecular signatures of a tissue of origin have become available. The authors reviewed the literature on existing molecular approaches to the diagnosis of metastatic tumors of uncertain origin and discuss the current status and future developments in this area. Published peer-reviewed literature, available information from medical organizations (NCCN), and other publicly available information from tissue-of-origin test providers and/or manufacturers were used in this review. The authors concluded that molecular tests for tissue-of-origin determination in metastatic tumors are available and have the potential to significantly impact patient management. However, available validation data indicate that not all tests have shown adequate performance characteristics for clinical use. Pathologists and oncologists should carefully evaluate claims for accuracy and clinical utility for tissue-of-origin tests before using test results in patient management. The personalized medicine revolution includes the use of molecular tools for identification/confirmation of the site of origin for metastatic tumors, and in

the future, this strategy might also be used to determine specific therapeutic approaches.

Anderson and Weiss (2010) noted that pathologists use various stains to identify the site of tissue of origin for metastatic tumors that are poorly or undifferentiated cancers of unknown or uncertain origin. Although clinicians believe that immunostains contribute greatly to the probable primary site among 3 or more possibilities, objective evidence has not been convincingly presented. This meta-analysis reviews the objective evidence supporting this practice and summarizes the performance reported in 5 studies published between 1993 and 2007. A literature search was conducted to identify IHC performance studies published since 1990 that were masked, included more than 3 tissues types, and used more than 50 specimens. The 5 studies found in this search were separated into 2 subgroups for analysis: those, which included only metastatic tumors (n = 368 specimens) and the blended studies, which combined primary tumors and metastases (n = 289 specimens). The meta-analysis found that IHCs provided the correct tissue identification for 82.3 % (95 % CI: 77.4 % to 86.3 %) of the blended primary and metastatic samples and 65.6 % (95 % CI: 60.1 % to 70.7 %) of metastatic cancers. This difference is both clinically and statistically significant. The authors concluded that this literature review confirms that there is still an unmet medical need in identification of the primary site of metastatic tumors. It establishes minimum performance requirements for any new diagnostic test intended to aid the pathologist and oncologist in tissue of origin determination.

According to the manufacturer, the Caris Life Sciences molecular profiling test, Caris Target Now, examines the genetic and molecular changes unique to a patient's tumor so that treatment options may be matched to the tumor's molecular profile. The manufacturer states that the Caris Target Now test is performed after a cancer diagnosis has been established and the patient has exhausted standard of care therapies or if questions in therapeutic management exist. Using tumor samples obtained from a biopsy, the tumor is examined to identify biomarkers that may have an influence on therapy. Using this information, Caris Target Now is intended to provide information on the drugs that will be more likely to produce a positive response. The manufacturer states that Caris Target Now can be used with any solid cancer such as lung cancer, breast cancer, and prostate cancer.

There is insufficient evidence to support the use of Caris Target Now molecular profiling. A study (Von Hoff, et al., 2010) compared the progression-free survival (PFS) of patients with refractory metastatic cancers using a treatment regimen selected by Caris Target Now molecular profiling of the patient's tumor with the PFS for the most recent regimen on which the patient had experienced progression. The investigators prespecified that a molecular profiling approach would be deemed of clinical benefit for the individual patient who had a PFS ratio (defined as a ratio of PFS on molecular profiling-selected therapy to PFS on prior therapy) of greater than or equal to 1.3. In 86 patients who had molecular profiling attempted, there was a molecular target detected in 84 (98%). Sixty-six of the 84 patients were treated according to molecular profiling results. Eighteen (27%) of 66 patients had a PFS ratio of greater than or equal 1.3 (95% confidence interval 17% to 38%). Therefore, the null hypothesis (that less than or equal to 15% of this patient population would have a PFS ratio of greater than or equal to 1.3) was rejected. The authors concluded that, in 27% of patients, the molecular profiling approach resulted in a longer PFS on an molecular profiling-suggested regimen than on the regimen on which the patient had just experienced progression. An accompanying editorial (Doroshow, 2010) noted that the trial had a number of significant limitations, including uncertainty surrounding the achievement of time to progression (the study’s primary endpoint), and a lack of a randomized design for this trial.

Kumaresan et al (2010) reviewed 1034 cases of morphologically difficult prostate cancer, which were divided into benign (585), malignant (399) and suspicious (50) and evaluated using CoA racemase (P504S) and HMWCK (34betaE12). Forty nine suspicious cases were resolved by using both markers whereas 1 case was resolved by further support with CD68. The original diagnosis was changed in 15 of 50 suspicious cases from benign to malignant, one case from benign to high grade PIN, and in one case from malignant to benign. The authors concluded that a combination of HMWCK and AMACR is of value in combating morphologically suspicious

cases and that although the sensitivity and specificity of HMWCK and AMACR in this study were high, “it should be used with caution, keeping in mind all their pitfalls and limitations.”

Murray et al (2010) studied P504S expressing circulating prostate cells as a marker for prostate cancer. The authors stated that PSA is the only biomarker routinely used in screening. This study aimed to develop a system to test the presence of circulating prostate cells in men without a diagnosis of prostate cancer in realation with age, serum PSA levels and prostate biopsy by determining the co-expression of several markers such as CD82, HER-2 and matrix metalloproteinase 2 MMP-20. The results indicated that among 409 men screened for prostate cancer 16.6% were positive for circulating prostate cells. The authors concluded that the study of circulating prostate cells with various markers could be a useful complementary screening test for prostate cancer in men with increased PSA level.

Prolaris (Myriad Genetics, Salt Lake City, UT) uses archived tumor specimens as the mRNA source, reverse transcriptase polymerase chain reaction amplification, and a low density RTPCR array platform. Prolaris is used to quantify expression levels of 31 cell cycle progression (CCP) genes and 15 housekeeper genes to generate a CCP score. An assessment by the BlueCross BlueShield Association Technology Evaluation Center (TEC) concluded that direct evidence is insufficient to establish the analytic validity, clinical validity, or clinical utility of the Prolaris test.

The NCCN Task Force issued a report in November of 2011 which updated their position regarding molecular markers for diagnosis, prognosis, prediction, and companion diagnostic markers (Febbo et. al., 2011). As a result of these recommendations, use of MGMT, IDH mutation and 1p/19q codeletion are now established for glioma. Also, use of ALK gene fusion has been established for non-small cell lung cancer. The updated NCCN guidelines have not yet established the efficacy of ColoPrint, CIMP, LINE-1 hypomethylation, or Immune cells for colon cancer. Similarly, the efficacy of FLT3-TKD mutation, WT1 mutation, RUNX1 mutation, MLL-PTD, IDH1 mutation, IDH2 R172, and IDH2 codon 140 mutation has not been established for use in acute myeloid leukemia.

The DecisionDx-UM test determines the molecular signature of a patient's tumor. The DecisionDx-UM test is also known as the gene expression profile test (GEP) for uveal melanoma. The results of the test provide knowledge regarding the risk of near term metastasis (5 years). Tumors with a Class 1 signature are associated with a good prognosis and a low potential to spread (or metastasize), while tumors with a Class 2 signature have a high potential to spread. There is a lack of adequate published evidence on the clinical utility of this test. Current guidelines on melanoma from the National Comprehensive Cancer Network make no recommendation for this test.

Guidelines on thyroid carcinoma from the National Comprehensive Cancer Network (NCCN, 2013) state: "Molecular diagnostics to detect individual mutations (eg, BRAF, RET/PTC, RAS, PAX8/PPAR gamma) or pattern recognition approaches using molecular classifiers may be useful in the evaluation of FNA samples that are indeterminate. For the 2013 update, the NCCN Panel added recommendations to consider molecular diagnostics for the evaluating FNA results that are suspicious for 1) follicular or Hürthle cell neoplasms; or 2) follicular lesions of undetermined significance (see Nodule Evaluation in the NCCN Thyroid Carcinoma algorithm). (63,64) Rather than proceeding to immediate surgical resection to obtain a definitive diagnosis in these categories, patients can be followed with observation if the application of a specific molecular diagnostic test results in a predicted risk of malignancy that is comparable to the rate seen in cytologically benign thyroid FNAs (approximately 5% or less)." For support, the guidelines reference validation studies of the Afirma Thyroid FNA Analysis (Alexander, et al., 2012; Chudova, et al., 2010). These studies demonstrate that this molecular diagnostic meets NCCN threshold of predicting malignancy of 5 percent or less (i.e., a negative predictive value of 95 percent), allowing physicians to observe an indeterminate thyroid nodule in lieu of surgery.

Quest Diagnostics offers a molecular test panel designed to help physicians determine if a thyroid

gland is cancerous and requires surgical removal. The test includes mutations associated with four gene markers indicated by the American Thyroid Association for the clinical management of indeterminate thyroid biopsies. According to Quest Diagnostics, the Quest Diagnostics Thyroid Cancer Mutation Panel aids in detecting cancer in thyroid biopsies which are found to be indeterminate for cancer by current cytology test methods. Approximately 15% to 20% of these biopsies, which are collected by fine needle aspiration (FNA), produce indeterminate results. An unclear result may increase the risk that a physician, in an abundance of caution, will biopsy additional tissue using a larger needle or surgically remove part or all of a thyroid suspected of having cancer that is later diagnosed as healthy. About 300,000 thyroid FNA biopsy procedures are performed annually in the United States. The panel identifies mutations of the molecular markers BRAF V600E, RAS, RET/PTC, and PAX8/PPAR gamma, which are associated with papillary and follicular thyroid cancer, two common forms of the disease. The manufacturer states that practice guidelines from the American Thyroid Association recommend that physicians consider these markers as aids in clinical management of patients with indeterminate biopsy test results. Results of a Quest Diagnostics study found that 90 of 149 FNA specimens, or about 60%, had mutations of one or more of the four markers tested by the new panel (Reitz, et al., 2014). The authors of the study stated that the presence of the four markers was generally mutually exclusive, suggesting potential value in a hierarchical screening strategy for samples with limited tissue. According to the American Cancer Society, about two tests in every 10 may need to be repeated because the sample does not contain enough cells for testing.

The Alberta Provincial Thoracic Tumour Team's clinical practice guideline on "Non-small cell lung cancer stage IV" (2011) stated that "First-line monotherapy with the epidermal growth factor receptor (EGFR) tyrosine kinase inhibitor gefitinib is recommended for patients with EGFR mutation-positive NSCLC. Testing for EGFR mutations should take place for all eligible patients with advanced NSCLC and adenocarcinoma histology who are being considered for first-line therapy with gefitinib, irrespective of their gender, ethnicity, and smoking status".

Gao et al (2012) stated that gefiinib and erlotinib are 2 similar small molecules of selective and reversible epidermal growth factor receptor-tyrosine kinase inhibitors (EGFR-TKIs), which have been approved for second-line or third-line indication in previously treated advanced NSCLC patients. The results of comparing the EGFR-TKI with standard platinum-based doublet chemotherapy as the first-line treatment in advanced NSCLC patients with activated EGFR mutation were still controversial. A meta-analysis was performed to derive a more precise estimation of these regimens. Finally, 6 eligible trials involved 1,021 patients were identified. The patients receiving EGFR-TKI as front-line therapy had a significantly longer PFS than patients treated with chemotherapy [median PFS was 9.5 versus 5.9 months; HR = 0.37; 95 % CI: 0.27 to 0.52; $p < 0.001$]. The overall response rate (ORR) of EGFR-TKI was 66.60 %, whereas the ORR of chemotherapy regimen was 30.62 %, which was also a statistically significant favor for EGFR-TKI [relative risk (RR) = 5.68; 95 % CI: 3.17 to 10.18; $p < 0.001$]. The OS was numerically longer in the patients received EGFR-TKI than patients treated by chemotherapy, although the difference did not reach a statistical significance (median OS was 30.5 versus 23.6 months; HR = 0.94; 95 % CI: 0.77 to 1.15; $p = 0.57$). Comparing with first-line chemotherapy, treatment of EGFR-TKI achieved a statistical significantly longer PFS, higher ORR and numerically longer OS in the advanced NSCLC patients harboring activated EGFR mutations, thus, it should be the first choice in the previously untreated NSCLC patients with activated EGFR mutation.

The BCBS TEC's assessment on "Multi-Analyte Testing for the Evaluation of Adnexal Masses" (2013) concluded that OVA1 does not meet TEC criteria. It noted that "evidence regarding the effect of OVA1 and ROMA and effects on health outcomes is indirect, and based on studies of diagnostic performance of the tests in patients undergoing surgery for adnexal masses. Although the studies show improvements in sensitivity and worsening of specificity with the use of the tests in conjunction with clinical assessment, there are problems in concluding that this results in improved health outcomes. The clinical assessment performed in the studies is not well characterized. Although OVA1 improves sensitivity, specificity declines so much that most patients test positive. ROMA does not improve the sensitivity of testing to a great extent.

Underlying these issues is some uncertainty regarding the benefit of initial treatment by a gynecologic oncologist beyond the need for reoperation is some cases".

Krijgsman et al (2012) noted that classification of breast cancer into molecular subtypes maybe important for the proper selection of therapy, as tumors with seemingly similar histopathological features can have strikingly different clinical outcomes. Herein, these researchers reported the development of a molecular subtyping profile (BluePrint), which enables rationalization in patient selection for either chemotherapy or endocrine therapy prescription. An 80-Gene Molecular Subtyping Profile (BluePrint) was developed using 200 breast cancer patient specimens and confirmed on 4 independent validation cohorts (n = 784). Additionally, the profile was tested as a predictor of chemotherapy response in 133 breast cancer patients, treated with T/FAC neoadjuvant chemotherapy. BluePrint classification of a patient cohort that was treated with neoadjuvant chemotherapy (n = 133) shows improved distribution of pathological Complete Response (pCR), among molecular subgroups compared with local pathology: 56 % of the patients had a pCR in the Basal-type subgroup, 3 % in the MammaPrint low-risk, luminal-type subgroup, 11 % in the MammaPrint high-risk, luminal-type subgroup, and 50 % in the HER2-type subgroup. The group of genes identifying luminal-type breast cancer is highly enriched for genes having an Estrogen Receptor binding site proximal to the promoter-region, suggesting that these genes are direct targets of the Estrogen Receptor. Implementation of this profile may improve the clinical management of breast cancer patients, by enabling the selection of patients who are most likely to benefit from either chemotherapy or from endocrine therapy.

Furthermore, there is no information regarding BluePrint/molecular subtyping from NCCN's clinical practice guideline on "Breast cancer" (Version 2.2013).

Yu and colleagues (2012) stated that the excision repair cross-complementation group 1 (ERCC1) plays an essential role in DNA repair and has been linked to resistance to platinum-based anticancer drugs among advanced NSCLC patients. These investigators examined if ERCC1 Asn118Asn and C8092A genetic variants are associated with treatment response of platinum chemotherapy. They performed a meta-analysis using 10 eligible cohort studies (including 11 datasets) with a total of 1,252 NSCLC patients to summarize the existing data on the association between the ERCC1 Asn118Asn and C8092A polymorphisms and response to platinum regiments. Odds ratio or hazard ratio with 95 % CI were calculated to estimate the correlation. These researchers found that neither ERCC1 C8092A polymorphism nor Asn118Asn variant is associated with different response of platinum-based treatment among advanced NSCLC patients. Additionally, these 2 genetic variants are not related to treatment response in either Caucasian patients or Asian patients. The authors concluded that the findings of this meta-analysis indicated that the ERCC1 Asn118Asn and C8092A polymorphisms may not be good prognostic biomarkers for platinum-based chemotherapy in patients with stage III-IV NSCLC.

Wang et al (2012) performed a meta-analysis by using 20 eligible studies to examine polymorphisms of ERCC1, GSTs, TS and MTHFR in predicting clinical outcomes (response rate, OS and toxicity) of gastric cancer (GC) patients treated with platinum/5-Fu-based chemotherapy. The association was measured using random/fixed effect odds ratios (ORs) or hazard ratios (HRs) combined with their 95 % CIs according to the studies' heterogeneity. Statistical analysis was performed with the software STATA 9.0 package. No significant association was found between response rate and genetic polymorphism in TS, MTHFR, ERCC1, GSTM1 and GSTP1. However, response rate was higher in GSTT1 (+) genotype compared with GSTT1 (-) genotype (T-/T+: OR = 0.67, 95 % CI: 0.47 to 0.97). With regard to long-term outcomes, these researchers observed a significant longer OS in TS 3R/3R [(2R2R+2R3R)/3R3R: HR = 1.29, 95 % CI: 1.02 to 1.64] and GSTP1 GG/GA [(GG+AG)/AA: HR = 0.51, 95 % CI: 0.39 to 0.67] genotypes. In addition, significant association was demonstrated between toxicity and genetic polymorphism in TS, MTHFR and GSTP1 in included studies. The authors concluded that polymorphisms of ERCC1, GSTs, TS and MTHFR were closely associated with clinical outcomes of GC patients treated with platinum/5-Fu-based chemotherapy. Moreover, they state that studies with large sample size using the method of multi-variant analyses may help us to give more persuasive data on the putative association in

future.

In a meta-analysis, Gong and colleagues (2012) examined if RRM1 expression is associated with the clinical outcome of gemcitabine-containing regimen in advanced NSCLC. An electronic search was conducted using the databases PubMed, Medline, EMBASE, Cochrane library and CNKI, from inception to May, 2011. A systemic review of the studies on the association between RRM1 expression in advanced NSCLC and clinical outcome of gemcitabine-containing regimen was performed. Pooled odds ratios (OR) for the response rate, weighted median survival and time to progression were calculated using the software Revman 5.0. The search strategy identified 18 eligible studies (n = 1,243). Response rate to gemcitabine-containing regimen was significantly higher in patients with low/negative RRM1 (OR = 0.31, 95 % CI: 0.21 to 0.45, $p < 0.00001$). Non-small cell lung cancer SCLC patients with low/negative RRM1 who were treated with gemicitabine-containing regimen survived 3.94 months longer (95 % CI: 2.15 to 5.73, $p < 0.0001$) and had longer time to progression for 2.64 months (95 % CI: 0.39 to 4.89, $p = 0.02$) than those with high/positive RRM1. The authors concluded that low/negative RRM1 expression in advanced NSCLC was associated with higher response rate to gemcitabine-containing regimen and better prognosis. Moreover, they stated that large phase III randomized trials are needed to identify whether RRM1 detection is clinically valuable for predicting the prognosis and sensitivity to gemcitabine-containing regimen in advanced NSCLC.

Friboulet et al (2013) stated that the ERCC1 protein is a potential prognostic biomarker of the effectiveness of cisplatin-based chemotherapy in (NSCLC. Although several ongoing trials are evaluating the level of expression of ERCC1, no consensus has been reached regarding a method for evaluation.

Besse et al (2013) noted that somatic ERCC1 and ribonucleotide reductase M1 (RRM1) expression levels have been extensively explored as markers of DNA repair capacity in tumor cells. Although low ERCC1 and/or RRM1 expression is generally associated with sensitivity to platinum, the results published in retrospective and prospective studies are not always consistent. These researchers examined the function of these 2 biomarkers as well as the tools available for their assessment and the associated technical issues. Their prognostic and predictive values were summarized and considered in terms of customizing systemic therapy according to biomarker (ERCC1 and RRM1) expression levels. The authors discussed why the use of both markers should at this point be restricted to clinical research.

Trock et al (2012) noted that hyper-methylation of genes such as glutathione-S-transferase P1 (GSTP1) and adenomatous polyposis coli (APC) occurs with high frequency in prostate tumor tissue but is much less common in the benign prostate; however, the potential value of gene methylation biomarkers as an adjunct to biopsy histopathology has had little study. When measured in histologically benign prostate biopsy tissue, APC gene hyper-methylation was found to have high negative-predictive value (NPV) and high sensitivity. GSTP1 hype-rmethylation was found to have lower performance than APC. These investigators evaluated the performance of DNA methylation biomarkers in the setting of repeat biopsy in men with an initially negative prostate biopsy but a high index of suspicion for missed prostate cancer. They prospectively evaluated 86 men with an initial histologically negative prostate biopsy and high-risk features. All men underwent repeat 12-core ultrasonography-guided biopsy. DNA methylation of GSTP1 and APC was determined using tissue from the initially negative biopsy and compared with histology of the repeat biopsy. The primary outcome was the relative NPV of APC compared with GSTP1, and its 95 % CI. On repeat biopsy, 21/86 (24 %) men had prostate cancer. APC and GSTP1 methylation ratios below the threshold (predicting no cancer) produced a NPV of 0.96 and 0.80, respectively. The relative NPV was 1.2 (95 % CI: 1.06 to 1.36), indicating APC has significantly higher NPV. Methylation ratios above the threshold yielded a sensitivity of 0.95 for APC and 0.43 for GSTP1. Combining both methylation markers produced a performance similar to that of APC alone. APC methylation patterns were consistent with a possible field effect or occurrence early in carcinogenesis. The authors concluded that APC methylation provided a very high NPV with a low percentage of false-negatives, in the first prospective study to evaluate performance of DNA methylation markers in a clinical cohort of

men undergoing repeat biopsy. They stated that the potential of APC methylation to reduce unnecessary repeat biopsies warrants validation in a larger prospective cohort.

In a systematic review and meta-analysis, Yu and colleagues (2013) examined the association between GSTP1 Ile105Val polymorphism and prostate cancer (PCa) in different inheritance models. A total of 13 eligible studies were pooled into this meta-analysis. There was significant association between the GSTP1 Ile158Val variant genotypes and PCa for Ile/Ile versus Val/Val comparison [odds ratio (OR) = 0.705; I 2 = 63.7 %; 95 % CI: 0.508 to 0.977], Ile/Val versus Val/Val comparison (OR = 0.736; I 2 = 8.0 %; 95 % CI: 0.613 to 0.883), and dominant model (OR = 0.712; I 2 = 45.5 %; 95 % CI: 0.555 to 0.913). However, no associations were detected for other genetic models. In the stratified analysis by ethnicity, significant associations between GSTP1 Ile105Val polymorphism and PCa risk were also found among Caucasians (Ile/Ile versus Val/Val comparison OR = 0.818, I 2 = 0.0 %, 95 % CI: 0.681 to 0.982; Ile/Val versus Val/Val comparison OR = 0.779, I 2 = 0.0 %, 95 % CI: 0.651 to 0.933; and dominant model OR = 0.794, I 2 = 0.0 %, 95 % CI: 0.670 to 0.941), while there were no associations found for other genetic models. However, no associations were found in Asians and African-Americans for all genetic models when stratified by ethnicity. The authors concluded that the findings of this meta-analysis indicated that GSTP1 Ile105Val polymorphisms contributed to the PCa susceptibility. However, they stated that a study with the larger sample size is needed to further evaluate gene-environment interaction on GSTP1 Ile105Val polymorphisms and PCa risk.

An UpToDate review on "Screening for breast cancer" (Fletcher, 2013) does NOT mention the use of carcinoembryonic antigen cell adhesion molecule 6 (CEACAM6). Also, the NCCN's clinical practice guideline on "Breast Cancer" (Version 2.2013) does NOT mention the use of carcinoembryonic antigen cell adhesion molecule 6 (CEACAM6).

An UpToDate review on “Ductal carcinoma in situ: Treatment and prognosis” (Collins et al, 2013) states that “A DCIS Recurrence Score utilizing a multigene assay has been developed and a prospective evaluation of this assay was performed using tumors from 327 patients who participated in the aforementioned E5194 trial. In a preliminary analysis, patients were stratified by recurrence score into three groups that were associated the following risks of an ipsilateral breast event (DCIS or invasive breast cancer) or invasive breast cancer:

- Low (less than 39) -- 12 and 5 %, respectively
- Intermediate (39 to 54) -- 25 and 9 %, respectively
- High (greater than or equal to 55) -- 27 and 19 %, respectively

These results suggest that the DCIS score may help select patients who should undergo adjuvant radiation. However, further validation of these results is required before the multigene assay can become a part of clinical practice. It is also worth noting that a 12 percent risk of an ipsilateral breast event at 10 years in the lowest risk category may not be low enough to justify the routine omission of post-excision RT”.

The NCCN’s clinical practice guideline on multiple myeloma (MM) (Version 2.2013) stated that “Further understanding of the molecular subtypes of MM is emerging from the application of high-throughput genomic tools such as gene expression profiling (GEP). With the currently available novel treatment approaches, a majority of patients with MM can now anticipate long-term disease control. However, patients with cytogenetically and molecularly defined high-risk disease do not receive the same benefit from current approaches as low-risk patients. GEP is a powerful and fast tool with the potential to provide additional prognostic value to further define risk-stratification, help therapeutic decisions, and inform novel drug design and development. At the present time, standardized testing for GEP is not available and there is inadequate data to determine how this prognostic information should be used to direct patient management”. The NCCN guideline does not include a specific recommendation for the use of the MyPRS test in risk-stratification or determining prognosis in the clinical management of patients with MM.

Oxnard et al (2013) stated that the identification of oncogenic driver mutations underlying

sensitivity to EGFR and anaplastic lymphoma kinase tyrosine kinase inhibitors has led to a surge of interest in identifying additional targetable oncogenes in NSCLC. A number of new potentially oncogenic gene alterations have been characterized in recent years, including BRAF mutations, HER2 insertions, phosphatidylinositol-4,5-bisphosphonate 3-kinase, catalytic subunit alpha polypeptide gene (PIK3CA) mutations, fibroblast growth factor receptor 1 (FGFR1) amplifications, discoidin domain receptor 2 (DDR2) mutations, ROS1 re-arrangements, and RET re-arrangements. These investigators discussed the techniques used to discover each of these candidate oncogenes, the prevalence of each in NSCLC, the pre-clinical data supporting their role in lung cancer, and data on small molecular inhibitors in development.

Shin and colleagues (2013) evaluated inhibitory effects of bevacizumab on VEGF signaling and tumor growth in-vitro and in-vivo, and assessed phosphorylation of VEGF receptor 2 (VEGFR2) and downstream signaling in endothelial cells as pharmacodynamic markers using phospho-flow cytometry. These researchers also validated markers in patients with mCRC treated with bevacizumab-based chemotherapy. In in-vitro studies, bevacizumab inhibited proliferation of human umbilical vein endothelial cells in association with reduced VEGF signaling. Notably, bevacizumab inhibited VEGF-induced phosphorylation of VEGFR-2, Akt, and extra-cellular signal-regulated kinase (ERK). In-vivo, treatment with bevacizumab inhibited growth of xenografted tumors and attenuated VEGF-induced phosphorylation of Akt and ERK. The median percentages of VEGFR2 + pAkt + and VEGFR2 + pERK + cells, determined by phospho-flow cytometry, were approximately 3-fold higher in mCRC patients than in healthy controls. Bevacizumab treatment decreased VEGFR2 + pAkt + cells in 18 of 24 patients on day 3. The authors concluded that bevacizumab combined with chemotherapy decreased the number of VEGFR2 + pAkt + cells, reflecting impaired VEGFR2 signaling. Together, these data suggested that changes in the proportion of circulating VEGFR2 + pAkt + cells may be a potential pharmacodynamic marker of the effectiveness of anti-angiogenic agents, and could prove valuable in determining drug dosage and administration schedule.

Janku et al (2013) noted that despite development of new therapies, metastatic colorectal cancer (mCRC) largely remains an incurable disease. Approximately 2 to 6 % of colorectal cancers harbor NRAS mutations. The anti-VEGF antibody bevacizumab is a backbone of most therapeutic regimens; however, biomarkers predicting its activity are not known. These investigators reported 2 cases of mCRC with a Q61K NRAS mutation that had a favorable response to bevacizumab and the histone deacetylase inhibitor valproic acid. In contrast, none of 10 patients with wild-type NRAS or unknown NRAS status and mutated KRAS (NRAS and KRAS mutations are mutually exclusive) responded to the same regimen. The authors concluded that these results suggested that NRAS mutation merits further investigation as a potential biomarker predicting the efficacy of bevacizumab-based treatment.

Carmignani et al (2004a) conducted a study to report the role of combined treatments, including cytoreductive surgery and perioperative regional chemotherapy, in patients with synchronous systemic and intraperitoneal dissemination of appendix cancer. Study subjects were treated with cytoreductive surgery and perioperative regional chemotherapy and statistical analysis of variables utilized survival as an end point and included demographic characteristics, prior surgical score (PSS), tumor marker levels, peritoneal cancer index (PCI), and completeness of cytoreduction (CC). With a mean follow-up of 42.6 months, median survival time (MST) for 15 patients was 28 months and 5-year survival rate was 29.4%. Female patients had a longer MST than male patients (p=0.0199) and survival was better in patients with PSS 0 and 1 (p=0.0277). Patients with elevated CEA and CA 19-9 levels had a shorter MST (p=0.0083 and p=0.0193, respectively) while PCI and CC comparisons did not show significant differences. The morbidity rate (n=2) was 13.3% and the mortality (n=2) rate was also 13.3%. The authors concluded that "acceptable morbidity and mortality and a 29.4% 5-year survival rate allows cytoreductive surgery and regional chemotherapy to be considered as a treatment option for selected patients with synchronous systemic and intraperitoneal dissemination of appendix cancer."

Carmignani et al (2004b) in a further publication regarding gastrointestinal cancer, stated that carcinoembryonic antigen (CEA) and carbohydrate antigen 19-9 (CA 19-9) tumor markers have

found selected clinical application. The authors remarked that the use of these tumor markers in mucinous epithelial tumors of the appendix has not been previously determined. Thus, the authors conducted a study in which, in patients with peritoneal dissemination of a mucinous epithelial malignancy of the appendix, tumor markers CEA and CA 19-9 were prospectively recorded preoperatively within 1 week prior to definitive treatment and if the appendiceal tumor recurred, the tumor marker was determined. The primary endpoint was the accuracy of these two tumor markers in the management of this disease for these two specific clinical situations. CEA was elevated in 56% of 532 patients and CA 19-9 was elevated in 67.1% of these patients. Although the absolute level of tumor marker did not correlate with prognosis, a normal value indicated an improved survival. CEA was elevated in 35.2% of 110 patients determined to have recurrent disease and CA 19-9 was elevated in 62.9%. At least one of the tumor markers was elevated in 68.2% of patients. An elevated CEA tumor marker at the time of recurrence indicated a reduced prognosis and both CEA and CA 19-9 tumor markers were elevated in a majority of these patients. This should be a valuable diagnostic tool previously underutilized in this group of patients. These tumor markers were also of benefit in the assessment of prognosis in that a normal level indicated an improved prognosis. At the time of a reoperative procedure, CEA and CA 19-9 tumor markers gave information regarding the progression of disease and have practical value in the management of epithelial appendiceal malignancy with peritoneal dissemination.

Andreopoulou et al (2007) stated that mucinous carcinoma of the appendix is a rare entity with a distinct natural history that poses diagnostic and therapeutic challenges and that mucinous peritoneal carcinomatosis is most commonly associated with primary tumors of the appendix and colon. The authors stated that usually the spread remains confined to the abdominal cavity and that imaging assessment of these mucinous lesions is difficult, while tumor markers (CEA and CA19.9) may be surrogates for extent of disease.

Recruitment for large scale studies given the rare nature of mucinous appendiceal carcinoma would be challenging. However, available evidence does illustrate a benefit to use of CA 19-9 in patients with mucinous appendiceal carcinoma.

Rasamny et al (2012) stated that cyclin D1 and FADD (Fas-associated protein with death domain) regulate the cell cycle and apoptosis, respectively, and are located on chromosome 11q13, which is frequently amplified in head and neck squamous cell carcinoma (HNSCC). This study evaluated these proteins as predictors of clinical outcomes for HNSCC. A total of 222 patients with upper aero-digestive HNSCC were included in this study. Patients with tumors that were strongly positive for cyclin D1 and FADD had reduced OS ($p = 0.003$ and $p < 0.001$), disease-specific survival (DSS; $p = 0.039$ and $p < 0.001$), and DFS ($p = 0.026$ and $p < 0.001$) survival, respectively. Together, the 2 markers effectively stratified OS ($p < 0.001$), DSS ($p < 0.001$), and DFS ($p = 0.002$). Strong FADD staining correlated with greater alcohol consumption and varied significantly with primary tumor site: 56 % of hypopharynx tumors expressed high levels of FADD but only 7 % of glottis tumors. Using Cox regression analysis, FADD and N stage were significant independent predictors of DSS and DFS, whereas cyclin D1, FADD, and N stage were independently significant for OS. The authors concluded that cyclin D1 and FADD may have utility as predictors of long-term outcomes for patients with HNSCC. Moreover, they stated that further study is needed to determine if these proteins predict response to different treatment approaches or assist in selecting patients for multi-modality therapy.

O'Sullivan and colleagues (2012) examined if the RNA assay uRNA® and its derivative Cxbladder® have greater sensitivity for the detection of bladder cancer than cytology, NMP22™ BladderChek™ and NMP22™ ELISA, and whether they are useful in risk stratification. A total of 485 patients presenting with gross hematuria but without a history of urothelial cancer were recruited prospectively from 11 urology clinics in Australasia. Voided urine samples were obtained before cystoscopy. The sensitivity and specificity of the RNA tests were compared to cytology and the NMP22 assays using cystoscopy as the reference. The ability of Cxbladder to distinguish between low grade, stage Ta urothelial carcinoma and more advanced urothelial carcinoma was also determined. uRNA detected 41 of 66 urothelial carcinoma cases (62.1 % sensitivity, 95 % confidence interval [CI]: 49.3 to 73.8) compared with NMP22 ELISA (50.0 %,

95 % CI: 37.4 to 62.6), BladderChek (37.9 %, 95 % CI: 26.2 to 50.7) and cytology (56.1 %, 95 % CI: 43.8 to 68.3). Cxbladder, which was developed on the study data, detected 82 %, including 97 % of the high grade tumors and 100 % of tumors stage 1 or greater. The cut-offs for uRNA and Cxbladder were pre-specified to give a specificity of 85 %. The specificity of cytology was 94.5 % (95 % CI: 91.9 to 96.5), NMP22 ELISA 88.0 %, (95 % CI: 84.6 to 91.0) and BladderChek 96.4 % (95 % CI: 94.2 to 98.0). Cxbladder distinguished between low-grade Ta tumors and other detected urothelial carcinoma with a sensitivity of 91 % and a specificity of 90 %. The authors concluded that uRNA and Cxbladder showed improved sensitivity for the detection of urothelial carcinoma compared to the NMP22 assays. Stratification with Cxbladder provides a potential method to prioritize patients for the management of waiting lists.

An UpToDate review on "Clinical presentation, diagnosis, and staging of bladder cancer" (Lotan and Choueiri, 2013) does not mention the use of mRNA biomarkers/PCR testing as a management tool for bladder cancer. Furthermore, NCCN's clinical practice guideline on "Bladder cancer" (Version 1.2014) does not mention the use of mRNA biomarkers/PCR testing as a management tool for bladder cancer.

Oncotype Dx Prostate Cancer Assay (Genomic Health, Redwood City, o quantify expression l evels of 12 cancer-related and 5 reference gen a Genomic Prostate Score (GPS). In the final analysis, the cell cycle progression (CCP) score (median 1.03, interquartile range 0.41–1.74) and GPS (range 0–100) are combined in proprietary algorithms with clinical risk criteria (PSA, Gleason grade, tumor stage) to generate new risk categories (i.e., reclassification) intended to reflect biological indolence or aggressiveness of individual lesions, and thus inform management decisions. An assessment by the BlueCross BlueShield Technology Evaluation Center (TEC, 2014) concluded that direct evidence is insufficient to establish the analytic validity, clinical validity, or clinical utility of the Oncotype Dx Prostate.

Glossary of Terms:

a2-PAG	Pregnancy-associated alpha2 glycoprotein
BCM	Breast cancer mucin
BTA	Bladder tumor antigen
CA19-9	Cancer antigen 19-9
CA50	Cancer antigen 50
CA72-4	Cancer antigen 72-4
CA195	Cancer antigen 195
CA242	Cancer antigen 242
CA549	Cancer antigen 549
CA-SCC	Squamous cell carcinoma
CAM17-1	Monoclonal antimucin antibody 17-1
CAM26	Monoclonal antimucin antibody 26
CAM29	Monoclonal antimucin antibody 29
CAR3	Antigenic determinant recognized by monoclonal antibody AR3
DU-PAN-2	Sialylated carbohydrate antigen DU-PAN-2
FDP	Fibrin/fibrinogen degradation products
GCC	Guanylyl cyclase C

MCA	Mucin-like carcinoma-associated antigen
NMP22	Nuclear matrix protein22
NSE	Neuron-specific enolase
PLAP	Placental alkaline phosphatase
PNA-ELLA	Peanut lectin-bonding assay
SLEX	Sialylated Lewis X-antigen
SLX	Sialylated SSEA-1 antigen
SPAN-1	Sialylated carbonated antigen SPAN-1
ST-439	Sialylated carbonated antigen ST-439
TAG12	Tumor-associated glycoprotein 12
TAG72	Tumor-associated glycoprotein 72
TAG72.3	Tumor-associated glycoprotein 72.3
TATI	Tumor-associated trypsin inhibitor
TNF-a	Tumor necrosis factor alpha
TPA	Tissue polypeptide antigen

CPT Codes / HCPCS Codes / ICD-9 Codes

Prostate-specific antigen (PSA):

CPT codes covered if selection criteria are met:

84152

84153

84154

HCPCS codes covered if selection criteria are met:

G0103 Prostate cancer screening; prostate specific antigen test (PSA)

HCPCS codes not covered for indications listed in the CPB:

S3721 Prostate cancer antigen 3 (PCA3) testing

ICD-9 codes covered if selection criteria are met:

185 Malignant neoplasm of prostate

233.4 Carcinoma in situ of prostate

236.5 Neoplasm of uncertain behavior of prostate

790.93 Elevated prostate specific antigen (PSA)

V10.46 Personal history of malignant neoplasm of prostate

V76.44 Special screening for malignant neoplasm of prostate

Carcinoembryonic antigen (CEA):

CPT codes covered if selection criteria are met:

82378

ICD-9 codes covered if selection criteria are met:

153.0 - 154.1	Malignant neoplasm of colon and rectum
230.3	Carcinoma in situ of colon
V10.05	Personal history of malignant neoplasm of large intestine
V10.06	Personal history of malignant neoplasm of rectum, rectosigmoid junction, and anus

ICD-9 codes not covered for indications listed in the CPB:

162.2 - 162.9	Malignant neoplasm of bronchus and lung
174.0 - 175.9	Malignant neoplasm of breast
217	Benign neoplasm of breast
231.2	Carcinoma in situ of bronchus and lung
233.0	Carcinoma in situ of breast
238.3	Neoplasm of uncertain behavior of breast
239.3	Neoplasm of unspecified nature of breast
V76.0	Special screening for malignant neoplasm of respiratory organs
V76.10	Breast screening for malignant neoplasms, unspecified
V76.19	Other screening breast examination for malignant neoplasms
V76.41	Special screening for malignant neoplasm of rectum
V76.51	Special screening for malignant neoplasm of colon

Other ICD-9 codes related to the CPB:

795.81	Elevated carcinoembryonic antigen [CEA]

Adenomatous polyposis coli (APC):

CPT codes covered if selection criteria are met:

81201 - 81203

ICD-9 covered if selection criteria are met:

211.3	Benign neoplasm of colon
238.1	Neoplasm of uncertain behavior of connective and other soft tissue
V18.51	Family history, colonic polyps [familial adenomatous polyposis]

Afirma Thyroid FNA analysis:

No specific code

ICD-9 covered if selection criteria are met:

237.4	Neoplasm of uncertain behavior of other and unspecified endocrine glands [indeterminate thyroid nodules]

FISH assay of the BCR/ABL gene:

CPT codes covered if selection criteria are met:

81206 - 81208

88271

88275

ICD-9 codes covered if selection criteria are met:

200.10 - 200.18	Lymphosarcoma [Lymphoblastic lymphoma]
204.00 - 204.02	Acute lymphoid leukemia
205.00 â€“ 205.02	Myeloid leukemia, acute
205.10 - 205.12	Chronic myeloid leukemia

Cancer antigen 125 (CA 125):

CPT codes covered if selection criteria are met:

86304

ICD-9 codes covered if selection criteria are met:

183.0	Malignant neoplasm of ovary
199.1	Malignant neoplasm without specification of site, other
236.2	Neoplasm of uncertain behavior of ovary
V10.43	Personal history of malignant neoplasm of ovary
V16.41	Family history of malignant neoplasm of ovary

ICD-9 codes not covered for indications listed in the CPB:

V76.41	Special screening for malignant neoplasm of rectum
V76.46	Special screening for malignant neoplasm of ovary
V76.51	Special screening for malignant neoplasm of colon

Other ICD-9 codes related to the CPB:

795.82	Elevated cancer antigen 125 [CA 125]

Serial measurements of CA 15-3 (also known as CA 27-29 or Truquant RIA):

CPT codes covered if selection criteria are met:

86300

ICD-9 codes covered if selection criteria are met:

174.0 - 174.9	Malignant neoplasm of the female breast
233.0	Carcinoma in situ of breast
V10.3	Personal history of malignant neoplasm of breast

ICD-9 codes not covered for indications listed in the CPB:

V76.10	Breast screening, unspecified

CA 19-9:

CPT codes covered if selection criteria are met:

86301

ICD-9 codes covered if selection criteria are met:

151.0 - 151.9	Malignant neoplasm of stomach [not covered for gastro-esophageal cancer]
153.5	Malignant neoplasm of appendix vermiformis [mucinous appendiceal carcinoma]
155.1	Malignant neoplasm of intrahepatic bile ducts [cholangiocarcinoma]
156.0 - 156.9	Malignant neoplasm of gallbladder and extrahepatic bile ducts

157.0 - 157.9	Malignant neoplasm of pancreas
230.2	Carcinoma in situ of stomach
230.8	Carcinoma in situ of liver and biliary system [covered for gallbladder and bile duct]
230.9	Carcinoma in situ of other and unspecified digestive organs
V10.04	Personal history of malignant neoplasm of stomach
V10.09	Personal history of malignant neoplasm of gastrointestinal tract, other
V49.83	Awaiting organ transplant status [liver transplant]

ICD-9 codes not covered for indications listed in the CPB (not all-inclusive):

150.0 - 150.9	Malignant neoplasm of esophagus
153.0 - 154.1	Malignant neoplasm of colon and rectum
155.0, 155.2	Malignant neoplasm of liver [primary and not specified as primary or secondary]
174.0 - 175.9	Malignant neoplasm of the breast
179 - 182.8	Malignant neoplasm of uterus
230.3	Carcinoma in situ of colon
230.8	Carcinoma in situ of liver and biliary system [not covered for liver]
233.0	Carcinoma in situ of breast
577.2	Cyst and pseudocyst of pancreas

Other ICD-9 codes related to the CPB:

576.1	Cholangitis [primary sclerosing] [only covered for persons undergoing liver transplantation]

Cardioembryonic antigen cellular adhesion modecule-7 (CEACAM-7):

There is no specific code for Cardioembryonic antigen cellular adhesion molecule-7 (CEACAM-7)

ICD-9 codes not covered if selection criteria are met:

154.0 - 154.8	Malignant neoplasm of rectum, rectosigmoid junction and anus
230.4	Carcinoma in situ of digestive organs (rectum)
V10.06	Personal history of malignant neoplasm of rectum, rectosigmoid junction, and anus

Caris Target Now Molecular Profiling Test:

No specific code

Human epidermal growth factor receptor 2 (HER2) evaluation:

CPT codes covered if selection criteria are met:

83950

ICD-9 codes covered if selection criteria are met:

150.0 - 150.9	Malignant neoplasm of esophagus
151.0 - 151.9	Malignant neoplasm of stomach
174.0 - 175.9	Malignant neoplasm of breast [see criteria]

IGH@ (Immunoglobulin heavy chain locus):

CPT codes covered if selection criteria are met:

81261

ICD-9 codes covered if selection criteria are met:

200.00 - 202.98	Malignant neoplasm of lymphatic and hematopoietic tissue [non- hodgkin lymphoma, code range includes hairy-cell leukemia]

IGK@ (Immunoglobulin kappa light chain locus):

CPT codes covered if selection criteria are met:

81264

ICD-9 codes covered if selection criteria are met:

200.00 - 202.98	Malignant neoplasm of lymphatic and hematopoietic tissue [non-hodgkin lymphoma]
277.30 - 277.39	Amyloidosis [systemic light chain]

Serial measurements of human chorionic gonadotropin (HCG):

CPT codes covered if selection criteria are met:

84702

ICD-9 codes covered if selection criteria are met:

181	Malignant neoplasm of placenta (e.g., choriocarcinoma)
183.0	Malignant neoplasm of ovary
186.0 - 186.9	Malignant neoplasm of testis
196.1	Secondary malignant neoplasm of intrathoracic lymph nodes [mediastinal nodes]
233.39	Carcinoma in situ of other and unspecified female genital organs [germinal cell tumors (teratocarcinoma and embryonal cell carcinoma) of the ovaries]
233.6	Carcinoma in situ of other and unspecified male genital organs
236.1	Neoplasm of uncertain behavior of placenta
630	Hydatidiform mole
V10.43	Personal history of malignant neoplasm of ovary
V10.47	Personal history of malignant neoplasm of testis

Serial measurements of AFP to diagnose germ cell tumors or the diagnosis and monitoring of hepatocellular carcinoma:

CPT codes covered if selection criteria are met:

82105

ICD-9 codes covered if selection criteria are met:

155.0 - 155.2	Malignant neoplasm of the liver and intrahepatic bile ducts
183.0	Malignant neoplasm of ovary
186.0 - 186.9	Malignant neoplasm of testis
196.1	Secondary malignant neoplasm of intrathoracic lymph nodes [mediastinal nodes]
230.8	Carcinoma in situ of liver and biliary system

233.39	Carcinoma in situ of other and unspecified female genital organs [germ cell tumors]
233.6	Carcinoma in situ of other and unspecified male genital organs
V10.43	Personal history of malignant neoplasm of ovary
V10.47	Personal history of malignant neoplasm of testis
V76.49	Special screening for malignant neoplasm of other sites
V76.89	Special screening for malignant neoplasm, other

ICD-9 codes not covered for indications listed in the CPB (not all-inclusive):

181	Malignant neoplasm of placenta (e.g., choriocarcinoma)
236.1	Neoplasm of uncertain behavior of placenta
630	Hydatidiform mole

Serial measurements of AFP and HCG together to diagnose and monitor testicular cancer:

CPT codes covered if selection criteria are met:

82105

84702

ICD-9 codes covered if selection criteria are met:

186.0 - 186.9	Malignant neoplasm of testis
233.6	Carcinoma in situ of other and unspecified male genital organs
V76.45	Special screening for malignant neoplasm of testis

Measurement of estrogen and progesterone receptors and steroid receptor status:

CPT codes covered if selection criteria are met:

84233

84234

ICD-9 codes covered if selection criteria are met:

174.0 - 175.9	Malignant neoplasm of breast
233.0	Carcinoma in situ of breast

Other ICD-9 codes related to the CPB:

627.2	Symptomatic menopausal or female climacteric states
V49.81	Asymptomatic postmenopausal status (age-related) (natural)

TCB@ (T cell antigen receptor, beta):

CPT codes covered if selection criteria are met:

81340

81341

ICD-9 codes covered if selection criteria are met:

204.00 - 204.92	Lymphoid leukemia [T-cell prolymphocytic leukemia]

K-ras (KRAS) with BRAF reflex testing:

CPT codes covered if selection criteria are met:

81210

81275

Other CPT codes related to the CPB:

88363

Other HCPCS codes related to the CPB:

J9055	Injection, cetuximab, 10 mg [to predict non-response to cetuximab (Erbitux) and panitumumab (Vectibix) in the treatment of anal adenocarcinoma]
J9303	Injection, panitumumab, 10 mg [to predict non-response to cetuximab (Erbitux) and panitumumab (Vectibix) in the treatment of anal adenocarcinoma]

ICD-9 codes covered if selection criteria are met:

152.0 - 152.9	Malignant neoplasm of small intestine, including duodenum [small bowel adenocarcinoma]
153.0 - 154.1	Malignant neoplasm of colon, rectum and rectosigmoid junction [metastatic colorectal cancer]
154.2 - 154.3	Malignant neoplasm of anal canal and anus [anal adenocarcinoma]
162.2 - 162.9	Malignant neoplasm of trachea, bronchus, and lung
211.4	Benign neoplasm of rectum and anal canal [if KRAS nonmutated] [Lynch syndrome (HNPCC)]
230.4	Carcinoma in situ of rectum [if KRAS nonmutated] [Lynch syndrome (HNPCC)]

MLH1, MSH2, MSH6:

CPT codes covered if selection criteria are met:

81292 - 81294

81295 - 81297

81298 - 81300

ICD-9 codes covered if selection criteria are met:

153.0 - 153.9	Malignant neoplasm of colon [Lynch syndrome (HNPCC)] [all persons with Stage 2 colon cancer]
154.0 - 154.8	Malignant neoplasm of rectum, rectosigmoid junction, and anus [Lynch syndrome (HNPCC)] [all persons with Stage 2 colon cancer] [under age 50]
211.4	Benign neoplasm of rectum and anal canal [under age 50]
230.4	Carcinoma in situ of rectum [under age 50]

ALK Gene Fusion:

No specific code

ICD-9 codes covered if selection criteria are met:

162.2 - 162.9	Malignant of neoplasm of bronchus and lung [non-small-cell lung cancer]

ALK Gene Rearrangement:

No specific code

ICD-9 codes covered if selection criteria are met:

200.70 - 200.78 Large cell lymphoma [B cell]

202.70 - 202.78 Peripheral T-cell lymphoma

238.77 Post-transplant lymphoproliferative disorder (PTLD)

ALK Translocations :

No specific code

Other CPT codes related to CPB:

81401

ICD-9 codes covered if selection criteria are met:

162.2 - 162.9 Malignant of neoplasm of bronchus and lung [non-small-cell lung cancer]

Urokinase plasminogen activator (uPA) and plasminogen activator inhibitor 1 (PAI-1):

CPT codes covered if selection criteria are met:

85415

ICD-9 codes covered if selection criteria are met:

174.0 - 175.9 Malignant neoplasm of breast [node negative]

233.0 Carcinoma in situ of breast

ICD-9 codes covered if selection criteria are met:

[for determining eligibility for treatment with Mylotarg]

204.00 - 204.02 Acute lymphoid leukemia

205.00 - 205.02 Acute myeloid leukemia

206.00 - 206.02 Acute monocytic leukemia

207.00 - 207.02 Acute erythremia and erythroleukemia

208.00 - 208.02 Acute leukemia of unspecified cell type

CD 52:

CPT codes covered if selection criteria are met:

88184

+ 88185

ICD-9 codes covered if selection criteria are met:

[for determining eligibility for treatment with Campath]

200.20 - 200.48 Burkitt's tumor or lymphoma, marginal zone lymphoma, or mantle cell lymphoma

200.70 - 200.78 Large cell lymphoma

202.00 - 202.88 Other malignant neoplasms of lymphoid and histiocytic tissue

204.10 - 204.12 Chronic lymphoid leukemia

Cyclin D1:

CPT codes covered if selection criteria are met:

81401

ICD-9 codes covered if selection criteria are met:

200.40 - 200.48	Mantle cell lymphoma [diagnosing and predicting disease recurrence]

ICD-9 codes not covered if selection criteria are met:

173.02, 173.12, 173.22, 173.32, 173.42	Squamous cell carcinoma of lip, eyelid including canthus, ear and external auditory canal, face scalp and skin of neck

Fas-Associated Protein with Death Domain FADD:

No specific code

ICD-9 codes not covered if selection criteria are met:

173.02, 173.12, 173.22, 173.32, 173.42	Squamous cell carcinoma of lip, eyelid including canthus, ear and external auditory canal, face scalp and skin of neck

Prostate PX, Post-op PX:

Other CPT codes related to the CPB:

88305

88313

88323

88342

88343

88347

Other HCPCS codes related to the CPB:

G0461	Immunohistochemistry or immunocytochemistry, per specimen; first single or multiplex antibody stain
G0462	each additional single or multiplex antibody stain (list separately in addition to code for primary procedure)

ICD-9 codes not covered for indications listed in the CPB:

185	Malignant neoplasm of prostate

NRAS mutation:

Other CPT codes related to the CPB:

81404

Ras oncogenes (except KRASand BRAF):

There is no specific code for ras oncogenes

Epidermal growth factor receptor (EGFR) Testing:

CPT codes covered if selection criteria are met:

81235

Other CPT codes related to the CPB:

88271

88275

88291

88313

88323

88342

88343

88358

88360

88361

88381

Other HCPCS codes related to the CPB:

G0461	Immunohistochemistry or immunocytochemistry, per specimen; first single or multiplex antibody stain
G0462	each additional single or multiplex antibody stain (list separately in addition to code for primary procedure)
J8565	Gefitinib (Iressa), oral, 250 mg

ICD-9 codes covered if selection criteria are met:

162.2 - 162.9	Malignant neoplasm of bronchus and lung [non small cell lung cancer]

ICD-9 codes not covered if selection criteria are met:

191.0 - 191.9	Malignant neoplasm of brain [Glioblastoma multiforme]
233.7	Carcinoma in situ of bladder [urothelial carcinoma]
233.9	Carcinoma in situ of other and unspecified urinary organs (ureter, renal pelvis) [urothelial carcinoma]

ROS-1:

No specific code

ICD-9 codes covered if selection criteria are met:

162.2 - 162.9	Malignant neoplasm of bronchus and lung [non small cell lung cancer]

ZAP-70:

CPT codes covered if selection criteria are met:

88184

+ 88185

ICD-9 codes covered if selection criteria are met :

204.10 - 204.12	Chronic lymphoid leukemia [assessing prognosis and need for aggressive therapy]

Oncotype Dx:

Other CPT codes related to the CPB:

88360

88361

88367

88368

HCPCS codes covered if selection criteria are met:

S3854	Gene expression profiling panel for use in the management of breast cancer treatment [not covered for Mammaprint, Rotterdam Signature 76-gene Panel, or Breast Cancer Gene Expression Ratio (HOXB13:IL17BR), or TargetPrint Gene Expression]

ICD-9 codes covered if selection criteria are met:

174.0 - 174.9	Malignant neoplasm of female breast [except node positive - see criteria]
175.0 - 175.9	Malignant neoplasm of male breast

ICD-9 codes not covered for indications listed in the CPB:

153.0 - 154.1	Malignant neoplasm of colon and rectum
185	Malignant neoplasm of prostate
230.3	Carcinoma in situ of colon
233.0	Carcinoma in situ of breast [ductal carcinoma in situ (DCIS)]
233.4	Carcinoma in situ of prostate
V10.05	Personal history of malignant neoplasm of large intestine
V10.06	Personal history of malignant neoplasm of rectum, rectosigmoid junction, and anus

Other ICD-9 codes related to the CPB:

V86.0	Estrogen receptor positive status [ER+]
V86.1	Estrogen receptor negative status [ER-]

T-cell receptor gamma chain gene rearrangement:

CPT codes covered if selection criteria are met:

81342

ICD-9 codes covered if selection criteria are met:

202.10 - 202.18	Mycosis fungoides
204.00 - 204.92	Lymphoid leukemia [T-cell prolymphocytic leukemia]

Myeloperoxidase (MPO) immunostaining FLT3-ITD, CEBPA mutation, NPM1 mutation, and KIT mutation:

CPT codes covered if selection criteria are met:

81244

81245

83876

ICD-9 codes covered if selection criteria are met:

205.00 - 205.02	Acute myeloid leukemia

PML/RARA:

CPT codes covered if selection criteria are met:

81315 - 81316

ICD-9 codes covered if selection criteria are met:

205.00 - 205.02	Myeloid leukemia, acute

Placental alkaline phosphatase (PLAP):

CPT codes covered if selection criteria are met:

84080

ICD-9 codes covered if selection criteria are met:

183.0	Malignant neoplasm of ovary
186.0 - 186.9	Malignant neoplasm of testes
233.39	Carcinoma in situ of other and unspecified female genital organs [germ cell tumors]
233.6	Carcinoma in situ of other and unspecified male genital organs
V10.43	Personal history of malignant neoplasm of ovary
V10.47	Personal history of malignant neoplasm of testis

Bladder tumor antigen (BTA) Stat Test, the nuclear matrix protein (NMP22) test, the fibrin/fibrinogen degradation products (Aura-Tek FDP) test, or the UroVysion fluorescent in situ hybridization (FISH) test:

CPT codes covered if selection criteria are met:

85362 - 85380

86294

86386

88120

88121

88365

ICD-9 codes covered if selection criteria are met:

188.0 - 188.9	Malignant neoplasm of bladder
233.7	Carcinoma in situ of bladder
V10.51	Personal history of malignant neoplasm of bladder

ICD-9 codes not covered for indications listed in the CPB (not all-inclusive):

599.70 - 599.72	Hematuria
V76.3	Special screening for malignant neoplasm of bladder

ImmunoCyte:

No specific code

ICD-9 codes covered if selection criteria are met:

188.0 - 188.9	Malignant neoplasm of bladder [as an adjunct to cystoscopy or cytology in monitoring]

ICD-9 codes not covered for indications listed in the CPB:

V76.3	Special screening for malignant neoplasm of bladder [diagnosis or screening in asymptomatic persons]

Janus Kinase 2 (JAK2) mutations:

CPT codes covered if selection criteria are met:

81270

ICD-9 codes covered if selection criteria are met:

205.10 - 205.12	Chronic myeloid leukemia
238.4	Polycythemia vera
238.71	Essential thrombocythemia
238.76	Myelofibrosis with myeloid metaplasia (Primary myelofibrosis)
238.79	Other lymphatic and hematopoietic tissues (Chronic myeloproliferative disease)
289.83	Myelofibrosis

BRAF mutation analysis:

CPT codes covered if selection criteria are met:

81210

ICD-9 codes covered if selection criteria are met:

153.0 - 153.9	Malignant neoplasm of colon [Lynch syndrome (HNPCC)]
154.0 - 154.8	Malignant neoplasm of rectum, rectosigmoid junction, and anus [Lynch syndrome (HNPCC)]
171.5	Malignant neoplasm of connective and other soft tissue of abdomen [gastrointestinal stromal tumors]
172.0 - 172.9	Melanoma of skin [for consideration of Vemurafenib, Dabrafenib and Trametinib]
202.40 - 202.48	Leukemic reticuloendotheliosis

ICD-9 codes not covered if selection criteria are met:

162.2 - 162.9	Malignant neoplasm of bronchus, and lung
193	Malignant neoplasm of thyroid gland

Assaying for loss of heterozygosity (LOH) on the long arm of chromosome 18 (18q) or deleted in colon cancer (DCC) protein (18q-LOH/DCC) for colorectal cancer:

There is no specific code for 18q-LOH/DCC

ICD-9 codes not covered for indications listed in the CPB:

153.0 - 154.1	Malignant neoplasm of colon, rectum, and rectosigmoid junction

OvaCheck test:

There is no specific code for OvaCheck

ICD-9 codes not covered for indications listed in the CPB:

183.0	Malignant neoplasm of ovary
V76.46	Special screening for malignant neoplasm of ovary

Ovasure:

There is no specific code for Ovasure

Other CPT codes related to the CPB:

82985

83520

84146

84305

86304

CellSearch assay:

CPT codes not covered for indications listed in the CPB:

86152 - 86153

88346

88361

Cofilin (CFL1):

There is no specific code for cofilin (CFL1)

162.2 - 162.9	Malignant neoplasm of lung [non-small cell lung carcinoma]

ColonSentry:

There is no specific code for ColonSentry

ICD-9 codes not covered for indications listed in the CPB:

V76.41	Special screening for malignant neoplasms; rectum
V76.51	Special screening for malignant neoplasms; colon

Early CDT-Lung Test:

CPT codes not covered for indications listed in the CPB:

83520

Mammaprint:

HCPCS codes not covered for indications listed in the CPB:

S3854	Gene expression profiling panel for use in the management of breast cancer treatment

Mammostrat:

There is no specific code for Mammostrat

Mucin 4 expression:

CPT codes not covered for indications listed in the CPB:

88313

ICD-9 codes not covered for indications listed in the CPB:

153.0 - 154.1	Malignant neoplasm of colon, rectum and rectosigmoid junction

Microarray-based gene expression profile testing:

Other CPT codes related to the CPB:

81406

OVA1:

There is no specific code for OVA1

CPT codes not covered for indications listed in the CPB:

81503

Pathwork Tissue of Origin Test:

CPT codes not covered for indications listed in the CPB:

81504

PreOvar Test for the KRAS-variant [to determine ovarian cancer risk]:

No specific code

ICD-9 codes not covered for indications listed in the CPB:

183.0	Malignant neoplasm of ovary
V10.43	Personal history of malignant neoplasm of ovary

ProOnc Tumor Source Dx Test:

No specific code

Rotterdam Signature 76-gene Panel:

HCPCS codes not covered for indications listed in the CPB:

S3854	Gene expression profiling panel for use in the management of breast cancer treatment

Serum amyloid A:

CPT codes not covered for indications listed in the CPB:

88342

88343

G0461

G0462

ICD-9 codes not covered for indications listed in the CPB:

182.0 - 182.8	Malignant neoplasm of corpus uteri, isthmus and uterus
V10.42	Personal history of malignant neoplasm of uterus

Breast Cancer Gene Expression Ratio (HOXB13:IL17BR):

HCPCS codes not covered for indications listed in the CPB:

S3854	Gene expression profiling panel for use in the management of breast cancer treatment

Panexia:

CPT codes not covered for indications listed in the CPB:

81406

ICD-9 codes not covered for indications listed in the CPB:

185	Malignant neoplasm of prostate

PTEN gene expression:

CPT codes covered if selection criteria are met:

81321 - 81323

ICD-9 codes covered if selection criteria are met:

759.6	Other congenital hamartoses, NEC [Cowden syndrome]

ICD-9 codes not covered for indications listed in the CPB:

162.2 - 162.9	Malignant neoplasm of bronchus and lung [non-small cell lung cancer]

GeneSearch Breast Lymph Node (BLN) assay:

There is no specific code for GeneSearch Breast Lymph Node (BLN) assay

Thymidylate synthase:

There is no specific code for Thymidylate synthase

Other CPT codes related to the CPB:

88342

88343

88360

88361

Other HCPCS codes related to the CPB:

G0461	Immunohistochemistry or immunocytochemistry, per specimen; first single or multiplex antibody stain
G0462	each additional single or multiplex antibody stain (list separately in addition to code for primary procedure)

Topographic genotyping (PathfinderTG):

No specific code

Biomarker Translation (BT):

No specific code

ICD-9 codes not covered for indications listed in the CPB:

174.0 - 175.9	Malignant neoplasm of breast

HE4:

CPT codes not covered for indications listed in the CPB:

81500

86305

Other CPT codes related to the CPB:

86316

ICD-9 codes not covered for indications listed in the CPB:

183.0	Malignant neoplasm of ovary

HERmark:

There is no specific code for HERmark

ICD-9 codes not covered for indications listed in the CPB:

174.0 - 175.9	Malignant neoplasm of breast
233.0	Carcinoma in situ of breast

Vascular endothelial growth factor (VEGF):

No specific code

Other CPT codes related to the CPB:

83520

TargetPrint Gene Expression:

Other CPT codes related to the CPB:

88360

88361

88367

88368

HCPCS codes not covered for indications listed in the CPB:

S3854	Gene expression profiling panel for use in the management of breast cancer treatment

ICD-9 codes not covered for indications listed in the CPB:

174.0 - 174.9	Malignant neoplasm of female breast
175.0 - 175.9	Malignant neoplasm of male breast

Other ICD-9 codes related to the CPB:

V86.0	Estrogen receptor positive status [ER+]
V86.1	Estrogen receptor negative status [ER-]

CK5, CK14, p63 and Racemase P504S:

Other CPT codes related to the CPB:

88342

88343

Other HCPCS codes related to the CPB:

G0461	Immunohistochemistry or immunocytochemistry, per specimen; first single or multiplex antibody stain
G0462	each additional single or multiplex antibody stain (list separately in addition to code for primary procedure)

ICD-9 codes not covered for indications listed in the CPB:

185	Malignant neoplasm of prostate

EML4-ALK:

Other CPT codes related to the CPB:

88381

ICD-9 codes not covered for indications listed in the CPB:

162.2 - 162.9	Malignant neoplasm of bronchus and lung [non-small-cell lung cancer]

Coloprint, CIMP, Line-1 hypomethylation and immune cells:

There are no specific codes for Coloprint, CIMP, Line-1 hypomethylation and immune cells

ICD-9 codes not covered for indications listed in the CPB:

153.0 - 154.1	Malignant neoplasm of colon and rectum

WT1 mutation, RUNX1 mutation, MLL-PTD mutation, IDH2 R172, and IDH2 codon 140 mutation:

Des-gamma-carboxyl prothrombin (DCP):

CPT codes not covered for indications listed in the CPB:

83951

ICD-9 codes not covered for indications listed in the CPB (not all-inclusive):

155.0, 155.2	Malignant neoplasm of the liver [primary or unspecified as primary or secondary]
230.8	Carcinoma in situ of liver and biliary system

Experimental and investigational circulating tumor markers:

CPT codes not covered for indications listed in the CPB:

0006M

0007M

0008M

82387

84275

86316

88342

88343

G0461

G0462

There are no specific codes for the circulating tumor markers listed below:

Affirma Thyroid FNA Analysis; anti-VEGF antibody bevacizumab; BluePrint molecular subtyping profile for breast cancer; Catalytic subunit alpha polypeptide gene (PIK3CA); C-Met expression; DCIS Recurrence Score; Glutathione-S-transferase P1 (GSTP1); Phosphatidylinositol-4,5-bisphosphonate 3-kinase; Proveri prostate cancer assay (PPCA); Ribonucleotide reductase subunit M1 (RRM1); ROS1 re-arrangements; vascular endothelial growth factor receptor 2 (VEGFR2); VeriStrat for non-small cell lung cancer and other indications; BreastNext Next-Gen Cancer Panel; CancerNext Next-Gen Cancer Panel; ColoNext Next-Gen Cancer Panel; Ovanext Next-Gen Cancer Panel; Mirinform thyroid test; Previstage GCC; Prostate core mitotic test; Prolaris; Oncovue; BREVAgen; UroCor cytology assay (DD23 and P53); CXBladder Test;

ABSTRACT

Heart failure (HF) biomarkers have dramatically impacted the way HF patients are evaluated and managed. B-type natriuretic peptide (BNP) and N-terminal proBNP (NT-proBNP) are the gold standard biomarkers in determining the diagnosis and prognosis of HF, and studies on natriuretic peptide-guided HF management look promising. An array of additional biomarkers has emerged, each reflecting different pathophysiological processes in the development and progression of HF: myocardial insult, inflammation and remodeling. Novel biomarkers, such as mid-regional pro atrial natriuretic peptide (MR-proANP), mid-regional pro adrenomedullin (MR-proADM), highly sensitive troponins, soluble ST2 (sST2), growth differentiation factor (GDF)-15 and Galectin-3, show potential in determining prognosis beyond the established natriuretic peptides, but their role in the clinical care of the patient is still partially defined and more studies are needed. This article is part of a Special Issue entitled: Heart failure pathogenesis and emerging diagnostic and therapeutic interventions.

1. Introduction

A wide range of cardiovascular disorders that result in the impairment of the heart's ability to fill or to pump out blood may eventually lead to the clinical syndrome of heart failure (HF). In recognition of the multiplicity of causes of the diagnosis, it is not surprising that HF is a common affliction. Currently an estimated 5.8 million people in the United States [1] and 23 million people worldwide [2] are living with HF. As the population ages and treatments for cardiovascular diseases are improving mortality in affected patients, the number of HF patients is expected to grow.

Patients with HF often present with signs and symptoms that are often nonspecific and with a wide differential diagnosis, making diagnosis by clinical presentation alone challenging. Some of the signs and symptoms, such as dyspnea, orthopnea and paroxysmal nocturnal dyspnea, are due to congestion while some are due to lack of adequate cardiac output, including fatigue, weakness and exercise intolerance. This heterogeneity of presentation often results in delays in definitive diagnosis and treatment, and such delays are linked with poor prognosis [3]. Thus, together with HF's well-described risk for death and hospitalization, the growing incidence and prevalence make it a priority.

The evaluation of a patient suspected of HF was traditionally based on clinical assessment with history, physical examination and chest x-ray. However, in isolation, the performance of these methods of diagnosis can be limited in accurately diagnosing HF. As a matter of fact, isolated symptoms and signs correlate poorly with objective methods of cardiac dysfunction [4–6]. One study looked at the relationship between three clinical criteria that combined findings from history, physical examination and chest x-ray for the diagnosis of HF: the Framingham, the Duke and the Boston criteria [7]. All of the clinical criteria were limited in sensitivity (50–73%) and/or specificity (54–78%). Beyond clinical variables, noninvasive imaging studies (such as echocardiography and radionuclide angiography) may be useful to identify or exclude HF. These modalities can determine ventricular ejection fraction and diastolic dysfunction, as well as estimate chamber pressures. Echocardiograms can also provide clues to the underlying etiology of HF and are an essential part of assessment once the diagnosis is secured. However, many patients with abnormal ventricular systolic function on imaging studies are asymptomatic and do not necessarily have the clinical syndrome of HF [8,9]. For example, in one study of community-dwelling urban patients, 48% of patients with left ventricular ejection fraction ≤30% were asymptomatic [8]. Echocardiograms are also costly and time consuming

Abstract: Cardiovascular diseases (CVD) are the major cause of death worldwide. The identification of markers able to detect the early stages of such diseases and/or their progression is fundamental in order to adopt the best actions in order to reduce the worsening of clinical condition. Brain natriuretic peptide (BNP) and NT-proBNP are the best known markers of heart failure (HF), while troponins ameliorated the diagnosis of acute and chronic coronary artery diseases. Nevertheless, many limitations reduce their accuracy. Physicians have tried to develop further detectable molecules in order to improve the detection of the early moments of CVD and prevent their development. Soluble ST2 (suppression of tumorigenicity 2) is a blood protein confirmed to act as a decoy receptor for interleukin-33. It seems to be markedly induced in mechanically overloaded cardiac myocytes. Thus, HF onset or worsening of a previous chronic HF status, myocardial infarct able to induce scars that make the myocardium unable to stretch well, *etc*, are all conditions that could be detected by measuring blood levels of soluble ST2. The aim of this review is to explore the possible role of ST2 derived-protein as an early marker of cardiovascular diseases, above all in heart failure and ischemic heart diseases.

Keywords: ST2; heart failure; coronary artery diseases; early markers

---

1. Introduction

Cardiovascular diseases (CVD) are the main leading cause of death worldwide [1]. Their incidence is still increasing, even in developing countries [2] and it greatly diminishes individuals' quality of life and survival rates.

Primary and secondary preventive actions are required in order to arrest the negative development of CVD. Thus, physicians are involved in searching for tools able to detect the early moments of CVD development. Early markers of CVD will allow immediate interventions in order to prevent the beginning of the diseases or, at least, minimize their negative consequences. Carotid intima-media thickness and brachial artery flow-mediated dilatation are instrumental, well-established early markers of atherosclerosis and chronic heart failure [3,4]. Biochemical markers work side by side with the latter ultrasonographic tools in order to detect early alterations of cardiovascular system. Ciccone *et al.* [5] recently pointed out the role of osteoprotegerin in acute/chronic coronary artery diseases (CAD). The natriuretic peptides (brain natriuretic peptide [BNP] and NT-proBNP) are the best known markers of heart failure (HF) condition [6]. Nevertheless, due to their limitations, research has been undertaken in order to implement and to find new, more accurate and complete markers of both CAD and HF conditions. Further research focused on cardiac remodelling has focused on biomechanical pathways activated during cardiac remodelling after the onset of cardiovascular diseases that could enhance production of compounds released in the bloodstream. Their early detection could detect the early moments of cardiac impairment in the case of CAD and HF. Genomic technology has discovered new genes and pathways involved in this process. A new gene, called ST2 (suppression of tumorigenicity 2) and its related protein was markedly induced in mechanically overloaded cardiac myocytes. This suggests that the protein can be overexpressed in remaining viable myocardium that has undergone great stress [7]. The aim of this review is to explore the possible role of ST2 derived-protein as an early marker of cardiovascular diseases, above all in heart failure and ischemic heart diseases.

2. ST2 Protein: Biological Structure and Function

Discovered in 1989, the gene named ST2 (also known as T1, IL1RL1, or Fit1) is placed on chromosome 2q12 as part of the wider interleukin 1 (IL-1) gene cluster [8]. Four isoforms are the transcriptional product of the gene and two of them are the most important: IL1RL1-b or ST2L, which is a membrane receptor member of the interleukin-1 receptor family, and IL1RL1-a or sST2a, which is a truncated soluble receptor that can be detected in serum. Alternative promoter splicing and 3' processing of the same mRNA seems to be responsible for the production of sST2 and ST2L [8]. ST2 gene shows two promoters: a proximal and a distal one, which are able to influence the mechanism of transcriptional regulation of the gene [9]. Each promoter could influence the expression of sST2 and ST2L mRNA: The alternative splicing involving the 3' end of the gene is responsible for such a difference. Baba *et al.* [9] found a different function of two GATA motifs (1 and 2), positioned upstream of the site where transcription of ST2 gene begins, which were able to influence the mRNA production and the final expression of the gene in human mast cells and in basophilic human cell line. In particular, GATA2 seemed to exert the major control in ST2 mRNA expression in both cells lines. Thus, the different expression and function of GATA motifs could play a role in the final expression

and function of ST2 in immune human cells and, probably, in other cells constitutively expressing the final products of the ST2 gene transcription. Nevertheless, poor data still persists about the inner control of sST2 and ST2L expressions. Caporali *et al.* [10] found that the neurotrophin p75 receptor, a member of tumor necrosis factor (TNF)-alpha receptors family involved in post-ischemic neovascularisation in diabetes mellitus induced critical limb ischemia, is able to enhance the sST2 transcription and this action did not allow a full revascularization attempt by endothelial cells.ST2L is composed by 3 extracellular immunoglobulin G domains, a single transmembrane domain, and an intracellular domain [7,8,11]. The sST2 lacks the transmembrane and intracellular domains and it travels freely through the bloodstream.

Interleukin-33 (IL-33) has been identified as a functional ligand of ST2L [7,11]. It binds ST2L on inflammatory cells membranes: this activates mitogen-activated protein kinase (MAPK)-kinases and several biochemical pathways. The end of these reactions is the activation of the inhibitor of nuclear factor-κB (NF-κB) kinase (IKK) complex, which makes NF-kB active and able to exert its pro-inflammatory actions [8]. sST2 seems to act as a decoy-receptor for IL-33: it binds IL-33 thus subtracting such a molecule from the interaction with ST2L. sST2 interaction with IL-33 could reduce the production and activation of NF-kB, thus it would reduce inflammatory response. IL-33 has been supposed to regulate by itself the ST2L and sST2 mRNA transcription [12]. In their experimental research on highly metastatic human pancreatic adenocarcinoma cell line Colo357, Schmieder *et al.* [12] observed the influence of IL-33 and (interleukin-1) IL-1 concentrations on both ST2L and sST2 mRNA expression. The particular behavior of both cytokines lied on their skill in increasing the mRNA expression of ST2L while reducing that of sST2. When considering low doses of IL-33 mRNA expression, the presence of IL-1 was sufficient to up-regulate ST2L mRNA transcription, as well as INF-γ concentrations which rose the expression of both mRNA and ST2L protein [12]. These aspects introduce the immunomodulatory role of ST2 [13] which is more complex than previously expressed. As Sweet *et al.* [13] demonstrated, sST2 is able to directly bind and interact with macrophages when bacterial lipopolysaccharide (LPS) flows through bloodstream [13]. The interaction seems to induce an inhibition of cytokines production such as interleukin-6 (IL-6), interleukin-12 (IL-12) and TNF-alpha thus modulating inflammatory response [13]. Furthermore, ST2L seems to be able to activate T helper type 2 (Th2) lymphocytes and to induce the production of several cytokines from these cells such as IL-4, IL-5, and IL-13 which enhance Th2 response to inflammatory events [7,14].

It is interesting to note that there is a reciprocal influence between immune system cells, their production of cytokines and the final expression of ST2. IL-6 production from antigen-presenting cell is able to increase ST2 expression during Th2 differentiation [15]. Minor effects are detected for other cytokines such as IL-1, TNF-α and IL-5. Therefore, while ST2 is able to activate naive T cell to type 2 conformation, immune system is parallel able to enhance ST2 expression [15]. Nevertheless, the inner mechanisms able to explain such interactions are not fully elucidated.

3. The Heart and the ST2: A Tight Relationship

ST2 is involved in cardiac function and dysfunction. ST2 action in cardiac muscle is complex and not fully understood and it is tightly related to IL-33 mode of action. IL-33 could be localized simultaneously onto nuclear euchromatin and membrane-bound cytoplasmic vesicles. Kakkar *et al.* [16]

demonstrated that the mechanical stretch of living cells could enhance the release of IL-33 from the cytoplasmatic vesicles. Such an exocytosis was not related to a possible stretch-induced necrosis: the cells viability was demonstrated after the periods of biaxial stretch [16]. Thus, the cellular stretch is able to increase the release of IL-33. Cardiomyocytes and cardiac fibroblasts show a parallel, increased release of both ST2L and sST2 when undergone biomechanical strain [14,17].

Such a release is an important step in the overall mechanism able to induce cardiac remodelling due to volume and/or pressure overload. IL-33 could exert an antihypertrophic effect by blocking the actions of angiotesin II or phenylephrine on myocardium. Angiotesin II or phenylephrine favour cardiac hypertrophy by inducing NF-kB action: IL-33, by interacting with ST2L, is able to attenuate NF-kB promoter activity and the phosphorylation of IKK [17]. Furthermore, it seems that the action of IL-33 via ST2L is to prevent MAPK pathway activation induced by angiotesin II or phenylephrine [17]. Histological analysis even demonstrated that ST2 presence reduced cardiac fibrosis and cardiomyocyte cross-sectional area as compared to ST2 deficient mice [17].

sST2, by acting as a decoy receptor, reduces the positive actions of IL-33 [17]. By binding IL33, it reduces the availability of the IL-33 for interaction with sarcolemmal receptor. Thus, an increase in sST2 could reduce the cardioprotective action of IL-33 on cardiac cells and could induce a negative prognostic effect on the overall cardiovascular risk profile [17]. As demonstrated by Weinberg *et al.* [14], the increased plasma levels of sST2 soon after a myocardial infarction event could be considered as a negative prognostic factor according to previous sentences.

Sanada *et al.*'s work [17] offers a more interesting point of view about the biological properties and uses of IL-33/ST2 in clinical practice. In particular, beyond its biomarker value, ST2 could be considered as a real therapeutic target. In order to demonstrate the biochemical properties of IL-33/ST2 interaction, Sanada *et al.* adopted IL-33 administration in their *in vivo*/*in vitro* experiments. It seemed that IL-33 administration was able to decrease p38 MAPK and Jun N-terminal kinase phosphorylation in MAPK pathway activation induced by angiotensin II [17]. Angiotensin II is able to exert cardiac damages by creating several reactive oxygen species (ROS): IL-33 external administration was able to reduce the ROS generation induced by angiotensin II in experimental models. Once more, an intriguing result was that the purified IL-33 2 μg/d i.p. for 4 weeks use in mice models wild type for ST2 receptor function and presence, was able to reduce the fibrotic and hypertrophic burden of cardiac cardiomyocytes and structures, as compared to ST2 −/− mice [17]. Although Sanada *et al.* concluded such part of their experiment only outlining the importance of deletion of ST2 in the general outcome of cardiac structure undergone angiotensin II action, one more idea could be represented by the possible role of ST2 as therapeutic target: IL-33 external administration in patients suffering from cardiac diseases could enhance ST2L activation and its own biochemical intracellular pathway in order to prevent or at least reduce the worsening of the clinical and structural condition of the heart. The same mice of Sanada *et al.* even demonstrated echocardiographic improvement in hypertrophy and systolic function of their heart after ST2 activation by IL-33 administration. These findings are still experimental and coming from animal models; nevertheless, the idea to develop drugs able to enhance ST2 activation in cardiac human cells could be considered as an interesting development for the next clinical future.

Nevertheless, such enthusiastic results should be tempered by novel insights about ST2 [18]. Ho *et al.* [18] pointed out the genetic landscape controlling ST2L and sST2 expression. There is a

strong genetic variability among individuals about sST2 blood concentrations in basal conditions and it could account for up to 40% in inter-individual variability. The reason could be attributed to single nucleotide polymorphisms that could account for the natural variation in ST2 expression. Some variants of IL1RL1 gene (G allele of rs1558648; T allele of rs13019803) were associated with lower sST2 levels and higher mortality rate [18]. Furthermore, missense mutations in the sequence of the IL1RL1 gene regulating intracellular domain were related to peculiar behavior: these variants were able to alter the biochemical pathway downstream ST2L and this induced an up-regulation in sST2 mRNA transcription and conversion in protein. This condition was even related to higher IL-33 production [18]. Thus, the genetic variability should be taken into account when considering the role of sST2 as biomarker and/or prognostic factor; in second line, genetics should be even considered for further trial considering therapeutic actions of the IL-33/ST2L on human organs.

Thus, despite the intriguing results coming from the biological and biochemical analyses conducted, many aspects of IL-33/ST2 interaction remained unclear and deserve much more attentions and further studies. This, far from reducing the role of ST2 in clinical settings, enforces the need of more objectives evaluations in order to obtain an objective picture of the ST2 use.

4. sST2 Assessment: A Novel Biomarker in Cardiovascular Diseases Detection

The increased knowledge about sST2 and ST2L actions on cardiovascular system led physicians to consider the assessment of plasma levels of sST2 as a novel marker of cardiovascular events and clinical conditions, above all related to heart failure and ischemic heart diseases [19,20].

The identification of novel biomarkers able to early detect worsening signs of such clinical conditions is a fundamental step in the evolution of clinical diagnosis in order to adopt measures able to stop or at least reduce their evolution and negative outcomes. Furthermore, they could be used to detect early the benefits from therapies and the prognosis of the disease [11,21].

Nevertheless, the identification of novel molecules able to make possible a clearer and earlier overview on diseases should face the presence and the authority of previous, well-established biomarkers [20,22,23]. Troponins, natriuretic peptides, *etc*., are well-established cardiovascular diseases biomarkers already entered the international guidelines for detection of heart pathologies [24,25].

Furthermore, the optimal biomarker should be independent from other factors. The blood measurements of sST2 should not be associated to other conditions than myocardial diseases, nor linked to confounding factors that could influence its blood concentrations. This should be the "optimal condition" for a molecule in order to become a reliable biomarker. Against such a preface, one could point out the limitations of the previous "well-established" biomarkers and their dependence from clinical conditions other than the pre-established targets and, despite such limitations, they continued to be considered as important biomarkers all over the world. Why we could consider sST2 as a reliable biomarker for cardiac diseases despite its limitations will be further discussed below.

5. sST2 Assessment in Patients with Acute Dyspnea

sST2 has been considered as a possible biomarker in dyspnoeic patients with and without acute destabilized HF referred to the emergency department [7,11,26]. Dyspnoea is the subjective symptom of breathlessness and it often characterizes different pathologies: heart failure, chronic obstructive

pulmonary disease/bronchitis/asthma, pneumonia, malignancy, pulmonary embolism, *etc*. [27]. The possibility to adopt a marker able to ameliorate diagnosis and, perhaps, differential diagnosis in dyspnoeic patients would improve their treatment and management [28–30]. The Pro-Brain Natriuretic Peptide Investigation of Dyspnea in the Emergency Department (PRIDE) project was a prospective, blinded study, aimed at evaluating sST2, amino-terminal pro-brain natriuretic peptide (NT-proBNP) and C-reactive protein (CRP) concentrations in 599 dyspnoeic subjects with and without acute destabilized HF admitted to the emergency department of the Massachussets General Hospital [26]. Patients supposed to show symptoms related to acute HF demonstrated sST2 serum concentrations higher than those whose symptoms seemed no-HF related (0.50 *vs.* 0.15 ng/mL; $p < 0.001$). Nevertheless, the relationship between sST2 and NT-proBNP concentrations revealed interesting results: receiver-operating characteristics (ROC) curves showed an area under the curve (AUC) of 0.74 (95% CI 0.70 to 0.78; $p < 0.001$) for sST2 when considered as a marker of acute HF [26]. The datum is inferior than that related to NT-proBNP for the same trial, *i.e.*, 0.94 ($p < 0.0001$) [31], thus the NT-proBNP confirmed its leadership as biomarker in acute HF rather than sST2. Nevertheless, sST2 seemed to have prognostic features: the combination of elevated NT-proBNP and low sST2 was observed in patients suffering from dyspnoea not related to acute HF onset [26]. Furthermore, a subgroup of patients with acute HF related symptoms showed an AUC of 0.80 (95% CI 0.75 to 0.84; $p < 0.001$) at ROC analyses regarding the relationship between sST2 and 1 year mortality [26], which was higher than the AUC value related to NT-proBNP for the same population (0.76, $p < 0.001$) [32].

Results from Socrates *et al.*'s research [29] pointed out no statistical significant difference between ROC analyses AUC regarding sST2, BNP and NT-proBNP in predicting 30 days, 90 days and 1 year mortality (30 days AUCs: sST2 = 0.76 *vs.* BNP = 0.63, $p = 0.14$; *vs.* NT-proBNP = 0.71, $p = 0.79$; 90 days AUCs: sST2 = 0.74 *vs.* BNP = 0.71, $p = 0.5$; *vs.* NT-proBNP = 0.75, $p = 0.72$. 1 year AUCs: sST2 = 0.72 *vs.* BNP = 0.71, $p = 0.76$; *vs.* NT-proBNP = 0.73, $p = 0.68$). Nevertheless, Kaplan-Meier curves showed further interesting information: the combination of sST2 to BNP and NT-proBNP measurements is able to increase the accuracy in detecting high risk dyspnoeic patients for acute HF onset. Socrates *et al.* outlined that the subgroup of patients with high sST2 levels and low levels of natriuretic peptides (both BNP/NT-proBNP) had increased mortality risk [29]. According to international guidelines [24], which do not advise sST2 evaluation in general assessment of heart failure patients, this subgroup would not receive a correct assignment. Dieplinger *et al.* [33] confirmed the same results in their recent evaluation of 251 dyspnoeic patients: sST2 is a good biomarker able to predict mortality at 1 years, above all if combined with detection of other plasma molecules (midregional-proadrenomedullin and chromogranin A).

According to Dieplinger *et al.*'s study, sST2 evaluation was not able to discriminate between patients suffering from dyspnoea due to HF or inflammatory pulmonary diseases, thus limiting its usefulness in differential diagnosis [33]. A subgroup analysis from the PRIDE [34] better evaluated such discriminatory point. The authors considered 139 patients (66% were further diagnosed with HF) who underwent complete echocardiographic evaluation at admission at the emergency department. sST2 demonstrated its tight relationship with myocardial function: both in HF and non-HF patients, sST2 was independently related to left (LV) and right (RV) ventricular function and morphological parameters at multivariate analysis (*i.e.*, RV systolic pressure: $t = 2.29$, $p = 0.002$; LV ejection fraction: $t = -2.15$, $p = 0.05$; LV end systolic dimension: $t = 2.57$, $p = 0.01$; LV end diastolic dimension:

t = 2.98, $p = 0.005$; transmitral E to tissue Doppler Ea ratio: t = −2.13, $p = 0.03$; tissue Doppler A wave peak velocity: t = 2.11, $p = 0.05$). Shah *et al.* further demonstrated the deep impact of sST2 as a prognostic biomarker when considering a 4-year mortality. The relationship was independent from others variables: addition of log-transformed sST2 concentration as a continuous variable to other markers of clinical risk really improved the C-statistic from 0.76 to 0.80 in a statistically significant way [34].

6. Role of sST2 Measurements in Acute De-Compensated HF

Acute decompensated HF is the ideal clinical condition to evaluate the real burden of sST2 as biomarker and its power as prognostic factor. Boisot *et al.* enrolled 150 patients suffering from acute decompensated HF in order to evaluate the predictive 90-day mortality power of sST2 percent change as compared to well-established heart failure biomarkers such as BNP or NT-proBNP [35]. ROC analysis demonstrated the comparable predictive value of sST2 and NT-proBNP changes in predicting 90-day mortality (sST2 AUC = 0.78 CI = 0.69 to 0.88 *vs.* NT-proBNP AUC = 0.78 CI = 0.67 to 0.90) rather than BNP (AUC = 0.67 CI = 0.56 to 0.79). The optimization of the statistical analysis led physicians to consider a reduction of more than 15.5% as the best cut-off value able to identify acute decompensated HF patients at high cardiovascular risk [35]. Some authors demonstrated that a sST2 ratio (*i.e.*, the ratio between sST2 two week values and sST2 baseline values) >0.75 would be able to really predict cardiac event rates independently from others confounding factors [36]. The predictive value of sST2 still persists at 1-year follow-up: the higher the sST2 plasma levels, the higher the mortality rates at 1-year, independently of possible confounders, remaining associated to that of BNP (rs = 0.317; 95% CI, 0.157 to 0.460; $p < 0.001$) [37]. A study from Rehman *et al.* [38] revealed that CRP (T = 6.79; $p < 0.001$), body temperature (T = 5.66; $p < 0.001$), heart rate (T = 4.44; $p < 0.001$), BNP (T = 3.0; $p = 0.003$), blood urea nitrogen (T = 2.76; $p = 0.006$), smoking history (T = 2.32; $p = 0.021$), and systolic blood pressure (T = 2.01; $p = 0.045$) are all predictors of sST2 blood concentrations in acute decompensated HF [38]. Surprisingly and in agreement with the work from Manzano-Fernández *et al.* [19], left ventricular ejection fraction is not involved in prediction of sST2 blood concentrations in acute decompensated HF patients. Furthermore, Rehman *et al.* found a 72% sensitivity (95% CI: 62% to 81%), 56% specificity (95% CI: 49% to 62%), a positive predictive value of 39%, and a negative predictive value of 84% for sST2 as a predictor of mortality [38]. The combination of sST2, NT-proBNP, BNP, renal function and C-reactive protein values was able to increase the AUC for 1-year mortality prediction till 0.80 in a statistically significant manner [38]. Such results were confirmed by further studies about this matter [22] which made reliable sST2 as a real marker of acute HF and/or a good mortality predictor in the same de-compensated patients [39].

7. Role of sST2 Plasma Levels in Chronic HF

One of the first attempts to define the role of sST2 in chronic HF was realized in the neurohormone-sub-study of the Prospective Randomized Amlodipine Survival Evaluation 2 (PRAISE-2) study [40], *i.e.*, a multicenter, randomized, double-blinded, placebo-controlled study evaluating the effects of amlodipine 10 mg/day on survival of patients suffering from congestive HF due to non-ischemic conditions. sST2 was significantly higher in patients with severe HF (0.24 ng/mL, CI: 0.16–0.70) than

controls (0.14 ng/mL, CI: 0.13–0.17; $p < 0.0001$). Scatter plots analysis suggested that sST2 values were related to BNP (r = 0.36, $p < 0.0001$), proatrial natriuretic peptide (ProANP) (r = 0.36, $p < 0.0001$), and norepinephrine (r = 0.39, $p < 0.0001$) concentrations. Nevertheless, sST2 was not able to predict mortality by itself in such a category of patients: multivariate analysis confirmed that the sST2 ratio (defined as the change in sST2 from baseline to 2 weeks treatment) was an independent predictor of mortality and/or transplantation ($p = 0.048$), above all if associated with BNP ($p < 0.0001$) and Pro-ANP ($p < 0.0001$) evaluation [40]. More interesting results came from Penn Heart Failure Study (PHFS), a multicenter, prospective cohort study involving chronic heart failure patients suffering from different range of disease severity [41]. Far from the severe HF patients of PRAISE-2, those from PHFS demonstrated that sST2 evaluation had a predictive 1-year mortality/transplantation rate similar at NT-proBNP one: the ROC curves showed comparable predictive values between the two biomarkers (sST2 AUC: 0.75, 95% CI, 0.69 to 0.79 *vs.* NT-proBNP AUC: 0.77, 95% CI, 0.72 to 0.81; $p = 0.24$) [41]. Furthermore, by combining sST2 and NT-proBNP evaluations, the AUC reached a 0.80 (95% CI, 0.76 to 0.84) value. Ky *et al.* [20] included the sST2 evaluation in a multi-markers score to be adopted in chronic HF patients in order to depict the mortality risk of such a category of patients. The new multi-markers model for chronic HF patients was superior than the Seattle Heart Failure Model (SHFM): the multi-markers score involving sST2 evaluation in combination with high-sensitivity CRP (hsCRP), myeloperoxidase (MPO), BNP, soluble fms-like tyrosine kinase receptor-1 (sFlt-1), troponin I (TnI), creatinine, and uric acid reached an AUC higher than that of SHFM (AUC multi-markers score [0.798, 95% CI 0.763–0.833 *vs.* AUC SHFM: 0.756, 95% CI 0.717–0.795)] at 1 year. But the combination of SHFM to the multi-markers allowed an improvement in 1-year mortality prediction up to an overall AUC of 0.803, 95% CI 0.769–0.837, $p = 0.003$.

In agreement with acute de-compensated data [19,38], Bartunek *et al.* [42] demonstrated the independence of sST2 blood levels from left ventricular systolic function. Nevertheless, chronic HF patients, above all if suffering with LV hypertrophy and/or aortic stenosis, revealed that sST2 levels were related to the diastolic overload. This reveals novel insights in the evaluation of sST2 role in myocardial function and the great importance that such a marker could play in the overall assessment of chronic HF patients [43,44]. Despite such evidences, an analysis involving 2,460 Framingham Heart Study participants (mean age 58 years) outlined that left ventricular hypertrophy and left ventricular systolic dysfunction were not related to sST2 concentrations [45]. In this recent research involving a wide sample size, sST2 failed in its predictive value, above all according to those cardiac characteristics (left ventricular hypertrophy and systolic dysfunction) that should theoretically be the main determinants of sST2 plasma levels.

8. sST2, IL-33 and ST2L Roles in Ischemic Heart Disease

The role of IL-33/ST2 signaling pathway in ischemic heart disease has been highlighted. *In vitro* and *in vivo* studies demonstrated that IL-33 plays a regulatory role in cardiac dysfunction after myocardial infarction [46]. In cultured rat cardiomyocytes, IL-33 treatment was dose-dependently able to inhibit hypoxia-induced apoptosis by increasing the expression of inhibitor of apoptosis proteins and by decreasing the activation of caspase-3, *i.e.*, an enzyme able to enhance apoptotic process [46]. sST2 attenuated such an effect by acting as a decoy receptor. Subcutaneous injection of IL-33 reduced

infarct volume, fibrosis, and apoptosis of myocardium after infarction due to coronary ligation, while the presence of sST2 was able to counteract the positive effects of IL-33 in a dose-dependent manner [46]. IL-33/ST2 signaling pathway seems to strengthen the stability of plaques. It is well-known that interferon (IFN)-γ from Th1 lymphocytes could enhance matrix metalloproteinases (MMPs) production from macrophages [47,48]. MMPs are enzymes able to damage the fibrous cap of an atherosclerotic plaque, making it unstable [49,50]. Serum levels of MMP-9 are effectively elevated in the acute phase of myocardial infarction [51,52], showing the maximum levels of concentrations in the culprit coronary artery rather than systemic circulation [53]. IL-33 decreases serum levels of IFN-γ, thus preventing MMPs activation, extracellular matrix destruction and plaque rupture [13]. Guzel *et al.* [54] found IL-33 serum levels significantly lower in non-ST segment elevation myocardial infarction (NSTEMI) patients than controls ($p < 0.05$) and negatively correlated with MMP-9 ($r = -0.461$, $p < 0.05$) levels [54]. Considering an increase in sST2 [14] and a parallel decrease in IL-33 [54] levels during myocardial infarction, one can image the increased risk of patients for coronaries damages.

Shimpo *et al.* developed the predictive value of sST2 in patients suffering from acute myocardial infarction presenting in form of ST-segment elevation myocardial infarction (STEMI) [55]. Patients with higher levels of serum sST2 at STEMI presentation had a statistically significant higher risk of death or of developing new congestive heart failure at 30 days ($p = 0.0009$) [55]. Such a relationship still persisted after adjustment for confounding factors (OR: 1.77, 95% CI 1.01 to 3.12; $p = 0.047$), although the adding of BNP and cTnI made the significance loss [55]. This enforces the important role of BNP and cTnI in STEMI patients rather than sST2 blood concentrations. Considering a subgroup of the CLopidogrel as Adjunctive ReperfusIon TherapY–Thrombolysis in Myocardial Infarction 28 (CLARITY-TIMI 28) trial involving STEMI patients, Sabatine *et al.* [23] demonstrated the independent predictive value of both sST2 and NT-proBNP in a multi-markers model, with an OR of 3.57 (95% CI 1.87 to 6.81) for sST2 and 2.41 (95% CI 1.17 to 4.95) for NT-proBNP. Furthermore, the authors demonstrated that, by introducing both sST2 and NT-proBNP to the TIMI Risk Score, the c statistic of this score improved from 0.73 (95% CI, 0.68 to 0.78) to 0.78 (95% CI, 0.74 to 0.83; $p = 0.0025$) [23].

Non-ST segment elevation acute coronary syndrome (NSTE-ACS) patients did not differ from their STE-ACS counterpart [56]. sST2 plasma levels deeply increased at early stages of the event, with a peak value reached at 6–11 h. According to outcome prediction, the sST2 c-statistics for 1-year mortality was 0.67 (95% CI 0.54–0.79), which was not different from that of cTnT (0.64 [95% CI 0.53–0.76], $p = 0.66$), although lower than that of NT-proBNP one (0.78 [95% CI 0.66–0.89], $p = 0.03$). The authors further demonstrated that 1-SD increase in ln-transformed ST2 was associated with an OR 2.3 [95% CI 1.1–4.6, $p = 0.03$] in a risk model adopted within their population by considering all the clinical variable of the sample [56]. These results were similar to those from Kohli *et al.* [57] who demonstrated that high sST2 levels (*i.e.*, >35 μg/L) in NSTE-ACS patients predicted a >3-fold higher risk of cardiovascular death and heart failure at 30 days and 1 year, even after adjustment for major clinical risk factors and biomarkers (cTnI and BNP) [57]. Nevertheless, adding sST2 evaluation to GRACE score and NT-proBNP values in NSTE-ACS patients, seemed not to be long-term predictive, thus did not improve cardiovascular risk stratification [58].

Furthermore, the value of sST2 as predictor of functional recovery and remodeling of LV in the post-infarct phase was also evaluated. Weir *et al.* [59] effectively noted that sST2 serum

concentrations were positively correlated with endocardial, epicardial extent and microvascular obstruction of infarct in 100 acute myocardial infarct patients. sST2 values significantly decreased from baseline to 24 weeks, predicting the degree in adverse LV functional recovery and remodeling: a slow change in sST2 concentrations was related to worse LVEF, LV end-diastolic volume index and infarct volume index [59].

9. Role of ST2 in Other Clinical Settings

sST2 role in predicting mortality was recently demonstrated in 588 outpatients referred for echocardiograms. The optimal cut-point of sST2 for predicting 1-year mortality was 28.25 ng/mL. Patients with high ST2 levels had an increased risk of death ($p = 0.02$); and if both ST2 and B-type natriuretic peptide levels were elevated, the risk resulted even higher ($p = 0.01$) [60].

In the Framingham Heart Study, sST2 concentrations were related to systolic blood pressure ($p = 0.006$), antihypertensive medication use ($p = 0.03$), and diabetes ($p = 0.001$) [61]. By adjusting for CAD, HF, atrial fibrillation, diabetes, hypertension, obesity, valvular disease, LV systolic dysfunction, and pulmonary and renal dysfunction, the Framingham Heart Study showed that male sex ($p < 0.0001$) and old age ($p = 0.004$) were related to higher sST2 concentrations [61].

Nevertheless, the measurement of sST2 in 348 patients presenting to the emergency department with chest pain sST2 was found to be increased in those suffering from pulmonary disease (obstructive sleep apnea, chronic obstructive pulmonary disease, asthma, pulmonary embolism, and pulmonary hypertension), systemic infection or inflammation, and alcohol abuse [62].

10. Conclusions

The ST2/IL-33 pathway is involved in pathophysiology of myocardial dysfunction by potentially attenuating the cardioprotective effects of IL-33. It seems to reduce the extent of cardiac damage after myocardial infarct, cardiomyocyte apoptosis, inflammatory cardiac activation, fibrosis, adverse myocardial remodeling. sST2, by acting as a decoy receptor, could prevent the beneficial effects of IL-33/ST2L interaction. sST2 measurements in blood samples could be a clinical prognostic biomarker useful in risk stratification of patients suffering from myocardial infarction, HF and dyspnea. Further studies are needed in order to better point out the evidence for a routine use of sST2 evaluation in the clinical evaluation of a patient suffering from myocardial infarction and HF.

Hepatitis B (chronic)

Diagnosis and management of chronic hepatitis B in children, young people and adults

Issued: June 2013

NICE clinical guideline 165

guidance.nice.org.uk/cg165

NICE has accredited the process used by the Centre for Clinical Practice at NICE to produce guidelines. Accreditation is valid for 5 years from September 2009 and applies to guidelines produced since April 2007 using the processes described in NICE's 'The guidelines manual' (2007, updated 2009). More information on accreditation can be viewed at www.nice.org.uk/accreditation

Introduction

This guideline updates and replaces recommendations in NICE technology appraisal 96 and incorporates recommendations from NICE technology appraisals 96, 153, 154 and 173. See About this guideline for details.

Chronic hepatitis B describes a spectrum of disease usually characterised by the presence of detectable hepatitis B surface antigen (HBsAg) in the blood or serum for longer than 6 months. In some people, chronic hepatitis B is inactive and does not present significant health problems, but others may progress to liver fibrosis, cirrhosis and hepatocellular carcinoma (HCC). The progression of liver disease is associated with hepatitis B virus (HBV) DNA levels in the blood. Without antiviral treatment, the 5-year cumulative incidence of cirrhosis ranges from 8 to 20%. People with cirrhosis face a significant risk of decompensated liver disease if they remain untreated. Five-year survival rates among people with untreated decompensated cirrhosis can be as low as 15%. Chronic hepatitis B can be divided into e antigen- (HBeAg) positive or HBeAg-negative disease based on the presence or absence of e antigen. The presence of HBeAg is typically associated with higher rates of viral replication and therefore increased infectivity.

The goal of treatment for chronic hepatitis B is to prevent cirrhosis, HCC and liver failure. In clinical practice surrogate markers are used to monitor progression of disease and treatment response, and include normalisation of serum alanine aminotransferase (ALT) levels, decrease in inflammation scores with no worsening or improvement in fibrosis on liver biopsies, suppression of serum HBV DNA to undetectable levels, loss of HBeAg and seroconversion to HBe antibody (anti-HBe), and loss of HBsAg and seroconversion to HBs antibody (anti-HBs).

Antiviral therapy suppresses HBV replication and decreases hepatic inflammation and fibrosis, thereby reducing the likelihood of serious clinical disease. Since the introduction of effective treatment in the form of interferon alfa, several nucleoside and nucleotide analogues are now approved for use in adults with chronic hepatitis B, together with a pegylated form of interferon alfa. With multiple treatment options that are efficacious and safe, the key questions are which patients need immediate treatment and what sequence and combination of drug regimens should be used, and which patients can be monitored and delay treatment.

In this guideline we cover the following:

- information needs of people with chronic hepatitis B and their carers

© NICE 2013. All rights reserved. Last modified June 2013

- where children, young people and adults with chronic hepatitis B should be assessed
- assessment of liver disease, including the use of non-invasive tests and genotype testing
- criteria for offering antiviral treatment
- the efficacy, safety and cost effectiveness of currently available treatments
- selection of first-line therapy
- management of treatment failure or drug resistance
- whether there is a role for combination therapy
- when it is possible to stop treatment
- managing the care of pregnant and breastfeeding women and prevention of vertical transmission
- prophylactic treatment during immunosuppressive therapy
- monitoring for treatment response, severity of fibrosis and development of HCC.

The spontaneous mutation rate of HBV DNA is high. Exposure of HBV to nucleoside or nucleotide analogues selects for mutations in the polymerase gene that confer resistance or decreased susceptibility to the drugs. The relative risk of drug resistance must be taken into account when considering treatment with nucleoside or nucleotide analogues, including the level of cross resistance between different agents.

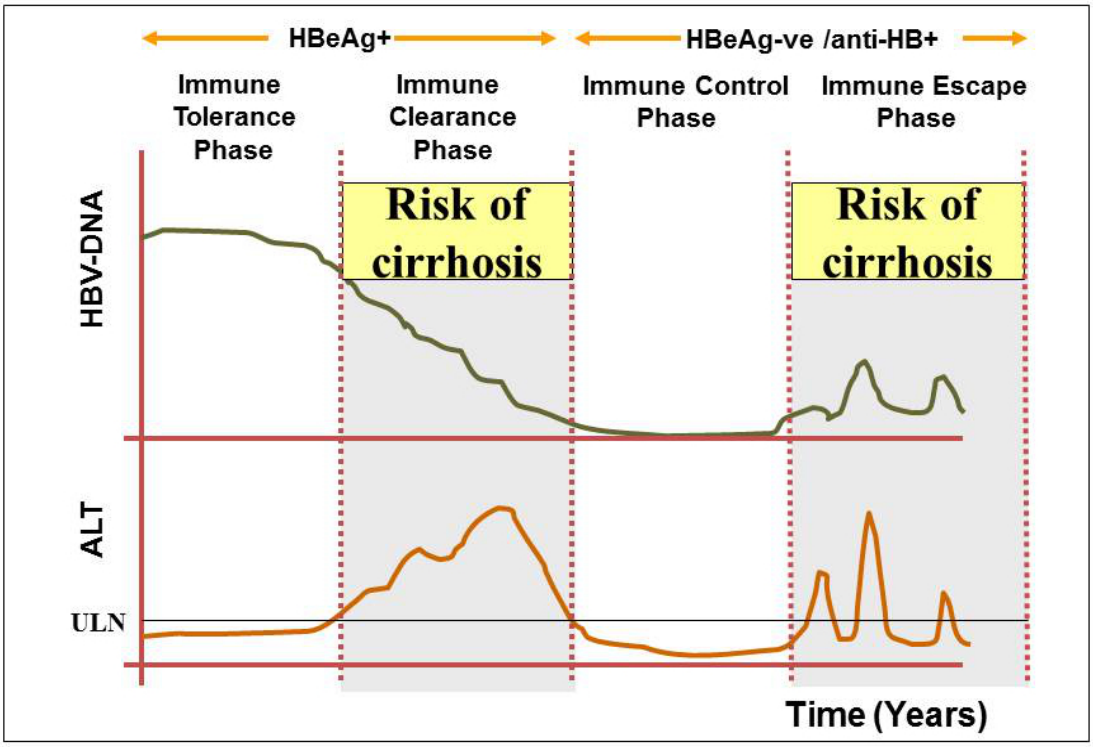
Figure 1 depicts the natural history of chronic HBV infection. The immune-tolerance phase is seen in HBeAg-positive disease and is characterised by high levels of HBV replication with normal ALT levels and limited liver necroinflammation. Because there is minimal immune response to the virus it is unusual for spontaneous HBeAg loss to occur. This phase is commonly seen in children. It is followed by an immune-clearance or immune-reactive phase in which the immune system recognises and starts to clear the virus. ALT levels are typically elevated or fluctuating, and there is a higher risk of liver fibrosis. This tends to be the initial phase in people infected with HBV as adults. It lasts from weeks to years and ends with HBeAg seroconversion.

With the loss of HBeAg the person may enter an immune-control phase with very low or undetectable HBV DNA levels, normal ALT and minimal fibrosis progression. However, some

© NICE 2013. All rights reserved. Last modified June 2013

people may experience rising HBV DNA levels despite HBeAg negativity. This is caused by virions that do not express HBeAg because of genetic mutations. This immune-escape phase can lead to active necroinflammation and progression of fibrosis.

Figure 1. Natural history of chronic HBV infection



After Chu et al, Hepatology 1985;5:431-34 ULN: upper limit of normal of ALT

Substantial progress has been made in the treatment of chronic hepatitis B in the past decade but the appropriate time for starting treatment remains a topic of debate. Although currently available treatment is effective in suppressing HBV replication, it fails to eradicate the virus necessitating long treatment duration and perhaps lifelong treatment.

The guideline will assume that prescribers will use a drug's summary of product characteristics to inform decisions made with individual patients.

This guideline recommends some drugs for indications for which they do not have a U marketing authorisation at the date of publication, if there is good evidence to support that use. The prescriber should follow relevant professional guidance, taking full responsibility for the decision. The patient (or those with authority to give consent on their behalf) should provide informed consent, which should be documented. See the General Medical Council's Good

© NICE 2013. All rights reserved. Last modified June 2013

practice in prescribing medicines □ guidance for doctors for further information. Where recommendations have been made for the use of drugs outside their licensed indications ('off-label use'), these drugs are marked with a footnote in the recommendations.

© NICE 2013. All rights reserved. Last modified June 2013

Patient-centred care

This guideline offers best practice advice on the care of children, young people and adults with chronic hepatitis B.

Patients and healthcare professionals have rights and responsibilities as set out in the NHS Constitution for England – all NICE guidance is written to reflect these. Treatment and care should take into account individual needs and preferences. Patients should have the opportunity to make informed decisions about their care and treatment, in partnership with their healthcare professionals. If the patient is under 16, their family or carers should also be given information and support to help the child or young person to make decisions about their treatment. Healthcare professionals should follow the Department of Health's advice on consent. If someone does not have capacity to make decisions, healthcare professionals should follow the code of practice that accompanies the Mental Capacity Act and the supplementary code of practice on deprivation of liberty safeguards. In Wales, healthcare professionals should follow advice on consent from the Welsh Government.

NICE has produced guidance on the components of good patient experience in adult NHS services. All healthcare professionals should follow the recommendations in Patient experience in adult NHS services.

If a young person is moving between paediatric and adult services, care should be planned and managed according to the best practice guidance described in the Department of Health's Transition: getting it right for young people.

Adult and paediatric healthcare teams should work jointly to provide assessment and services to young people with chronic hepatitis B. Diagnosis and management should be reviewed throughout the transition process, and there should be clarity about who is the lead clinician to ensure continuity of care.

© NICE 2013. All rights reserved. Last modified June 2013

Terms used in this guidance

Chronic hepatitis B

Chronic hepatitis B is defined as persistence of hepatitis B surface antigen (HBsAg) for 6 months or more after acute infection with hepatitis B virus (HBV).

HBV DNA

HBV DNA level, or 'viral load', is an indicator of viral replication. Higher HBV DNA levels are usually associated with an increased risk of liver disease and hepatocellular carcinoma. HBV DNA level typically falls in response to effective antiviral treatment.

Hepatitis B surface antigen (HBsAg)

Hepatitis B surface antigen (HBsAg) is a viral protein detectable in the blood in acute and chronic hepatitis B infection.

HBsAg seroconversion

The development of antibodies against HBsAg is known as HBsAg seroconversion. It signifies clearance of HBsAg and resolution of the chronic infection.

Hepatitis B e antigen (HBeAg)

Hepatitis B e antigen (HBeAg) is an indicator of viral replication, although some variant forms of the virus do not express HBeAg (see 'HBeAg-negative chronic hepatitis B' below). Active infection can be described as HBeAg-positive or HBeAg-negative according to whether HBeAg is secreted.

HBeAg-negative chronic hepatitis B

HBeAg-negative hepatitis B is a form of the virus that does not cause infected cells to secrete HBeAg. People can be infected with the HBeAg-negative form of the virus from the beginning, or

© NICE 2013. All rights reserved. Last modified June 2013

the viral mutation can emerge later in the course of infection in people initially infected with the HBeAg-positive form of the virus.

HBeAg seroconversion

HBeAg seroconversion occurs when people infected with the HBeAg-positive form of the virus develop antibodies against the 'e' antigen. The seroconverted disease state is referred to as the 'inactive HBV carrier state' when HBeAg has been cleared, anti-HBe is present and HBV DNA is undetectable or less than 2000 IU/ml. Once seroconversion has taken place, most people remain in the inactive HBV carrier state (the immune-control phase; see figure 1). However, increasing HBV DNA and recurrent hepatitis after seroconversion indicate the emergence of the HBeAg-negative strain of the virus (the immune-escape phase; see figure 1).

© NICE 2013. All rights reserved. Last modified June 2013

Key priorities for implementation

The following recommendations have been identified as priorities for implementation.

Assessment and referral

- Arrange the following tests in primary care for adults who are hepatitis B surface antigen (HBsAg) positive:
  - hepatitis B e antigen (HBeAg)/antibody (anti-HBe) status
  - HBV DNA level
  - IgM antibody to hepatitis B core antigen (anti-HBc IgM)
  - hepatitis C virus antibody (anti-HCV)
  - hepatitis delta virus antibody (anti-HDV)
  - HIV antibody (anti-HIV)
  - IgG antibody to hepatitis A virus (anti-HAV)
  - additional laboratory tests including alanine aminotransferase (ALT) or aspartate aminotransferase (AST), gamma-glutamyl transferase (GGT), serum albumin, total bilirubin, total globulins, full blood count and prothrombin time
  - tests for hepatocellular carcinoma (HCC), including hepatic ultrasound and alpha-fetoprotein testing.
- Include the results of the initial tests with the referral (see recommendation 1.2.1).

Treatment sequence in adults with HBeAg-positive chronic hepatitis B and compensated liver disease

- Offer a 48-week course of peginterferon alfa-2a as first-line treatment in adults with HBeAg-positive chronic hepatitis B and compensated liver disease[1].

© NICE 2013. All rights reserved. Last modified June 2013

- Offer tenofovir disoproxil as second-line treatment to people who do not undergo HBeAg seroconversion or who relapse (revert to being HBeAg positive following seroconversion) after first-line treatment with peginterferon alfa-2a.
- Offer entecavir as an alternative second-line treatment to people who cannot tolerate tenofovir disoproxil or if it is contraindicated.

Treatment sequence in adults with HBeAg-negative chronic hepatitis B and compensated liver disease

- Offer a 48-week course of peginterferon alfa-2a as first-line treatment in adults with HBeAg-negative chronic hepatitis B and compensated liver disease[1].
- Offer entecavir or tenofovir disoproxil as second-line treatment to people with detectable HBV DNA after first-line treatment with peginterferon alfa-2a.

Women who are pregnant or breastfeeding

- Offer tenofovir disoproxil to women with HBV DNA greater than 10^7 IU/ml in the third trimester to reduce the risk of transmission of HBV to the baby[2].

Prophylactic treatment during immunosuppressive therapy

- In people who are HBsAg positive and have HBV DNA greater than 2000 IU/ml, offer prophylaxis with entecavir or tenofovir disoproxil[3].
    - Start prophylaxis before beginning immunosuppressive therapy and continue for a minimum of 6 months after HBeAg seroconversion and HBV DNA is undetectable.
- In people who are HBsAg positive and have HBV DNA less than 2000 IU/ml, offer prophylaxis:
    - consider lamivudine[3] if immunosuppressive therapy is expected to last less than 6 months
        - monitor HBV DNA monthly in people treated with lamivudine and change to tenofovir disoproxil if HBV DNA remains detectable after 3 months

© NICE 2013. All rights reserved. Last modified June 2013

- consider entecavir or tenofovir disoproxil[3] if immunosuppressive therapy is expected to last longer than 6 months
- start prophylaxis before beginning immunosuppressive therapy and continue for a minimum of 6 months after stopping immunosuppressive therapy.

[1] Avoid use of peginterferon alfa-2a in pregnancy unless the potential benefit outweighs risk. Women of childbearing potential must use effective contraception throughout therapy.

[2] At the time of publication (June 2013), tenofovir disoproxil did not have a U□ marketing authorisation for this indication. The prescriber should follow relevant professional guidance, taking full responsibility for the decision. Informed consent should be obtained and documented. See the General Medical Council's Good practice in prescribing medicines □guidance for doctors for further information.

[3] At the time of publication (June 2013), entecavir, lamivudine and tenofovir disoproxil did not have a U□ marketing authorisation for this indication. The prescriber should follow relevant professional guidance, taking full responsibility for the decision. Informed consent should be obtained and documented. See the General Medical Council's Good practice in prescribing medicines □guidance for doctors for further information.

© NICE 2013. All rights reserved. Last modified June 2013

1 Recommendations

The following guidance is based on the best available evidence. The full guideline gives details of the methods and the evidence used to develop the guidance.

The wording used in the recommendations in this guideline (for example, words such as 'offer' and 'consider') denotes the certainty with which the recommendation is made (the strength of the recommendation). See About this guideline for details.

In this guideline, children and young people are defined as aged up to 18 years. Please follow the recommendations for women who are pregnant for young people with chronic hepatitis B who are pregnant.

1.1 Patient information

1.1.1 Provide information on the following topics to people with chronic hepatitis B and to family members or carers (if appropriate) before assessment for antiviral treatment:

- the natural history of chronic hepatitis B, including stages of disease and long-term prognosis
- lifestyle issues such as alcohol, diet and weight
- family planning
- monitoring
- routes of hepatitis B virus (HBV) transmission
- the benefits of antiviral treatment, including reduced risk of serious liver disease and death and reduced risk of transmission of HBV to others
- treatment options and contraindications based on the patient's circumstances, including peginterferon alfa-2a and nucleoside or nucleotide analogues
- short- and long-term treatment goals

© NICE 2013. All rights reserved. Last modified June 2013

- causes of treatment failure, including non-adherence to prescribed medicines, and options for re-treatment
- risks of treatment, including adverse effects and drug resistance.

1.1.2 Offer a copy of the personalised care plan to people with chronic hepatitis B and to family members or carers (if appropriate) outlining proposed treatment and long-term management, for example, a copy of the hospital consultation summary.

1.1.3 Provide information on self-injection techniques to people beginning peginterferon alfa-2a or to family members or carers.

1.1.4 NICE has produced public health guidance on ways to promote and offer testing to people at increased risk of infection with hepatitis B. All healthcare professionals should follow the recommendations in Hepatitis B and C: ways to promote and offer testing to people at increased risk of infection (NICE public health guidance 43).

1.1.5 NICE has produced guidance on the components of good patient experience in adult NHS services. All healthcare professionals should follow the recommendations in Patient experience in adult NHS services (NICE clinical guidance 138).

1.2 Assessment and referral in primary care

Adults who are HBsAg positive

1.2.1 Arrange the following tests in primary care for adults who are hepatitis B surface antigen (HBsAg) positive:

- hepatitis B e antigen (HBeAg)/antibody (anti-HBe) status
- HBV DNA level
- IgM antibody to hepatitis B core antigen (anti-HBc IgM)
- hepatitis C virus antibody (anti-HCV)

© NICE 2013. All rights reserved. Last modified June 2013

- hepatitis delta virus antibody (anti-HDV)
- HIV antibody (anti-HIV)
- IgG antibody to hepatitis A virus (anti-HAV)
- additional laboratory tests including alanine aminotransferase (ALT) or aspartate aminotransferase (AST), gamma-glutamyl transferase (GGT), serum albumin, total bilirubin, total globulins, full blood count and prothrombin time
- tests for hepatocellular carcinoma (HCC), including hepatic ultrasound and alpha-fetoprotein testing.

1.2.2 Refer all adults who are HBsAg positive to a hepatologist or to a gastroenterologist or infectious disease specialist with an interest in hepatology.

1.2.3 Include the results of the initial tests with the referral (see recommendation 1.2.1).

Pregnant women who test HBsAg positive at antenatal screening

1.2.4 Refer pregnant women who are HBsAg positive to a hepatologist, or to a gastroenterologist or infectious disease specialist with an interest in hepatology, for assessment within 6 weeks of receiving the screening test result and to allow treatment in the third trimester (see recommendation 1.5.39).

Adults with decompensated liver disease

1.2.5 Refer adults who develop decompensated liver disease immediately to a hepatologist or to a gastroenterologist with an interest in hepatology. Symptoms of decompensated liver disease include (but are not limited to) ascites, encephalopathy and gastrointestinal haemorrhage.

Children and young people who are HBsAg positive

1.2.6 Arrange the following tests for children and young people who are HBsAg positive:

© NICE 2013. All rights reserved. Last modified June 2013

- HBeAg/anti-HBe status
- HBV DNA level
- anti-HBc IgM
- anti-HCV
- anti-HDV
- anti-HIV
- anti-HAV
- additional laboratory tests, including ALT or AST, GGT, serum albumin, total bilirubin, total globulins, full blood count and prothrombin time
- tests for HCC, including hepatic ultrasound and alpha-fetoprotein testing.

1.2.7 Refer all children and young people who are HBsAg positive to a paediatric hepatologist or to a gastroenterologist or infectious disease specialist with an interest in hepatology.

1.2.8 Include the results of the initial tests with the referral (see recommendation 1.2.6).

1.3 Assessment of liver disease in secondary specialist care

Adults with chronic hepatitis B

Please refer to recommendations 1.5.3 to 1.5.7 for detailed guidance on offering antiviral treatment.

1.3.1 Ensure all healthcare professionals who refer adults for non-invasive tests for liver disease are trained to interpret the results and aware of co-factors that influence liver elasticity (for example, fatty liver caused by obesity or alcohol misuse).

© NICE 2013. All rights reserved. Last modified June 2013

1.3.2 Discuss the accuracy, limitations and risks of the different tests for liver disease with the patient.

1.3.3 Offer transient elastography as the initial test for liver disease in adults newly referred for assessment.

1.3.4 Offer antiviral treatment without a liver biopsy to adults with a transient elastography score greater than or equal to 11 kPa[4], in line with recommendation 1.5.6.

1.3.5 Consider liver biopsy to confirm the level of fibrosis in adults with a transient elastography score between 6 and 10 kPa[5]. Offer antiviral treatment in line with recommendations 1.5.3 to 1.5.7.

1.3.6 Offer liver biopsy to adults with a transient elastography score less than 6 kPa if they are younger than 30 years and have HBV DNA greater than 2000 IU/ml and abnormal ALT (greater than or equal to 30 IU/L for males and greater than or equal to 19 IU/L for females) on 2 consecutive tests conducted 3 months apart[6]. Offer antiviral treatment in line with recommendations 1.5.3 to 1.5.7.

1.3.7 Do not offer liver biopsy to adults with a transient elastography score less than 6 kPa who have normal ALT (less than 30 IU/L in males and less than 19 IU/L in females) and HBV DNA less than 2000 IU/ml as they are unlikely to have advanced liver disease or need antiviral treatment (see recommendations 1.5.3 to 1.5.7)[6].

1.3.8 Offer an annual reassessment of liver disease using transient elastography to adults who are not taking antiviral treatment.

Children and young people with chronic hepatitis B

1.3.9 Discuss the accuracy, limitations and risks of liver biopsy in determining the need for antiviral treatment with the child or young person and with parents or carers (if appropriate).

1.3.10 Consider liver biopsy to assess liver disease and the need for antiviral treatment in children and young people with HBV DNA greater than 2000 IU/ml

© NICE 2013. All rights reserved. Last modified June 2013

and abnormal ALT (greater than or equal to 30 IU/L for males and greater than or equal to 19 IU/L for females) on 2 consecutive tests conducted 3 months apart. Offer biopsy under a general anaesthetic to children who are too young to tolerate the procedure under a local anaesthetic.

1.4 Genotype testing

1.4.1 Do not offer genotype testing to determine initial treatment in people with chronic hepatitis B.

1.5 Antiviral treatment

Adults with chronic hepatitis B

Recommendations 1.5.8 to 1.5.12 are reproduced from existing NICE technology appraisals on options for the treatment of chronic hepatitis B, and 1.5.13 to 1.5.15 update guidance in NICE technology appraisal 96[7]. The GDG has reviewed the evidence and has made recommendations on treatment sequences and combination drug regimens (see recommendations 1.5.16 to 1.5.28).

Recommendations 1.5.8 to 1.5.43 do not apply to people with chronic hepatitis B who also have hepatitis C, hepatitis D or HIV.

1.5.1 Discuss treatment options, adverse effects and long-term prognosis with the patient before starting treatment.

1.5.2 Re-assess the person's risk of exposure to HIV before starting treatment and offer repeat testing if needed.

1.5.3 Offer antiviral treatment to adults aged 30 years and older who have HBV DNA greater than 2000 IU/ml and abnormal ALT (greater than or equal to 30 IU/L in males and greater than or equal to 19 IU/L in females) on 2 consecutive tests conducted 3 months apart.

1.5.4 Offer antiviral treatment to adults younger than 30 years who have HBV DNA greater than 2000 IU/ml and abnormal ALT (greater than or equal to 30 IU/L in

© NICE 2013. All rights reserved. Last modified June 2013

males and greater than or equal to 19 IU/L in females) on 2 consecutive tests conducted 3 months apart if there is evidence of necroinflammation or fibrosis on liver biopsy or a transient elastography score greater than 6 kPa.

1.5.5 Offer antiviral treatment to adults who have HBV DNA greater than 20,000 IU/ml and abnormal ALT (greater than or equal to 30 IU/L in males and greater than or equal to 19 IU/L in females) on 2 consecutive tests conducted 3 months apart regardless of age or the extent of liver disease.

1.5.6 Offer antiviral treatment to adults with cirrhosis and detectable HBV DNA, regardless of HBeAg status, HBV DNA and ALT levels.

1.5.7 Consider antiviral treatment in adults with HBV DNA greater than 2000 IU/ml and evidence of necroinflammation or fibrosis on liver biopsy.

1.5.8 Peginterferon alfa-2a is recommended as an option for the initial treatment of adults with chronic hepatitis B (HBeAg-positive or HBeAg-negative), within its licensed indications. [This recommendation is from Adefovir dipivoxil and peginterferon alfa-2a for the treatment of chronic hepatitis B (NICE technology appraisal guidance 96).]

1.5.9 Entecavir, within its marketing authorisation, is recommended as an option for the treatment of people with chronic HBeAg-positive or HBeAg-negative hepatitis B in whom antiviral treatment is indicated. [This recommendation is from Entecavir for the treatment of chronic hepatitis B (NICE technology appraisal guidance 153).]

1.5.10 Tenofovir disoproxil, within its marketing authorisation, is recommended as an option for the treatment of people with chronic HBeAg-positive or HBeAg-negative hepatitis B in whom antiviral treatment is indicated. [This recommendation is from Tenofovir disoproxil fumarate for the treatment of hepatitis B (NICE technology appraisal guidance 173).]

1.5.11 Telbivudine is not recommended for the treatment of chronic hepatitis B. [This recommendation is from Telbivudine for the treatment of chronic hepatitis B (NICE technology appraisal guidance 154).]

© NICE 2013. All rights reserved. Last modified June 2013

1.5.12 People currently receiving telbivudine should have the option to continue therapy until they and their clinicians consider it appropriate to stop. [This recommendation is from Telbivudine for the treatment of chronic hepatitis B (NICE technology appraisal guidance 154).]

1.5.13 Do not offer adefovir dipivoxil for treatment of chronic hepatitis B.

1.5.14 People currently receiving adefovir dipivoxil should be offered the option to switch to a different treatment. Offer tenofovir disoproxil or entecavir, depending on previous antiviral exposure:

- offer tenofovir disoproxil to people with a history of lamivudine resistance.

1.5.15 Antiviral treatment should be initiated only by an appropriately qualified healthcare professional with expertise in the management of viral hepatitis. Continuation of therapy under shared-care arrangements with a GP is appropriate.

Treatment sequence in adults with HBeAg-positive chronic hepatitis B and compensated liver disease

1.5.16 Offer a 48-week course of peginterferon alfa-2a as first-line treatment in adults with HBeAg-positive chronic hepatitis B and compensated liver disease[8].

1.5.17 Consider stopping peginterferon alfa-2a 24 weeks after starting treatment if HBV DNA level has decreased by less than 2 $\log_{10}$ IU/ml and/or if HBsAg is greater than 20,000 IU/ml, and offer second-line treatment in line with recommendations 1.5.18 and 1.5.19.

1.5.18 Offer tenofovir disoproxil as second-line treatment to people who do not undergo HBeAg seroconversion or who relapse (revert to being HBeAg positive following seroconversion) after first-line treatment with peginterferon alfa-2a.

1.5.19 Offer entecavir as an alternative second-line treatment to people who cannot tolerate tenofovir disoproxil or if it is contraindicated.

© NICE 2013. All rights reserved. Last modified June 2013

1.5.20 Review adherence in people taking tenofovir disoproxil who have detectable HBV DNA at 48 weeks of treatment and, if appropriate, provide support in line with Medicines adherence (NICE clinical guidance 76).

- If HBV DNA remains detectable at 96 weeks, and there is no history of lamivudine resistance, consider adding lamivudine to tenofovir disoproxil.
- In people with a history of lamivudine resistance, consider adding entecavir to tenofovir disoproxil.

1.5.21 Consider stopping nucleoside or nucleotide analogue treatment 12 months after HBeAg seroconversion in people without cirrhosis.

1.5.22 Do not stop nucleoside or nucleotide analogue treatment 12 months after HBeAg seroconversion in people with cirrhosis.

Treatment sequence in adults with HBeAg-negative chronic hepatitis B and compensated liver disease

1.5.23 Offer a 48-week course of peginterferon alfa-2a as first-line treatment in adults with HBeAg-negative chronic hepatitis B and compensated liver disease[8].

1.5.24 Consider stopping peginterferon alfa-2a 24 weeks after starting treatment if HBV DNA level has decreased by less than 2 $\log_{10}$ IU/ml and HBsAg has not decreased, and consider second-line treatment in line with recommendation 1.5.25.

1.5.25 Offer entecavir or tenofovir disoproxil as second-line treatment to people with detectable HBV DNA after first-line treatment with peginterferon alfa-2a.

1.5.26 Consider switching from tenofovir disoproxil to entecavir, or from entecavir to tenofovir disoproxil, as third-line treatment in people who have detectable HBV DNA at 48 weeks of treatment.

1.5.27 Consider stopping nucleoside or nucleotide analogue treatment 12 months after achieving undetectable HBV DNA and HBsAg seroconversion in people without cirrhosis.

© NICE 2013. All rights reserved. Last modified June 2013

1.5.28 Do not stop nucleoside or nucleotide analogue treatment after achieving undetectable HBV DNA and HBsAg seroconversion in patients with cirrhosis.

Children and young people with chronic hepatitis B and compensated liver disease

1.5.29 Discuss treatment options, adverse effects and long-term prognosis with the child or young person and with parents or carers (if appropriate) before starting treatment.

1.5.30 Re-assess the child or young person's risk of exposure to HIV before starting treatment and offer repeat testing if necessary.

1.5.31 Offer antiviral treatment if there is evidence of significant fibrosis (METAVIR stage greater than or equal to F2 or Ishak stage greater than or equal to 3) or abnormal ALT (greater than or equal to 30 IU/L for males and greater than or equal to 19 IU/L for females) on 2 consecutive tests conducted 3 months apart.

1.5.32 Consider a 48-week course of peginterferon alfa-2a as first-line treatment in children and young people with chronic hepatitis B and compensated liver disease[8],[9].

1.5.33 Consider stopping peginterferon alfa-2a 24 weeks after starting treatment if HBV DNA level has decreased by less than 2 $\log_{10}$ IU/ml and/or if HBsAg is greater than 20,000 IU/ml.

1.5.34 Consider a nucleoside or nucleotide analogue as second-line treatment in children and young people with detectable HBV DNA after first-line treatment with peginterferon alfa-2a[10].

Adults with decompensated liver disease

1.5.35 Manage decompensated liver disease in adults in conjunction with a liver transplant centre.

1.5.36 Do not offer peginterferon alfa-2a to people with chronic hepatitis B and decompensated liver disease.

© NICE 2013. All rights reserved. Last modified June 2013

1.5.37 Offer entecavir as first-line treatment in people with decompensated liver disease if there is no history of lamivudine resistance.

- Offer tenofovir disoproxil to people with a history of lamivudine resistance.
- Reduce the dose of tenofovir disoproxil in people with renal impairment, in line with guidance in the summary of product characteristics.

Women who are pregnant or breastfeeding

1.5.38 Discuss with pregnant women the benefits and risks of antiviral treatment for them and their baby.

1.5.39 Offer tenofovir disoproxil to women with HBV DNA greater than 10^7 IU/ml in the third trimester to reduce the risk of transmission of HBV to the baby[11].

1.5.40 Monitor quantitative HBV DNA 2 months after starting tenofovir disoproxil and ALT monthly after the birth to detect postnatal HBV flares in the woman.

1.5.41 Stop tenofovir disoproxil 4 to 12 weeks after the birth unless the mother meets criteria for long-term treatment (see recommendations 1.5.4 to 1.5.8).

1.5.42 Offer active and passive hepatitis B immunisation in infants and follow up in line with the guidance below:

- Hepatitis B antenatal screening and newborn immunisation programme: best practice guidance
- Immunisation against infectious disease (the Green book)
- Hepatitis B and C: ways to promote and offer testing. NICE public health guidance 43 (2012)
- Reducing differences in the uptake of immunisations. NICE public health guidance 21 (2009).

1.5.43 Advise women that there is no risk of transmitting HBV to their babies through breastfeeding if guidance on hepatitis B immunisation has been followed, and that they may continue antiviral treatment while they are breastfeeding.

© NICE 2013. All rights reserved. Last modified June 2013

Adults who are co-infected with hepatitis C

1.5.44 Offer peginterferon alfa and ribavirin in adults co-infected with chronic hepatitis B and C[8].

Adults who are co-infected with hepatitis D

1.5.45 Offer a 48-week course of peginterferon alfa-2a in people co-infected with chronic hepatitis B and hepatitis delta infection who have evidence of significant fibrosis (METAVIR stage greater than or equal to F2 or Ishak stage greater than or equal to 3)[6].

1.5.46 Consider stopping peginterferon alfa-2a if there is no decrease in HDV RNA after 6 months to 1 year of treatment. Otherwise, continue treatment and re-evaluate treatment response annually.

1.5.47 Stop treatment after HBsAg seroconversion.

Prophylactic treatment during immunosuppressive therapy

1.5.48 Perform the following tests in people who are HBsAg and/or anti-HBc positive before starting immunosuppressive therapy for autoimmune or atopic diseases, chemotherapy, bone marrow or solid organ transplantation:

- antibody to hepatitis B surface antigen (anti-HBs)
- plasma or serum HBV DNA level
- ALT.

1.5.49 In people who are HBsAg positive and have HBV DNA greater than 2000 IU/ml, offer prophylaxis with entecavir or tenofovir disoproxil[12].

- Start prophylaxis before beginning immunosuppressive therapy and continue for a minimum of 6 months after HBeAg seroconversion and HBV DNA is undetectable.

1.5.50 In people who are HBsAg positive and have HBV DNA less than 2000 IU/ml, offer prophylaxis.

© NICE 2013. All rights reserved. Last modified June 2013

- Consider lamivudine[12] if immunosuppressive therapy is expected to last less than 6 months.
  - Monitor HBV DNA monthly in people treated with lamivudine and change to tenofovir disoproxil if HBV DNA remains detectable after 3 months.
- Consider entecavir or tenofovir disoproxil[12] if immunosuppressive therapy is expected to last longer than 6 months.
- Start prophylaxis before beginning immunosuppressive therapy and continue for a minimum of 6 months after stopping immunosuppressive therapy.

1.5.51 In people who are HBsAg negative and anti-HBc positive (regardless of anti-HBs status) and are starting rituximab or other B cell-depleting therapies:

- offer prophylaxis with lamivudine[12]
- start prophylaxis before beginning immunosuppressive therapy and continue for a minimum of 6 months after stopping immunosuppressive therapy.

1.5.52 In people who are HBsAg negative, anti-HBc positive and anti-HBs negative and are not taking rituximab or other B cell-depleting therapies:

- monitor HBV DNA monthly and offer prophylaxis to people whose HBV DNA becomes detectable
  - consider lamivudine[12] in people with HBV DNA less than 2000 IU/ml and for whom immunosuppressive therapy is expected to last less than 6 months; change to tenofovir disoproxil if HBV DNA remains detectable after 6 months
  - consider entecavir or tenofovir disoproxil[12] in people with HBV DNA greater than 2000 IU/ml and for whom immunosuppressive therapy is expected to last longer than 6 months
  - continue antiviral therapy for a minimum of 6 months after stopping immunosuppressive therapy.

1.5.53 Do not offer prophylaxis to people who are HBsAg negative and anti-HBc and anti-HBs positive who are not taking rituximab or other B cell-depleting therapies.

© NICE 2013. All rights reserved. Last modified June 2013

1.6 Monitoring

Monitoring in people who do not meet criteria for antiviral treatment

Further information on the progression of chronic hepatitis B can be found in the Introduction (see Figure 1).

Adults with HBeAg-positive disease in the immune-tolerant and immune clearance phases

1.6.1 Monitor ALT levels every 24 weeks in adults with HBeAg-positive disease who are in the immune-tolerant phase (defined by active viral replication and normal ALT levels [less than 30 IU/L in males and less than 19 IU/L in females]).

1.6.2 Monitor ALT every 12 weeks on at least 3 consecutive occasions if there is an increase in ALT levels.

Adults with inactive chronic hepatitis B (immune-control phase)

1.6.3 Monitor ALT and HBV DNA levels every 48 weeks in adults with inactive chronic hepatitis B infection (defined as HBeAg negative on 2 consecutive tests with normal ALT [less than 30 IU/L in males and less than 19 IU/L in females] and HBV DNA less than 2000 IU/ml).

- Consider monitoring more frequently (for example, every 12–24 weeks) in people with cirrhosis who have undetectable HBV DNA.

Children and young people

1.6.4 Monitor ALT levels every 24 weeks in children and young people with HBeAg-positive disease who have normal ALT levels (less than 30 IU/L for males and less than 19 IU/L for females) and no evidence of significant fibrosis (METAVIR stage less than F2 or Ishak stage less than 3).

1.6.5 Review annually children and young people with HBeAg-negative disease who have normal ALT (less than 30 IU/L for males and less than 19 IU/L for

© NICE 2013. All rights reserved. Last modified June 2013

females), no evidence of significant fibrosis (METAVIR stage less than F2 or Ishak stage less than 3) and HBV DNA less than 2000 IU/ml.

1.6.6 Review every 12 weeks children and young people with HBeAg-negative disease who have abnormal ALT (greater than or equal to 30 IU/L for males and greater than or equal to 19 IU/L for females) and HBV DNA greater than 2000 IU/ml.

Children, young people and adults with HBeAg or HBsAg seroconversion after antiviral treatment

1.6.7 In people with HBeAg seroconversion after antiviral treatment, monitor HBeAg, anti-HBe, HBV DNA level and liver function at 4, 12 and 24 weeks after HBeAg seroconversion and then every 6 months.

1.6.8 Monitor HBsAg and anti-HBs annually in people with HBsAg seroconversion after antiviral treatment and discharge people who are anti-HBs positive on 2 consecutive tests.

Monitoring in people taking antiviral treatment

Children, young people and adults taking peginterferon alfa-2a

1.6.9 Review injection technique and adverse effects weekly during the first month of treatment in people taking peginterferon alfa-2a[10].

1.6.10 Monitor full blood count, liver function (including bilirubin, albumin and ALT), renal function (including urea and electrolyte levels) and thyroid function (and in children, weight and height) before starting peginterferon alfa-2a and 2, 4, 12, 24, 36 and 48 weeks after starting treatment to detect adverse effects[10].

1.6.11 Monitor HBV DNA and quantitative HBsAg levels and HBeAg status before starting peginterferon alfa-2a at 12, 24 and 48 weeks after starting treatment to determine treatment response[10].

© NICE 2013. All rights reserved. Last modified June 2013

Children, young people and adults with compensated liver disease taking entecavir or lamivudine

1.6.12 Monitor full blood count, liver function (including bilirubin, albumin and ALT) and renal function (including urea and electrolyte levels) in people with compensated liver disease before starting entecavir or lamivudine, 4 weeks after starting treatment and then every 3 months to detect adverse effects[10].

1.6.13 Monitor HBV DNA and quantitative HBsAg levels and HBeAg status before starting entecavir or lamivudine, 12, 24 and 48 weeks after starting treatment and then every 6 months to determine treatment response and medicines adherence[10].

1.6.14 Monitor HBV DNA levels every 12 weeks in people with HBeAg-negative disease who have been taking lamivudine for 5 years or longer[10].

Children, young people and adults with compensated liver disease taking tenofovir disoproxil

1.6.15 Monitor full blood count, liver function (including bilirubin, albumin and ALT), renal function (including urea and electrolyte levels and urine protein/creatinine ratio), and phosphate levels in people with compensated liver disease before starting tenofovir disoproxil, 4 weeks after starting treatment and then every 3 months to detect adverse effects[10].

1.6.16 Monitor HBV DNA and quantitative HBsAg levels and HBeAg status before starting tenofovir disoproxil, 12, 24 and 48 weeks after starting treatment and then every 6 months to determine treatment response and medicines adherence[10].

Children, young people and adults with decompensated liver disease who are taking entecavir or lamivudine

1.6.17 Monitor full blood count, liver function (including bilirubin, albumin and ALT), renal function (including urea and electrolyte levels and urine protein/creatinine ratio), blood clotting, HBV DNA level and HBeAg status in people with decompensated liver disease before starting entecavir or lamivudine and

© NICE 2013. All rights reserved. Last modified June 2013

weekly after starting treatment to assess treatment response and adverse effects. When the person is no longer decompensated, follow the recommendations in 'Children, young people and adults with compensated liver disease taking entecavir or lamivudine'[10].

Children, young people and adults with decompensated liver disease who are taking tenofovir disoproxil

1.6.18 Monitor full blood count, liver function (including bilirubin, albumin and ALT), renal function (including urea and electrolyte levels and urine protein/creatinine ratio) and phosphate, blood clotting, HBV DNA level and HBeAg status in people with decompensated liver disease before starting tenofovir disoproxil and weekly after starting treatment to assess treatment response and adverse effects. When the person is no longer decompensated, follow the recommendations in 'Children, young people and adults with compensated liver disease taking tenofovir disoproxil'[10].

1.7 Surveillance testing for hepatocellular carcinoma in adults with chronic hepatitis B

1.7.1 Perform 6-monthly surveillance for HCC by hepatic ultrasound and alpha-fetoprotein testing in people with significant fibrosis (METAVIR stage greater than or equal to F2 or Ishak stage greater than or equal to 3) or cirrhosis.

1.7.2 In people without significant fibrosis or cirrhosis (METAVIR stage less than F2 or Ishak stage less than 3), consider 6-monthly surveillance for HCC if the person is older than 40 years and has a family history of HCC and HBV DNA greater than or equal to 20,000 IU/ml.

1.7.3 Do not offer surveillance for HCC in people without significant fibrosis or cirrhosis (METAVIR stage less than F2 or Ishak stage less than 3) who have HBV DNA less than 20,000 IU/ml and are younger than 40 years.

[4] Adults with a transient elastography score greater than or equal to 11 kPa are very likely to have cirrhosis and confirmation by liver biopsy is not needed.

© NICE 2013. All rights reserved. Last modified June 2013

[5] The degree of fibrosis cannot be accurately predicted in adults with a transient elastography score between 6 to 10 kPa. Some people may choose to have a liver biopsy in these circumstances to confirm the extent of liver disease.

[6] Adults with a transient elastography score less than 6 kPa are unlikely to have significant fibrosis.

[7] Adefovir dipivoxil and peginterferon alfa-2a for the treatment of chronic hepatitis B (NICE technology appraisal guidance 96), Entecavir for the treatment of chronic hepatitis B (NICE technology appraisal guidance 153), Telbivudine for the treatment of chronic hepatitis B (NICE technology appraisal guidance 154) and Tenofovir disoproxil fumarate for the treatment of hepatitis B (NICE technology appraisal guidance 173).

[8] Avoid use of peginterferon alfa-2a in pregnancy unless the potential benefit outweighs risk. Women of childbearing potential must use effective contraception throughout therapy.

[9] At the time of publication (June 2013), peginterferon alfa-2a did not have a U□ marketing authorisation for use in children for this indication. The prescriber should follow relevant professional guidance, taking full responsibility for the decision. Informed consent should be obtained and documented. See the General Medical Council's Good practice in prescribing medicines □guidance for doctors for further information.

[10] At the time of publication (June 2013), peginterferon alfa-2a and entecavir did not have a U□ marketing authorisation for use in children for this indication, and tenofovir disoproxil did not have a U□ marketing authorisation for use in children younger than 12 years for this indication. The prescriber should follow relevant professional guidance, taking full responsibility for the decision. Informed consent should be obtained and documented. See the General Medical Council's Good practice in prescribing medicines □guidance for doctors for further information.

[11] At the time of publication (June 2013), tenofovir disoproxil did not have a U□ marketing authorisation for this indication. The prescriber should follow relevant professional guidance, taking full responsibility for the decision. Informed consent should be obtained and documented. See the General Medical Council's Good practice in prescribing medicines □guidance for doctors for further information.

© NICE 2013. All rights reserved. Last modified June 2013

[12] At the time of publication (June 2013), entecavir, lamivudine and tenofovir disoproxil did not have a U□ marketing authorisation for this indication. The prescriber should follow relevant professional guidance, taking full responsibility for the decision. Informed consent should be obtained and documented. See the General Medical Council's Good practice in prescribing medicines □guidance for doctors for further information.

2 Research recommendations

The Guideline Development Group has made the following recommendations for research, based on its review of evidence, to improve NICE guidance and patient care in the future.

2.1 Stopping antiviral treatment in HBeAg-negative disease

Further research should be undertaken to evaluate the clinical and cost effectiveness of hepatitis B surface antigen (HBsAg) quantitative assays in determining treatment duration in hepatitis B e antigen- (HBeAg) negative disease.

Why this is important

In HBeAg-positive disease, HBeAg seroconversion is a predictor of durable response to antiviral treatment and can be used as a milestone after which treatment can be stopped. At present, similar parameters have not been defined in HBeAg-negative disease. □uantitative HBsAg may have a role in determining treatment duration in this setting. Establishing threshold levels for HBsAg titre associated with durable off-treatment control in HBeAg-negative disease would transform current treatment strategies. People on long-term nucleoside or nucleotide analogues could safely stop treatment once they achieved a threshold level of HBsAg. Further research is needed to define these levels of HBsAg and to determine when treatment in HBeAg-negative disease can be safely stopped.

2.2 ALT values for children and young people

Further research should be undertaken to examine whether the upper limit of normal ALT values for adults (below 30 IU/L for males and below 19 IU/L for females) are appropriate for use in children and young people with chronic hepatitis B when making decisions on when to initiate treatment.

Why this is important

Recent studies have highlighted the imprecision of using biochemical activity as a measure of immune activity in children and young people with chronic hepatitis B. Researchers have found T-cell exhaustion and even HBV-specific immune responses in children and young people considered to have immune-tolerant disease. These findings need to be validated in larger

© NICE 2013. All rights reserved. Last modified June 2013

studies to see if upper limit of normal ALT values derived from adults accurately reflect disease activity in children and young people. Further research is needed to investigate whether there is a genuine state of immune tolerance in children and young people reflected in lower levels of biochemical activity and a lower upper limit of normal ALT value.

2.3 Long-term safety of tenofovir disoproxil in chronic hepatitis B

Further research should be undertaken to determine the long-term safety of tenofovir disoproxil, including the risk of clinically significant hypophosphataemia and related bone toxicity, in people with chronic hepatitis B. The cost effectiveness of routine monitoring for phosphate loss and bone disease in people with chronic hepatitis B who are receiving tenofovir disoproxil treatment needs further evaluation.

Why this is important

Tenofovir disoproxil is recommended as an option for treatment of people with chronic hepatitis B, and is typically prescribed for long-term use. □idney dysfunction has been reported in people treated with tenofovir disoproxil, including rare cases of proximal renal tubular dysfunction that appear related to long-term exposure but are not well understood. Adverse renal effects such as hypophosphataemia may have an impact on bone architecture which could result in clinical problems such as fragility fractures. Monitoring for phosphate loss and bone disease could have a role in preventing clinically significant bone problems in people with chronic hepatitis B receiving long-term tenofovir disoproxil. However, the cost effectiveness and clinical utility of routine monitoring needs to be established before recommendations can be made about its use.

2.4 Prophylactic treatment in people receiving immunosuppressive therapy

Further research should be undertaken to determine whether long-term use of mild immunosuppressive agents for autoimmune and allergic problems presents a risk for reactivation of HBV infection in people with previous or current chronic hepatitis B, including occult HBV infection. The cost effectiveness of routine tests for HBV in this population, including HBV DNA for occult HBV infection, and the need for prophylactic treatment with nucleoside or nucleotide analogues needs further evaluation.

© NICE 2013. All rights reserved. Last modified June 2013

Why this is important

Reactivation of HBV may occur spontaneously or arise during immunosuppression. Solid organ transplantation, chemotherapy and immunosuppressive drugs used to treat autoimmune diseases are key causes of HBV reactivation. Antiviral agents can be used as prophylaxis to prevent reactivation of HBV infection in people receiving immunosuppressive therapy but the optimal treatment and duration of therapy are unknown. Decision-making and cost-effectiveness studies are needed to determine optimal screening strategies to identify people at risk of HBV reactivation. People with occult HBV (including people coming from high endemicity regions) might carry a low, but not negligible, risk of viral reactivation. Prospective studies are needed to assess the risk of HBV reactivation in people receiving mild immunosuppressants or biological treatment for autoimmune diseases, to identify risk factors that predict HBV reactivation in this population, and evaluate treatment or pre-emptive strategies using existing nucleoside and nucleotide analogues.

3 Other information

3.1 Scope and how this guideline was developed

NICE guidelines are developed in accordance with a scope that defines what the guideline will and will not cover.

How this guideline was developed

NICE commissioned the National Clinical Guideline Centre to develop this guideline. The Centre established a Guideline Development Group (see section 4), which reviewed the evidence and developed the recommendations.

The methods and processes for developing NICE clinical guidelines are described in The guidelines manual.

3.2 Related NICE guidance

Details are correct at the time of consultation on the guideline (January 2013). Further information is available on the NICE website.

Published

General

- Patient experience in adult NHS services. NICE clinical guidance 138 (2012).
- Medicines adherence. NICE clinical guidance 76 (2011).
- Looked-after children and young people. NICE public health guidance 28 (2010)

Condition-specific

- Hepatitis B and C: ways to promote and offer testing to people at increased risk of infection. NICE public health guidance 43 (2012).
- Increasing the uptake of HIV testing among men who have sex with men. NICE public health guidance 34 (2011).

4 The Guideline Development Group, National Collaborating Centre and NICE project team

4.1 Guideline Development Group

Aftab Ala
Consultant Gastroenterologist and Hepatologist, Frimley Park Hospital NHS Foundation Trust, Surrey

Elizabeth Boxall
Virologist and consultant clinical scientist

Steven Bradley (September 2011 □ January 2012, replaced by Sarah Wise)
Patient and carer member

Ashley Brown (co-optee)
Consultant Hepatologist, Imperial College, London

Joyeta Das (co-optee)
Lead Pharmacist, Hepatology, Imperial College Healthcare NHS Trust, London

Geoffrey Dusheiko
Professor of Medicine, UCL Division of Liver and Digestive Health and Royal Free Hospital, University College London Medical School

Patrick Kennedy
Consultant Hepatologist and Senior Lecturer, Barts and the London NHS Trust

Emily Lam
Patient and carer member

Alan Mitchell
General Practitioner and Clinical Director, Renfrewshire Community Health Partnership and East Renfrewshire Community Health and Care Partnership

© NICE 2013. All rights reserved. Last modified June 2013

Angela Narbey
Nurse consultant, liver disease, □ueen Elizabeth Hospital, Woolwich

Nadia Permaloo (co-optee)
Regional antenatal screening coordinator, London □hosted by Inner North West London NHS for the National Screening Committee

Howard Thomas (Chair)
Emeritus Professor, Department of Hepatology and Gastroenterology Division of Medicine, Imperial College, London

Gareth Tudor-Williams
Reader in Paediatric Infectious Diseases, Imperial College, London

Javier Vilar
Consultant in Infectious Diseases, North Manchester General Hospital, Pennine Acute Hospitals

Sarah Wise (April □September 2012, not replaced)
Patient and carer member

Changes after publication

January 2014: A correction has been made to the units used for abnormal alanine aminotransferase (ALT) in men and women. The abnormal ALT levels should read greater than or equal to 30 IU/L for males and greater than or equal to 19 IU/L for females, not IU/ml. This has been changed in recommendations 1.3.6, 1.3.7, 1.3.10, 1.5.3□5, 1.5.31, 1.6.1, 1.6.3□6, and 2.2.

About this guideline

NICE clinical guidelines are recommendations about the treatment and care of people with specific diseases and conditions in the NHS in England and Wales.

NICE guidelines are developed in accordance with a scope that defines what the guideline will and will not cover.

This guideline was developed by the National Clinical Guideline Centre, which is based at the Royal College of Physicians. The Centre worked with a Guideline Development Group, comprising healthcare professionals (including consultants, GPs and nurses), patients and carers, and technical staff, which reviewed the evidence and drafted the recommendations. The recommendations were finalised after public consultation.

The methods and processes for developing NICE clinical guidelines are described in The guidelines manual.

Update information

In this guideline, recommendations 1.5.13 to 1.5.15 update and replace recommendations 1.2 to 1.4 on the use of adefovir dipivoxil for treating chronic hepatitis B in Adefovir dipivoxil and peginterferon alfa-2a for the treatment of chronic hepatitis B (NICE technology appraisal guidance 96). NICE technology appraisal guidance 153, 154, 173 and recommendation 1.1 of NICE technology appraisal guidance 96 have been incorporated into this guideline and remain extant.

Strength of recommendations

Some recommendations can be made with more certainty than others. The Guideline Development Group makes a recommendation based on the trade-off between the benefits and harms of an intervention, taking into account the quality of the underpinning evidence. For some interventions, the Guideline Development Group is confident that, given the information it has looked at, most patients would choose the intervention. The wording used in the recommendations in this guideline denotes the certainty with which the recommendation is made (the strength of the recommendation).

© NICE 2013. All rights reserved. Last modified June 2013

For all recommendations, NICE expects that there is discussion with the patient about the risks and benefits of the interventions, and their values and preferences. This discussion aims to help them to reach a fully informed decision (see also Patient-centred care).

Interventions that must (or must not) be used

We usually use 'must' or 'must not' only if there is a legal duty to apply the recommendation. Occasionally we use 'must' (or 'must not') if the consequences of not following the recommendation could be extremely serious or potentially life threatening.

Interventions that should (or should not) be used □ a 'strong' recommendation

We use 'offer' (and similar words such as 'refer' or 'advise') when we are confident that, for the vast majority of patients, an intervention will do more good than harm, and be cost effective. We use similar forms of words (for example, 'Do not offer□ ') when we are confident that an intervention will not be of benefit for most patients.

Interventions that could be used

We use 'consider' when we are confident that an intervention will do more good than harm for most patients, and be cost effective, but other options may be similarly cost effective. The choice of intervention, and whether or not to have the intervention at all, is more likely to depend on the patient's values and preferences than for a strong recommendation, and so the healthcare professional should spend more time considering and discussing the options with the patient.

Other versions of this guideline

The full guideline, 'Hepatitis B (chronic): Diagnosis and management of chronic hepatitis B in children, young people and adults' contains details of the methods and evidence used to develop the guideline. It is published by the National Clinical Guideline Centre.

The recommendations from this guideline have been incorporated into a NICE Pathway.

We have produced information for the public about this guideline.

Implementation

Implementation tools and resources to help you put the guideline into practice are also available.

Your responsibility

This guidance represents the view of NICE, which was arrived at after careful consideration of the evidence available. Healthcare professionals are expected to take it fully into account when exercising their clinical judgement. However, the guidance does not override the individual responsibility of healthcare professionals to make decisions appropriate to the circumstances of the individual patient, in consultation with the patient and/or guardian or carer, and informed by the summaries of product characteristics of any drugs.

Implementation of this guidance is the responsibility of local commissioners and/or providers. Commissioners and providers are reminded that it is their responsibility to implement the guidance, in their local context, in light of their duties to have due regard to the need to eliminate unlawful discrimination, advance equality of opportunity and foster good relations. Nothing in this guidance should be interpreted in a way that would be inconsistent with compliance with those duties.

July 2013

Evidence

KEY TO EVIDENCE STATEMENTS AND GRADES OF RECOMMENDATIONS

LEVELS OF EVIDENCE	
1^{++}	High quality meta-analyses, systematic reviews of RCTs, or RCTs with a very low risk of bias
1^{+}	Well conducted meta-analyses, systematic reviews, or RCTs with a low risk of bias
1^{-}	Meta-analyses, systematic reviews, or RCTs with a high risk of bias
2^{++}	High quality systematic reviews of case control or cohort studies High quality case control or cohort studies with a very low risk of confounding or bias and a high probability that the relationship is causal
2^{+}	Well conducted case control or cohort studies with a low risk of confounding or bias and a moderate probability that the relationship is causal
2^{-}	Case control or cohort studies with a high risk of confounding or bias and a significant risk that the relationship is not causal
3	Non-analytic studies, eg case reports, case series
4	Expert opinion

GRADES OF RECOMMENDATION	
Note: The grade of recommendation relates to the strength of the evidence on which the recommendation is based. It does not reflect the clinical importance of the recommendation.	
A	At least one meta-analysis, systematic review, or RCT rated as 1^{++}, and directly applicable to the target population; or A body of evidence consisting principally of studies rated as 1^{+}, directly applicable to the target population, and demonstrating overall consistency of results
B	A body of evidence including studies rated as 2^{++}, directly applicable to the target population, and demonstrating overall consistency of results; *or* Extrapolated evidence from studies rated as 1^{++} or 1^{+}
C	A body of evidence including studies rated as 2^{+}, directly applicable to the target population and demonstrating overall consistency of results; *or* Extrapolated evidence from studies rated as 2^{++}
D	Evidence level 3 or 4; or Extrapolated evidence from studies rated as 2^{+}

GOOD PRACTICE POINTS	
✓	Recommended best practice based on the clinical experience of the guideline development group

NHS Evidence
accredited provider
NHS Evidence - provided by NICE
www.evidence.nhs.uk

NHS Evidence has accredited the process used by **Scottish Intercollegiate Guidelines Network** to produce guidelines. Accreditation is applicable to guidance produced using the processes described in SIGN 50: a guideline developer's handbook, 2008 edition (**www.sign.ac.uk/guidelines/fulltext/50/index.html**). More information on accreditation can be viewed at **www.evidence.nhs.uk**

Healthcare Improvement Scotland (HIS) is committed to equality and diversity and assesses all its publications for likely impact on the six equality groups defined by age, disability, gender, race, religion/belief and sexual orientation.

SIGN guidelines are produced using a standard methodology that has been **equality impact assessed** to ensure that these equality aims are addressed in every guideline. This methodology is set out in the current version of SIGN 50, our guideline manual, which can be found at **www.sign.ac.uk/guidelines/fulltext/50/index.html.** The EQIA assessment of the manual can be seen at **www.sign.ac.uk/pdf/sign50eqia.pdf.** The full report in paper form and/or alternative format is available on request from the Healthcare Improvement Scotland Equality and Diversity Officer.

Every care is taken to ensure that this publication is correct in every detail at the time of publication. However, in the event of errors or omissions corrections will be published in the web version of this document, which is the definitive version at all times. This version can be found on our web site **www.sign.ac.uk.**

This document is produced from elemental chlorine-free material and is sourced from sustainable forests.

1 Introduction

1.1 THE NEED FOR A GUIDELINE

The hepatitis C virus (HCV) was first identified in 1989 and HCV infection has become a major health problem worldwide.[1] Approximately 0.8% of the Scottish population are thought to be chronically infected with HCV (around 37,500 individuals). The prevalence of infection varies between population groups, ranging from 50% in injecting drug users (IDU) to less than 0.04% among new blood donors.[1]

Up to 80% of patients infected with HCV become chronically infected and most of these patients will show evidence of chronic hepatitis.[2]

Hepatitis C is usually slowly progressive over a period of many years. Five to fifteen per cent of patients with chronic hepatitis may progress to liver cirrhosis over 20 years.[3] Four to nine per cent of patients with cirrhosis will develop liver failure; and two to five per cent of patients with cirrhosis will develop hepatocellular carcinoma (HCC) per annum.

In the UK the two major routes of transmission of HCV have been sharing of drug injecting equipment by IDU and transfusion of infected blood or blood products. Virus inactivation treatment of blood products began in 1987 and from 1991 blood has been screened for hepatitis C, virtually eliminating blood products as a source of HCV infection.

HCV infection can be effectively treated with combination drug therapy (pegylated interferon alfa and ribavirin) with sustained viral response (SVR) rates in 50-80% of patients. Although there are existing guidelines for the selection of patients for treatment[4-7] there are no national guidelines for screening, testing, diagnosis, service configuration, care during treatment or post-treatment follow up in adults or children.

1.1.1 UPDATING THE EVIDENCE

This guideline updates SIGN 92: Management of hepatitis C to reflect the most recent evidence around protease inhibitor treatment as an adjunct to current standard dual therapy treatment.

This update was limited in scope and covered treatment of chronic hepatitis C (CHC), provision of information for patients and carers and several other minor updates (*see section 1.2.3 and Annex 1*. In the sections not updated text and recommendations are reproduced verbatim from SIGN 92. The original supporting evidence was not re-appraised by the current guideline development group.

1.2 REMIT OF THE GUIDELINE

1.2.1 OVERALL OBJECTIVES

The guideline provides evidence based recommendations covering all stages of the patient care pathway; screening, testing, diagnosis, referral, treatment, care and follow up of infants, children and adults with, or exposed to, HCV infection. The remit encompasses prevention of secondary transmission of the virus but specifically excludes primary prevention of HCV infection. Primary prevention of hepatitis C infection is an important public health concern but is outwith the remit of this guideline. The principles and evidence for the prevention of blood borne viruses are generalisable and while reviewing this large body of evidence would have been beyond the capacity of the guideline development group, reviewing the HCV evidence alone would have produced a distorted view.

1.2.2 TARGET USERS OF THE GUIDELINE

This guideline will be of interest to all health professionals in primary and secondary care involved in the management of people with hepatitis C infection.

1.2.3 SUMMARY OF UPDATES TO THE GUIDELINE, BY SECTION

2	Key recommendations	New
4	Prevention of secondary transmission	Minor update at 4.1
6	Children and hepatitis C	Minor update at 6.4
8	Assessment of liver disease	Minor update at 8.2
10	Treatment of chronic hepatitis C	Completely revised at 10.1, 10.2, 10.3.1, 10.3.3, 10.3.4, 10.3.6, 10.6.2, 10.6.4, 10.6.10 and 10.7.1
11	Treatment of advanced infection	Minor update at 11.1.1
13	Provision of information	Completely revised
14	Implementing the guideline	Minor update

1.3 STATEMENT OF INTENT

This guideline is not intended to be construed or to serve as a standard of care. Standards of care are determined on the basis of all clinical data available for an individual case and are subject to change as scientific knowledge and technology advance and patterns of care evolve. Adherence to guideline recommendations will not ensure a successful outcome in every case, nor should they be construed as including all proper methods of care or excluding other acceptable methods of care aimed at the same results. The ultimate judgement must be made by the appropriate healthcare professional(s) responsible for clinical decisions regarding a particular clinical procedure or treatment plan. This judgement should only be arrived at following discussion of the options with the patient, covering the diagnostic and treatment choices available. It is advised, however, that significant departures from the national guideline or any local guidelines derived from it should be fully documented in the patient's case notes at the time the relevant decision is taken.

1.3.1 PRESCRIBING OF LICENSED MEDICINES OUTWITH THEIR MARKETING AUTHORISATION

Recommendations within this guideline are based on the best clinical evidence. Some recommendations may be for medicines prescribed outwith the marketing authorisation (MA) also known as product licence. This is known as 'off label' use.

Medicines may be prescribed off label in the following circumstances:

- for an indication not specified within the marketing authorisation
- for administration via a different route
- for administration of a different dose
- for a different patient population.

An unlicensed medicine is a medicine which does not have MA for medicinal use in humans.

Generally the off label use of medicines becomes necessary if the clinical need cannot be met by licensed medicines within the marketing authorisation. Such use should be supported by appropriate evidence and experience. [8]

"Prescribing medicines outside the conditions of their marketing authorisation alters (and probably increases) the prescribers' professional responsibility and potential liability". [8]

The General Medical Council (GMC) recommends that when prescribing a medicine off-label, doctors should:

- be satisfied that such use would better serve the patient's needs than an authorised alternative (if one exists)
- be satisfied that there is sufficient evidence/experience of using the medicines to show its safety and efficacy, seeking the necessary information from appropriate sources
- record in the patient's clinical notes the medicine prescribed and, when not following common practice, the reasons for the choice
- take responsibility for prescribing the medicine and for overseeing the patient's care, including monitoring the effects of the medicine.

Non-medical prescribers should ensure that they are familiar with the legislative framework and their own professional prescribing standards.

Prior to any prescribing, the licensing status of a medication should be checked in the current version of the British National Formulary (BNF). [8] The prescriber must be competent, operate within the professional code of ethics of their statutory bodies and the prescribing practices of their employers. [9]

1.3.2 ADDITIONAL ADVICE TO NHSSCOTLAND FROM HEALTHCARE IMPROVEMENT SCOTLAND AND THE SCOTTISH MEDICINES CONSORTIUM

Healthcare Improvement Scotland processes multiple technology appraisals (MTAs) for NHSScotland that have been produced by the National Institute for Health and Care Excellence (NICE) in England and Wales.

The Scottish Medicines Consortium (SMC) provides advice to NHS Boards and their Area Drug and Therapeutics Committees about the status of all newly licensed medicines and any major new indications for established products.

SMC advice relevant to this guideline is summarised in section 14.

2 Key recommendations

The following recommendations were highlighted by the guideline development group as the key clinical recommendations that should be prioritised for implementation. The grade of recommendation relates to the strength of the supporting evidence on which the recommendation is based. It does not reflect the clinical importance of the recommendation.

2.1 TREATMENT OF CHRONIC HEPATITIS C

A **All treatment-naive patients infected with HCV genotype 1 should be considered for treatment with pegylated IFN and weight-based ribavirin with the addition of a protease inhibitor as triple therapy.**

A **All treatment-experienced patients infected with HCV genotype 1 should be considered for treatment with pegylated IFN and weight-based ribavirin with the addition of a protease inhibitor as triple therapy.**

B **Treatment-naive patients co-infected with HIV and HCV genotype 1 who are unsuitable for treatment with a regimen which includes HCV protease inhibitors should be considered for treatment with pegylated IFN and weight-based ribavirin for 48-72 weeks depending on viral response.**

The recent availability of protease inhibitors to use with pegylated IFN and ribavirin in triple therapy, has significantly improved the SVR rates for patients with genotype 1 HCV infection with the prospect of reducing the overall length of treatment depending on response to therapy. Genotype 2 and 3 HCV infected patients continue to achieve high SVR rates with pegylated IFN and ribavirin dual therapy. These combination treatments should be discussed and offered as standard of care to all suitable patients with HCV infection.

2.2 CHILDREN AND HEPATITIS C

A **Children infected with all genotypes of hepatitis C with evidence of moderate or severe liver disease should be considered for treatment with pegylated IFN and ribavirin.**

B **Children infected with HCV genotypes 2 and 3 should be considered for treatment with pegylated IFN and ribavirin irrespective of disease stage.**

C **In children with mild disease and infection with other genotypes, benefits of treatment need to be balanced against risks of side effects.**

The outcome in children after treatment with pegylated IFN and ribavirin is equivalent to that in adults.[10] Side effects of treatment are seen with similar frequency and weekly injections cause distress. The advantages of achieving SVR early in life, eliminating the risk of onward transmission (particularly before girls reach child bearing age) and before the onset of chronic liver disease, will outweigh these disadvantages in many children infected with favourable genotypes. However, for those with less favourable genotypes and no evidence of chronic liver disease, it is appropriate to wait until more effective and acceptable treatment becomes available.

2.3 TESTING

D **Dried blood spot testing should be considered as a convenient and cost-effective method of accessing some target populations.**

D **There should be consideration given to methods to raise awareness and highlight information regarding hepatitis C amongst at-risk groups and the general public. The targeting of awareness campaigns to particular audiences is recommended. Staff should have access to appropriate training.**

D **Anyone who has a negative test but remains at risk of infection should be offered further testing on an annual basis.**

D **Testing for HCV should be offered to migrants from countries with a medium or high prevalence of HCV.**

The NICE guidance *Hepatitis B and C: Ways to promote and offer testing to people at increased risk of infection* [11] contains a number of key recommendations on testing. Although designed for the NHS in England and Wales it has direct applicability to Scotland on testing for HCV.

3 Testing

3.1 CLINICAL AND COST-EFFECTIVE TESTING FOR HEPATITIS C VIRUS

National and international guidelines recommend that individuals who have an excess risk of being infected and might benefit from knowing their HCV status should be offered an HCV test.[5, 12-14] This recommendation is based primarily on the need to diagnose an often silent infection, allowing the initiation of prompt antiviral treatment if appropriate.[15] Since treatment cannot be offered unless a diagnosis of chronic HCV infection is made, the offering, and uptake, of testing among populations at risk of HCV will convey a degree of clinical benefit. **4**

Further benefits of diagnosing people infected with HCV include the opportunity to convey information aimed at slowing the rate of HCV disease progression (such as advice about the dangers of excess alcohol consumption) and reducing the chances of infection being transmitted to others. No robust, consistent evidence to indicate the effectiveness of these interventions was identified.

UK guidelines consistently recommend that people who may convey an HCV risk to patients in the healthcare setting should undergo HCV testing.[5, 12-14] Several instances of healthcare worker to patient and blood/organ donor to recipient transmission of HCV have been recorded.[16, 17] **4**

Controlled trials or cohort studies to gauge the cost effectiveness of offering an HCV test to different population groups have not been undertaken. Limited evidence from economic modelling work indicates that offering an HCV test to former injecting drug users (IDU) in drug treatment and perhaps other settings would convey cost-effective clinical benefits.[18] Former IDU are more likely to have a higher prevalence of HCV and comply with therapy than current IDU. Models of best practice for the identification and testing of former IDU have not been developed and evaluated. Expert opinion suggests that general practices, particularly those that serve areas with a high prevalence of drug use, may constitute environments where focused, well supported testing initiatives might be successful. Prisons may also offer similar opportunities.[19] Targeted and generalised HCV awareness/testing campaigns have been conducted but no evaluations of their success in encouraging people (including former IDU) at high risk of HCV to engage with services have been reported. **4**

In populations where prevalence of HCV is low (eg genitourinary medicine clinic attendees), economic modelling indicates that universal testing does not convey cost-effective clinical benefit.[18] **4**

D **The following groups should be tested for HCV:**

- **blood/tissue donors**
- **patients on haemodialysis**
- **healthcare professionals who intend to pursue a career in a specialty that requires them to perform exposure prone procedures.**

D **The following groups should be offered an HCV test:**

- **patients with an otherwise unexplained persistently elevated alanine aminotransferase**
- **people with a history of injecting drug use**
- **people who are human immunodeficiency virus (HIV) positive**
- **recipients of blood clotting factor concentrates prior to 1987**
- **recipients of blood and blood components before September 1991 and organ/tissue transplants in the UK before 1992**
- **children whose mother is known to be infected with HCV**
- **healthcare professionals following percutaneous or mucous membrane exposure to blood which is, or is suspected to be, infected with HCV**
- **people who have received medical or dental treatment in countries where HCV is common and infection control may be poor**
- **people who have had tattoos or body piercing in circumstances where infection control procedure is, or is suspected to be, suboptimal**
- **people who have had a sexual partner or household contact who is HCV infected.**

The NICE guidance *Hepatitis B and C: Ways to promote and offer testing to people at increased risk of infection* [11] contains a number of key recommendations on testing. Although designed for the NHS in England and Wales it has direct applicability to Scotland on testing for HCV. | **4**

D **Dried blood spot testing should be considered as a convenient and cost-effective method of accessing some target populations.**

D **There should be consideration given to methods to raise awareness and highlight information regarding hepatitis C amongst at-risk groups and the general public. The targeting of awareness campaigns to particular audiences is recommended. Staff should have access to appropriate training.**

D **Anyone who has a negative test but remains at risk of infection should be offered further testing on an annual basis.**

D **Testing for HCV should be offered to migrants from countries with a medium or high prevalence of HCV.**

3.2 HEPATITIS C VIRUS DIAGNOSTIC TESTING

3.2.1 PRINCIPLES OF TESTING

Detection of viral ribonucleic acid (RNA) by nucleic acid tests (NAT, usually using reverse transcriptase polymerase chain reaction; RT PCR) indicates current infection. Detection of antibodies indicates resolved or current infection. The testing algorithm suggested in Figure 1 is based on:

Diagnostic assays are most reliable when used on plasma or serum.[20] | **2++**

Assays for antibody in saliva are very sensitive if optimum salivary collection devices and modified enzyme linked immunosorbent assays (ELISA) are used, but NAT for viral RNA is unreliable.[20-22] | **2++**

Nucleic acid testing sensitive enough to detect 50-100 IU/ml of virus must be performed to detect current infection.[23] | **2+**

Viral RNA can be detected as early as one to two weeks after infection, whereas antibody can be detected at seven to eight weeks after infection.[24] | **4**

Antibody to infection may not be generated, particularly if the individual is immune-suppressed.[25] | **4**

Following acute infection, HCV RNA may oscillate between positive and negative for several months. Results from samples taken at this time may be misleading.[24] In an individual positive for HCV antibody, but negative for HCV RNA, a second sample should be tested to confirm the initial diagnosis, especially as the date of infection is unknown in most cases. **4**

Individuals with a positive HCV antibody test and repeatedly negative RNA do not require further active management of hepatitis C infection.[25] **4**

Since hepatitis C is a serious communicable disease, after an initial laboratory diagnosis, a second sample should be taken from the patient to confirm correct identification of the original sample.[26] **4**

Genotyping of individuals with proven HCV infection is required to determine likely response to treatment. Those with genotype 1 infection require longer duration of treatment than those with genotype 2 and 3 (*see section 10.2.1*).[27] **1++**

Expert guidance suggests that healthcare professionals who have, or might have, sustained an occupational exposure to HCV should be offered RNA testing at 6, 12 and 24 weeks, with anti-HCV testing at 12 and 24 weeks.[28] **4**

B **Diagnostic testing for HCV should be performed on serum or plasma where possible.**

D **HCV genotyping should be undertaken if antiviral therapy is being considered.**

D **Following an isolated acute percutaneous exposure to blood infected, or strongly suspected of being infected, with HCV, healthcare professionals should be offered HCV RNA testing at six, 12 and 24 weeks and anti-HCV testing at 12 and 24 weeks.**

4 Prevention of secondary transmission

Secondary transmission is defined as the onward transmission of infection from individuals who are known to be HCV infected.

4.1 TRANSMISSION THROUGH SEXUAL AND HOUSEHOLD CONTACT

Observational studies indicate that there is a very small risk of people with diagnosed HCV infection transmitting infection to their family, or close contacts, and sexual partners. Cohort studies of couples discordant for HCV indicated an HCV incidence of 0-2 per 1,000 years of sexual contact.[29-31] Those with HIV co-infection, particularly men who have sex with men, may be more likely to transmit HCV to their sexual partners.[32, 33] The findings suggest that transmission may occur through exposure to blood as a consequence of, for example, the sharing of razors and toothbrushes (ie activities which might result in percutaneous or mucous membrane exposure to infected blood), and through unprotected sexual intercourse. **2+ 1-**

No studies were identified to ascertain if interventions such as educational initiatives, including the promotion of condom use, aimed at people diagnosed with HCV infection, are effective in reducing the frequency of such risk behaviours and/or preventing associated secondary transmission of HCV. Expert opinion suggests that people infected with HCV should be advised that the use of condoms and the avoidance of activities which could lead to percutaneous or mucous membrane exposure to infected blood will eliminate the albeit very small risk of them transmitting the virus to others.[14, 34] **4**

✓ After being advised of the low risk of HCV being transmitted sexually, individuals infected with HCV should be asked to consider using condoms for sexual intercourse if they are men who have sex with men or if either partner is infected with HIV.

D **Individuals co-infected with HIV/HCV should be advised always to practice safe sex and use condoms.**

D **Individuals infected with HCV should be advised to avoid activities which could result in percutaneous or mucous membrane exposure to their infected blood, such as the sharing of razors and toothbrushes.**

4.2 TRANSMISSION THROUGH INJECTING DRUG USE

The sharing of injecting equipment by drug users is the principal means through which infection is transmitted in developed countries.[14, 34] Observational data demonstrate that interventions such as needle and syringe exchange and methadone maintenance therapy are likely to have reduced, though not controlled, HCV transmission among IDU in a number of countries including Scotland.[35] Studies of interventions aimed specifically at preventing IDU known to be infected with HCV transmitting their infection to others through the sharing of injecting equipment, were not identified. **2+**

No robust consistent evidence on the influence of knowledge of HCV infection status among IDU on their injecting risk behaviour was identified. Expert opinion suggests that advising current IDU with chronic HCV on how to prevent transmission of their infection to other IDU, through for example safe injecting practice, may be an effective intervention.[14,34] **4**

D **Injecting drug users known to be infected with HCV should be given advice on how they can prevent transmission of infection to other injecting drug users.**

4.3 TRANSMISSION BETWEEN HEALTHCARE PROFESSIONALS AND PATIENTS

4.3.1 RISK OF HEALTHCARE PROFESSIONAL INFECTION

Expert opinion suggests that infection control precautions should be standard and universal and not determined by knowledge of patients' blood borne virus status.[36] **4**

Estimates of transmission risk following needlestick injury vary, with one large prospective study of 4,403 exposed healthcare professionals finding an overall transmission rate of 0.31%, whilst a review of 25 smaller studies reported a combined rate of 1.9% from 2,357 exposures.[16, 37] The relative risk is higher when injuries are deep and from blood filled needles. Risk arising from superficial or mucocutatenous exposures is likely to be much lower, though difficult to quantify, while transmission from solid needles is extremely unlikely.[37] Transmission occurs only from RNA positive sources. **2+ 4**

✓ Standard infection control precautions against blood borne virus transmission should be undertaken by all healthcare professionals regardless of the patient's known or suspected infective status.

✓ Healthcare professionals sustaining needlestick injuries from HCV infected sources should be advised that:

- the overall risk of transmission is probably less than 2% and may be much lower
- the risk is higher from deep injuries and from blood filled needles
- transmission from solid needles is very unlikely.

4.3.2 RISK OF PATIENT INFECTION

Several reports have shown that HCV can be transmitted from healthcare professionals to patients.[17] Most of these occurred after exposure-prone procedures usually after deep-cavity surgery. Estimates of transmission rates to patients in two retrospective analyses involving infected cardiothoracic surgeons were 2.3% and 0.36%, whilst the risk of transmission from an infected gynaecologist was only 0.04%.[38-40] UK health departments advise that healthcare professionals who are HCV RNA positive should not undertake exposure prone procedures.[17, 41] **3 4**

D **Healthcare professionals who are aware they are HCV RNA positive should not undertake exposure-prone procedures.**

5 Referral

Referral to specialist care should be considered for all patients with active HCV infection (HCV RNA positive) and not be restricted to potential candidates for antiviral therapy. Specialist clinics are often a source of information for patients and relatives, including health promotion and methods of avoiding secondary transmission of the virus.

Modelling suggests that 90% of individuals with HCV in Scotland are current or former IDU.[1] Factors associated with injecting drug use (eg poverty, chaotic lifestyle, comorbidity, including alcohol dependence) can be obstacles to individuals navigating their way through and remaining in investigation, referral and treatment pathways.[15, 19] Expert consensus suggests that uptake of services may be improved by integrated multidisciplinary care which also addresses, for example, individuals' alcohol and drug use problems simultaneously with their HCV specialist care.[15] **4**

No evidence was identified supporting the view that investigation and treatment of current IDU with HCV infection should not be promoted because they are unlikely to have progressed to at least moderate hepatitis, or are unlikely to adhere to such care.

Two observational studies and one five-year follow-up study have shown that IDU, described as active at the time of enrolment and undergoing management of their drug problem, adhered to antiviral treatment to the same degree as those who had never injected drugs.[42-44] These studies were small and no details of participants' injecting behaviour were provided. **2**

All patients with acute HCV should be referred to specialist care immediately as treatment given during the acute phase is more likely to be successful (*see section 7.3*).[45] **1++**

Ideally the specialist clinic should be integrated with other services by means of outreach clinics so that the patient journey is seamless, especially for those who find it difficult to access medical care. Such integration should encourage agencies such as drug problems services and prison medical services to positively and repeatedly address the issue of HCV infection.

D **Individuals, including injecting drug users, diagnosed with chronic HCV should be offered integrated multidisciplinary care as it can maximise their uptake of, and retention in, services.**

A **Patients with acute HCV infection should be referred to specialist care immediately.**

✓ Current injecting drug users infected with HCV should not be excluded from consideration for HCV clinical management, including antiviral therapy, on the basis of their injecting status.

✓ All patients should be referred to a setting that periodically reassesses the state of infection and the progression of liver disease, to determine if further interventions or therapies are needed.

6 Children and hepatitis C

6.1 MOTHER TO CHILD TRANSMISSION

Pregnant women who are HCV RNA negative do not pose a risk of transmission to their child.[46,47] 2+

The risk of women who are HCV infected and RNA positive transmitting infection to their babies in utero or during parturition is approximately 5%; the rate is twice as high for those co-infected with HIV.[48] The baby's risk of acquiring HCV from a mother infected with HCV is not increased by mode of delivery or breast feeding.[48] One prospective study has indicated that fetal scalp monitoring may increase the risk of mother to child transmission.[49] A large retrospective study did not demonstrate any excess risk.[48] Vaginal delivery may increase the risk of HCV transmission if the mother is co-infected with detectable HIV viral load.[48] 2++

B **In pregnant women knowledge of HCV RNA positive status should not influence obstetric management or standard advice regarding breast feeding.**

6.2 HCV TESTING IN CHILDREN AND INFANTS

The aim of testing infants born to women with hepatitis C is not primarily to identify all children to whom the virus has been transmitted, but to identify those at risk of persistent infection and its long term consequences.

Infants born to women who are HCV antibody positive will test positive for HCV antibody at birth.[50] Infants who are not infected become negative for HCV antibody between six and 20 months of age. Around 80% will be negative by 12 months of age.[46, 51] Positive results for viral RNA by NAT may be obtained in the early months of life in children who subsequently become negative and lose HCV antibody.[51-54] Some infected infants may not become HCV RNA positive until 12 months of age or older.[54] One study indicates that the sensitivity of a positive reverse transcriptase polymerase chain reaction (RT PCR) result obtained on two occasions between two and six months of life in predicting infection is 81% (95% confidence interval; CI 58 to 97%).[55] 2+

Infants of mothers with HIV co-infection who are consistently positive for viral RNA may have negative HCV antibody tests between 12 and 18 months of age.[56] 3

B **Infants born to women who are HCV antibody positive and HCV RNA negative do not need to be tested.**

B **In children born to women infected with HCV, an HCV antibody test should be performed at 12 months of age or older to identify the minority of children who are infected.**

B **In children whose mothers are co-infected with HIV, and in infants found to be HCV antibody positive after 12 months, an HCV RNA test should be performed, and if positive, confirmed on a second sample.**

B **If information regarding the risk of HCV infection in an individual child is required before 12 months of age, an HCV RNA test and retest can be performed after two months of age. Further testing is still required to make a definitive diagnosis.**

6.3 NATURAL HISTORY OF HCV INFECTION IN CHILDREN

Cross-sectional studies indicate that 20-40% of children who are HCV antibody positive after 18 months of age have undetectable HCV RNA, suggesting spontaneous clearance.[57,58] In those with chronic infection who remain HCV RNA positive, subsequent spontaneous clearance is rare (3.5%).[59] **3**

Levels of alanine aminotransferase (ALT) twice the upper limit of normal are found in 50% of infected children.[59] **3**

D **Children infected with HCV should be monitored to identify the minority who are at risk of progressive fibrosis during childhood, and who may be candidates for treatment.**

✓ Children infected with HCV should be assessed clinically every 6-12 months, and have blood taken for tests of liver function. Those with clinical or ultrasound abnormalities, or with serum ALT persistently twice the upper limit of normal should be considered for liver biopsy.

6.4 TREATMENT OF CHILDREN WITH HEPATITIS C

Response rates to treatment in children are of a similar magnitude to, and show the same influences of genotype, as adults (*see section 10*).[60] Combination treatment with interferon (IFN) and ribavirin gives an overall SVR of 50-60%.[60-63] There is potential for effects on thyroid function and growth problems.[62, 63] **3**

Combination therapy with pegylated IFN and ribavirin is superior to pegylated interferon alone, and results in outcomes similar to that in adult studies (*see section 10*).[10] **1+**

Combination treatment with interferon and ribavirin gives an SVR rate of 80-93% in children with genotype 3 infection, but only 47-59% in those with genotype 1 disease, which is similar to those in adult studies.[10, 64, 65] **2+**

A **Children infected with all genotypes of hepatitis C with evidence of moderate or severe liver disease should be considered for treatment with pegylated IFN and ribavirin.**

B **Children infected with HCV genotypes 2 and 3 should be considered for treatment with pegylated INF and ribavirin irrespective of disease stage.**

C **In children with mild disease and infection with other genotypes, benefits of treatment need to be balanced against risks of side effects.**

✓ Treatment of children with genotype 1 disease using protease inhibitors should only be considered as part of a clinical trial.

✓ Children infected with HCV should be managed in consultation with a paediatric service with specialist expertise in hepatitis C.

7 Acute hepatitis C

7.1 NATURAL HISTORY

The incidence of hepatitis C is unknown but can be estimated from the prevalence of chronic hepatitis C (CHC).[66] Acute hepatitis C infection is usually asymptomatic.[67] The full clinical spectrum of acute hepatitis C symptoms can occur but is rare (<15% patients).[68] The mortality of acute hepatitis C is very low (0.1% or less) and chronic infection is the most common outcome.[67-69] **3**

Laboratory diagnosis should start with testing for anti-HCV but in early cases HCV RNA may be the only marker of infection (*see section 3.2*).[70] **2+**

Spontaneous recovery occurs in 30-50% of patients with symptomatic infection, usually within three months of diagnosis. This is most common in females with an icteric illness.[66, 67, 71, 72] **3**

D **Patients with acute hepatitis C virus infection require clinical and laboratory monitoring** (looking for spontaneous viral clearance) **for the initial three months following diagnosis as they will often have a self limiting illness.**

7.2 POST-EXPOSURE PROPHYLAXIS

No trials were identified that show whether or not immunoglobulin, IFN based therapies or antiviral agents are effective at preventing transmission when given immediately post-exposure. Two reviews which considered older studies of immunoglobulin did not establish efficacy and concluded that immunoglobulin and IFN based therapies are not recommended after HCV exposure.[28, 73] **4**

7.3 TREATMENT OF PATIENTS WITH ACUTE HEPATITIS C

7.3.1 TIMING OF TREATMENT

Most patients who spontaneously clear hepatitis C do so within 12 weeks of diagnosis.[66, 72] There are no data to suggest that delaying treatment from three to six months post-diagnosis compromises treatment response, whilst allowing for spontaneous clearance to occur.[45] Delaying treatment to one year post-acquisition compromises a sustained viral response.[45] **3** **1++**

D **Treatment should start between three and six months after diagnosis of acute hepatitis C, if the infection has not resolved spontaneously.**

7.3.2 CHOICE AND DURATION OF TREATMENT

Two systematic reviews examined the effectiveness of non-pegylated IFN for the treatment of patients with acute hepatitis C.[74, 75] In one study participants in the treatment groups had higher sustained viral response rates (62%) than those in untreated groups (12%).[74] A Cochrane review demonstrated that increasing the dose of non-pegylated IFN during the induction phase of treatment was associated with higher sustained viral response.[75] There are no data on the influence of genotype on response to treatment for acute hepatitis C infection. **1++**

No randomised controlled trials (RCTs) of pegylated IFN versus conventional IFN for patients with acute hepatitis C were identified. A case series treated 16 patients, who had not seroconverted by three months, with pegylated IFN alone for 24 weeks, and reported a sustained viral response of 94%.[66]

3

A **Patients with acute HCV infection should be treated with IFN therapy if the infection does not resolve spontaneously.**

D **Patients can be treated with either pegylated IFN or non-pegylated IFN.**

D **Patients with acute HCV infection should be treated with IFN therapy for 24 weeks irrespective of genotype.**

8 Assessment of liver disease

8.1 CLINICAL ASSESSMENT

Clinical assessment of the severity of liver disease in patients with chronic hepatitis C is inaccurate and tends to underestimate the severity of change seen on liver biopsy.[76] **3**

8.2 FIBROSIS MARKERS

Studies of non-invasive prediction of the severity of liver disease using combinations of clinical and biochemical scores have found that it may be possible to distinguish patients with cirrhosis from those with mild disease. Intermediate stages are not distinguishable.[77] **2++**

A systematic review demonstrated that surrogate markers of fibrosis either reflecting disordered liver function (alanine aminotransferase, platelets) or fibrosis metabolism (eg tissue inhibitor of matrix metalloproteinase 1, hyaluronic acid) cannot be used individually to predict fibrosis. In individual patients such markers used alone cannot differentiate the stage of fibrosis reliably. Used in panels they can determine whether an individual has high or low levels of fibrosis. The 14 studies in the systematic review used 10 different panels of markers, none of which was superior to any other in statistical comparisons. The tests were compared against the gold standard of liver biopsy as part of their validation, although liver biopsy may potentially be inaccurate due to sampling error. Comparison of surrogate markers and liver biopsy to clinical outcomes would be more relevant.[78] **2++**

B **Biochemical markers should not be used as an alternative to liver biopsy for staging of intermediate grades of fibrosis.**

B **Biochemical tests may be used as an alternative to liver biopsy to diagnose cirrhosis or to direct screening for complications of fibrosis.**

✓ Measurement of liver stiffness may be useful as a non-invasive assessment of liver fibrosis.

8.3 LIVER BIOPSY

A liver biopsy needs to be at least 25 mm long in order to report stage of fibrosis with 75% accuracy.[79] The mortality rate of liver biopsy is between 0.13 and 0.33% and the rate of significant morbidity is about 5.9%.[80] **3**

8.3.1 WHEN TO BIOPSY

Liver biopsy of patients with CHC infection can reveal additional diagnoses such as alcoholic liver disease or steatosis (10% patients) and may influence management decisions in five per cent of patients.[81] Repeat liver biopsies may be useful in identifying individuals for treatment; one third of patients with mild CHC show one stage of fibrosis progression on the Ishak scale (0-6) at a median of 30 months.[82] The frequency and timing of liver biopsy should be tailored to individual patients as progression of fibrosis is non-linear. **3**

Advanced fibrosis or cirrhosis on liver biopsy compared with milder disease predicts a modest reduction in SVR after antiviral therapy.[83] **1++**

Liver biopsy before and after successful antiviral therapy (median 20 months interval) has shown both improvement in fibrosis (277 out of 1,094 patients) and downgrading of stage in cirrhosis (75 out of 153 patients).[84] **1+**

D **Liver biopsy should be performed if there is concern about additional causes of liver disease.**

D **Repeat liver biopsies should be considered in patients with mild disease who remain untreated, if progression of liver fibrosis would influence the decision to opt for antiviral therapy.**

✓ In patients with congenital bleeding disorders liver biopsy should be performed in consultation with a haemophilia specialist.

8.3.2 BIOPSY AND GENOTYPE

The sustained viral response rate after pegylated IFN and ribavirin therapy for patients with genotype 2 and 3 infection is 76-82% and is 41-51% for patients with genotype 1 infection.[7] The UK Health Technology Assessment Centre has recommended that pre-treatment liver biopsy in patients with genotype 2 and 3 may not be required.[7]

4

D **Liver biopsy should not be considered an essential test prior to using antiviral therapy, especially in patients with genotype 2 and 3 disease.**

9 Progression of untreated disease

Chronic hepatitis C infection is associated with a significant risk of progression to cirrhosis and hepatocellular carcinoma (HCC).[3, 85] Quantifying the magnitude of risk of progression to cirrhosis and HCC with time is difficult as reported outcomes are strongly influenced by study design and the characteristics of the population sampled.[3, 85] **2++**

A systematic review of 57 studies (both cross-sectional and longitudinal) which included liver clinic, post-transfusion, blood donor and community based patients, calculated the following estimates for the risk of progressing to cirrhosis after 20 years:[3] **2++**

- liver clinic: 22% (95% CI 18 to 26%)
- post-transfusion: 24% (95% CI 11 to 37%)
- blood donor: 4% (95% CI 1 to 7%)
- community based: 7% (95% CI 4 to 10%).

Due to the selection biases inherent in the cross-sectional liver clinic data, the community based cohort studies may be the most representative of true disease progression at a population level. The community based cohorts indicate that in those who acquire HCV infection in young adulthood, less than 10% will develop cirrhosis within 20 years. Older age at HCV acquisition, male gender and heavy alcohol consumption were associated with more rapid disease progression.[3] **2++**

The mean time from HCV infection to the development of HCC also shows considerable variation between studies, ranging from nine to 31 years in one systematic review.[85] Virtually no cases of HCC occur during the first decade of HCV infection, most are detected after 20 years of infection.[85] **2++**

Patients with established HCV related cirrhosis have a seven per cent risk of developing HCC by five years follow up.[86,87] **2+**

Patients with established CHC related cirrhosis are also at risk of complications such as ascites, gastrointestinal bleeding and hepatic encephalopathy.[86,87] The cumulative probability of all forms of decompensation in cirrhotic patients who remained tumour free was 18% at five years in one study, with an overall five-year survival rate of 91%.[87] **2+**

9.1 AGE, GENDER AND ETHNICITY

Increasing age at time of infection with HCV is associated with more rapid progression of liver fibrosis and reduced time from infection to cirrhosis.[88-90] Age over 40 years at time of infection is particularly associated with more rapid progression.[89, 90] **3**

Three cohort studies reported that men infected with HCV are more likely to progress to advanced stages of hepatic fibrosis than women.[89,91,92] **3**

Variations in disease progression have been observed in patients of different race. Two cohort studies demonstrated that disease progressed less rapidly in African-American than non African-American patients.[93, 94] The likely rate of progression in these patients should be considered when deciding whether to proceed with antiviral therapy. **2+**

D **When estimating the likely rate of progression of liver disease age at infection, gender and ethnicity should be considered.**

9.2 BODY WEIGHT

Studies have identified body mass index (BMI) >25 as being associated with hepatic steatosis (*see section 12.1.3*).

9.3 TOBACCO SMOKING

Smoking is an independent risk factor for the progression of hepatic inflammation and fibrosis in patients with CHC.[95,96] No data were identified on the impact of stopping smoking. **3**

D **Patients with CHC should be advised that smoking tobacco can accelerate progression of liver disease.**

9.4 ALCOHOL

Heavy alcohol consumption in patients infected with CHC is associated with more severe liver disease including cirrhosis, endstage liver disease and HCC.[97, 98] Average alcohol intake of more than six UK units per day is associated with more rapid progression of liver fibrosis.[88, 89, 92] Even moderate amounts of alcohol (within government recommended guidelines) have been associated with increased liver fibrosis compared to those who abstain.[89, 99] **2+** **2++**

Patients who are aware of their HCV status are more likely to heed advice on reducing alcohol intake than those who perceive themselves to be uninfected.[100] **2++**

B **Patients with CHC should be advised that drinking alcohol** (even in moderation) **can accelerate progression of liver disease.**

9.5 ALANINE AMINOTRANSFERASE

Approximately 25% (range 10-40%) of patients with CHC have persistently normal serum alanine aminotransferase (PNALT). Such patients are more likely to be female and have mild disease.[101] Although there is a substantial overlap between patients with PNALT and patients with mild liver disease, the terms are not synonymous and the groups are regarded separately for treatment purposes (*see sections 10.3.1 and 10.3.3*). The definition of 'persistently normal' varies in the literature with ALT measurements made every two to three months for time periods ranging between six and 18 months.[101] Flares in ALT have been reported in 21.5% of patients after being normal for 12 months.[102] There is no association with hepatitis C genotype or viral load.[101] **1-** **2-**

Progression of liver fibrosis is slower in patients with PNALT than in patients with elevated ALT.[103] In patients with untreated mild liver disease the progression to moderate or severe disease during follow up of 5.6 years is 5% in patients with PNALT and 24% in patients with elevated ALT. **2++**

Routine liver biopsy is not believed to be indicated unless specific information is required in selected patients.[101] **1+**

D **When defining PNALT serum ALT measurement should be undertaken every two to three months to ensure that flares in ALT are not missed.**

✓ The duration of follow up to define PNALT should be 12 months.

✓ Liver biopsy should only be considered if there are clinical or other concerns about the individual patient.

9.6 HIV CO-INFECTION

There is an increased rate of progression to end-stage liver disease in patients with HIV and HCV co-infection compared to those with HCV mono-infection (relative risk; RR 6.14, 95% CI: 2.86 to 13.2).[104] Median time to cirrhosis in patients with co-infection is 26 years, compared to 38 years in those with HCV mono-infection.[104] Patients with HCV infection with mild immunodepression as a result of HIV also have more severe liver disease than those with HCV mono-infection.[105] There is a marked increase in liver related mortality in patients with CHC and HIV co-infection (RR 17.5).[106] **1+ 2+**

Effective anti-HIV therapy and the associated immune recovery may limit HCV liver disease progression.[107] **2++**

B **The increased rate of progression to decompensated liver disease in patients with HCV and HIV co-infection should prompt early consideration of antiviral therapy.**

9.7 CO-INFECTION WITH HEPATITIS A OR B VIRUSES

Vaccination against hepatitis A and B is recommended in people with HCV.[108] A consensus report on the treatment of hepatitis recommended vaccination for hepatitis B virus (HBV) but not hepatitis A.[109] One case study of patients with HCV who contracted hepatitis A reported a very high level of fulminant hepatitis.[110] **4**

Antibody response to hepatitis B vaccination is reduced in patients with chronic HCV.[111] **3**

D **Vaccination against hepatitis A and B should be considered for patients infected with hepatitis C.**

Patients who are infected with HCV who have serological evidence of current or past infection with HBV are more likely to have advanced liver disease.[91, 112, 113] **3**

D **When estimating the likely rate of progression of liver disease as a result of hepatitis C infection, active or previous hepatitis B virus infection should be considered.**

✓ Patients infected with HCV should be tested for evidence of active or previous HBV infection.

9.8 IRON STATUS

Patients with CHC can have elevated iron stores, but there is debate over whether this has any influence on the disease. Serum ferritin and transferrin saturation are increased in 20-60% of patients and correlate with serum ALT, suggesting they are markers of inflammation.There is a poor correlation with hepatic iron concentration (HIC).[114] HIC is rarely significantly elevated in pre-cirrhotic patients.Twenty to fifty per cent of patients with cirrhosis will have elevated HIC but this is also a common finding in patients with cirrhosis due to hepatitis B and alcoholic liver disease.[114] **4**

It is uncertain whether hepatic iron excess as a single factor has any influence on response to treatment with IFN alone.[114] **4**

No evidence was found that iron depletion (by venesection) has any influence on the virus or the activity of liver disease.[114] There is some evidence from four small RCTs that venesection on selected patients with markers of iron excess prior to IFN monotherapy may improve the SVR.[114, 115] **4 1-**

D **Modest iron loading does not justify specific intervention prior to antiviral therapy as it is unlikely to be of clinical importance.**

D **Patients with significant iron retention require further investigation for additional conditions known to result in iron overload.**

9.9 HCV GENOTYPE

No consistent link between HCV genotype and disease progression has been demonstrated in several cohort studies.[88, 91,92, 116,117] **2+**

9.10 CRYOGLOBULINAEMIA

A poor quality meta-analysis of the influence of cryoglobulinaemia suggested that cirrhosis is diagnosed more frequently in patients with cryoglobulinaemia.[118] **1-**

10 Treatment of chronic hepatitis C

10.1 ANTIVIRAL THERAPY

Several meta-analyses and systematic reviews confirm that a combination of pegylated IFN and ribavirin dual therapy is effective in treating patients with CHC, leading to high levels of sustained viral response (SVR).[7, 119-121] All patients should be considered as candidates for treatment. **1+**

A **All patients with chronic HCV infection should be considered for antiviral therapy.**

10.1.1 SUSTAINED VIRAL RESPONSE

Sustained viral response has become the accepted objective of treatment programmes for CHC and is currently achieved in 41-51% of patients with genotype 1 disease and 73-82% of patients with genotype 2 and 3 disease who have received a course of combination therapy with pegylated IFN and ribavirin.[122, 123] Data are available on long term outcomes after SVR but are limited in number, quality and length of follow up:

- viral relapse is uncommon after SVR (1-13% of patients)[124-126] **1+**
- mortality is reduced after SVR[127] **2+**
- patients with an SVR have a reduced risk of developing cirrhosis and primary hepatocellular carcinoma[124,128] **2++**
- occult hepatitis C may persist in macrophages, lymphocytes to hepatocytes in some patients who have achieved an SVR. There may be a small risk of future relapse in this event.[129,130] **3**

B **Sustained viral response should be used as a marker for viral clearance.**

An SVR of 80% is achieved in patients who take 80% of the dose of both pegylated IFN and ribavirin dual therapy for more than 80% of the duration. This compares with 33% in less adherent patients.[131] **2+**

10.2 TREATMENT VARIATION BY GENOTYPE

10.2.1 GENOTYPE 1 AND DURATION OF TREATMENT

A systematic review assessed adjunct treatment with the protease inhibitors boceprevir and telaprevir in patients with genotype 1 hepatitis C. In both treatment-naive and treatment-experienced patients, sustained viral response rates were achieved more often with the protease inhibitors boceprevir or telaprevir in combination as triple therapy with pegylated IFN and weight-based ribavirin compared with pegylated IFN and weight-based ribavirin alone. Both medications were well tolerated, with anaemia presenting as the most treatment-limiting adverse effect.[132] Figures 1 and 2 show treatment algorithms for patients with genotype 1 HCV infection. **1+**

Three RCTs reviewed in two systematic reviews found that telaprevir administered for at least 12 and up to 48 weeks in combination with pegylated IFN and weight-based ribavirin as triple therapy was effective in the treatment of previously untreated or treatment-experienced adults with genotype 1 chronic hepatitis C infection. The trials included treatment-experienced adults who were non-responders, partial responders and relapsers following pegylated IFN and weight-based ribavirin. Sustained viral responses were significantly better than pegylated IFN and weight-based ribavirin dual therapy alone.[133,134] **1+**

Two systematic reviews found that boceprevir administered for 24-44 weeks as triple therapy in combination with pegylated IFN and weight-based ribavirin for up to 48 weeks was effective in the treatment of previously untreated or treatment-experienced adults with genotype 1 chronic hepatitis C infection. These trials included treatment-experienced adults who were either partial responders or relapsers following pegylated IFN and weight-based ribavirin but did not include previous non-responders. Sustained virological responses were significantly better than with pegylated IFN and weight-based ribavirin dual therapy alone; 66% for fixed duration triple therapy versus 63% for response guided triple therapy versus 38% for control group receiving standard dual therapy.[134,135] **1+**

A regimen including boceprevir requires a four week lead-in of pegylated IFN and weight-based ribavirin, whereas this is not required for telaprevir. A lead-in with boceprevir, however, does not reduce SVR. The response to the lead-in period can indicate likelihood of SVR in both treatment-naive and experienced patients.

A **All treatment-naive patients infected with HCV genotype 1 should be considered for treatment with pegylated IFN and weight-based ribavirin with the addition of a protease inhibitor as triple therapy.**

A **All treatment-experienced patients infected with HCV genotype 1 should be considered for treatment with pegylated IFN and weight-based ribavirin with the addition of a protease inhibitor as triple therapy.**

✓ In treatment-experienced patients with a lower likelihood of SVR, benefits of treatment need to be weighed against potential risks and side effects.

A **Response-guided therapy can only be used in treatment-naive patients and previous treatment relapsers who are not cirrhotic.**

No direct comparison studies of boceprevir and telaprevir were identified, therefore neither drug can be recommended over the other.

No evidence was identified suggesting that a particular pegylated IFN should be used in combination with a particular protease inhibitor.

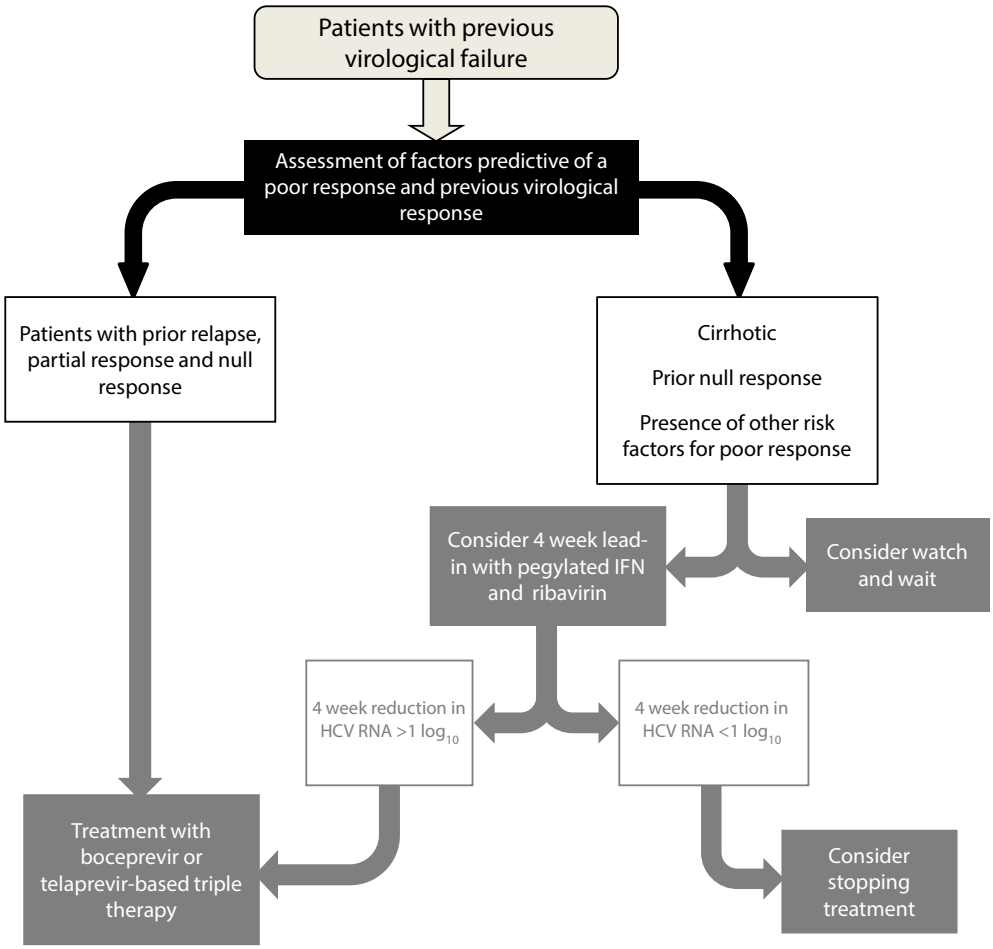
UK consensus guidelines for the use of the protease inhibitors boceprevir and telaprevir in genotype 1 chronic hepatitis C infected patients (2012) with the permission of the authors under acknowledgement by John Wiley & Sons.

Figure 2: Algorithm for the use of protease inhibitors in HCV genotype 1 infected patients who have had prior viralogical failure on treatment.



Reprinted from Alimentary Pharmacology and Therapeutics 35, Ramachandran et al. UK consensus guidelines for the use of the protease inhibitors boceprevir and telaprevir in genotype 1 chronic hepatitis C infected patients (2012) with the permission of the authors under acknowledgement by John Wiley & Sons.

10.2.2 GENOTYPE 1 AND DURATION OF TREATMENT FOR PATIENTS UNSUITABLE FOR PROTEASE INHIBITORS

The optimal duration of treatment for patients with genotype 1 hepatitis C is 48 weeks.[7,119,120] **1++**

Patients with genotype 1 infection who fail to achieve an early viral response (EVR) at 12 weeks have a less than five per cent chance of achieving a SVR.[136] Of those genotype 1 patients who failed to achieve an EVR but continued on therapy and were still HCV RNA positive at 24 weeks, none had an SVR.[137] Following careful clinical assessment some patients infected with genotype 1 HCV may be considered unsuitable for treatment with a regimen which includes a protease inhibitor. This includes patients with potentially dangerous drug-drug interactions with prescribed or illicit medications, and those with co-morbid conditions that may impair adherence to therapy thus reducing the effectiveness of triple therapy and increasing the risk of developing drug resistance.[134] **1+**

The registration studies for telaprevir and boceprevir both demonstrate in post hoc analysis that patients with low viral loads, treated with pegylated INF and weight-based ribavirin and who achieve a rapid viral response (RVR), have the same SVR rate as those treated with the addition of a protease inhibitor.[138] A meta-analysis looked at shortened therapy for those treated with pegylated INF and weight-based ribavirin. Including all patients, relapse rates were significantly higher in patients with genotype 1 RVR if the treatment duration was reduced to 24 weeks with an overall reduction in SVR of -13.6% (95% CI -22.8% to -4.4%, p=0.004). If the viral load was less than 400,000 IU/ml there was no statistical significant reduction in SVR with 24 weeks of treatment with a mean difference of -3.1% (96% CI -8.6% to 2.4%). [138] **1+**

A
- **Patients with genotype 1 infection should be tested for an EVR at 12 weeks.**
- **Patients with genotype 1 infection who fail to achieve an EVR at 12 weeks should be considered for cessation of treatment.**
- **Patients with genotype 1 infection with an EVR at 12 weeks should continue treatment for 48 weeks. Those who are still HCV RNA positive at 24 weeks should discontinue treatment.**

B
Following informed discussion, treatment-naive patients with genotype 1 infection and:
- **minimal or no fibrosis**
- **low viral load** (less than 400,000 IU/ml)
- **who achieve an RVR following a lead in with pegylated IFN and weight-based ribavirin for four weeks can be considered for 24 weeks of treatment without the addition of a protease inhibitor.**

10.2.3 GENOTYPE 2 AND 3 AND DURATION OF TREATMENT

The optimal treatment for patients with genotype 2 and 3 infection is pegylated INF and weight-based ribavirin.[7, 119, 120] The primary outcome of one meta-analysis was comparison of SVR rates in patients with either genotype 2 or 3 infection. After 24 weeks of therapy, SVR rates were 74% and 69% respectively with an OR of 1.49 (95% CI 1.23 to 1.80) however the percentage difference was not significant (p=0.90). Among those with higher viral loads, the SVR rate in genotype 2 infection (75%) differed from genotype 3 infection (58%) with an OR of 2.36 (95% CI 1.80 to 3.09). The percentage difference of 24.9 % (95% CI 12.8 to 37.0; p=0.07) was not significant. In patients with low viral loads respective rates were 79% and 75% with an OR of 1.50 (95% CI 1.08 to 2.09) again with a non-significant difference (p=0.84). As a secondary outcome shortened therapy in patients with RVR treated for 12–16 or 24 weeks was analysed. SVR rates in genotype 2 infected patients were 83% and 84%, respectively, and in genotype 3 infected patients 84% and 86%. In patients without RVR treated for 24 weeks, the SVR was higher in those with genotype 2 infection, with a 17.8% weighted difference (95% CI: 8.7 to 27.0) and a pooled OR of 2.06 (95% CI 1.40 to 3.02). The authors concluded that 24 weeks of therapy should remain the standard duration for patients with genotype 2 or 3 infection. However, in patients who achieve an RVR, those with genotype 3 HCV respond to shortened treatment as well as those with genotype 2, irrespective of basal viraemia.[139] **1++**

The aim of a second meta-analysis was to determine the optimal length of treatment in patients with HCV genotypes 2 and 3. The results for these two genotypes were pooled. Pooled SVR data were higher for standard treatment in RCTs that randomised at baseline, with an RR of 0.88 (95% CI 0.76 to 1.01) favouring standard therapy over shortened therapy. The pooled proportion of SVR rates of RCTs that randomised at RVR were similar in the shortened treatment group (82%) and in the standard treatment (83%), with the pooled effect given by an RR of 1.00 (95% CI 0.92 to 1.09). The authors' conclusions should be treated with caution given the lack of detail about the methodology and a high level of heterogeneity between the included studies. The authors conclude that based on baseline characteristics all patients should be treated for 24 weeks with dual therapy. However patients who achieve an RVR at four weeks can have their therapy shortened to between 12-16 weeks of dual therapy with pegylated IFN and weight-based ribavirin. They found no difference between 12 or 16 weeks but numbers were small. Numbers of patients with cirrhosis were too small to allow any inference about that group. Weight-based ribavirin achieved higher SVRs than low fixed dose ribavirin.[140] **1+**

Evidence from two studies suggests that patients with genotype 2 or 3 infection who achieve a rapid viral response (HCV RNA negative) at four weeks can receive 12 or 16 weeks of pegylated IFN and weight-based ribavirin therapy with similar results to 24 weeks of treatment.[141, 142] **1+**

A
For patients with HCV genotype 2 or 3 standard treatment should be pegylated IFN and weight-based ribavirin for 24 weeks.

B
Non-cirrhotic patients, with genotype 2 or 3, who achieve an RVR at week 4 of therapy, could be considered for shortened duration of therapy of 12 to 16 weeks.

10.2.4 GENOTYPE 4, 5 AND 6 AND DURATION OF TREATMENT

The optimal duration of treatment for patients with genotype 4 hepatitis C is 48 weeks.[7, 119, 120] 1++

A meta-analysis of two large phase three/four prospective randomised clinical trials conducted in Belgium in patients with chronic hepatitis C (n = 1,073) compared the response to antiviral therapy of those with HCV genotype 5 with that of those with other HCV genotypes. The study found that genotype 5 infection responds to therapy in a similar way to genotype 1, however the genotype 5 population is older, more likely to have acquired infection by blood transfusion and more likely to have cirrhosis. The meta-analysis recommended treating patients with genotype 5 infection for 48 weeks with dual therapy.[143] 1+

A systematic review found very few studies of treatment of patients with HCV genotype 6 infection. Treatment with pegylated IFN and weight-based ribavirin is effective, with SVR rates around 70% after 48 weeks of therapy. SVR rates are similar in patients with HCV genotype 6 infection who receive 24 weeks of pegylated IFN and weight-based ribavirin, although additional studies are needed before recommending 24 weeks as the optimal treatment duration for these patients.[144] 1+

A **For patients with HCV genotype 4, 5 or 6 infection, standard treatment should be 48 weeks of pegylated IFN and weight-based ribavirin.**

10.3 PATIENT SUBGROUPS

10.3.1 PATIENTS WITH MILD CHRONIC HEPATITIS

In patients with mild CHC the efficacy and safety of non-pegylated IFN and ribavirin combination therapy is similar to that in other patients with hepatitis C. Liver biopsy to exclude patients with mild disease is therefore not required prior to considering antiviral treatment.[145] 1++

B **Patients with mild CHC should be considered for treatment.**

10.3.2 PATIENTS WITH CIRRHOSIS

See section 11.1.1 for information on patients with cirrhosis.

10.3.3 PATIENTS WITH PERSISTENTLY NORMAL ALT LEVELS

The efficacy and safety of pegylated IFN and ribavirin combination therapy in patients with CHC and persistently normal ALT level is similar to that seen in patients with elevated ALT levels (*see section 9.5*).[146] 1+

A **Patients with chronic hepatitis C and normal ALT should be considered for treatment.**

10.3.4 PATIENTS WITH HIV CO-INFECTION

Pegylated IFN and ribavirin for 48 weeks is effective in treating patients with HCV-HIV co-infection, leading to sustained viral response in 60% of patients with genotype 2 and 3 and 14-29% in patients with genotype 1. For patients with genotype 1 infection and low HCV viral load (<800,000 IU/ml), the sustained viral response rate is around 60%.[147-149] 1+

Ninety eight per cent of patients with HIV-HCV co-infection who did not have an EVR at week 12 did not achieve an SVR at week 48.[149] 1+

Patients co-infected with HIV and HCV genotypes 2 and 3 with undetectable HCV-RNA at week 4 did not benefit from prolonging therapy beyond 24 weeks.[150] 1+

Pegylated IFN plus weight-based ribavirin for the treatment of HCV was more effective than standard IFN plus weight-based ribavirin in achieving a sustained viralogical response in patients co-infected with HIV: 55% versus 26% overall, 46% versus 18% in genotype 1 and 4 and 71% versus 43% in genotype 2 and 3. The differences between cohorts were HCV-genotype dependant during the first 12 weeks of pegylated IFN therapy, regardless of HIV status. Among patients with HCV genotype 2 or 3, the study found a significantly sharper decrease in HCV RNA in HCV mono-infected patients compared with HCV-HIV co-infected patients 1+

only at week 4, whereas significant differences among patients with HCV genotype 1 were observed only after 12 weeks of therapy. Overall, longer duration of treatment (48-72 weeks) showed better treatment responses irrespective of genotype than shorter duration (24-48 weeks).[150-152] 1+

The expert opinion of the guideline development group was that recommendations could be made for treatment of patients co-infected with HIV and HCV genotype 1 by extrapolating from HCV genotype 1 mono-infected patient treatment regimens which include protease inhibitors.

A **All patients co-infected with HCV and HIV should be considered for HCV treatment.**

A **For patients with HCV genotype 1 infection and HIV, who do not achieve an EVR, treatment should be stopped.**

A
- **Co-infected non-genotype 1 patients who are considered suitable for treatment should be offered treatment with pegylated IFN and weight-based ribavirin for 48 weeks.**
- **Co-infected genotype 2 or 3 patients who achieve an RVR may be considered for 24 weeks of treatment.**

C **All patients co-infected with HIV and HCV genotype 1 should be considered for treatment with a regimen which includes an HCV protease inhibitor.**

B **Treatment-naive patients co-infected with HIV and HCV genotype 1 who are unsuitable for treatment with a regimen which includes HCV protease inhibitors should be considered for treatment with pegylated IFN and weight-based ribavirin for 48-72 weeks depending on viral response.**

✓ Genotype 1 co-infected patients who are not cured of their HCV infection should be monitored for disease progression.

10.3.5 PATIENTS WITH HEPATITIS B CO-INFECTION

Treatment outcomes with a combination of non-pegylated IFN and ribavirin in patients co-infected with chronic hepatitis B and C are similar to those achieved in patients with HCV mono-infection.[153,154] No trials were found examining pegylated IFN and ribavirin in patients co-infected with chronic hepatitis B and C. 2++

No evidence was identified to make a recommendation on treatment with protease inhibitors for patients who are genotype 1 and co-infected with hepatitis B as these patients were excluded from clinical trials.

C **Patients with chronic hepatitis B and C co-infection should be considered for treatment with pegylated IFN and weight-based ribavirin.**

✓ Patients with chronic hepatitis B and C genotype 1 co-infection could be considered for combination treatment with pegylated IFN and weight-based ribavirin with the addition of a protease inhibitor on an individual basis in centres with an expertise in management of hepatitis B.

10.3.6 PATIENTS IN DRUG TREATMENT PROGRAMMES

In patients with CHC who are on a stable drug treatment programme, management with a combination of pegylated IFN and ribavirin is effective, leading to high levels of sustained viral response. Whilst drop-out rates are higher than in other cohorts, the drop-outs occur early, within the first eight weeks. After eight weeks adherence to treatment is similar to other groups.[44,155] 2+

Recent studies suggest active drug users have comparable treatment outcomes to non-drug users.[156-158] 2+ 1+

B **Patients with CHC who are on a drug treatment programme should be considered for treatment.**

✓ Active drug users should be engaged in efforts to address their healthcare needs and in harm reduction.

✓ Active drug users should have a comprehensive assessment of their psychological needs and of their likely adherence to antiviral treatment.

10.4 FACTORS INFLUENCING EFFECTIVENESS

10.4.1 AGE, GENDER AND ETHNICITY

Antiviral therapy is less effective in patients over the age of 40 and men are less likely than women to achieve a sustained viral response.[7,119,120] Variations have been observed in the response of patients of different race to antiviral therapy. A meta-analysis of ethnic differences showed that patients of African-American or Hispanic origin had lower SVRs than Caucasian or Asian groups (16% and 24% versus 32% and 59% with genotype 1 achieved SVR).[159] **1+**

A **Patients should be advised that older age at the time of treatment leads to a lower sustained viral response.**

B **Patients should be advised about the likelihood of sustained viral response according to their ethnic origin.**

10.4.2 BODY WEIGHT

Three systematic reviews report that in patients with CHC whose weight is greater than 75 kg, treatment with a combination of pegylated IFN and ribavirin leads to a lower SVR than in patients weighing less than 75 kg.[7,119,120] Dosage of pegylated IFN and ribavirin in these studies was given at a cut-off point of 75 kg and not weight related, therefore caution should be taken when extrapolating results. Weight and diet are discussed in section 12. **1+**

10.4.3 ALCOHOL

Treatment studies in patients continuing to use alcohol are limited. Two cohort studies have shown that response rate to standard IFN treatment was inversely proportional to the amount of alcohol ingested.[160, 161] A six month abstinence from alcohol did not offset previous lifetime alcohol intake.[162] **2+**

✓ Patients should be advised that drinking alcohol (even in moderation) can reduce the response to treatment with pegylated IFN and ribavirin.

10.5 CONTRAINDICATIONS

10.5.1 PREGNANCY AND RISK OF PREGNANCY

There are no studies on the effects of antiviral therapy on human pregnancy. Studies in animals have shown that ribavirin therapy, at well below the recommended human dose, causes malformations in the fetus. The incidence and severity of the teratogenic effects increased with escalation of the ribavirin dose. Survival of the fetus and the offspring was reduced.[163] Further animal studies have shown abnormalities in sperm.[163]

There are no data on the use of pegylated IFN in pregnant women and it is not known whether pegylated IFN or ribavirin are excreted in human milk.

✓ Pegylated IFN and ribavirin must not be prescribed to women who are pregnant.

✓ Treatment with pegylated IFN and ribavirin should not be initiated until pregnancy has been excluded.

✓ Couples, with one partner receiving pegylated IFN and ribavirin, should use two forms of contraception during treatment and for six months after therapy has ended.

10.5.2 PATIENTS WITH RENAL FAILURE

Ribavirin causes a dose-dependent haemolytic anaemia and the degree of haemolysis is dependent on the severity of the renal failure.[164] Treatment with pegylated IFN monotherapy at a dose of 135 µg subcutaneously per week for patients on haemodialysis may be considered but patients need to be closely monitored.[165] **1+ 3**

D **Patients with CHC and renal failure may be treated with IFN monotherapy, with careful monitoring required.**

10.5.3 PATIENTS WITH MENTAL HEALTH PROBLEMS

Patients with mental health problems respond equally well to IFN and ribavirin therapy but their psychiatric symptoms should be managed carefully, particularly in the first four weeks of treatment.[166,167] **2+ 3**

B **Patients with stable mental health problems should not be excluded from treatment for CHC.**

B **Patients with mental health problems should have their psychiatric symptoms monitored prior to and throughout IFN treatment.**

✓ Formal psychiatric assessment should be considered for selected patients if necessary.

10.5.4 PATIENTS TAKING OTHER MEDICINES

The protease inhibitors telaprevir and boceprevir are both inhibitors and substrates of the metabolising enzyme, cytochrome P450 (CYP) 3A4. Co-administration of either telaprevir or boceprevir with drugs metabolised by this enzyme can result in clinically significant and possibly life threatening drug-drug interactions. Due to the potential for toxicity and/or suboptimal treatment particular care should be taken to ensure a full drug history and medication review of all patients (including prescribed medication, over-the-counter products, herbal and/or illicit drugs).[134,168] An assessment should be made to ensure that co-administration will not result in any clinically significant alteration to drug metabolism. Reference sources such as the summary of product characteristics for each drug and University of Liverpool Hepatitis C drug interaction website should be consulted as the main sources of information;[169] however, all possible sources of reliable information should be used to prevent problems with drug interactions. In patients with complex medication regimens, referral to a specialist pharmacist should be considered to ensure that complex interactions are explored adequately. Primary care providers should be alerted to the potential for interactions by communicating the results of the medication review. In patients whose concurrent prescribed or illicit medicines are contraindicated with protease inhibitors, treatment should be with pegylated IFN and ribavirin only after consultation with the local multidisciplinary team.[134] **4**

Caution should be taken if co-prescribing protease inhibitors with drugs known to prolong the QT interval. Prescribing information for individual drugs provides directions on ECG monitoring. Other mechanisms for drug metabolism may be involved but not yet identified and prescribers should remain vigilant. Caution and close monitoring should be adopted when co-prescribing other medicines.

D **Patients should have a full drug history taken including prescribed, over-the-counter and illicit drugs.**

D **The co-administration of any drugs should be assessed to ensure there is no unacceptable potential for toxicity or suboptimal efficacy of either agent.**

✓ Patients with complex polypharmacy may benefit from input of a specialist pharmacist.

✓ Patients should be made aware of potentially dangerous interactions between over-the-counter medicines, illicit drugs and HCV therapy, even if they are not known to use illicit drugs.

10.6 MANAGEMENT OF ADVERSE EFFECTS

10.6.1 FLU-LIKE SYMPTOMS

Virtually all patients taking pegylated IFN and ribavirin will experience flu-like symptoms such as fever, myalgia, rigors, arthralgia and headache. These tend to become less severe after the first month of treatment.[170] Simple interventions such as paracetamol use and increased fluid intake and rest can minimise these effects.[170, 171] **4**

D **Patients experiencing flu-like side effects from pegylated IFN and ribavirin can be advised to use paracetamol within manufacturers' guidelines.**

D **Patients should be advised to maintain an adequate fluid intake throughout treatment with pegylated IFN and ribavirin.**

D **Patients should be advised to coordinate their injections of pegylated IFN and ribavirin with periods of reduced activity, such as weekends and holidays.**

10.6.2 ANAEMIA AND NEUTROPENIA

In clinical trials the use of erythropoietin (EPO) in patients who developed anaemia (haemoglobin level ≤120g/l) while on pegylated IFN and ribavirin therapy improved the anaemia and lessened the need to reduce the dose of ribavirin. It also improved quality of life.[172,173] There is no direct evidence that this results in an increase in the SVR. None of the erythropoietins are currently licensed for this indication. **1+**

Haemoglobin levels should be maintained at a level that prevents a need for dose reduction or discontinuation of pegylated IFN and ribavirin therapy as this can cause a reduction in SVR.[174] Up to a third of patients receiving combination therapy develop anaemia and 13% progress to a haemoglobin of less than100 g/l. With the addition of protease inhibitors to pegylated INF and ribavirin treatment, anaemia can be more frequent and severe, occurring in the first few weeks of therapy.[174] An RCT compared the use of EPO as first line therapy to maintain haemoglobin, with ribavirin dose reduction in patients receiving boceprevir. This demonstrated that dose reduction of ribavirin maintained haemoglobin levels and provided similar SVR (71%) to patients whose treatment was supplemented with EPO. This finding was confirmed in patients with cirrhosis[175] and during phase three trials using telaprevir in triple therapy regimes.[176] **2+** **1+**

Granulocyte-colony stimulating factor (G-CSF) may relieve drug-induced neutropenia in patients receiving pegylated IFN and ribavirin therapy. It is most commonly needed in patients given antiviral therapy post liver transplant.[177] **3**

B **Erythropoietin should be considered in CHC patients receiving pegylated IFN and ribavirin therapy who develop anaemia, to prevent curtailment or dose reduction of ribavirin.**

B **For patients receiving a protease inhibitor in combination with pegylated IFN and ribavirin therapy, consider ribavirin dose reduction as an alternative to the addition of EPO for controlling anaemia.**

D **Granulocyte-colony stimulating factor should be considered on a case-by-case basis for patients who develop significant neutropenia while receiving treatment with pegylated IFN and ribavirin for CHC infection, to prevent curtailment or dose reduction of pegylated IFN.**

10.6.3 DEPRESSION

Depression is a commonly reported side effect of pegylated IFN and ribavirin therapy in both patients who have previously experienced depression and those who have not.[178] Antidepressants can be successfully used for treatment related depression and as a preventative measure prior to exposure to antiviral treatment.[166, 179] **1++** **1+** **3**

B **All patients receiving pegylated IFN and ribavirin should be monitored for signs of depression before, during and immediately post-treatment.**

B **Patients treated with pegylated IFN and ribavirin who experience depression should be considered for treatment with antidepressants and for referral to a specialist, if necessary.**

✓ A validated assessment tool (eg Hospital Anxiety and Depression score) should be used for monitoring depression.

10.6.4 SKIN REACTIONS

Severe skin reactions are uncommon during pegylated IFN or ribavirin therapy but dry skin, pruritus and diffuse eczematous lesions occur in approximately 20% of patients.[170] Psoriasis may also be exacerbated by treatment for CHC. Injection site reactions occur in over 50% of treated patients.[171] Skin lesions appear most commonly on the distal limbs and head and neck region, suggesting a predominance in sun-exposed areas.[180] Patients respond well to antihistamines, emollients and topical steroids, allowing continuation of treatment.[180] Discontinuation rates for dermatological side effects are approximately 3-4%.[181] **4** **3**

Three RCTs report on a potentially fatal rash, one of the principal adverse events of telaprevir treatment. This leads to discontinuation of telaprevir in 5-7% of patients. Once the medication is discontinued the rash resolves (although this may take several weeks). The rash is predominantly eczematous and pruritic. Fifty per cent of patients developing a rash do so within the first four weeks of treatment although it can occur at any time. Early intervention with topical steroids reduces the severity of rash. Rarely, telaprevir has been associated with Drug Reaction with Eosinophilia and Systemic Symptoms (DRESS) or Severe Cutaneous Adverse Reactions to Drugs (SCAR) syndromes, which includes Stevens Johnson syndrome and toxic epidermal necrolysis, and these should be monitored for and, if detected, therapy should be discontinued.[182-184] **1+** **1++**

D **All patients on pegylated IFN and ribavirin should be advised to ensure appropriate skin hygiene and hydration.**

D **Patients should be advised to avoid overexposure to sun.**

D **Patients should be advised to rotate injection sites.**

D **The use of emollients and topical corticosteroids can be considered for non-specific rashes.**

A **Patients taking telaprevir must be monitored closely for rash and treatment centres should have a rash management plan.**

✓ The use of antihistamines can be considered for pruritus.

✓ Severe dermatological reactions or those that do not respond to first line treatment should be referred for dermatological opinion.

✓ Patients taking telaprevir should be promptly assessed for severity according to the percentage of body surface area involved and the presence of systemic symptoms.

✓ Patients with a history of rash or skin problems should be considered for treatment with boceprevir rather than telaprevir.

10.6.5 THYROID DISFUNCTION

IFN therapy is associated with the development of thyroid dysfunction (both hypothyroid and hyperthyroid) in up to 6% of those treated.[170] Females are more at risk, especially those with thyroid autoantibodies before treatment.[185] IFN is associated with the induction and enhancement of thyroid autoimmunity, which is not always reversible.[186,187] Pre-treatment autoantibodies are not universally predictive of thyroid dysfunction during treatment.[170]

4
1-
2+

D **Thyroid function should be monitored at baseline before IFN therapy, at week 12 of treatment and at any time where there is a suspicion of thyroid dysfunction.**

✓ Patients developing thyroid dysfunction should be referred to an endocrinologist.

10.6.6 WEIGHT LOSS

Chronic hepatitis C infection causes increased basal metabolic rate in non-cirrhotic patients.[188] Weight loss is commonly reported in patients on antiviral treatment.[170,171,189] Nutritional therapy of patients with HCV is discussed in section 12.1.

2-
4

10.6.7 DYSPNOEA

Dyspnoea is a rarely reported side effect of pegylated IFN and ribavirin therapy. It may occur as a result of treatment-related anaemia but may also be caused by more serious cardiovascular or respiratory conditions.[170, 171,190]

2-
4

D **Patients treated with pegylated IFN or ribavirin who report dyspnoea that is not related to anaemia should be urgently assessed medically for cardiopulmonary problems.**

10.6.8 RETINOPATHY

Retinopathy during pegylated IFN therapy is common but generally mild and transient. It resolves spontaneously on discontinuing IFN and treatment is seldom required. The long term consequences are unknown.[191] Patients with hypertension or diabetes are at greater risk of developing retinopathy.[171] Other ophthalmic side effects are uncommon.

1+
4

D **Patients with CHC and hypertension or diabetes should have an ophthalmic examination prior to commencing treatment, paying particular attention to cotton wool spots and retinal haemorrhage.**

D **Any patient reporting visual disturbance during treatment should be examined further by an ophthalmologist.**

D **IFN should be discontinued in any patient with visual disturbance until it has resolved or an ophthalmologist has confirmed there is no retinal injury.**

10.6.9 ALOPECIA

Alopecia is a relatively common reported side effect of IFN and ribavirin therapy. Hair will grow again on cessation of treatment.[170, 171]

D **Patients should be advised that treatment related hair loss is reversible on cessation of treatment.**

10.6.10 OTHER SIDE EFFECTS

Other reported side effects of protease inhibitors include insomnia, poor concentration, oral disease, anal/rectal discomfort, gastrointestinal problems, altered taste, nausea, and post-treatment withdrawal symptoms. No evidence on their effective management was identified.

Fatigue is one of the most commonly reported side effects of IFN or ribavirin treatment and may be multifactorial with anaemia, hypothyroidism, sleep disturbance and depression all contributing.[170, 171]

4

10.7 RELAPSE OR FAILED TREATMENT

10.7.1 IFN AND RIBAVIRIN

Retreatment with a combination of pegylated IFN and ribavirin is effective in patients with CHC who have had unsuccessful treatment with non-pegylated IFN with or without ribavirin, and leads to sustained viral response in a proportion of patients. The SVR is highest in patients who had received prior treatment with non-pegylated IFN monotherapy, those infected with genotypes 2 or 3, those who had relapsed rather than not responded to previous treatment, and those who were not cirrhotic at time of retreatment.[192] **3**

Two trials which addressed retreatment of patients with genotype 1 HCV, in whom treatment had been previously unsuccessful, showed that there was significant benefit in repeating treatment with a pegylated IFN and ribavirin regimen with the addition of a protease inhibitor.[134] For telaprevir triple therapy the overall SVR were 64% (without lead-in), 66% (with a four week lead-in) and 17% in the dual therapy control group, the differences of 47% (95% CI 37 to 57; p<0.001) and 50% (95% CI 40 to 60; p<0.001) between the triple therapy and control groups were significant.[193] For boceprevir triple therapy the overall SVR were 59% (32 week triple therapy), 66% (44 week triple therapy) and 21% in the control group. The differences of 38% (95% CI 25.7 to 49.1; p<0.001) and 45% (95% CI 33.7 to 56.8; p=0.001) between triple therapy and control groups were significant.[194] **1+**

D **Patients with CHC who have had unsuccessful treatment with non-pegylated IFN and ribavirin should be considered for pegylated IFN and ribavirin retreatment.**

A **Patients with genotype 1 CHC who have had any unsuccessful treatment should be considered for treatment with a protease inhibitor based regimen.**

✓ Patients with genotype 2 or 3 CHC who have undergone a suboptimal therapy could be considered for retreatment with pegylated INF and ribavirin for 48 weeks.

10.8 MONITORING PATIENTS WHO ARE NOT RECEIVING TREATMENT

10.8.1 CLINICAL REVIEW

No evidence was identified regarding effective practice in monitoring and advising patients who are not candidates for treatment or who have received unsuccessful treatment.

✓ Patients should be encouraged to continue attending follow-up clinics for review in order to monitor their condition and discuss new therapies as they emerge.

✓ Patients should have access to counselling and specialist nurse services to provide support on lifestyle issues relating to hepatitis C.

10.8.2 ROLE OF LIVER BIOPSY

Routine liver biopsy during or after antiviral treatment is not indicated unless specific information is required in selected patients.[101] **1-**

11 Treatment of advanced infection

11.1 ANTIVIRAL THERAPY

11.1.1 PATIENTS WITH CIRRHOSIS

Patients with cirrhosis are defined as having compensated or decompensated cirrhosis. Those with decompensation have deterioration with development of one or more of the following: jaundice, ascites, variceal bleeding or encephalopathy.

There are several large well conducted RCTs of IFN and ribavirin, pegylated IFN and ribavirin, and pegylated IFN monotherapy in patients with chronic HCV who have a high likelihood of progressing to end stage liver disease.[122, 123, 195, 196] Subgroups within these trials had cirrhosis or advanced fibrosis. Randomisation distributed them evenly between the interventions so that subgroup analysis was possible. Therapy appeared no more toxic to the patients with cirrhosis compared to those without cirrhosis, but was less effective. The SVRs achieved were 50-70% for genotype 2 and 3, and 20-30% for genotype 1. A further systematic review in patients with cirrhosis have confirmed reduced risk in hepatocellular carcinoma in those who achieve SVR (RR 0.25; 95% CI 0.14 to 0.46; p=0.00001).[97] **1+**

Whilst improved over previous therapies, SVR rates are likely to remain low in previously non-responding patients with cirrhosis, particularly in the context of a poor response to lead-in pegylated IFN and ribavirin. Treating these patients with protease inhibitors is also likely to increase development of drug resistant mutants, potentially jeopardising the use of future direct-acting antivirals. Therefore, careful consideration should be given to the best management option for this group. In patients with advanced fibrosis or cirrhosis there are non-significant trends towards better SVR rates with fixed duration therapy, but there is currently insufficient evidence for the use of response-guided therapy in patients with cirrhosis.[134] Further study of the efficacy of protease inhibitors in patients with cirrhosis would be beneficial as major trials on telaprevir excluded patients with a platelet count of <90,000/mm^3.[133] **1+**

No head-to-head trials of the different pegylated IFNs were identified. Studies of long term therapy for patients with cirrhosis are ongoing.

A **Patients with compensated cirrhosis should be considered for therapy, unless contraindicated.**

Treatment with weekly maintenance low-dose pegylated IFN in patients with cirrhosis showed no significant difference in slowing disease progression or reducing clinical outcomes compared to patients receiving no treatment. There were no differences in development of HCC, decompensation or transplantation.[198,199] **1++**

One RCT showed that 48 weeks of escalating pegylated IFN monotherapy in predominantly treatment-experienced patients with cirrhosis showed a reduction in all cause mortality and non-oncological morbidity; however this study was inadequately powered and not as yet reproduced by other researchers.[200] The prospectively defined sub-analysis in another RCT of patients with portal hypertension showed that pegylated IFN delayed significant portal hypertensive events such as variceal bleeding.[201] **1-** **1+**

A **Low-dose pegylated IFN maintenance monotherapy should not be used in patients with compensated cirrhosis.**

There was insufficient evidence on the treatment of patients with HCV and decompensated cirrhosis to make a recommendation.

11.1.2 PATIENTS REFERRED FOR LIVER TRANSPLANT

Several studies have addressed the benefits of antiviral therapy given in the period leading up to, or following, orthotopic liver transplantation (OLT).[177, 202-205] In the period before transplantation many patients are excluded from therapy because of contraindications. SVR rates are low. There is little evidence for treatment in the peri-transplant period (the time period immediately before, during and after transplantation). Post-transplant therapy is poorly tolerated, due to anaemia and leucopenia, but appears safe in regard to graft failure. In those patients able to tolerate full dose therapy, high SVRs are achieved. **3** **1+**

D **Patients in whom transplant is planned should not receive antiviral therapy in the pre-transplant or peri-transplant stages, except as part of clinical trials.**

D **Patients should be considered for antiviral therapy post liver transplant to achieve HCV clearance in cases of recurrence of HCV related liver disease.**

11.2 LIVER TRANSPLANTATION

In early studies of patients transplanted for HCV cirrhosis, the five- and 10-year survival rates were equivalent to patients after OLT for non-HCV causes (68% and 60%).[205] In an analysis of the United Network for Organ Sharing (UNOS) database outcomes were studied in HCV positive (n=5,640, 43%) and HCV negative recipients (n=7,386, 56.7%). In the HCV negative and the HCV positive recipient populations, five-year patient survival rates were 83.5% versus 74.6% ($p<0.00001$) and five-year graft survival rates 80.6% *v* 69.9% ($p<0.00001$), respectively. HCV infection reduces outcome following transplantation but this effect is not sufficient to deny an individual patient transplantation.[206] **2+**

Patients with HCV and transplantable hepatocellular carcinoma (one lesion <5 cm or fewer than three lesions <3 cm, on cross-sectional imaging) have no decrease in survival benefit up to 48 months post orthotopic liver transplantation when compared to patients with HCV alone.[205, 207] **2+**

Quality of life in patients post OLT for HCV is equivalent to patients with non-HCV at three years.[208] **3**

C **Patients with hepatitis C virus and concurrent operable hepatocellular carcinoma should be offered liver transplantation.**

C **Patients with HCV associated chronic liver failure should be considered for assessment for liver transplantation.**

No studies were found on the effectiveness of retransplantation in patients with graft loss due to HCV recurrence.

11.3 SCREENING FOR HEPATOCELLULAR CARCINOMA

The results of studies evaluating the sensitivity and specificity of serum alfa-fetoprotein for detection of HCC in individuals with HCV indicate that in isolation this marker is of limited value.[209] **1+**

Annual ultrasound scanning of patients with cirrhosis and HCV does not detect tumours at a stage that permits likely curative treatment.[210] Scanning on a six-monthly basis may result in the detection of tumours at a stage that permits curative therapy.[211] **2+**

Methods of screening and surveillance other than alfa-fetoprotein and ultrasound remain experimental.

The rate of development of HCC in patients with HCV who are non-cirrhotic compared with patients who are is extremely low (7.6% versus 92.4%).[212] **2+**

A **The measurement of alfa-fetoprotein should not be used in isolation for screening or surveillance of the development of HCC in patients with hepatitis C.**

D **Surveillance using ultrasound should take place at six-monthly intervals.**

C **Surveillance should be confined to patients with cirrhosis.**

12 Nutrition, supportive care and complementary therapies

12.1 NUTRITIONAL INTERVENTIONS

12.1.1 DIETARY INTERVENTIONS

Protein energy malnutrition is common in all patients with chronic liver disease and can lead to weight loss. Chronic hepatitis C infection increases basal metabolic rate in non-cirrhotic patients.[188] Malnutrition (either under- or overweight) negatively affects nutritional status, quality of life and survival. Nutritional assessment to identify patients at risk and provision of nutritional support (enteral and parenteral) to improve clinical outcome should play an important role in patient care.[213] **2- 4**

Weight loss is commonly reported in patients on antiviral therapy.[170, 171, 189] This is possibly a result of other side effects, such as fatigue and depression, which may have a negative impact on appetite.[170, 171] **2- 3**

D

- **Nutritional care for people infected with hepatitis C should involve promotion of optimal nutrition and prevention or treatment of malnutrition or deficiencies of specific nutrients.**
- **Patients should have a nutritional screen and if needed a nutritional assessment and appropriate advice from a dietitian.**

D **Patients with advanced liver disease should be given nutritional support to minimise malnutrition.**

✓ Antiviral therapy represents a high risk period for weight loss so patients should be monitored closely and given nutritional support, as required, during treatment.

A systematic review of 11 RCTs found no conclusive evidence to support any benefit of branched chain amino acids (BCCA) in patients with cirrhosis and hepatic encephalopathy.[214] It was unclear how many of the patients included in the study were HCV positive. BCCA improve serum albumin levels in the compensated stage of cirrhosis in patients with a branch chain tyrosine ratio (BTR) <4 and serum albumin level between 35-39 g/l.[215, 216] The methodology used in these studies gave little consideration to confounding variables. **1++ 1-**

Coffee may have a protective effect against the development of hepatocellular carcinoma in patients with liver disease when consumed in quantities of three or more cups per day. It is unclear which compound in coffee causes the effect.[217, 218] **2+**

12.1.2 VITAMINS AND MINERALS

There is little evidence that individual vitamins and minerals may influence the natural history of CHC.

Zinc supplementation of 34 mg/day may have some beneficial effect on sustained viral response in patients taking IFN therapy; with genotype 1b; with viral load lower than $5x10^5$ copies/ml.[219] **2-**

Vitamin K2 may be beneficial in the prevention of development of HCC in patients with hepatitis C.[220] **2-**

Vitamin E supplementation had no beneficial effect in patients taking pegylated IFN and ribavirin. It does not appear to prevent ribavirin haemolysis or enhance virological clearance.[221] **1-**

Iron restricted to <7 mg/day in conjunction with a controlled calorie intake of 30 kcals/kg, protein intake of 1.1-1.2 g/kg, and fat at 15% of dietary intake, reduces aminotransferase levels.[222] **4**

Vitamin C supplementation of 600 mg/day is not beneficial in the prevention of retinopathy associated with IFN therapy.[191] **1-**

✓ Patients with chronic hepatitis C should be encouraged to achieve the UK recommended nutrient intake of vitamins and minerals.[223] They should be advised that there is no identified evidence to support amounts in excess of this.

✓ Patients whose serum ferritin levels are consistently high should not be advised to reduce dietary iron intake.

12.1.3 OVERWEIGHT

Studies have identified BMI>25 as being associated with hepatic steatosis, which leads to more severe fibrosis.[89, 224] Liver fibrosis, steatosis and ALT level decrease with supervised weight loss programmes of diet and regular exercise, aiming at 0.5 kg weight loss weekly.[225] **2+** **3**

C **Patients who are overweight should be advised to lose weight, within a realistic weight loss target, as this may have a beneficial effect on the degree of liver damage associated with hepatitis C infection.**

✓ Weight loss should only be considered if the patient is stable in their management of hepatitis C. Interventions aimed at weight reduction during antiviral treatment are not recommended, as side effects may lead to excessive unintentional weight loss.

✓ Patients on weight loss programmes should receive regular follow up and support.

12.2 SPECIALIST NURSE INTERVENTIONS

Specialist nursing support is key to maintaining adherence to treatment in patients with psychiatric conditions.[226] Specialist hepatology nursing has a significant role to play in helping patients to attain and maintain SVR.[227] **2-**

✓ Clinical nurse specialists should be an integral member of the clinical team caring for patients with chronic hepatitis C.

12.3 PSYCHOSOCIAL INTERVENTIONS

Two studies on psychological interventions for patients with hepatitis C showed no evidence of benefit. One small non-randomised trial showed some benefit, but the other, an RCT which tested individually tailored interventions, showed no difference in outcome from standard care.[228, 229] **2-** **1+**

12.4 EXERCISE

Light to moderate exercise programmes have been recommended for patients receiving treatment for hepatitis C.[170] A small cohort study found that patients on antiviral therapy have a reduced exercise tolerance.[230] **4** **2-**

D **Patients with hepatitis C should be encouraged to take mild to moderate exercise. Those on antiviral therapy should be advised that they may find their capacity for exercise reduced.**

12.5 COMPLEMENTARY THERAPIES

Two meta-analyses have concluded that there is no evidence to support the use of complementary or alternative medicines in the treatment of patients with hepatitis C.[231, 232] **1++**

None of the trials identified ran for a long enough period to show the long term safety or harm of herbal remedies.

✓ Patients should be made aware that there is a potential for harm associated with some complementary preparations.

12.6 PALLIATIVE CARE

No evidence was identified looking specifically at palliative care for patients with HCV.

13 Provision of information

To find out patients' main information needs, interviews and focus groups were held with patients, and questionnaires sent to people with hepatitis C across the UK by the Scottish Hepatitis C support network and the UK Hepatitis C resource centre. The results have been translated into questions and suggested answers (*see section 13.2*), which could be used to encourage discussions between patients and health professionals. Several of the organisations listed in section 13.1 produce good-quality patient leaflets.

13.1 SOURCES OF FURTHER INFORMATION

British Liver Trust
Portman House
44 High Street
Ringwood BH24 1AG
Tel: 01425 463080 • Fax: 01425 470706
www.britishlivertrust.org.uk

The British Liver Trust provides a range of publications on individual liver conditions and offers support to patients with liver disease and those who care for them.

Haemophilia Scotland
4b Gayfield Lane
Gayfield Place Lane
Edinburgh EH7 4AB
Tel: 0131 557 5953
Email: dan@haemophiliia.org.uk

Haemophilia Scotland provides services for people with haemophilia and von Willebrand's affected by HIV and viral hepatitis.

Hepatitis C Trust
5 Charlotte Square
Edinburgh EH2 4DR
Tel: 0131 777 0989 • Helpline: 0845 223 4424
www.hepctrust.org.uk • Email: helpline@hepctrust.org.uk

The Hepatitis C Trust was set up by people with the illness and runs a range of services that provide support, information and representation for people with hepatitis C.

Hepatitis New South Wales
www.hep.org.au

This Australian website has a wealth of excellent interesting and helpful information and resources on hepatitis, however some resources are specific to Australian healthcare systems.

Hepatitis Scotland
1/91 Mitchell Street
Glasgow G1 3LN

Tel: 0141 225 0419 • Fax: 0141 248 6414
www.hepatitisscotland.org.uk • Email: enquiries@hepatitisscotland.org.uk

Hepatitis Scotland is the national voluntary sector organisation funded by the Scottish Government to help improve responses to viral hepatitis prevention, treatment and support.

13.2 INFORMATION ABOUT HEPATITIS C FOR PATIENTS AND CARERS

WHAT IS HEPATITIS C?

Hepatitis C is an illness caused by a virus which can be passed through blood from one person to another. It mainly affects the liver.

When your liver becomes inflamed it can become damaged and eventually has difficulty carrying out its various and vital functions. Over a long period of time, this can progress to serious liver damage (such as fibrosis and cirrhosis) or, in some people, liver cancer (hepatocellular carcinoma).

HOW DOES IT AFFECT PEOPLE?

Hepatitis C is a potentially life threatening condition that can affect you physically and emotionally. It can affect your quality of life. Treatment is available which can cure hepatitis C in the majority of people.

WHAT ARE THE SYMPTOMS OF HEPATITIS C?

Some people have no symptoms at all for many years while others may feel extreme tiredness, have sweats (especially at night), aches and pains, loss of appetite and concentration problems. Symptoms may come and go. In the later stages of the infection if the liver is more seriously damaged, there may be symptoms such as jaundice, itchiness, internal bleeding and a swollen abdomen.

HAVE I BEEN AT RISK?

Times when blood from someone infected with hepatitis C may get into the bloodstream of another person include:

- having a blood transfusion or surgical treatment abroad or in the UK before 1991, or blood products in the UK before about 1987 (transfusions and blood products are now safe from HCV infection in the UK);
- having medical or dental treatment in countries where hepatitis C is common and infection control may be poor;
- sharing any equipment when injecting or snorting drugs;
- sharing items such as razors, toothbrushes or any item that can scratch the skin;
- piercing, tattooing and cosmetic injection procedures (eg botox) if any equipment is reused;
- sexual activity, although the risk is low except where there is a risk of bleeding;
- being exposed to blood at work, for example, a needlestick injury, cuts, cleaning up blood, and dealing with violent incidents where blood is involved;
- transmission from mother to child around the time of birth.

SHOULD I BE TESTED?

If you think you may have been at risk, then you should get tested. The earlier treatment starts the more likely it is to provide a cure for the infection. If you know you are positive you can avoid infecting others.

WHAT DOES THE TEST TELL YOU ABOUT BEING POSITIVE OR NEGATIVE?

There are three types of test. The first type of test (the HCV antibody test) tells you if you have ever had the virus. Some people get rid of the virus naturally without medical help. The second type (PCR test) tells you if you still have the virus in your body (that is if you are infected with hepatitis C). If the PCR test is positive a further test will reveal the genotype (strain) of virus you have. The genotype will determine the treatment you receive.

WHAT ABOUT CONFIDENTIALITY?

Confidential testing is available in GP surgeries and at other sites. Your test results are confidential and will not be shared with others without your permission. GPs will only pass on information about positive tests to insurance companies if you have applied for insurance and given your consent for release of medical information. Negative tests will not be disclosed.

You can find information on hepatitis services across Scotland by visiting the Hepatitis Scotland website (*see section 13.1*)

ARE MY FAMILY AND FRIENDS AT RISK? SHOULD I TELL THEM?

The support of your family and friends is important and you should consider telling them about your diagnosis and what the effects and side effects of treatment are likely to be. You cannot infect your family and friends through everyday activities, such as sharing utensils, hugging or kissing.

To avoid infecting others,

- do not share items such as toothbrushes or razors
- clean up any blood spills with diluted bleach
- do not share any drug taking equipment (eg tooters, needles and syringes, water or cookers etc).

The risk of sexual transmission is very low in the absence of other complicating factors such as:

- blood from menstruation or anal sex
- ulcers or sores on your genitalia ie from a sexually transmitted infection such as gonorrhea, herpes or genital warts.

HOW WILL IT AFFECT MY JOB AND JOB PROSPECTS?

Many people stay well enough to work but you may have to make some adjustments to your routine if you have extreme tiredness or other symptoms.

You do not usually have to tell your employer that you have hepatitis C (unless you are a healthcare worker involved in procedures that may involve exposure to blood, for example some surgeries. However side effects of treatment may mean that you feel ill and unable to work for a period of time. It may be helpful to tell them that you are having treatment. For example, they may support you by changing your working hours or reducing any physical activities associated with your job during treatment.

HOW WILL A POSITIVE DIAGNOSIS AFFECT MY LIFE INSURANCE COVER?

In common with any serious health condition, a diagnosis of hepatitis C will have an impact when taking out life insurance. There are many types of life insurance cover so it is worth checking any policies you have as you may need to tell the insurer if you have a change in your health status. It is important to remember that any information you provide to your insurer forms part of a legal contract. If the information is inaccurate or untrue the agreement may be invalid.

If you are applying for insurance and consented for release of medical information, the person who tested you is legally obliged to pass on information about a positive test result if asked to by an insurance company.

You should read the small print on current or new insurance agreements before signing.

HOW WILL A NEGATIVE TEST AFFECT MY LIFE INSURANCE COVER?

Doctors do not need to give insurers any information about a negative test. Insurers can only ask for information where someone has had a positive test or is receiving treatment.

WHAT HAPPENS DURING TESTING?

Before you have a test a healthcare professional will discuss with you what happens. This will help you to understand the testing process, the test results and confidentiality.

Blood samples will be sent for laboratory testing. If your exposure to the virus has been in the last six months, you may be asked to return for a repeat test. This is because there is a 'window' period after exposure until the test becomes positive.

If your test is negative, the healthcare team will give you advice on how to avoid putting yourself at risk in the future. If your test is positive, they will explain what this means and refer you to a specialist clinic for assessment.

WHAT HAPPENS NEXT?

Assessment will include blood tests such as liver function tests (LFT), a genotype (strain of hepatitis C virus) test, an examination, discussions about lifestyle, other medical conditions and medicines you take, ultrasound scan, fibroscan and, in rare circumstances, a liver biopsy. A liver biopsy means taking a small piece of the liver for laboratory analysis. This is done under local anaesthetic but is not required before starting treatment.

When the assessment is complete, your healthcare team will talk to you about treatment. Treatment is very effective and side effects can be managed with good care and support. Your clinic should help you to find support as part of your care while on treatment. Treatment is not suitable for everyone and depends on other medical conditions or complications you may have.

While you or your partner are on treatment, and for six to 12 months afterwards, you should both use contraception to avoid pregnancy because these drugs may be harmful to an unborn baby.

LIVING WITH HEPATITIS C

There are a number of things that you can do for yourself that make living with chronic hepatitis C easier.

- Do not drink alcohol. Alcohol and hepatitis C damage the liver, and in combination cause damage at a faster rate. Professional support is available to help you reduce or stop drinking.
- Cut down on rich, fatty and sugary foods as a balanced diet is crucial. Losing excess weight puts less strain on your liver. However, weight loss can be a side effect of treatment and food supplements may be required. Professional help to reach a healthy balanced diet is available.
- If you have a poor appetite, try and eat smaller meals more often.
- Try to exercise regularly. It can reduce stress and depression, increase energy levels and help boost your immune system.
- Follow the dosage instructions for prescribed and over-the-counter medications. Both over-the-counter and illicit drugs are processed by the liver and may put extra strain on it. Illicit drugs may also contain impurities which are harmful.
- Stop smoking if you have hepatitis C. Stopping smoking reduces the risk of getting cancer. Help is available to stop smoking.
- Speak to your GP about vaccinations against hepatitis A and B. Other types of liver infection, especially when you already have hepatitis C, put much more strain on your liver and can slow or stop recovery for all types of hepatitis. You should also make sure you get the seasonal flu vaccination as an extra precaution when your immune system may be weakened.

There is very little evidence that complementary medicines are effective, but many patients find them helpful in dealing with the many different symptoms associated with this disease. It is important to get professional advice before starting these.

WHAT SUPPORT CAN I GET?

There are various specialist support services for people with hepatitis C, such as counselling, peer support from other people with hepatitis C, and support to help with making decisions.

Hepatitis C can make people feel very isolated and emotional support is important. You should expect:

- comprehensive team services providing good communication;
- good quality information;
- involvement at all stages of your care and treatment;
- access to specialist services as you require them, and
- regular assessment of your support needs.

14 Implementing the guideline

14.1 IMPLEMENTATION STRATEGY

Implementation of national clinical guidelines is the responsibility of each NHS Board and is an essential part of clinical governance. Mechanisms should be in place to review care provided against the guideline recommendations. The reasons for any differences should be assessed and addressed where appropriate. Local arrangements should then be made to implement the national guideline in individual hospitals, units and practices.

14.2 RESOURCE IMPLICATIONS OF KEY RECOMMENDATIONS

No recommendations were identified as having significant budgetary impact.

14.3 AUDITING CURRENT PRACTICE

There are two mechanisms for auditing practice around the testing, treatment care and support provided by hepatitis C services in Scotland. The first is the Healthcare Improvement Scotland Hepatitis C Quality Indicators which are self audited by health boards. The second is the performance indicators contained within the Blood Borne Virus and Sexual Health framework which are audited nationally by the Scottish Government.

14.4 ADDITIONAL ADVICE TO NHS SCOTLAND FROM HEALTHCARE IMPROVEMENT SCOTLAND AND THE SCOTTISH MEDICINES CONSORTIUM

In September 2011, the Scottish Medicines Consortium (SMC) advised that boceprevir was accepted for use within NHSScotland for the treatment of CHC genotype 1 infection, in combination with pegylated IFN and ribavirin, in adult patients with compensated liver disease who have failed previous therapy or who have been previously untreated.

In September 2011, the Scottish Medicines Consortium (SMC) advised that telaprevir in combination with pegylated IFN and ribavirin, is indicated for the treatment of genotype 1 CHC in adult patients with compensated liver disease (including cirrhosis) who have previously been treated with interferon alfa (pegylated or non-pegylated) alone or in combination with ribavirin, including relapsers, partial responders and null responders or patients who are treatment naive.

15 The evidence base

15.1 SYSTEMATIC LITERATURE REVIEW

The evidence base for this guideline was synthesised in accordance with SIGN methodology. A systematic review of the literature was carried out using an explicit search strategy devised by a SIGN Evidence and Information Scientist. Databases searched include Medline, Embase, Cinahl, PsycINFO and the Cochrane Library. The year range covered was 2006-2012. Internet searches were carried out on various websites including the US National Guidelines Clearinghouse. The main searches were supplemented by material identified by individual members of the development group. Each of the selected papers was evaluated by one member of the group and one SIGN staff member using standard SIGN methodological checklists before conclusions were considered as evidence.

15.1.1 LITERATURE SEARCH FOR PATIENT ISSUES

At the start of the guideline development process, a SIGN Evidence and Information Scientist conducted a literature search for qualitative and quantitative studies that addressed patient issues of relevance to early management of patients with hepatitis C. Databases searched include Medline, Embase, Cinahl and PsycINFO, and the results were summarised and presented to the guideline development group.

15.2 RECOMMENDATIONS FOR RESEARCH

The guideline development group was not able to identify sufficient evidence to answer all of the key questions asked in this guideline (*see Annex 1*). The following areas for further research have been identified:

- management of hepatitis C in children
- treatment in active drug users
- care pathways for the management of hepatitis C (older patients, prisoners, transplant patients, decompensated cirrhotic patients)
- testing and screening approaches.

15.3 REVIEW AND UPDATING

This guideline was issued in 2013 and will be considered for review in three years. Any updates to the guideline in the interim period will be noted on the SIGN website: **www.sign.ac.uk**

16 Development of the guideline

16.1 INTRODUCTION

SIGN is a collaborative network of clinicians, other healthcare professionals and patient organisations and is part of Healthcare Improvement Scotland. SIGN guidelines are developed by multidisciplinary groups of practising clinicians using a standard methodology based on a systematic review of the evidence. Further details about SIGN and the guideline development methodology are contained in SIGN 50: A Guideline Developer's Handbook, available at **www.sign.ac.uk**

16.2 THE GUIDELINE DEVELOPMENT GROUP

Dr John Dillon *(Chair)*	*Consultant Hepatologist and Gastroenterologist, Ninewells Hospital, Dundee*
Dr Andrew Bathgate	*Consultant Hepatologist, Royal Infirmary of Edinburgh*
Dr Pete Bramley	*Consultant Gastroenterologist, Stirling Royal Infirmary*
Ms Katherine Davidson	*Senior Pharmacist (Liver Transplant), Royal Infirmary of Edinburgh*
Ms Pauline Dundas	*Nurse Specialist, Summerfield House, Aberdeen*
Dr Ray Fox	*Consultant Physician, Brownlee Centre, Gartnavel General Hospital, Glasgow*
Dr Andrew Fraser	*Consultant Physician in Gastroenterology, Summerfield House, Aberdeen*
Dr Rosie Hague	*Consultant in Paediatric Infectious Diseases and Immunology, Royal Hospital for Sick Children, Glasgow*
Mr Stephen Heller-Murphy	*Programme Manager/Health Services Researcher, SIGN, Healthcare Improvement Scotland*
Ms Fiona Marra	*Advanced Pharmacist HIV/HCV, Brownlee Centre, Gartnavel General Hospital, Glasgow*
Ms Kim McBeth	*Clinical Nurse Practitioner (Gastroenterology), Royal Infirmary of Edinburgh*
Mr Tom McEwan	*Specialist Clinical Pharmacist, Ninewells Hospital, Dundee*
Ms Pauline Morrison	*Specialist Pharmacist, Stirling Royal Infirmary*
Ms Joy Nicholson	*Pharmacist, Medicines Strategy, Healthcare Improvement Scotland*
Mr Walter Speirs	*Patient Representative*
Ms Jan Tait	*Clinical Nurse Specialist, Ninewells Hospital, Dundee*
Ms Petra Wright	*Scottish Officer, Hepatitis C Trust, Edinburgh*
Mr Leon Wylie	*Director, Hepatitis Scotland, Glasgow*
Dr David Yirrell	*Consultant Clinical Scientist (Virology), Ninewells Hospital, Dundee*

The membership of the guideline development group was confirmed following consultation with the member organisations of SIGN. All members of the guideline development group made declarations of interest and further details of these are available on request from the SIGN Executive.

Guideline development and literature review expertise, support and facilitation were provided by the SIGN Executive. All members of the SIGN Executive make yearly declarations of interest and further details of these are available on request.

Mrs Karen Graham	*Patient Involvement Officer*
Mr Stuart Neville	*Publications Designer*
Miss Gaynor Rattray	*Guideline Coordinator*
Mr Campbell Reynolds	*Distribution and Office Coordinator*

16.2.1 ACKNOWLEDGEMENTS

SIGN would like to acknowledge the guideline development group responsible for the development of SIGN 92: Management of hepatitis C, on which this guideline is based.

16.3 CONSULTATION AND PEER REVIEW

16.3.1 SPECIALIST REVIEWERS INVITED TO COMMENT ON THIS DRAFT

This guideline was reviewed in draft form by the following independent expert referees, who were asked to comment primarily on the comprehensiveness and accuracy of interpretation of the evidence base supporting the recommendations in the guideline. The guideline group addresses every comment made by an external reviewer, and must justify any disagreement with the reviewers' comments. All expert referees made declarations of interest and further details of these are available on request from the SIGN Executive.

SIGN is very grateful to all of these experts for their contribution to the guideline.

Dr Stephen Barclay	*Consultant Gastroenterologist, Glasgow Royal Infirmary*
Dr David Bell	*Consultant in Infectious Diseases, Brownlee Centre, Gartnavel General Hospital, Glasgow*
Mr. Charles Gore	*Director of the Hep C Trust*
Dr Magdalena Harris	*Lecturer, London School of Hygiene and Tropical Medicine*
Dr Carole Hunter	*Lead Pharmacist, Addiction Services, NHS Greater Glasgow and Clyde*
Professor William Irving	*Professor and Honorary Consultant in Virology, University of Nottingham and Nottingham University Hospitals NHS Trust.*
Dr Janice Main	*Reader and Consultant Physician in Infectious Diseases and General Medicine, Imperial College at St Mary's Hospital, London*
Dr Claire McIntosh	*Consultant Addiction Psychiatrist, Community Alcohol and Drug Service, Falkirk Community Hospital*
Dr Ewan Stewart	*Clinical Lead, Lothian Hepatitis MCN, NHS Lothian*

16.3.2 SIGN EDITORIAL GROUP

As a final quality control check, the guideline is reviewed by an editorial group comprising the relevant specialty representatives on SIGN Council to ensure that the specialist reviewers' comments have been addressed adequately and that any risk of bias in the guideline development process as a whole has been minimised. The editorial group for this guideline was as follows. All members of the SIGN Editorial group make yearly declarations of interest and further details of these are available on request from the SIGN Executive.

Professor Keith Brown	*Chair of SIGN; Co-Editor*
Dr Roberta James	*SIGN Programme Lead; Co-Editor*
Dr Sara Twaddle	*Director of SIGN; Co-Editor*

Abbreviations

ALT	alanine aminotransferase
BBV	blood borne virus
BCCA	branched chain amino acids
BMI	body mass index
BNF	British National Formulary
BTR	branch chain tyrosine ratio
CHC	chronic hepatitis C
CI	confidence interval
CYP	cytochrome P450
DDI	drug-drug interaction
DRESS	Drug Reaction (or rash) with Eosinophilia and Systemic Symptoms
ELISA	enzyme linked immunosorbent assay
EPP	exposure prone procedures
EPO	erythropoietin
EVR	early viral response
G-CSF	granulocyte-colony stimulating factor
GMC	General Medical Council
GUM	genitourinary medicine
HBV	hepatitis B virus
HCC	hepatocellular carcinoma
HCV	hepatitis C virus
HIC	hepatic iron concentration
HIV	human immunodeficiency virus
IDU	injecting drug users
IFN	interferon
IU	international units
LFT	liver function tests
MA	marketing authorisation
MTA	medical technology assessment
NAT	nucleic acid test
NICE	National Institute for Health and Care Excellence
OLT	orthotopic liver transplantation
PCR	polymerase chain reaction
PNALT	persistently normal serum alanine aminotransferase
QOL	quality of life
RCT	randomised controlled trial

RNA	ribonucleic acid
RR	relative risk
RT PCR	reverse transcriptase polymerase chain reaction
RVR	rapid viral response
SCAR	Severe Cutaneous Adverse Reaction to Drugs
SEM	standard error of the mean
SIGN	Scottish Intercollegiate Guidelines Network
SMC	Scottish Medicines Consortium
SVR	sustained viral response
UK	United Kingdom
UNOS	United Network for Organ Sharing

Annex 1

Key questions addressed in this update

This guideline is based on a series of structured key questions that define the target population, the intervention, diagnostic test, or exposure under investigation, the comparison(s) used and the outcomes used to measure efficacy, effectiveness, or risk. These questions form the basis of the systematic literature search strategy (*see section 15.1)*.

Key question
1. What is the evidence for treating patients with acute hepatitis C in terms of: • viral genotype • optimal timing of treatment • duration of treatment • choice of therapy – interferon versus pegylated interferon versus. pegylated interferon + ribavirin Outcome: sustained viral response/symptoms/Quality of Life (QOL)/adverse effects.
2. What is the evidence for the benefit of antiviral therapy (pegylated interferon + ribavirin) in patients with chronic hepatitis C in terms of: • viral genotype • duration of therapy • early viral response • viral kinetics Outcome: sustained viral response/symptoms/QOL/adverse effects How effective is treatment in the following subgroups? Consider: a) Age/age of acquisition b) Gender c) Different ethnic groups (South East Asian, Indian, Pakistani, Bangladeshi, Caucasian) d) Severity of disease – mild disease/cirrhosis e) Normal serum transaminases f) HIV co-infection g) Hepatitis B co-infection h) Obesity i) Smoking j) Alcohol intake above recommended guidelines k) Iron overload l) Viral genotype m) Active drug addiction or use n) Oral methadone/buprenorphine o) Patients with extrahepatic disease – fatigue, arthralgia, cryoglobulinaemia, glomerulonephritis, sicca syndrome, porphyria cutanea tarda, lichen planus, B cell non-Hodgkin lymphoma p) Non-response/relapse after previous interferon monotherapy or interferon/ribavirin combination therapy

3. What is the evidence that standard antiviral treatment is best avoided in the following subgroups (absolute and relative contraindications)?

   Consider:

   a) Pregnancy, breast feeding, inability to use effective contraception

   b) Chronic renal failure

   c) Age

   d) Alcohol intake above recommended guidelines

   e) Active drug addiction and use
      - ongoing injecting drug use
      - ongoing drug use (non-injecting)
      - substitute prescribing

   f) Mental health problems – depression, psychosis, learning disability

   g) Epilepsy or history of seizures

   h) Neoplasia

   i) Congestive cardiac failure/respiratory failure

   j) Psoriasis

   k) Haemolytic anaemia

   l) Anaemia, leucopenia, thrombocytopaenia

   m) Retinopathy – diabetic, hypertensive

   n) Obesity – body mass index ≥ 30

   o) Organ transplantation – liver, renal, bone marrow

   p) Autoimmune conditions – autoimmune hepatitis, hyperthyroidism

   q) Normal serum transaminases

   r) Mild chronic hepatitis C

   s) Relapse/non-response after previous antiviral therapy

   t) Hypersensitivity to interferon or ribavirin

   u) Other medications – immunosuppressants, myelosuppressants, theophylline, nucleoside reverse transcriptase inhibitors.

4. For patients who relapse following treatment or who are non-responders to standard antiviral treatment what evidence is there for additional drug therapies?

Consider:

Amantadine, thymosin, histamine, long term interferon treatment.

Recommendations for Testing, Managing, and Treating Hepatitis C

Downloaded from http://www.hcvguidelines.org

Visit the HCV Guidance website to access the most up-to-date version

Revised Date: August 11, 2014

Collaborating Partner

INTRODUCTION

NOTICE: Guidance for hepatitis C treatment is changing constantly with the advent of new therapies and other developments. A static version of this guidance, such as printout of this website material, booklet, slides, and other materials, may be outdated by the time you read this. We urge you to review this guidance on this website (www.hcvguidelines.org) for the latest recommendations.

The landscape of treatment for hepatitis C virus (HCV) infection has evolved substantially since the introduction of highly effective HCV protease inhibitor therapies in 2011. The pace of change is expected to increase rapidly, as numerous new drugs with different mechanisms of action will likely become available over the next few years. To provide healthcare professionals with timely guidance as new therapies are available and integrated into HCV regimens, the Infectious Diseases Society of America (IDSA) and American Association for the Study of Liver Diseases (AASLD) have developed a web-based process for the rapid formulation and dissemination of evidence-based, expert-developed recommendations for hepatitis C management. The International Antiviral Society–USA (IAS–USA) provides the structure and assistance to sustain the process that represents the work of leading authorities in hepatitis C prevention, diagnosis, and treatment.

The AASLD/IDSA/IAS–USA hepatitis C Guidance addresses management issues ranging from testing and linkage to care, the crucial first steps toward improving health outcomes for HCV-infected persons, to the optimal treatment regimen in particular patient situations. Recommendations are based on evidence and are rapidly updated as new data from peer-reviewed evidence become available. For each treatment option, recommendations reflect the best possible management for a given patient and a given point of disease progression. Recommendations are graded with regard to the level of the evidence and strength of the recommendation. The AASLD/IDSA/IAS–USA hepatitis C Guidance is supported by the membership-based societies and not by pharmaceutical companies or other commercial interests. The Boards of Directors of AASLD and IDSA have appointed an oversight panel of 5 co-chairs and have selected panel members from the 2 societies based on their expertise in hepatitis C research and care**.** Likewise, the Guidance development process is generally consistent with that used by the IAS-USA (https://www.iasusa.org/about/program-development-policy).

This Guidance should be considered a "living document" in that new sections will be added (eg, Who and When to Initiate Treatment, and Monitoring Patients Who are On or Have Completed Therapy are coming soon) and the Guidance will be updated frequently as new information and treatments become available. This continually evolving report provides guidance on FDA-approved regimens. At times, it may also recommend off-label use of certain drugs or tests or provide guidance for regimens not yet approved by FDA. Readers should consult prescribing information and other resources for further information. Of note, the choice of treatment may, in the future, be further guided by data from cost-effectiveness studies.

Changes made on this page on March 12, 2014.

METHODS

The Guidance was developed by a panel of HCV experts in the fields of hepatology and infectious diseases, using an evidence-based review of information that is largely available to healthcare practitioners. The process and detailed methods for developing the Guidance are detailed in **Methods Table 1**. Recommendations were graded according to the strength of the recommendation and quality of the supporting evidence (see **Methods Table 2**). Commonly used abbreviations are expanded in **Methods Table 3**.

Methods Table 1. Summary of the Process and Methods for the Guidance Development

Topic	Description
Statement of Need	The introduction of direct-acting agents against HCV in 2011 has rapidly changed the treatment of HCV and the timely diagnosis of infection remains essential. This ever increasing pace of change anticipates numerous additional therapies in the next few years, requiring timely guidance on how each new development changes practice for health care professionals.
Goal of the Guidance	The goal of the Guidance is to provide up-to-date recommendations to health care practitioners on the optimal screening, management, and treatment for adults with HCV infection in the United States, considering the best available evidence. The Guidance will be updated regularly, as new data, information, and tools and treatments become available. The initial recommendations address 4 areas of priority: screening, testing, and linkage to care; initial treatment regimens in persons for whom the decision to treat has been made; retreatment regimens and considerations for persons for whom the decision to treat has been made; and treatment in unique patient populations.
Panel members	The Panel members were chosen because of their expertise in the diagnosis, management, and treatment of HCV infection in terms of research and patient care. Members from the fields of hepatology and infectious diseases are included. Members were appointed by the respective Sponsor Societies after vetting by an appointed Sponsor Society committee. At least 1 representative from the hepatitis C community serves on the Panel. The Panel chairs were appointed by the Society boards, 2 each from the Sponsor Societies and 1 representing the Collaborating Partner. All Panel chairs and members serve as volunteers (not compensated) for defined terms (3 years), which may be renewed.
Conflict of interest management	The panel was established with the goal of having no personal (ie, direct payment to the individual) financial conflicts among its chairs and among fewer than half of its members. All potential panel members were asked to disclose any relationship with a pharmaceutical, biotechnology, medical device, or health-related company or venture that may result in financial benefit. Disclosures were obtained prior to the panel member appointments and prior to the initiation of the work of the panel (October 2013). Individuals were asked to report activities and personal financial relationships/investments that were current or planned and for the preceding year (prior to October 2013). Individuals were also asked to disclose commercial funding of research activities to their institutions or organizations. Disclosures were reviewed by the HCV Guidance Chairs , which made assessments based on the conflict of interest policies of the sponsoring organizations (AASLD and IDSA) and the collaborative partner (IAS-USA). Personal and institutional financial relationships with commercial entities that

	have products in the field of hepatitis C were assessed. The following relationships were prohibited: ▪ Employment with an affected company ▪ An ownership interest in an affected company ▪ Participation in/payment for promotional or marketing activities including non-CME or speakers bureaus and lectures for affected companies The following relationships/activities were reportable but were not deemed to merit exclusion: ▪ Commercial support of Research. Due to the rapidly evolving nature of the subject matter, having individuals with expertise in the particular clinical topic was critical to developing the highest-quality and most-informed recommendations. To that end, research was not considered an unresolvable conflict if the funding of the research was paid to the institution, as opposed to the individual. In the instance of someone conducting clinical research in a community practice, research funds to the group practice were acceptable. ▪ Participation on commercial company Scientific advisory boards. Participation in advisory boards or in consultancies sponsored by the research arm of a company (eg, study design or data safety monitoring board) was considered a potential personal conflict but was not considered a criterion for exclusion. The HCV Guidance Chairs achieved a majority of panel members with no personal financial interests. The Panel met face-to-face in October 2013 and meets by conference call regularly to develop and update the Guidance. Panel members were asked to inform the group of any changes to their disclosure status and were given the opportunity to recuse themselves (or be recused) from the discussion where a perceived conflict of interest that could not be resolved existed. Financial disclosures for each Panel member can be accessed here.
Intended Audience	Medical practitioners especially those who provide care to or manage patients with hepatitis C.
Sponsors, funding, and collaborating partner	The American Association for the Study of Liver Diseases (AASLD) and the Infectious Diseases Society of America (IDSA) are the Sponsors of the Guidance and provide financial support. The International Antiviral Society-USA (IAS-USA) is the Collaborating Partner responsible for providing expertise and managing the Panel and the Guidance development process. Centers for Disease Control and Prevention (CDC) provided financial support for the gathering and review of evidence related to hepatitis C screening and testing recommendations and interventions to implement HCV screening in clinical settings.

Evidence identification and collection	The Guidance was developed using an evidence-based review of information that is largely available to health care practitioners. Data from the following sources are considered by Panel members when making recommendations: research published in the peer-reviewed literature or presented at major national or international scientific conferences, safety warnings from FDA or other regulatory agencies or from manufacturers, drug interaction data, prescribing information from FDA-approved products, and registration data for new products under FDA review. Unpublished or presented reports, data on file, and personal communications are generally not considered. Panel members were appointed based on their collective broad knowledge of available data and current research in the field. These experts were responsible for initially identifying and discussing relevant data, including recent reports from scientific conferences. An initial literature search was conducted on November 4, 2013, to ensure that the Panel addressed all relevant published data. A total of 3939 unique citations were retrieved. Medical subject headings and free text terms were combined to maximize retrieval of relevant citations from the PubMed, Scopus, EMBASE, and Web of Science databases. To be considered for inclusion, articles were required to have been published in English from 2010 to the present. Review articles, studies using mice or rats, and in vitro studies were excluded from consideration. The Panel members regularly monitor the field for new evidence, and the literature search is updated as needed.
Grading of the evidence and RECOMMENDATIONS	The Guidance is presented in the form of RECOMMENDATIONS. Each RECOMMENDATION is graded in terms of the level of the evidence and strength of the recommendation, using a scale adapted from the American College of Cardiology and the American Heart Association Practice Guidelines. (American Heart Association, 2014); (Shiffman, 2003) A summary of the supporting (and conflicting) evidence follows each RECOMMENDATION or set of RECOMMENDATIONS.
Data review and synthesis and preparation of RECOMMENDATIONS and supporting information	The Guidance was initially divided into 3 subsections: 1) Testing and Linkage to Care; 2) Choice of Regimen in Treatment-Naive Patients For Whom the Decision to Treat Has Been Made, and 3) Retreatment for Patients in Whom the decision to treat has been made. It was later decided to make treatment for unique patient populations a separate section. Subgroups of the panel were assigned to collect, review, and prepare initial draft RECOMMENDATIONS. Draft RECOMMENDATIONS were reviewed at the first full Panel meeting in October 2013. Subgroups of the Panel then met regularly by conference call and presented their updated RECOMMENDATIONS and supporting evidence at each of 3 full-Panel conference calls. Final approval of all RECOMMENDATIONS was made by full-Panel, general consensus. Initial recommendations and their grades were individually subject to Panel survey; panelists were given the opportunity to agree,

	disagree, and provide comment. This procedure helped identify any disagreement or inconsistency between Panel members for each recommendation. Sponsor Societies have final review and approval of each recommendation prior to release of the Guidance on the website, www.hcvguidelines.org.
Update Process	The Guidance will be expanded to cover more management issues as needed, and will be updated on an ongoing basis. Panel members will regularly monitor the field for data that may warrant modification of the Guidance. Updates may be prompted by new publications or presentations at major national or international scientific conferences, new drug approvals (or new indications, dosing formulations, or frequency of dosing), new safety warnings, or other information that may have a substantial impact on the clinical care of patients. Updated RECOMMENDATIONS and ratings, once agreed on by the full Panel and approved by the Sponsor Societies, are posted on the Guidance website.
Abbreviations	Commonly used abbreviations in the text with their expansions are listed in Methods Table 3.
Opportunity for Comments	Evidence-based comments may be submitted to the Panel by email hcvguidelines@iasusa.org, or clicking on the “Send a comment to the Panel” button on www.hcvguidelines.org/contact-us. The Panel considers evidence-based comments about the RECOMMENDATIONS, grades, and evidence summary, but should not be contacted for individual patient management questions.

Methods Table 2. Grading System Used to Rate the Level of the Evidence and Strength of the Recommendation for Each Recommendation

Recommendations are based on scientific evidence and expert opinion. Each recommended statement includes a Roman numeral (**I**, **II**, or **III**) that represents the level of the evidence that supports the recommendation, and a letter (**A**, **B**, or **C**) that represents the strength of the recommendation.

Classification	Description
Class I	Conditions for which there is evidence and/or general agreement that a given diagnostic evaluation, procedure, or treatment is beneficial, useful, and effective
Class II	Conditions for which there is conflicting evidence and/or a divergence of opinion about the usefulness and efficacy of a diagnostic evaluation, procedure, or treatment
Class IIa	Weight of evidence and/or opinion is in favor of usefulness and efficacy
Class IIb	Usefulness and efficacy are less well established by evidence and/or opinion
Class III	Conditions for which there is evidence and/or general agreement that a diagnostic evaluation, procedure, or treatment is not useful and effective or if it in some cases may be harmful
Level of Evidence	**Description**
Level A*	Data derived from multiple randomized clinical trials, meta-analyses, or equivalent
Level B*	Data derived from a single randomized trial, nonrandomized studies, or equivalent
Level C	Consensus opinion of experts, case studies, or standard of care

Adapted from the American College of Cardiology and the American Heart Association Practice Guidelines. (American Heart Association, 2011); (Shiffman, 2003)

*In some situations, such as for IFN-sparing HCV treatments, randomized clinical trials with an existing standard-of-care arm cannot ethically or practicably be conducted. The US Food and Drug Administration (FDA) has suggested alternative study designs, including historical controls or immediate versus deferred, placebo-controlled trials. For additional examples and definitions see FDA link: http://www.fda.gov/downloads/Drugs/GuidanceComplianceRegulatoryInformation/Guidances/UCM225333.pdf. In those instances for which there was a single pre-determined, FDA-approved equivalency established, panel members considered the evidence as equivalent to a randomized controlled trial for levels A or B.

Methods Table 3. Commonly Used Abbreviations and Their Expansions

Abbreviation	Expansion or Notes
These terms are not expanded in text	
HCV	hepatitis C virus. In this Guidance "hepatitis C virus" and HCV refer to the virus. Hepatitis C and HCV infection or HCV disease refer to the resulting disease.
IFN	interferon alfa
PEG	peginterferon alfa
These terms are expanded at first mention in text	
ALT	alanine aminotransferase
AST	aspartate aminotransferase
BOC	boceprevir
CBC	complete blood cell (eg, complete blood cell count)
CrCl	creatinine clearance
CTP	Child Turcotte Pugh (see below)
DAA	direct-acting antiviral
ESRD	end-stage renal disease
GFR	glomerular filtration rate
HBsAg	hepatitis B virus surface antigen
HBV	hepatitis B virus
HCC	hepatocellular carcinoma
IDU	injection drug use or user
INR	international normalized ratio
MELD	model for end-stage liver disease
MSM	men who have sex with men
OATP	organic anion-transporting polypeptide
P-gp	p-glycoprotein
RAV	resistance-associated variant
RBC	red blood cell (eg, red blood cell count)
RBV	ribavirin
RGT	response-guided therapy
RVR	rapid virologic response
sAg	surface antigen
SMV	simeprevir; used for the treatment of those with genotype 1 of hepatitis C virus (HCV) who have compensated liver disease, including cirrhosis
SOF	sofosbuvir; a nucleoside analogue used in combination with other drugs for the treatment of HCV infection
SVR12 (or 24 or 48, etc)	sustained virologic response at 12 weeks (or at 24 weeks, or at 48 weeks, etc)
TSH	thyroid-stimulating hormone
TVR	telaprevir; an antiviral agent to treat hepatitis C
US FDA	US Food and Drug Administration

Definition of Terms			
Child Turcotte Pugh	**Class A**	**Class B**	**Class C**

(CTP) classification of the severity of cirrhosis	Total points	5–6	7–9	10–15
	Factor	**1 Point**	**2 Points**	**3 Points**
	Total bilirubin (µmol/L)	<34	34–50	>50
	Serum albumin (g/L)	>35	28–35	<28
	Prothrombin time/international normalized ratio	<1.7	1.71–2.30	>2.30
	Ascites	None	Mild	Moderate to Severe
	Hepatic encephalopathy	None	Grade I–II (or suppressed with medication)	Grade III–IV (or refractory)
IFN ineligible	IFN ineligible is defined as one or more of the below: • Intolerance to IFN • Autoimmune hepatitis and other autoimmune disorders • Hypersensitivity to PEG or any of its components • Decompensated hepatic disease • Major uncontrolled depressive illness • A baseline neutrophil count below 1500/µL, a baseline platelet count below 90,000/µL or baseline hemoglobin below 10 g/dL • A history of preexisting cardiac disease			
Relapser	a person who has achieved an undetectable level of virus during a prior treatment course of PEG/RBV and relapsed after treatment was stopped			

HCV TESTING AND LINKAGE TO CARE

Expansions and notes for abbreviations used in this section can be found in Methods Table 3.

A summary of recommendations for Testing and Linkage to Care is found in the BOX.

HCV testing is recommended at least once for persons born between 1945 and 1965.

Rating: Class I, Level B

Other persons should be screened for risk factors for HCV infection, and one-time testing should be performed for all persons with behaviors, exposures, and conditions associated with an increased risk of HCV infection.

1. *Risk behaviors*

Injection-drug use (current or ever, including those who injected once)

Intranasal illicit drug use

2. *Risk exposures*

Long-term hemodialysis (ever)

Getting a tattoo in an unregulated setting

Healthcare, emergency medical, and public safety workers after needle sticks, sharps, or mucosal exposures to HCV-infected blood

Children born to HCV-infected women

Prior recipients of transfusions or organ transplants, including persons who:

- were notified that they received blood from a donor who later tested positive for HCV infection
- received a transfusion of blood or blood components, or underwent an organ transplant before July 1992
- received clotting factor concentrates produced before 1987

Persons who were ever incarcerated

3. *Other medical conditions*

HIV infection

Unexplained chronic liver disease and chronic hepatitis including elevated alanine aminotransferase levels

Rating: Class I, Level B

Of the estimated 2.7 million to 3.9 million persons (1999 to 2008 National Health and Nutrition Examination Survey data [Armstrong, 2006]) chronically infected with HCV in the United States, 45% to 85% are unaware that they are infected. (Smith, 2012) Identification of those with active infection is the first step toward improving health outcomes among persons with HCV infection and preventing transmission. (Smith, 2012); (US Preventive Services Task Force, 2013); (Centers for Disease Control and Prevention, 1998)

HCV testing is recommended in select populations based on demography, prior exposures, high-risk behaviors, and medical conditions. Recommendations for testing are based on HCV prevalence in these populations, proven benefits of care and treatment in reducing the risk of hepatocellular carcinoma and all-cause mortality, and the potential public health benefit of reducing transmission through early treatment, viral clearance, and reduced risk behaviors. (Smith, 2012); (US Preventive Services Task Force, 2013); (Centers for Disease Control and Prevention, 1998)

HCV is primarily transmitted through percutaneous exposure to blood. Other modes of transmission include mother-to-infant and contaminated devices shared for non-injection drug use; sexual transmission also occurs but generally seems to be inefficient except among HIV-infected men who have unprotected sex with men. (Schmidt, 2014) The most important risk for HCV infection is injection-drug use, accounting for at least 60% of acute HCV infections in the United States. Health-care exposures are important sources of transmission, including the receipt of blood products before 1992 (after which routine screening of blood supply was implemented), receipt of clotting factor concentrates before 1987, long-term hemodialysis, needle-stick injuries among healthcare workers, and patient-to-patient transmission resulting from poor infection control practices. Other risk factors include having been born to an HCV-infected mother, having been incarcerated, and having received a tattoo in an unregulated setting. The importance of these risk factors might differ based on geographic location and population. (US Preventive Services Task Force, 2013); (Centers for Disease Control and Prevention, 1998). An estimated 29% of incarcerated persons in North America are anti-HCV positive, supporting the recommendation to test this population for HCV. (Larney, 2013) Because of shared transmission modes, persons with HIV infection are at risk for HCV; sexual transmission is a particular risk for HIV-infected men who have unprotected sex with men. (Hosein, 2013); (van de Laar, 2010) Recent data also support testing in all cadaveric and living solid-organ donors because of the risk of HCV infection posed to the recipient. (Seem, 2013); (Lai, 2013)

In 2012, CDC expanded its guidelines originally issued in 1998 (Centers for Disease Control and Prevention, 1998) for risk-based HCV testing with a recommendation to offer a 1-time HCV test to all

persons born between 1945 and 1965 without prior ascertainment of HCV risk-factors. This recommendation was supported by evidence demonstrating that a risk-based strategy alone failed to identify more than 50% of HCV infections in part due to patient underreporting of their risk and provider limitations in ascertaining risk-factor information. Furthermore, persons in the 1945 to 1965 birth cohort accounted for nearly three-fourths of all HCV infections, with a 5-times higher prevalence (3.25%) than other persons, reflecting a higher incidence of HCV infections in the 1970s and 1980s (peaking at 230,000 versus 15,000 in 2009). A recent retrospective review showed that 68% of persons with HCV infection would have been identified through a birth-cohort testing strategy, whereas only 27% would have been screened with the risk-based approach. (Mahajan, 2013) The cost-effectiveness of 1-time birth cohort testing is comparable to that of current risk-based screening strategies. (Smith, 2012)

CDC and the US Preventive Services Task Force (USPSTF) both recommend a 1-time HCV test in asymptomatic persons belonging to the 1945 to 1965 birth cohort and other persons based on exposures, behaviors, and conditions that increase risk for HCV infection.

Annual HCV testing is recommended for persons who inject drugs and for HIV-seropositive men who have unprotected sex with men. Periodic testing should be offered to other persons with ongoing risk factors for exposure to HCV.

Rating: Class IIA, Level C

Evidence regarding the frequency of testing in persons at risk for ongoing exposure to HCV is lacking; therefore, clinicians should determine the periodicity of testing based on the risk of reinfection. Because of the high incidence of HCV infection among persons who inject drugs and among HIV-infected MSM who have unprotected sex (Aberg, 2013); (Linas, 2012); (Wandeler, 2012); (Witt, 2013); (Bravo, 2012); (Williams, 2011), at least annual HCV testing is recommended in these subgroups.

An anti-HCV test is recommended for HCV testing, and if the result is positive, current infection should be confirmed by a sensitive RNA test.

Rating: Class I, Level A

Among persons with a negative anti-HCV test who are suspected of having liver disease, testing for HCV RNA or follow-up testing for HCV antibody is recommended if exposure to HCV occurred within the past 6 months; testing for HCV RNA can also be considered in persons who are immunocompromised.

Rating: Class I, Level C

Among persons suspected of reinfection after previous spontaneous or treatment-related viral clearance, initial HCV-RNA testing is recommended because an anti-HCV test is expected to be positive.

Rating: Class I, Level C

Quantitative HCV RNA testing is recommended prior to the initiation of antiviral therapy to document the baseline level of viremia (ie, baseline viral load).

Rating: Class I, Level A

Testing for HCV genotype is recommended to guide selection of the most appropriate antiviral regimen.

Rating: Class I, Level A

If found to have positive results for anti-HCV test and negative results for HCV RNA by PCR, persons should be informed that they do not have evidence of current (active) HCV infection.

Rating: Class I, Level A

All persons recommended for HCV testing should first be tested for HCV antibody (anti-HCV) (Centers for Disease Control and Prevention [CDC], 2013); (Alter, 2003) using an FDA-approved test. FDA-approved tests include laboratory-based assays and a point-of-care assay (ie, OraQuick HCV Rapid Antibody Test [OraSure Technologies]). (Lee, 2011) The latter is an indirect immunoassay with a sensitivity and specificity similar to those of FDA-approved laboratory-based HCV antibody assays.

A positive test result for anti-HCV indicates either current (active) HCV infection (acute or chronic), past infection that has resolved, or a false-positive test result. (Pawlotsky, 2002) Therefore, an HCV nucleic acid test (NAT) to detect viremia is necessary to confirm current (active) HCV infection and guide clinical management, including initiation of HCV treatment. HCV RNA testing should also be performed in persons with a negative anti-HCV test who are either immunocompromised (eg, persons receiving chronic hemodialysis) (KDIGO, 2008) or who might have been exposed to HCV within the last 6 months (including those who are possibly reinfected after previous spontaneous or treatment-related viral clearance) because these persons may be anti-HCV negative. An FDA-approved quantitative or qualitative NAT with a detection level of 25 IU/mL or lower should be used to detect HCV RNA. **Testing and Linkage to Care Table 1** lists FDA-approved, commercially available anti-HCV screening assays. **Testing and Linkage to Care Figure 1** shows the CDC-recommended testing algorithm.

Prior to the initiation of HCV therapy, quantitative HCV RNA testing is necessary to document the baseline level of viremia (ie, viral load), because the degree of initial viral decline is a crucial marker of the effectiveness of treatment. Testing for HCV genotype helps to guide selection of the most appropriate treatment regimen. Persons who have positive results for an anti-HCV test and negative results for HCV RNA by PCR should be informed that they do not have laboratory evidence of current (active) HCV infection. Additional HCV testing is typically unnecessary. However, some practitioners or persons may seek additional testing to learn if the HCV antibody test represents a remote HCV infection that has

resolved or a false-positive result. For patients with no apparent risk for HCV infection, the likelihood of a false-positive HCV antibody test is directly related to the HCV prevalence in the tested population; false-positive test results for anti-HCV are most common for populations with a low prevalence of HCV infection. (Alter, 2003) If further testing is desired to distinguish between true positivity and biologic false positivity for HCV antibody, testing may be done with a second FDA-approved HCV antibody assay that is different from the assay used for initial antibody testing. A biologic false result should not occur with 2 different tests. (Vermeersch, 2008); (Centers for Disease Control and Prevention [CDC]), 2013) The HCV RNA test can be repeated when there is a high index of suspicion of infection or in patients with prior or ongoing risk factors for HCV infection.

Persons with current (active) HCV infection should receive education and interventions aimed at reducing progression of liver disease and preventing transmission of HCV.

Rating: Class IIa, Level B

1. *Abstinence from alcohol and, when appropriate, interventions to facilitate cessation of alcohol consumption should be advised for all persons with HCV infection.*

   Rating: Class IIa, level B

2. *Evaluation for other conditions that may accelerate liver fibrosis, including HBV and HIV infections, is recommended for all persons with HCV infection.*

   Rating: Class IIb, level B

3. *Evaluation for advanced fibrosis, using liver biopsy, imaging, or non-invasive markers, is recommended in all persons with HCV infection to facilitate an appropriate decision regarding HCV treatment strategy and determine the need for initiating additional screening measures (eg, hepatocellular carcinoma [HCC] screening).*

   Rating: Class I, Level B

4. *Vaccination against hepatitis A and hepatitis B is recommended for all persons with HCV infection who are susceptible to these types of viral hepatitis.*

   Rating: Class IIa, Level C

5. *All persons with HCV infection should be provided education on how to avoid HCV transmission to others.*

   Rating: Class I, level C

In addition to receiving therapy, HCV-infected persons should be educated about how to prevent further damage to their liver. Most important is prevention of the potential deleterious effect of alcohol. Numerous studies have found a strong association between the use of excess alcohol and the development or progression of liver fibrosis and even the development of HCC. (Poynard, 1997); (Harris, 2001); (Wiley, 1998); (Corrao, 1998); (Bellentani, 1999); (Noda, 1996); (Safdar, 2004)

Excess alcohol intake may also cause steatohepatitis. The daily consumption of more than 50 grams of alcohol has a high likelihood of worsening fibrosis. Some studies indicate that daily consumption of smaller amounts of alcohol also have a deleterious effect on the liver; however, these data are controversial. (Westin, 2002) Alcohol screening and brief interventions such as those outlined by the National Institute of Alcohol Abuse and Alcoholism (http://pubs.niaaa.nih.gov/publications/Practitioner/CliniciansGuide2005/clinicians_guide.htm) have been demonstrated to reduce alcohol consumption and episodes of binge drinking in the general population and among HCV-infected persons who consume alcohol heavily.(Whitlock, 2004); (Dieperink, 2010); (Proeschold-Bell, 2012) Persons identified as abusing alcohol and having alcohol dependence require treatment and consideration for referral to an addiction specialist.

HBV and HIV coinfection have been associated with poorer prognosis of HCV in cohort studies. (Thein, 2008); (Zarski, 1998) Due to overlapping risk factors for these infections and additional benefits of their identification and treatment, persons with HCV should be tested for HIV antibody and HBsAg using standard assays for screening (Moyer, 2013); (Centers for Disease Control and Prevention, 2008) (http://www.aafp.org/afp/2008/0315/p819.html and http://www.cdc.gov/mmwr/preview/mmwrhtml/rr5708a1.htm) and counseled how to reduce their risk of acquiring these infections, including through HBV vaccination (see below).

Patients with obesity and metabolic syndrome having underlying insulin resistance are more prone to have nonalcoholic fatty liver disease, which is a risk factor for fibrosis progression in HCV-infected persons. (Hourigan, 1999); (Ortiz, 2002) Therefore, HCV-infected persons who are overweight or obese (defined by a body mass index 25 kg/m^2 or higher or 30 kg/m^2 or higher, respectively) should be counseled regarding strategies to reduce weight and improve insulin resistance via diet, exercise, and medical therapies. (Musso, 2010); (Shaw, 2006) Patients with HCV infection and hyperlipidemia or cardiovascular comorbidities may also benefit from various hypolipidemic drugs. Prospective studies have demonstrated the safety and efficacy of statins in patients with chronic HCV and others with compensated chronic liver disease. (Lewis, 2007) Therefore, these agents should not be withheld in HCV-infected patients.

The severity of liver disease associated with chronic HCV infection is a key factor in determining the initial and follow-up evaluation of patients. Although patients with more advanced disease generally have a lower response to HCV therapy, they are also most likely to derive the greatest survival benefit. (Ghany, 2011) A liver biopsy can provide objective, semi-quantitative information regarding the amount and pattern of collagen or scar tissue in the liver, which can assist with treatment and monitoring plans. The Metavir fibrosis score (0-4) and Ishak fibrosis score (0-6) are commonly used to score the amount of hepatic collagen. A liver biopsy can also help assess the severity of liver inflammation, or of hepatic steatosis, and help exclude competing causes of liver injury. (Kleiner, 2005) However, the procedure has a low but real risk of complications, and sampling artifact makes its serial use in most patients less desirable. (Regev, 2002) Non-invasive methods frequently used to estimate liver disease severity include a liver-directed physical exam (normal in most patients), routine blood tests (eg, serum alanine transaminase, albumin, bilirubin, international normalized ratio levels, and complete cell blood counts with platelets), serum fibrosis

marker panels, liver imaging (eg, ultrasound, computed tomography scan), and liver elastography. Simple blood tests (eg, serum aspartate aminotransferase/platelet ratio index) (Wai, 2003) (http://www.hepatitisc.uw.edu/page/clinical-calculators/apri) and assessment of liver surface nodularity and spleen size by liver ultrasound or other cross-sectional imaging modalities can help determine if patients with HCV have occult portal hypertension, which is associated with a greater likelihood of developing future hepatic complications in untreated patients. (Chou, 2013); (Rockey, 2006) Liver elastography can provide instant information regarding liver stiffness at the point-of-care but can only reliably distinguish cirrhosis from non-cirrhosis. (Castera, 2012) Since persons with known or suspected bridging fibrosis and cirrhosis are at increased risk of developing complications of advanced liver disease, they require more frequent follow up; these persons also should avoid ulcerogenic drugs and receive ongoing imaging surveillance for liver cancer and varices. (Sangiovanni, 2006); (Fontana, 2010)

Exposure to infected blood is the primary mode of HCV transmission. HCV-infected persons must be informed of the precautions needed to avoid exposing others to infected blood. This is particularly important for persons who use injection drugs, given that HCV transmission in this population primarily results from the sharing of needles and other infected implements. Recently, epidemics of acute HCV due to sexual transmission in HIV-infected men who have sex with men have also been described. (van de Laar, 2009); (Urbanus, 2009); (Fierer, 2008) **Testing and Linkage Table 2** outlines measures to avoid HCV transmission. HCV is not spread by sneezing, hugging, holding hands, coughing, or sharing eating utensils or drinking glasses, nor is it transmitted through food or water.

Evaluation by a practitioner who is prepared to provide comprehensive management, including consideration of antiviral therapy, is recommended for all persons with current (active) HCV infection.

Rating: Class IIa, level C

The definition of evaluation is: *Patient has attended a medical care visit with a practitioner able to complete a full assessment, the pros and cons of antiviral therapy have been discussed, and the patient has been transitioned into treatment, if appropriate.*

Improvement in identification of current (active) HCV infection and advances in treatment regimens will have limited impact on HCV-related morbidity and mortality without concomitant improvement in linkage to care. All patients with current HCV infection and a positive HCV RNA test result should be evaluated by a practitioner with expertise in assessment of liver disease severity and HCV treatment. Subspecialty care is required for persons with HCV infection who have advanced fibrosis/cirrhosis (stage III or above on METAVIR scale), including possible referral for consideration of liver transplantation. In the United States, only an estimated 13% to 18% of persons chronically infected with HCV receive treatment. (Holmberg, 2013) Lack of appropriate practitioner assessment and delays in linkage to care can result in negative health outcomes. Further, patients who are lost to follow-up fail to benefit from evolving evaluation and treatment options.

Commonly cited patient-related barriers to treatment initiation include contraindications to treatment (eg, medical or psychiatric comorbidities), lack of acceptance of treatment (eg, asymptomatic nature of disease, competing priorities, low treatment efficacy, and long treatment duration and adverse effects), and lack of

access to treatment (eg, cost and distance to specialist). (Khokhar, 2007); (Arora, 2011); (Clark, 2012) Common practitioner–related barriers include perceived patient-related barriers (eg, fear of adverse effects, treatment duration, cost, and effectiveness), lack of expertise in HCV treatment, lack of specialty referral resources, resistance to treating persons currently using illicit drugs or alcohol, and concern about cost of HCV treatment. (Morrill, 2005); (Reilley, 2013); (McGowan, 2013) Some possible strategies to address these barriers are listed in **Testing and Linkage to Care Table 3**. One strategy that addresses several barriers is co-localization of HCV screening, evaluation, and treatment with other medical or social services. Co-localization has already been applied to settings with a high prevalence of HCV infection (eg, correctional facilities and programs providing needle exchange, substance abuse treatment, and methadone maintenance) but is not uniformly available. (Islam, 2012); (Stein, 2012); (Bruggmann, 2013)

A strategy that addresses lack of access to specialists (a primary barrier to hepatitis C care) is participation in models involving close collaboration between primary-care practitioners and subspecialists. (Arora, 2011); (Rossaro, 2013); (Miller, 2012) Such collaborations have used telemedicine and knowledge networks to overcome geographic distances to specialists. (Arora, 2011); (Rossaro, 2013) For example, Project ECHO (Extension for Community Healthcare Outcomes [http://www.echohcvexperts.com]) uses videoconferencing to enhance primary care practitioner capacity in rendering HCV care and treatment to New Mexico's large rural and underserved population. (Arora, 2011) Through case-based learning and real-time feedback from a multidisciplinary team of specialists (ie, gastroenterology, infectious diseases, pharmacology, and psychiatry practitioners), Project ECHO has expanded access to HCV infection treatment in populations that might have otherwise remained untreated.

Additional strategies of enhancing linkage to care could be adapted from other fields, such as tuberculosis and HIV, but remain to be evaluated for HCV infection. For example, use of directly observed therapy has enhanced adherence to TB treatment, and use of case managers and patient navigators has reduced loss of follow-up in HIV care. (Govindasamy, 2012) An assessment of efficacy and comparative effectiveness of these strategies is a crucial area of future research for patients with HCV infection. Replication and expansion of best practices and new models for linkage to HCV care will also be crucial to maximize the public health impact of newer treatment paradigms.

Testing and Linkage to Care Box: Summary of Recommendations for Testing and Linkage to Care

Testing and Linkage To Care Box. Summary of Recommendations for Testing and Linkage to Care

HCV testing is recommended at least once for persons born between 1945 and 1965.

Rating: Class I, Level B

Other persons should be screened for risk factors for HCV infection, and one-time testing should be performed for all persons with behaviors, exposures, and conditions associated with an increased risk of HCV infection.

1. *Risk behaviors*

    Injection drug use (current or ever, including those who injected once)

    Intranasal illicit drug use

2. *Risk exposures*

    Long-term hemodialysis (ever)

    Getting a tattoo in an unregulated setting

    Healthcare, emergency medical, and public safety workers after needle sticks, sharps, or mucosal exposures to HCV-infected blood

    Children born to HCV-infected women

    Prior recipients of transfusions or organ transplants, including persons who:

    - were notified that they received blood from a donor who later tested positive for HCV infection
    - received a transfusion of blood or blood components, or underwent an organ transplant before July 1992

- received clotting factor concentrates produced before 1987

Persons who were ever incarcerated

3. *Other medical conditions*

HIV infection

Unexplained chronic liver disease and chronic hepatitis including elevated alanine aminotransferase levels

Rating: Class I, Level B

Annual HCV testing is recommended for persons who inject drugs and for HIV-seropositive men who have unprotected sex with men. Periodic testing should be offered to other persons with ongoing risk factors for exposure to HCV.

Rating: Class IIA, Level C

An anti-HCV test is recommended for HCV testing, and if the result is positive, current infection should be confirmed by a sensitive RNA test.

Rating: Class I, Level A

Among persons with a negative anti-HCV test who are suspected of having liver disease, testing for HCV RNA or follow-up testing for HCV antibody is recommended if exposure to HCV occurred within the past 6 months; testing for HCV RNA can also be considered in persons who are immunocompromised.

Rating: Class I, Level C

Among persons suspected of reinfection after previous spontaneous or treatment-related viral clearance, initial HCV-RNA testing is recommended because an anti-HCV test is expected to be positive.

Rating: Class I, Level C

Quantitative HCV RNA testing is recommended prior to the initiation of antiviral therapy to document the baseline level of viremia (ie, baseline viral load).

Rating: Class I, Level A

Testing for HCV genotype is recommended to guide selection of the most appropriate antiviral regimen.

Rating: Class I, Level A

If found to have positive results for anti-HCV test and negative results for HCV RNA by PCR, persons should be informed that they do not have evidence of current (active) HCV infection.

Rating: Class I, Level A

Persons with current (active) HCV infection should receive education and interventions aimed at reducing progression of liver disease and preventing transmission of HCV.

Rating: Class IIa, Level B

1. *Abstinence from alcohol and, when appropriate, interventions to facilitate cessation of alcohol consumption should be advised for all persons with HCV infection.*

   Rating: Class IIa, level B

2. *Evaluation for other conditions that may accelerate liver fibrosis, including HBV and HIV infections, is recommended for all persons with HCV infection.*

   Rating: Class IIb, level B

3. *Evaluation for advanced fibrosis is recommended using liver biopsy, imaging, or non-invasive markers in all persons with HCV infection to facilitate an appropriate decision regarding HCV treatment strategy and to determine the need for initiating additional screening measures (eg, hepatocellular carcinoma [HCC] screening).*

   Rating: Class I, Level B

4. *Vaccination against hepatitis A and hepatitis B is recommended for all persons with HCV infection who are susceptible to these types of viral hepatitis.*

   Rating: Class IIa, Level C

5. *All persons with HCV infection should be provided education on how to avoid HCV transmission to others.*

Rating: Class I, level C

Evaluation by a practitioner who is prepared to provide comprehensive management, including consideration of antiviral therapy, is recommended for all persons with current (active) HCV infection.

Rating: Class IIa, level C

Testing and Linkage to Care Table 1. FDA-approved, Commercially Available Anti-HCV Screening Assays

Assay	Manufacturer	Format
Abbott HCV EIA 2.0	Abbott	EIA (Manual)
Advia Centaur HCV	Siemens	CIA (Automated)
ARCHITECT Anti-HCV	Abbott	CMIA (Automated)
AxSYM Anti-HCV	Abbott	MEIA (Automated)
OraQuick HCV Rapid Antibody Test	OraSure	Immunochromatographic (Manual)
Ortho HCV Version 3.0 EIA	Ortho	EIA (Manual)
VITROS Anti-HCV	Ortho	CIA (Automated)

Anti-HCV = HCV antibody; EIA = enzyme immunoassay; CIA = chemiluminescent immunoassay; MEIA = microparticle enzyme immunoassay; CMIA = chemiluminescent microparticle immunoassay

Table prepared by Saleem Kamili, PhD, Centers for Disease Control and Prevention.

Testing and Linkage to Care Table 2. Measures to Prevent Transmission of HCV

Persons with HCV infection should be counseled to avoid sharing toothbrushes and dental or shaving equipment, and be cautioned to cover any bleeding wound to prevent the possibility of others coming into contact with their blood.

Persons should be counseled to stop using illicit drugs and enter substance abuse treatment. Those who continue to inject drugs should be counseled to avoid reusing or sharing syringes, needles, water, cotton, and other drug preparation equipment; use new sterile syringes and filters and disinfected cookers; clean the injection site with a new alcohol swab; and dispose of syringes and needles after one use in a safe, puncture-proof container.

Persons with HCV infection should be advised not to donate blood and to discuss HCV serostatus prior to donation of body organs, other tissue, or semen.

Persons with HIV infection and those with multiple sexual partners or sexually transmitted infections should be encouraged to use barrier precautions to prevent sexual transmission. Other persons with HCV infection should be counseled that the risk of sexual transmission is low and may not warrant barrier protection.

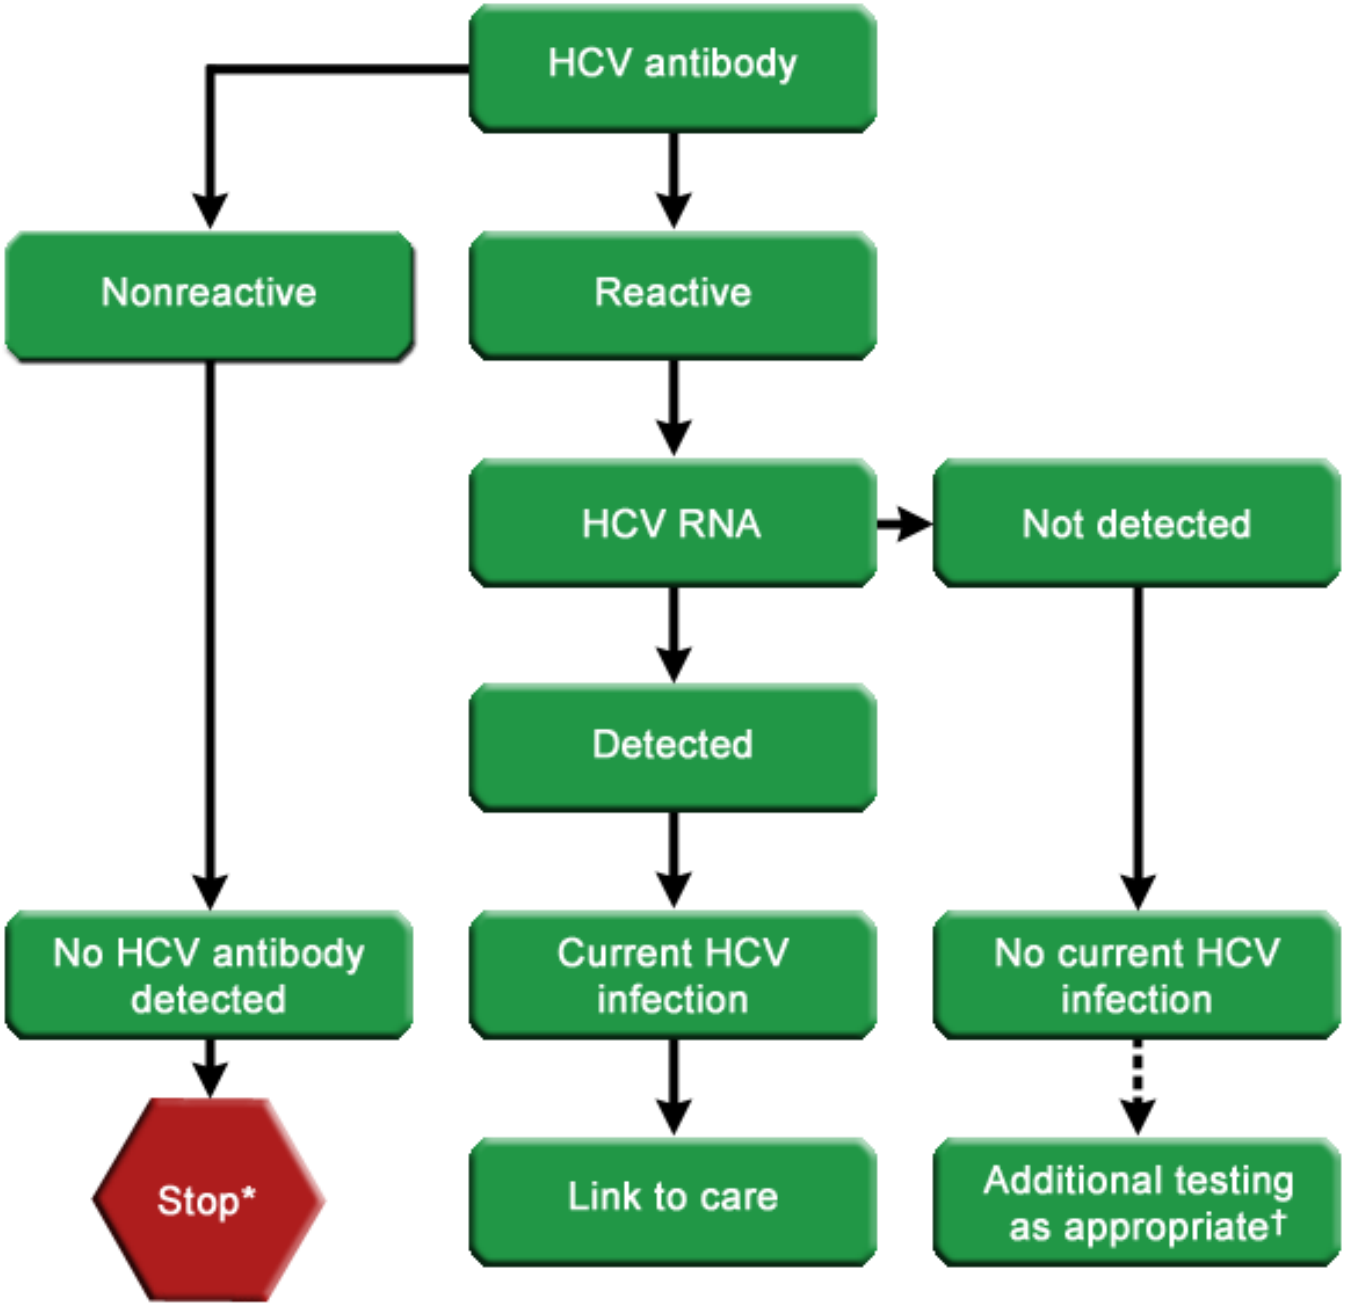
Household surfaces and implements contaminated with visible blood from an HCV-infected person should be cleaned using a dilution of 1 part household bleach to 9 parts water. Gloves should be worn when cleaning up blood spills.

Testing and Linkage to Care Table 3: Common Barriers to HCV Treatment and Potential Strategies

Barrier	Strategy
Contraindications to treatment (eg, comorbidities, substance abuse, and psychiatric disorders)	Counseling and education Referral to services (eg, psychiatry and opioid substitution therapy) Optimize treatment with simpler and less toxic regimens
Competing priority and loss to follow-up	Conduct counseling and education Engage case managers and patient navigators (HIV model) Co-localize services (eg, primary care, medical homes, and drug treatment)
Long treatment duration and adverse effects	Optimize treatment with simpler and better tolerated regimens Education and monitoring Directly observed therapy (tuberculosis model)
Lack of access to treatment (high cost, lack of insurance, geographic distance, and lack of availability of specialists)	Leverage expansion of coverage through the Patient Protection and Affordable Care Act Participate in models of care involving close collaboration between primary care practitioners and specialists

	Pharmaceutical patient assistance programs Co-localize services (primary care, medical homes, drug treatment)
Lack of practitioner expertise	Collaboration with specialists (eg, via Project ECHO-like models and telemedicine) Develop accessible and clear HCV treatment guidelines Develop electronic health record performance measures and clinical decision support tools (eg, pop-up reminders and standing orders)

Testing and Linkage to Care Figure 1. CDC Recommended Testing Sequence for Identifying Current HCV Infection



* For persons who might have been exposed to HCV within the past 6 months, testing for HCV RNA or follow-up testing for HCV antibody should be performed. For persons who are immunocompromised, testing for HCV RNA should be performed.

† To differentiate past, resolved HCV infection from biologic false positivity for HCV antibody, testing with another HCV antibody assay can be considered. Repeat HCV RNA testing if the person tested is suspected to have had HCV exposure within the past 6 months or has clinical evidence of HCV disease, or if there is concern regarding the handling or storage of the test specimen.

Adapted from Centers for Disease Control and Prevention (CDC), 2013. (Centers for Disease Control and Prevention [CDC], 2013)

WHEN AND IN WHOM TO INITIATE HCV THERAPY

Successful hepatitis C treatment results in sustained virologic response (SVR), which is tantamount to virologic cure; virologic cure is expected to benefit chronically infected persons. Limitations of workforce and societal resources may limit the feasibility of treating all patients within a short period of time. Therefore, when such limitations exist, initiation of therapy should be prioritized first to those specific populations that will derive the most benefit or have the greatest impact on further HCV transmission. Others should be treated as resources allow.

Expansions and notes for abbreviations used in this section can be found in Methods Table 3.

A summary of recommendations for When and in Whom to Initiate HCV Therapy is found in the BOX.

Goal of treatment

The goal of treatment of HCV-infected persons is to reduce all-cause mortality and liver-related health adverse consequences, including end-stage liver disease and hepatocellular carcinoma, by the achievement of virologic cure as evidenced by an SVR.

Rating: Class I, Level A

Clinical Benefit of Cure

The proximate goal of HCV therapy is SVR (virologic cure), defined as the continued absence of detectable HCV RNA at least 12 weeks after completion of therapy. SVR is a marker for cure of HCV infection and has been shown to be durable in large prospective studies in more than 99% of patients followed up for 5 years or more. (Swain, 2010); (Manns, 2013) Patients in whom an SVR is achieved have HCV antibodies, but no longer have detectable HCV RNA serum, liver tissue, or mononuclear cells, and achieve substantial liver histology improvement. (Marcellin, 1997); (Coppola, 2013); (Garcia-Bengoechea, 1999) Assessment of viral response, including documentation of SVR, requires use of US Food and Drug Administration (FDA)-approved quantitative or qualitative nucleic acid test (NAT) with a detection level of 25 IU/mL or lower.

Patients who are cured of their HCV infection experience numerous health benefits, including a decrease in liver inflammation as reflected by improved aminotransferase (ie, alanine aminotransferase [ALT], aspartate aminotransferase[AST]) levels and a reduction in the rate of progression of liver fibrosis. (Poynard, 2002b) Of 3010 treatment-naive HCV-infected patients with pretreatment and posttreatment biopsies from 4 randomized trials of 10 different IFN-based regimens (biopsies separated by a mean of 20 months), 39% to 73% of patients achieving an SVR had improvement in liver fibrosis and necrosis (Poynard, 2002b) and cirrhosis resolved in half of the cases. Portal hypertension, splenomegaly, and other clinical manifestations of advanced liver disease also improved. Among HCV-infected persons, SVR is

associated with a more than 70% reduction in the risk of liver cancer (hepatocellular carcinoma) and a 90% reduction in the risk of liver-related mortality and liver transplantation. (Morgan, 2013); (van der Meer, 2012); (Veldt, 2007)

Cure of HCV infection also reduces symptoms and mortality from severe extrahepatic manifestations, including cryoglobulinemic vasculitis, a condition affecting 10% to 15% of HCV-infected patients. (Fabrizi, 2013); (Landau, 2010) HCV-infected persons with non-Hodgkin lymphoma and other lymphoproliferative disorders achieve complete or partial remission in up to 75% of cases following successful antiviral therapy for HCV infection. (Gisbert, 2005); (Takahashi, 2012); (Svoboda, 2005); (Mazzaro, 2002); (Hermine, 2002) These reductions in disease severity contribute to dramatic reductions in all-cause mortality. (van der Meer, 2012); (Backus, 2011) Lastly, patients achieving SVR have substantially improved quality of life, which includes physical, emotional, and social health. (Neary, 1999); (Younossi, 2013) Because of the myriad benefits associated with successful HCV treatment, clinicians should treat HCV-infected patients with antiviral therapy with the goal of achieving an SVR, preferably early in the course of their chronic HCV infection before the development of severe liver disease and other complications.

Recommendations for when and in whom to initiate treatment

Treatment is recommended for patients with chronic HCV infection.

Rating: Class I, Level A

Treatment is assigned the highest priority for those patients with advanced fibrosis (Metavir F3), those with compensated cirrhosis (Metavir F4), liver transplant recipients, and patients with severe extrahepatic hepatitis C (Table 1).

Based on available resources, treatment should be prioritized as necessary so that patients at high risk for liver-related complications and severe extrahepatic hepatitis C complications are given high priority (Table 1).

Ratings: See tables

The most immediate and high-impact benefits of SVR will be realized by populations that are at the highest risk for liver-related complications due to progressive liver disease (Metavir F3 or F4) and transplant recipients or those with clinically severe extrahepatic manifestations **(**Table 1**)**.

Other populations at high risk for liver disease progression (Metavir F2) or with substantial extrahepatic manifestations **(**Table 1**)** are also expected to garner appreciable benefits, although the time course for realizing these benefits may be more protracted.

SVR will also remove the risk of further transmission. Treatment of individuals at high risk to transmit HCV to others **(**Table 2**)** may yield long-term future benefits from decreased transmission and a potential decrease in HCV disease prevalence.

When and in Whom to Initiate HCV Therapy Table 1. Settings of Liver-Related Complications and Extrahepatic Disease in Which HCV Treatment is Most Likely to Provide the Most Immediate and Impactful Benefits

Highest Priority for Treatment Owing to Highest Risk for Severe Complications

Advanced fibrosis (Metavir F3) or compensated cirrhosis (Metavir F4)

Rating: Class I, Level A

Organ transplant

Rating: Class I, Level B

Type 2 or 3 essential mixed cryoglobulinemia with end-organ manifestations (eg, vasculitis)

Rating: Class I, Level B

Proteinuria, nephrotic syndrome, or membranoproliferative glomerulonephritis

Rating: Class IIa, Level B

High Priority for Treatment Owing to High Risk for Complications

Fibrosis (Metavir F2)

Rating: Class I, level B

HIV-1 coinfection

Rating: Class I, Level B

Hepatitis B virus (HBV) coinfection

Rating: Class IIa, Level C

Other coexistent liver disease (eg, [NASH])

Rating: Class IIa, Level C

Debilitating fatigue

Rating: Class IIa, Level B

Type 2 Diabetes mellitus (insulin resistant)

Rating: Class IIa, Level B

Porphyria cutanea tarda

Rating: Class IIb, Level C

Ratings refer to the strength and level of evidence with regard to benefits of treatment in these settings.

When and in Whom to Initiate HCV Therapy Table 2. Persons Whose Risk of HCV Transmission is High and in Whom HCV Treatment May Yield Transmission Reduction Benefits

High HCV Transmission Risk*

Men who have sex with men (MSM) with high-risk sexual practices

Active injection drug users

Incarcerated persons

Persons on long-term hemodialysis

Rating: Class IIa, Level C

---

*Patients at high risk of transmitting HCV should be counseled on ways to decrease transmission and minimize the risk of reinfection.

Persons with Advanced Liver Disease

For persons with advanced liver disease (Metavir stage F3 or F4), the risk of developing complications of liver disease such as hepatic decompensation (child Turcotte Pugh [CTP] Class B or C [Methods Table 3]) or hepatocellular carcinoma is substantial and may occur in a relatively short timeframe. A large prospective study of patients with cirrhosis resulting from HCV infection examined the risk of decompensation, including hepatocellular carcinoma, ascites, jaundice, bleeding, and encephalopathy, and found that the overall annual incidence rate was 3.9%. (Sangiovanni, 2006) The National Institutes of Health (NIH)-sponsored HALT–C study included a group of 220 patients with cirrhosis resulting from HCV infection who were observed for approximately 8 years. A primary outcome of death, hepatic decompensation, hepatocellular carcinoma, or advance in CTP score of 2 or higher occurred at a rate of 7.5% per year. (Everson, 2006); (Di Bisceglie, 2008) Patients with a CTP score of 7 or higher experienced a death rate of 10% per year.

Numerous studies have demonstrated that hepatitis C therapy and the achievement of an SVR in this population results in dramatic decreases in hepatic decompensation events, hepatocellular carcinoma, and liver-related mortality. (Morgan, 2013); (van der Meer, 2012); (Backus, 2011); (Dienstag, 2011); (Berenguer, 2009); (Mira, 2013) In the HALT-C study, patients with advanced fibrosis secondary to HCV infection who achieved an SVR, compared with patients with similarly advanced liver fibrosis who did not achieve an SVR, had a decreased need for liver transplantation (hazard ratio [HR], .17, 95% confidence interval [CI], .06–.46), development of liver-related morbidity and mortality (HR, .15, 95% CI, .06–.38) and hepatocellular carcinoma (HR, .19, 95% CI, .04–.80). (Dienstag, 2011) Based on these considerations, prompt HCV treatment is recommended for persons with advanced liver disease unless contraindicated (eg, hypersensitivity) or substantial nonhepatic life-limiting comorbidities are present. Importantly, persons

with advanced liver disease also require long-term follow-up and hepatocellular carcinoma (HCC) surveillance regardless of treatment outcome (see **Monitoring Section**).

Given the clinical complexity and the need for close monitoring, patients with advanced liver disease that has already decompensated (CTP Class B or C [Methods Table 3]) should, in general, be treated by physicians with experience in treating HCV in conjunction with a liver transplantation center if possible.

Persons Who Have Undergone Liver Transplantation

In HCV-infected individuals, HCV infection of the allograft occurs universally in patients in whom viral replication is ongoing at the time of transplantation. Histologic features of hepatitis develop in about 75% of recipients in the first 6 months following liver transplantation. (Neumann, 2004) By the fifth postoperative year, untreated, up to 30% have progressed to cirrhosis. (Neumann, 2004); (Charlton, 1998) A small proportion of patients (4%-7%) develop an accelerated course of liver injury (cholestatic hepatitis C, associated with very high levels of viremia) with subsequent rapid allograft failure. Recurrence of HCV infection post- transplantation has led to shorter period of graft survival for recipients with HCV infection than for recipients who undergo liver transplantation for other indications. (Forman, 2002)

Effective antiviral therapy pre-transplantation resulting in a SVR (virologic cure) prevents HCV recurrence post-transplantation. (Everson, 2003) In addition, complete HCV viral suppression prior to transplantation prevents recurrent HCV infection of the graft in the majority of cases. (Forns, 2004); (Everson, 2005) Preliminary data from a study of patients with complications of cirrhosis secondary to HCV infection who are wait-listed for liver transplantation that included patients with MELD scores up to 14 and CPT scores up to 8 found that treatment with sofosbuvir and weight-based ribavirin (RBV) for up to 48 weeks was well tolerated and was associated with an overall post-transplant SVR of 69%. (Curry, 2013b) Post-transplant SVR was near ubiquitous among patients who had undetectable HCV RNA for 28 days or longer prior to transplantation.

Treatment of established HCV infection post-transplantation also yields substantial improvements in patient and graft survival. (Berenguer, 2008); (Picciotto, 2007) The availability of effective IFN-free HCV treatment regimens has addressed the major hurdles to treating HCV recurrence post-transplantation: poor tolerability and efficacy. In a multicenter, open-label study evaluating the ability of sofosbuvir plus RBV to induce virologic suppression in 40 post–liver-transplant patients with compensated recurrence of HCV infection, daily sofosbuvir and RBV for 24 weeks achieved an SVR at 12 weeks (SVR12) in 70%. (Charlton, 2013) No deaths, graft losses, or episodes of rejection occurred. Six patients had serious adverse events, all of which were considered unrelated to study treatment. There were no drug interactions with sofosbuvir and any of the concomitant immunosuppressive agents reported. In contrast, treatment with sofosbuvir plus RBV with or without PEG in 64 patients with severe, decompensated cirrhosis resulting from recurrence of HCV infection following liver transplantation was associated with an overall SVR12 of 57% and a mortality rate of 25%. (Forns, 2013c) On an intent-to-treat basis, treatment was associated with clinical improvement in 64% and stable disease in 11% of patients.

Persons at Greater Risk of Rapidly Progressive Fibrosis and Cirrhosis

Fibrosis progression is variable across different patient populations as well as within the same individual over time. Many of the components that determine fibrosis progression and development of cirrhosis in an individual are unknown. However, certain factors, such as coinfection with HIV or hepatitis B virus (HBV) and prevalent coexistent liver diseases (eg, nonalcoholic steatohepatitis [NASH]), are well-recognized contributors to accelerated fibrosis progression. Patients with these conditions should be prioritized for hepatitis C therapy.

HIV coinfection. HIV coinfection accelerates fibrosis progression among HCV-infected persons, (Benhamou, 1999); (Macias, 2009); (Konerman, 2014) although control of HIV replication and restoration of CD4+ cell counts may mitigate this to some extent. (Benhamou, 2001); (Bräu, 2006) In the largest paired biopsy study, 282 HIV/HCV-coinfected patients with 435 paired biopsies were prospectively evaluated; (Konerman, 2014) one-third of patients showed fibrosis progression of at least 1 Metavir stage at a median of 2.5 years. Importantly, 45% of patients with no fibrosis on initial biopsy had progression. Finally, a more rapid progression to death following decompensation, combined with a lack of widespread access to liver transplantation and poor outcomes following transplantation, argue for treatment prioritization in this population, regardless of the current fibrosis stage. (Pineda, 2005); (Merchante, 2006); (Terrault, 2012)

HBV coinfection and other coexistent liver diseases. The prevalence of HBV/HCV coinfection is estimated at 1.4% in the United States and 5% to 10% globally. (Tyson, 2013); (Chu, 2008) Persons with HBV/HCV coinfection and detectable viremia of both viruses are at increased risk for disease progression, decompensated liver disease, and the development of hepatocellular carcinoma.

HBV/HCV coinfected individuals are susceptible to a process called viral interference wherein one virus may interfere with the replication of the other virus. Thus, when treating one or both viruses with antiviral drugs, it is prudent to periodically retest HBV DNA and HCV RNA levels during and after therapy, particularly if only one of the viruses is being treated at a time. Treatment of HCV in such cases utilizes the same genotype-specific regimens as are recommended for HCV monoinfection **(see** Treatment Section**)**. HBV infections in such cases should be treated as recommended for HBV monoinfection. (Lok, 2009)

Persons with other chronic liver diseases who have coincident chronic HCV infection should be considered for hepatitis C therapy, given the potential for rapid progression of liver disease. An IFN-free regimen is generally preferred for immune-mediated liver diseases such as autoimmune hepatitis because of the potential for IFN to exacerbate them.

Persons with Severe Extrahepatic Manifestations of Chronic HCV Infection

Chronic hepatitis C is associated with a syndrome of cryoglobulinemia and an immune complex and lymphoproliferative disorder that produces arthralgias, fatigue, palpable purpura, renal disease (eg, membranoproliferative glomerulonephritis), neurologic disease (eg, peripheral neuropathy, central nervous system vasculitis), and reduced complement levels. (Agnello, 1992) Because patients with chronic hepatitis C frequently have laboratory evidence of cryoglobulins (more than 50% in some series), antiviral treatment should be prioritized for those with the syndrome of cryoglobulinemia and symptoms or objective evidence of end-organ manifestations. IFN-based regimens can produce clinical remission; however, the adverse effects of IFN may mimic manifestations of cryoglobulinemia. (Saadoun, 2014) Although clinical data are not yet available, the use of IFN-free direct-acting antiviral (DAA) regimens is an attractive alternative for these patients. Organ-threatening disease (eg, severe neuropathy, renal failure, digital ischemia), in addition to the antiviral HCV therapy, should also be treated more acutely with immunosuppressive agents or plasmapheresis to clear immune complexes.

Glomerular disease results from deposition of HCV-related immune complexes in the glomeruli. (Johnson, 1993) Successful treatment of HCV using IFN-based regimens can reverse proteinuria and the nephrotic syndrome, but usually does not fully ameliorate azotemia. (Johnson, 1994) No clinical trial data are yet available using IFN-free regimens, but the high rates of SVR (virologic cure) using antiviral therapy support their use in management of hepatitis C-related renal disease and cryoglobulinemia.

The relationship between chronic hepatitis C and diabetes (most notably type 2 diabetes and insulin

resistance) is complex and incompletely understood. The prevalence and incidence of diabetes is increased in the context of hepatitis C. (White, 2008) In the United States, type 2 diabetes occurs more frequently in HCV-infected patients with a more than 3-fold greater risk in persons over 40 years of age. (Mehta, 2000) The positive correlation between quantity of plasma HCV RNA and established markers of insulin resistance confirms this relationship. (Yoneda, 2007) Insulin resistance and type 2 diabetes are independent predictors of a more rapid progression of liver fibrosis and impaired response to IFN-based therapy. (Petta, 2008) Patients with type 2 diabetes and insulin resistance also are at increased risk for hepatocellular carcinoma. (Hung, 2010)

Successful antiviral treatment has been associated with improved markers of insulin resistance and greatly reduced incidence of new onset of type 2 diabetes and insulin resistance in HCV-infected patients. (Arase, 2009) Most recently, antiviral therapy for HCV infection has been shown to improve clinical outcomes related to diabetes. In a large prospective cohort from Taiwan, the incidence of ESRD, ischemic stroke, and acute coronary syndrome were greatly reduced in HCV-infected patients with diabetes who received antiviral therapy compared with untreated, matched controls. (Hsu, 2014) Therefore, antiviral therapy in patients with pre-diabetes who have hepatitis C may prevent progression to diabetes and reduce renal and cardiovascular complications in hepatitis C patients with established diabetes.

Persons with Other Extrahepatic Manifestations of HCV Infection

In patients with chronic hepatitis C, fatigue is the most frequently reported symptom and has a major effect on quality of life and activity level evidenced by numerous measures of impaired quality of life. (Foster, 1998) The presence and severity of fatigue appears to correlate poorly with disease activity, although it may be more common and severe in HCV-infected individuals with cirrhosis. (Poynard, 2002a) Despite difficulties in separating fatigue symptoms associated with hepatitis C from those associated with other concurrent conditions (eg, anemia, depression), numerous studies have reported a reduction in fatigue after cure of HCV. (Bonkovsky, 2007) In the Virahep-C study, 401 HCV patients were evaluated for fatigue prior to treatment and after therapy using validated scales assessing presence and severity of fatigue. (Sarkar, 2012) At baseline, 52% of patients reported having fatigue, which was more frequent and severe in patients with cirrhosis than in those without cirrhosis. Achieving an SVR was associated with a substantial decrease in frequency and severity of fatigue. A recent analysis of 413 patients who achieved an SVR12 from the NEUTRINO and FUSION trials treated with a sofosbuvir-containing regimen demonstrated improvement in patient fatigue (present in 12%) from the pretreatment level. (Younossi, 2014) After achieving an SVR12, participants had marked improvement in fatigue over their pretreatment scores using 3 separate validated questionnaires.

The reported prevalence of HCV infection in patients with porphyria cutanea tarda approximates 50% and occurs disproportionately in those with cirrhosis. (Gisbert, 2003) The treatment of choice for active porphyria cutanea tarda is iron reduction by phlebotomy and maintenance of a mildly iron-reduced state without anemia. However, although improvement of porphyria cutanea tarda during HCV treatment with IFN has frequently been described (Takikawa, 1995), there are currently insufficient data to determine whether treating HCV infection with DAAs and achieving an SVR improves porphyria cutanea tarda.

Lichen planus is characterized by pruritic papules involving mucous membranes, hair, and nails. Antibodies to HCV are present in 10% to 40% of patients with lichen planus, but the causal link with chronic infection is not established. Resolution of lichen planus has been reported with IFN-based regimens, but there have also been reports of exacerbation of lichen planus with these treatments. Although it is unknown whether DAAs will have more success against lichen planus, treatment with IFN-free regimens would appear to be a more advisable approach to addressing this disorder. (Gumber, 1995)

Persons at High Risk of Transmitting HCV

Persons who have successfully achieved an SVR (virologic cure) no longer transmit the virus to others. As such, successful treatment benefits public health. Several health models have shown that even modest increases in successful treatment of HCV infection among persons who inject drugs can decrease prevalence and incidence. (Martin, 2013a); (Durier, 2012); (Martin, 2013b); (Hellard, 2012) Models developed to estimate the impact of HCV testing and treatment on the burden of hepatitis C at a country level reveal that large decreases in HCV prevalence and incidence are possible as more persons are successfully treated. (Wedemeyer, 2014) There are also benefits between couples and among families to eradicating HCV infection and thus eliminating the perception that an individual might be contagious. The safety and efficacy of treating pregnant women to prevent transmission to the fetus have not yet been established.

Successful treatment of HCV-infected persons at greatest risk for transmission represents a formidable tool to help stop HCV transmission in those who continue to engage in high-risk behaviors. To guide implementation of hepatitis C treatment as a prevention strategy, studies are needed to define the best candidates for treatment to stop transmission; the additional interventions needed to maximize the benefits of HCV treatment (eg, preventing reinfection), and the cost effectiveness of the strategies when used in the target populations.

Persons who inject drugs. Injection drug use is the most common risk factor for HCV infection in the United States and Europe with an HCV seroprevalence from 10% to 70%; (Amon, 2008); (Nelson, 2011) injection drug use also accounts for the majority of new infections (approximately 70%) and is the key driving force in perpetuation of the epidemic. Given these facts, and the absence of an effective vaccine against HCV, testing and linkage to care combined with treatment of HCV infection using potent IFN-free regimens has the potential to dramatically decrease HCV incidence and prevalence. (Martin, 2013b) However, treatment-based strategies to prevent HCV transmission have yet to be studied, including how to integrate hepatitis C treatment with other risk reduction strategies including opiate substitution therapy and needle and syringe exchange programs. (Martin, 2013a)

Studies of IFN-containing treatments in persons who inject drugs have shown comparable adherence and efficacy rates to patients who do not use injection drugs. A recent meta-analysis of treatment in active or recent injection drug users with PEG with or without RBV showed SVR rates of 37% and 67% for genotype 1 or 4 and 2 or 3, respectively. (Aspinall, 2013) As shorter, better-tolerated, more-efficacious IFN-free therapies are introduced, these SVR rates are expected to improve. Importantly, the rate of reinfection in this population is lower (2.4/100 person years of observation) than incident infection in the injection drug user population in general (6.1-27.2/100 person years); though reinfection increases with active or ongoing injection drug use (6.44/100 person years) and available data are limited in follow-up duration. (Aspinall, 2013); (Grady, 2013)

Ideally, treatment of HCV-infected persons who inject drugs should be delivered in a multidisciplinary care setting with services to reduce the risk of reinfection and for management of the common social and psychiatric comorbidities in this population. Regardless of the treatment setting, recent and active injection drug use should not be seen as an absolute contraindication to HCV therapy. Scale up of HCV treatment in persons who inject drugs is necessary to positively impact the HCV epidemic in the United States and globally.

HIV-infected men who have sex with men (MSM) with high-risk sexual practices. Over the past decade a dramatic increase in incident HCV infections has been demonstrated in several US cities among

HIV-infected MSM who did not report injection drug use as a risk factor. (van de Laar, 2010) Recognition and treatment of HCV (including acute infection) in this population may represent an important step in preventing subsequent infections. As with persons who inject drugs, HIV-infected MSM with ongoing high-risk sexual practices should be treated for their HCV infection in conjunction with continued education on risk reduction strategies. In particular, safer sex strategies should be emphasized given the high rates of reinfection after SVR, which may approach 30% over 2 years, in HIV-infected MSM with acute HCV infection. (Lambers, 2011)

Incarcerated persons. Among incarcerated individuals, the HCV seroprevalence ranges from 30% to 60% (Post, 2013) and an acute infection rate of about 1%. (Larney, 2013) Screening for HCV is relatively uncommon in state prison systems. Treatment uptake has been limited in part because of the toxic effects and long treatment duration of older IFN-based therapies as well as concerns about cost. (Spaulding, 2006) In particular, truncation of treatment owing to release from prison during therapy has been cited as a major limitation to widespread, effective HCV treatment in correctional facilities. (Post, 2013); (Chew, 2009) Shorter (12-week to 24-week) HCV therapies reduce duration of stay-related barriers to HCV treatment in prisons. Likewise, the improved safety of newer, all-oral regimens diminishes toxicity concerns. Coordinated treatment efforts within prison systems would likely rapidly decrease the prevalence of HCV infection in this at-risk population, although research is needed in this area.

Persons on hemodialysis. The prevalence of HCV infection is markedly elevated in persons on hemodialysis and ranged from 2.6 to 22.9% in a large multinational study. (Fissell, 2004) Studies in the United States found a similarly elevated prevalence of 7.8% to 8.9%. (Centers for Disease Control and Prevention, 2001); (Finelli, 2005) Importantly, the seroprevalence of HCV was found to increase with time on dialysis suggesting that nosocomial transmission, among other risk factors, plays a role in HCV acquisition in these patients. (Fissell, 2004) Improved education and strict adherence to universal precautions can drastically reduce nosocomial HCV transmission risks for persons on hemodialysis, (Jadoul, 1998) but clearance of HCV viremia through treatment-induced SVR eliminates the potential for transmission.

HCV-infected persons on hemodialysis have a decreased quality of life and increased mortality compared with persons on hemodialysis without HCV infection. (Fabrizi, 2002); (Fabrizi, 2007); (Fabrizi, 2009) HCV infection in this population also has a deleterious impact on kidney transplantation outcomes with decreased patient and graft survival. (Fabrizi, 2014) The increased risk for nosocomial transmission combined with the substantial clinical impact of HCV infection in those on hemodialysis suggest that this group should also be prioritized for HCV therapy as effective antiviral regimens that can be used in advanced renal failure become available.

For all these populations, the decision to treat should be based on a favorable risk-benefit ratio taking into account the anticipated reduction in transmission(s) versus the likelihood of reinfection.

Populations Unlikely to Benefit from HCV Treatment

Patients with limited life expectancy for whom HCV therapy would not improve symptoms or prognosis do not require treatment. Chronic hepatitis C is associated with a wide range of comorbid conditions. (Butt, 2011); (Louie, 2012) Little evidence exists to support initiation of HCV treatment in patients with limited life expectancy (less than 12 months) due to non–liver-related comorbid conditions. For these patients, the benefits of HCV treatment are unlikely to be realized, and palliative care strategies should take precedence. (Holmes, 2006); (Maddison, 2011)

Recommendations for pretreatment assessment

An assessment of the degree of hepatic fibrosis, using noninvasive testing or liver biopsy, is recommended.

Rating: Class I, Level A

An accurate assessment of fibrosis is vital in assessing the urgency for treatment. The degree of hepatic fibrosis is one of the most robust prognostic factors used to predict disease progression and clinical outcomes. (Everhart, 2010) Those with substantial fibrosis (defined as Metavir F2 or higher) should be given priority for therapy in an effort to decrease the risk of clinical consequences such as cirrhosis, liver failure, and hepatocellular cancer. However, those with severe fibrosis (Metavir stage F3 and F4) are most in need of immediate therapy. In addition to urgency for antiviral therapy, individuals with severe fibrosis require surveillance monitoring for liver cancer, esophageal varices, and hepatic function. (Garcia-Tsao, 2007); (Bruix, 2011)

Although liver biopsy is the diagnostic standard, sampling error and observer variability limit test performance, particularly when inadequate sampling occurs. Up to one-third of bilobar biopsies had a difference of at least 1 stage between the lobes. (Bedossa, 2003) In addition, the test is invasive and minor complications are common, limiting patient and practitioner acceptance. Serious complications such as bleeding, although rare, are well recognized.

Noninvasive tests to stage the degree of fibrosis in patients with chronic HCV infection include models incorporating indirect serum biomarkers (routine tests), direct serum biomarkers (components of the extracellular matrix produced by activated hepatic stellate cells), and vibration-controlled transient liver elastography. No single method is recognized to have high accuracy alone and each test must be interpreted carefully. A recent publication of the Agency for Healthcare Research and Quality found evidence in support of a number of blood tests; however, at best they are only moderately useful for identifying clinically significant fibrosis or cirrhosis. (Selph, 2014)

Vibration-controlled transient liver elastography is a noninvasive way to measure liver stiffness and correlates well with measurement of substantial fibrosis or cirrhosis in patients with chronic HCV infection. A cutoff value of 8.7 kPa correlates with Metavir F2 or higher fibrosis stage; greater than 9.5 kPa with F3; and 14.5 or higher kPa with F4 or cirrhosis. The measurement range does overlap between stages. (Ziol, 2005)

The most efficient approach to fibrosis assessment is to combine direct biomarkers and vibration-controlled transient liver elastography. (Boursier, 2012) A biopsy should be considered for any patient who has discordant results between the 2 modalities that would affect clinical decision making. For example, 1 shows cirrhosis and the other does not. The need for liver biopsy with this approach is markedly reduced.

Alternatively, if direct biomarkers or vibration-controlled transient liver elastography are not available, the aspartate aminotransferase-to-platelet ratio index (APRI) or fibrosis-4 index (FIB-4) can help identify those most likely to have F3 or F4 fibrosis stage. (Sebastiani, 2009); (Castera, 2010); (Chou, 2013b) An APRI above 2.0 or FIB-4 above 3.25 has a high specificity for advanced fibrosis or cirrhosis, although neither test

is sensitive enough to rule out substantial fibrosis if values are below these thresholds. (Chou, 2013b) Biopsy should be considered in those in whom more accurate fibrosis staging would impact treatment decisions.

Individuals with clinically evident cirrhosis do not require additional staging (biopsy or noninvasive assessment).

Recommendation for repeat liver disease assessment

Ongoing assessment of liver disease is recommended for persons in whom therapy is deferred.

Rating: Class I, Level C

When therapy is deferred, it is especially important to monitor liver disease in these patients. Among individuals with less-advanced stages of fibrosis, fibrosis progression over time will help determine the urgency of subsequent antiviral therapy. Fibrosis progression varies markedly between individuals based on host, environmental, and viral factors (**Table 3**). (Feld, 2006) Fibrosis may not progress linearly. Some individuals (often those who are aged 50 years or older) may progress slowly for many years followed by an acceleration of fibrosis progression. Others may never develop substantial liver fibrosis despite longstanding infection. The presence of existing fibrosis is a strong risk factor for future fibrosis progression. Fibrosis results from chronic hepatic necroinflammation and thus a higher activity grade on liver biopsy and higher serum transaminase values is associated with more rapid fibrosis progression. (Ghany, 2003) However, even patients with normal alanine aminotransferase (ALT) levels may develop substantial liver fibrosis over time. (Pradat, 2002); (Nutt, 2000)

Host factors associated with more rapid fibrosis progression include male sex, longer duration of infection, and older age at the time of infection. (Poynard, 2001) Many patients have concomitant nonalcoholic fatty liver disease, and the presence of hepatic steatosis with or without steatohepatitis on liver biopsy as well as elevated body mass index and insulin resistance are associated with fibrosis progression, as is iron overload. (Konerman, 2014); (Everhart, 2009) Chronic alcohol use is an important risk factor because alcohol consumption has been associated with more rapid fibrosis progression. (Feld, 2006) A safe amount of alcohol consumption has not been established. Cigarette smoking may also lead to more rapid fibrosis progression.

Immunosuppression leads to more rapid fibrosis progression, particularly HIV coinfection and solid organ transplantation. (Macias, 2009); (Konerman, 2014); (Berenguer, 2013) Therefore, immunocompromised patients should be prioritized for antiviral therapy even if they have mild liver fibrosis at presentation.

The level of virus in the serum (HCV RNA) is not highly correlated with the stage of disease (degree of inflammation or fibrosis). Available data suggest that fibrosis progression occurs most rapidly in patients with genotype 3 HCV infection. (Kanwal, 2014) (Bochud, 2009) Aside from coinfections with HBV or HIV, no other viral factors are consistently associated with disease progression.

Although an ideal interval for assessment has not been established, annual evaluation is appropriate to

discuss modifiable risk factors and update testing for hepatic function and markers for disease progression. For all individuals with advanced fibrosis, liver cancer screening dictates a minimum of every 6 months evaluation.

When and in Whom to Initiate HCV Therapy Table 3. Factors Associated with Accelerated Fibrosis Progression

When and in Whom to Initiate HCV Therapy Box. Summary of Recommendations for When and in Whom to Initiate HCV Therapy

When and in Whom to Initiate HCV Therapy Box. Summary of Recommendations for When and in Whom to Initiate HCV Therapy

Goal of treatment

The goal of treatment of HCV-infected persons is to reduce all-cause mortality and liver-related health adverse consequences, including end-stage liver disease and hepatocellular carcinoma, by the achievement of virologic cure as evidenced by an SVR.

Rating: Class I, Level A

Recommendations for when and in whom to initiate treatment

Treatment is recommended for patients with chronic HCV infection.

Rating: Class I, Level A

Treatment is assigned the highest priority for those patients with advanced fibrosis (Metavir F3), those with compensated cirrhosis (Metavir F4), liver transplant recipients, and patients with severe extrahepatic hepatitis C (Table 1).

Based on available resources, treatment should be prioritized as necessary so that patients at high risk for liver-related complications and severe extrahepatic hepatitis C complications are given high priority (Table 1).

Ratings: See tables

Recommendations for pretreatment assessment

An assessment of the degree of hepatic fibrosis, using noninvasive testing or liver

biopsy, is recommended.

Rating: Class I, Level A

Recommendation for repeat liver disease assessment

Ongoing assessment of liver disease is recommended for persons in whom therapy is deferred.

Rating: Class I, Level C

Table 1. Settings of Liver-Related Complications and Extrahepatic Disease in Which HCV Treatment is Most Likely to Provide the Most Immediate and Impactful Benefits

Highest Priority for Treatment Owing to Highest Risk for Severe Complications
Advanced fibrosis (Metavir F3) or compensated cirrhosis (Metavir F4) **Rating:** Class I, Level A
Organ transplant **Rating:** Class I, Level B
Type 2 or 3 essential mixed cryoglobulinemia with end-organ manifestations (eg, vasculitis) **Rating:** Class I, Level B

INITIAL TREATMENT OF HCV INFECTION IN PATIENTS STARTING TREATMENT

*/

Expansions and notes for abbreviations used in this section can be found in Methods Table 3.

A summary of recommendations for initial treatment is found in the BOX***.***

This section provides guidance on the recommended initial treatments for persons with chronic HCV infection who are naive to HCV treatment or who have achieved an undetectable level of virus during a prior treatment course of PEG/RBV and relapsed (relapsers). Although PEG/RBV relapsers are being retreated, their treatment recommendations are presently the same as for persons being treated for the first time as described below. This section assumes that ***a decision to treat has been made*** and provides guidance regarding optimal treatment. In many instances, however, it may be advisable to delay treatment for some patients with documented early fibrosis stage (F 0-2), because waiting for future highly effective, pangenotypic, DAA combinations in IFN-free regimens may be prudent. Potential advantages of waiting to begin treatment will be provided in a future update to this guidance.

The level of evidence available to inform the best treatment decisions for each patient varies, as does the strength of the recommendation, and is graded accordingly (see **Methods Table 2**). In addition, when treatment differs for a particular group, such as those infected with specific HCV genotypes, specific recommendations are given. A regimen is classified as either "Recommended" when it is favored for most patients or "Alternative" when optimal in a particular subset of patients in that category. When a treatment is clearly inferior or is deemed harmful, it is classified as "Not Recommended." Unless otherwise indicated, such regimens should not be administered to patients with HCV infection. Specific considerations of persons with HIV/HCV coinfection, compensated and decompensated cirrhosis (moderate or severe hepatic impairment; CTP class B or C), post-liver transplant HCV, and those with severe renal impairment or ESRD are addressed in other sections of the document.

As always, patients receiving antiviral therapy require careful pretreatment assessment for comborbidities that may influence treatment response. All patients should have careful monitoring during treatment, particularly for anemia if ribavirin is included in the regimen.

I. Genotype 1

Recommended regimen for treatment-naive patients with HCV genotype 1 who are eligible to receive IFN.

Daily sofosbuvir (400 mg) and weight-based RBV (1000 mg [<75 kg] to 1200 mg [≥75 kg]) plus weekly PEG for 12 weeks is recommended for IFN-eligible persons with HCV genotype 1 infection, regardless of subtype.

Rating: Class I, Level A

Sofosbuvir is a prodrug of a nucleotide analogue inhibitor of the HCV NS5B RNA-dependent RNA polymerase. The phase 3 NEUTRINO trial evaluated sofosbuvir (400 mg daily) in combination with PEG (2a) (180 ?g by subcutaneous injection weekly) and weight-based RBV (1000 mg to 1200 mg daily) for 12 weeks in 291 treatment-naive patients with chronic HCV genotype 1 infection. (Lawitz, 2013b) The SVR12 for patients with genotype 1 infection was 89%. SVR12 did not differ substantially by baseline characteristic but was lower in patients with cirrhosis (80%) than in those without cirrhosis (92%). (Lawitz, 2013b)

Recommended regimen for treatment-naive patients with HCV genotype 1 who are not eligible to receive IFN.

Daily sofosbuvir (400 mg) plus simeprevir (150 mg), with or without weight-based RBV (1000 mg [<75 kg] to 1200 mg [≥75 kg] for 12 weeks is recommended for IFN-ineligible IFN ineligible is defined as one or more of the below:
• Intolerance to IFN
• Autoimmune hepatitis and other autoimmune disorders
• Hypersensitivity to PEG or any of its components
• Decompensated hepatic disease
• Major uncontrolled depressive illness
• A baseline neutrophil count below 1500/?L, a baseline platelet count below 90,000/?L or baseline hemoglobin below 10 g/dL
• A history of preexisting cardiac disease **patients with HCV genotype 1 infection, regardless of subtype.**

Rating: Class I, Level B

COSMOS is an ongoing phase 2 clinical trial of sofosbuvir (400 mg daily) plus simeprevir (150 mg daily), a specific inhibitor of the HCV NS3/4A serine protease, with or without RBV for 12 or 24 weeks. (Jacobson, 2013b) The study enrolled 2 cohorts: cohort 1 included patients with a prior null response to PEG/RBV with Metavir fibrosis stage of 0 or 2 (n=80); Cohort 2 included patients who were either treatment-naive or had a prior null response with Metavir fibrosis stage of 3 or 4 (n=87). In cohort 1, the 12-week treatment groups, SVR12 was 96% and 93% in patients treated with or without RBV, respectively. The 24-week treatment groups had SVR12 of 79.3% and 93% in patients treated with or without RBV, respectively. No viral breakthrough was observed in cohort 1 during treatment, and 3 patients experienced viral relapse after stopping therapy. All 3 patients with viral relapse were infected with HCV genotype 1a and had the Q80K polymorphism.

Preliminary SVR4 results are available for cohort 2. The 12-week treatment duration group had 100% SVR in treatment-naive patients treated with or without RBV, and 100% and 93.3% in prior null responder patients treated with or without RBV, respectively. No viral breakthrough was observed during treatment; 1 patient infected with HCV genotype 1a/Q80K experienced viral relapse after stopping therapy. No SVR

data are yet available from cohort 2, which received 24 weeks of treatment.

Among patients who had viral relapse, simeprevir (protease) resistance-associated variants have been observed; sofosbuvir (polymerase) resistance-associated variants have not been detected. Safety data have been presented for all 167 patients treated. The combination was well tolerated, with only 2.4% of patients prematurely discontinuing therapy due to adverse events. Data on the use of simeprevir in patients with hepatic impairment are not available at this time.

For patients infected with genotype 1a HCV, baseline resistance testing for the Q80K polymorphism may be considered. However, in contrast to using simeprevir to treat a genotype 1a HCV patient with PEG/RBV when the mutation markedly alters the probability of an SVR, the finding of the Q80K polymorphism does not preclude treatment with simeprevir and sofosbuvir, because the SVR rate was high in patients with genotype 1a/Q80K infection (SVR12 rate for cohort 1 was 86% [24 of 28 patients]; SVR4 rate for cohort 2 was 90% [10 of 11 patients]). To date, virologic failure has not been observed in patients in either cohort infected with HCV genotype 1b and with HCV genotype 1a in the absence of the Q80K polymorphism. Thus Q80K testing can be considered but is not strongly recommended.

This regimen should be considered only in those patients who require immediate treatment, because it is anticipated that safer and more effective IFN-free regimens will be available by 2015.

Alternative regimens for treatment-naive patients with HCV genotype 1 who are eligible to receive IFN.

Daily simeprevir (150 mg) for 12 weeks and weight-based RBV (1000 mg [<75 kg] to 1200 mg [≥75 kg]) plus weekly PEG for 24 weeks is an acceptable regimen for IFN-eligible persons with either

1. *HCV genotype 1b or*
2. *HCV genotype 1a infection in whom the Q80K polymorphism is not detected prior to treatment.*

Rating: Class IIa, Level A

Two randomized, placebo-controlled phase 3 trials evaluated the efficacy and safety of simeprevir (150 mg once daily) for 12 weeks plus PEG and weight-based RBV for a total of 24 weeks (RGT design found no advantage to extending PEG/RBV to 48 weeks). (Jacobson, 2013a); (Poordad, 2013)

In both studies, SVR24 rates were significantly higher among the simeprevir-containing arms (80% to 81%) than in the non-simeprevir-containing arms (50%). If the HCV RNA at week 4 of treatment is less than 25 IU/mL, therapy should be continued to week 24. If the HCV RNA is greater than 25 IU/mL at treatment week 4 or any treatment week thereafter, the regimen should be discontinued. In patients with HCV genotype 1a infection, the presence of a naturally occurring NS3-4A protease polymorphism (Q80K) prior

to treatment was associated with a substantial reduction in SVR among patients treated with simeprevir. A statistically significant difference in SVR12 rates exists between simeprevir-treated persons who are infected with HCV genotype 1a but do not have the Q80K polymorphism and placebo-treated patients who likewise have no such polymorphism. This difference was noted in both the pooled treatment-naive studies and the relapser study (SVR rates of 84% versus 43%, respectively [treatment-naive study] and 78% versus 24%, respectively [relapse study]). The overall SVR in the subgroup of patients with baseline Q80K polymorphism was no better than that in the placebo group. In the United States, persons with genotype 1a HCV infection have a high prevalence of Q80K polymorphism. Because these persons may require alternative therapy, baseline testing for Q80K is recommended for all patients before treatment with the simeprevir plus PEG/RBV regimen is initiated.

For the simeprevir plus PEG/RBV treatment regimen, if the HCV RNA at week 4 of treatment is less than 25 IU/mL, therapy should be continued to week 24. If the HCV RNA is greater than 25 IU/mL at treatment week 4 or any treatment week thereafter, the regimen should be discontinued.

Alternative regimens for treatment-naive patients with HCV genotype 1 who are not eligible to receive IFN.

Daily sofosbuvir (400 mg) and weight-based RBV (1000 mg [<75 kg] to 1200 mg [≥75 kg]) for 24 weeks is an acceptable regimen for IFN-ineligible IFN ineligible is defined as one or more of the below:

- Intolerance to IFN
- Autoimmune hepatitis and other autoimmune disorders
- Hypersensitivity to PEG or any of its components
- Decompensated hepatic disease
- Major uncontrolled depressive illness
- A baseline neutrophil count below 1500/?L, a baseline platelet count below 90,000/?L or baseline hemoglobin below 10 g/dL
- A history of preexisting cardiac disease **persons with HCV genotype 1 infection, regardless of subtype; however, preliminary data suggest that this regimen may be less effective than daily sofosbuvir (400 mg) plus simeprevir (150 mg), particularly among patients with cirrhosis.**

Rating: Class IIb, Level B

Sofosbuvir plus RBV was evaluated in 60 treatment-naive patients with HCV genotype 1 with unfavorable treatment characteristics (eg, African American race and advanced fibrosis). (Osinusi, 2013) In part 1 of the study, 10 participants with early to moderate liver fibrosis were treated with sofosbuvir (400 mg daily) plus weight-based RBV for 24 weeks. Nine participants (90%) achieved SVR24. In part 2, 50 participants with any stage of liver fibrosis were randomized 1:1 to receive 400 mg sofosbuvir with RBV either weight-based or low-dose (600 mg daily) for 24 weeks; SVR24 was 68% (17/25) in the weight-based group and 48% (12/25) in the low-dose group. The regimens used in part 2 of this study were well tolerated, with no

discontinuations due to adverse events. Seven of the 13 participants (54%) with advanced liver fibrosis treated in this study relapsed, including all 4 with cirrhosis.

Several additional studies have evaluated the effectiveness of sofosbuvir in persons with HCV genotype 1. In the QUANTUM trial, 38 treatment-naive patients with HCV genotype 1 who did not have cirrhosis were assigned either 12 (n=19) or 24 (n=19) weeks of sofosbuvir (400 mg daily) and weight-based RBV. (Lalezari, 2013) Ten of 19 (53%) in the 12-week arm and 9 of 19 (47%) subjects in the 24-week arm achieved SVR12 (overall 50%). In the ELECTRON trial, 25 treatment-naive subjects with HCV genotype 1 who did not have cirrhosis received sofosbuvir plus RBV for 12 weeks. Twenty-one (84%) achieved SVR12. (Gane, 2013b) In the PHOTON-1 trial, 86 of 113 (76%) treatment-naive subjects with genotype 1 HCV/HIV coinfection achieved SVR12 with sofosbuvir plus RBV for 24 weeks. (Sulkowski, 2013c) Taken together, in a total of 211 subjects, the range of SVR for regimens incorporating sofosbuvir plus daily weight-based RBV (1000 mg to 1200 mg) for up to 24 weeks in treatment-naive persons with HCV genotype 1 was 50% to 84%, with an overall SVR of 72%. Sofosbuvir resistance-associated amino acid variants have not been detected among those patients treated with this combination who did not achieve SVR.

This regimen should be considered only in those patients who require immediate treatment. It is estimated that the FDA will approve safer and more effective IFN-free regimens by 2015.

The following regimens are NOT recommended for treatment-naive patients with HCV genotype 1.

PEG/RBV with or without telaprevir or boceprevir for 24 to 48 weeks

Rating: Class IIb, Level A

Monotherapy with PEG, RBV, or a DAA

Rating: Class III, Level A

Although regimens of PEG/RBV plus telaprevir or boceprevir for 24 to 48 weeks using RGT are also FDA approved, they are markedly inferior to the preferred and alternative regimens. These regimens are associated with their higher rates of serious adverse events (eg, anemia and rash), longer treatment duration, high pill burden, numerous drug-drug interactions, frequency of dosing, intensity of monitoring for continuation and stopping of therapy, and the requirement to be taken with food or with high-fat meals.

PEG/RBV for 48 weeks for treatment-naive subjects with HCV genotype 1 has been superseded by treatments incorporating DAAs and should not be used.

II. Genotype 2

Recommended regimen for treatment-naive patients with HCV genotype 2, regardless of eligibility for IFN therapy:

Daily sofosbuvir (400 mg) and weight-based RBV (1000 mg [<75 kg] to 1200 mg [≥75 kg]) for 12 weeks is recommended for treatment-naive patients with HCV genotype 2 infection.

Rating: Class I, Level A

Sofosbuvir (400 mg daily) was combined with weight-based RBV (1000 mg to 1200 mg) to treat HCV genotype 2 treatment-naive patients across 3 clinical trials: FISSION, POSITRON, and VALENCE. (Lawitz, 2013b); (Jacobson, 2013c); (Zeuzem, 2013b) The FISSION study randomized patients to daily PEG/RBV (800 mg) for 24 weeks or sofosbuvir plus daily weight-based RBV (1000 mg to 1200 mg). (Lawitz, 2013b) The SVR was higher (94%) in patients who received sofosbuvir plus RBV compared with those who received PEG/RBV (78%) (52/67). Across all 3 trials, 201 of 214 (94%) patients with HCV genotype 2 achieved SVR with sofosbuvir plus RBV. Among patients who did not achieve SVR, sofosbuvir resistance-associated amino acid variants were not detected. (US FDA, 2013a)

Alternative Regimens for treatment-naive patients with genotype 2:

None

The following regimens are NOT recommended for treatment-naive patients with HCV genotype 2.

PEG/RBV for 24 weeks

Rating: Class IIb, Level A

Monotherapy with PEG, RBV, or a DAA

Rating: Class III, Level A

Telaprevir-, boceprevir-, or simeprevir-based regimens

Rating: Class III, Level A

PEG (2a) (180 µg weekly) or PEG (2b) (1.5 µg/kg weekly) plus RBV (800 mg daily) for 24 weeks was directly compared with sofosbuvir (400 mg daily) plus weight-based RBV (1000 mg to 1200 mg daily) in the

FISSION trial. (Lawitz, 2013b) The SVR12 achieved with PEG/RBV was lower than that achieved with sofosbuvir/RBV overall (78% and 95%, respectively) and in the subgroups of patients with or without cirrhosis. Safety and tolerability of PEG/RBV was inferior to the profile observed with sofosbuvir and RBV, with greater frequency of reported adverse events and laboratory abnormalities as well as a higher rate of treatment due to adverse events. Further, the duration of therapy with PEG/RBV is 12 weeks longer than that of sofosbuvir plus RBV.

Due to their poor in vitro and in vivo activity, boceprevir and simeprevir should not be used as therapy for patients with HCV genotype 2 infection. Although telaprevir combined with PEG/RBV has antiviral activity against HCV genotype 2, (Foster, 2011) the additional side effects and longer duration of therapy do not support use of this regimen.

III. Genotype 3

Recommended regimen for treatment-naive patients with HCV genotype 3, regardless of eligibility for IFN therapy:

Daily sofosbuvir (400 mg) and weight-based RBV (1000 mg [<75 kg] to 1200 mg [≥75 kg]) for 24 weeks is recommended for treatment-naive patients with HCV genotype 3 infection.

Rating: Class I, Level B

The VALENCE study assessed the efficacy and safety of sofosbuvir (400 mg daily) plus RBV for 24 weeks in 250 treatment-naive (42%) and treatment-experienced (58%) subjects with HCV genotype 3 infection. The overall SVR12 was 84% and was higher among treatment-naive than treatment-experienced patients (93% versus 77%, respectively). These results suggest higher response rates can be achieved with a 24-week duration of sofosbuvir plus RBV than those reported for the 12- or 16-week durations studied in the FISSION (Lawitz, 2013b) (12 weeks, SVR12: 63%), POSITRON, (Jacobson, 2013c) (12 weeks, SVR 12: 61%) and FUSION (12 weeks, SVR12: 30%, 16 weeks, SVR12: 62%) trials. The primary reason for the higher SVR with extended therapy among treatment-naive patients was a reduction in the relapse rate from 40% to 5%. In sub-analysis, response rates were similarly high among those with (n=45) and without (n=100) cirrhosis (92% and 93%, respectively).

Alternative regimens for treatment-naive patients with genotype 3 who are eligible to receive IFN.

Daily sofosbuvir (400 mg) and weight-based RBV (1000 mg [<75 kg] to 1200 mg [≥75 kg]) plus weekly PEG for 12 weeks is an acceptable regimen for IFN-eligible persons with HCV genotype 3.

Rating: Class IIa, Level A

The combination of sofosbuvir plus PEG/RBV has been evaluated in patients with genotype 3 infection. In 2 phase 2 clinical trials, PROTON and ELECTRON, 38 of 39 (97%) treatment-naive patients with genotype 3 infection achieved SVR with sofosbuvir plus PEG (4 to 12 weeks of therapy)/RBV. (Gane, 2013b) For many patients with genotype 3, the adverse effects and increased monitoring requirements of PEG make this less acceptable than the recommended regimen of sofosbuvir plus weight-based RBV.

The following regimens are NOT recommended for treatment-naive patients with HCV genotype 3.

PEG/RBV for 24 to 48 weeks

Rating: Class IIb, Level A

Monotherapy with PEG, RBV, or a DAA

Rating: Class III, Level A

Telaprevir-, boceprevir-, or simeprevir-based regimens should not be used for patients with genotype 3 HCV infection.

Rating: Class III, Level A

Although the combination of PEG/RBV is an FDA-approved regimen for HCV genotype 3, its less acceptable adverse effect profile, requirement for more intensive monitoring, and overall lower efficacy make it less desirable than the recommended regimen.

Because of their limited in vitro and in vivo activity against genotype 3, boceprevir, telaprevir, and simeprevir should not be used as therapy for patients with HCV genotype 3 infection.

IV. Genotype 4

Few data are available to help guide decision-making in patients infected with HCV genotype 4. Nonetheless, for those patients for whom immediate treatment is required, the following recommendations have been drawn from available data.

Recommended regimen for treatment-naive patients with HCV genotype 4 who are eligible to receive IFN.

Daily sofosbuvir (400 mg) and weight-based RBV (1000 mg [<75 kg] to 1200 mg [≥75 kg]) plus weekly PEG for 12 weeks is recommended for IFN-eligible persons

with HCV genotype 4 infection.

Rating: Class IIa, Level B

In the Phase 3 NEUTRINO trial, (Lawitz, 2013b) 28 treatment-naive patients with HCV genotype 4 infection were treated with sofosbuvir (400 mg daily) plus PEG (2a) (180 µg weekly) and weight-based RBV (1000 mg 1200 mg once daily) for 12 weeks. Of the 28 patients with genotype 4, 27 (96%) achieved SVR12. The one patient who did not achieve SVR had cirrhosis and relapsed after therapy. The adverse event profile was similar to that seen with PEG/RBV therapy.

Recommended regimen for treatment-naive patients with genotype 4 who are not eligible to receive IFN.

Daily sofosbuvir (400 mg) plus weight-based RBV (1000 mg [<75 kg] to 1200 mg [≥75 kg]) for 24 weeks is recommended for IFN-ineligible IFN ineligible is defined as one or more of the below:
• Intolerance to IFN
• Autoimmune hepatitis and other autoimmune disorders
• Hypersensitivity to PEG or any of its components
• Decompensated hepatic disease
• Major uncontrolled depressive illness
• A baseline neutrophil count below 1500/?L, a baseline platelet count below 90,000/?L or baseline hemoglobin below 10 g/dL
• A history of preexisting cardiac disease **patients with HCV genotype 4 infection.**

Rating: Class IIb, Level B

In a small study of Egyptian patients in the United States treated with sofosbuvir plus weight-based RBV (1000 mg to 1200 mg), SVR12 was achieved in 11/14 (79%) and 14/14 (100%) in treatment-naive patients treated for 12 weeks and 24 weeks, respectively. In treatment-experienced patients treated for 12 weeks and 24 weeks, SVR12 was achieved in 10/17 (59%) and 13/15 (87%), respectively. (Ruane, 2014)

Alternative regimens for treatment-naive patients with HCV genotype 4 who are eligible to receive IFN.

Daily simeprevir (150 mg) for 12 weeks and weight-based RBV (1000 mg [<75 kg] to 1200 mg [≥75 kg]) plus weekly PEG for 24 to 48 weeks is an alternative regimen for IFN-eligible persons with HCV genotype 4 infection.

Rating: Class IIb, Level B

A Phase 3 trial in patients with HCV genotype 4 is currently under way. This trial compares PEG and weight-based RBV (1000 mg to 1200 mg) for 48 weeks with a 12-week regimen of simeprevir 150 mg once daily plus PEG and weight-based RBV (1000 mg to 1200 mg) followed by an additional 12 or 36 weeks of PEG/RBV alone. (Moreno, 2013) In another study, the RESTORE trial, an RGT approach is used in place of the simeprevir arm. Patients who have HCV RNA below 25 IU/mL at week 4 and undetectable HCV RNA by week 12 continue PEG/RBV for an additional 12 weeks, and those who do not achieve this response continue PEG/RBV for an additional 36 weeks (total 48 weeks of therapy). The study has enrolled 107 patients, of whom 35 are treatment-naive, including 2 with cirrhosis. To date, 10 of 11 patients (91%) who met criteria for shortened therapy have achieved SVR4, and 3 of 3 have achieved SVR12. To date, therapy has failed in 4 patients: 3 had detectable virus at the end of treatment and 1 experienced virologic relapse. Anemia was reported in 8.4% and hyperbilirubinemia in 1.9% of all study participants (n=107) (including treatment-experienced patients). Four serious adverse events were attributed to simeprevir. No episodes of rash were reported. (Moreno, 2013)

The following regimens are NOT recommended for treatment-naive patients with HCV genotype 4.

PEG/RBV for 48 weeks

Rating: Class IIb, Level A

Monotherapy with PEG, RBV, or a DAA

Rating: Class III, Level A

Telaprevir- or boceprevir-based regimens

Rating: Class III, Level A

PEG/RBV for 48 weeks was the previously recommended regimen for patients with HCV genotype 4. The addition of sofosbuvir (400 mg daily) to PEG/RBV increases response rates and markedly shortens therapy with no apparent additional adverse effects. The addition of simeprevir to PEG/RBV increases response rates with a minimal increase in adverse events and can shorten therapy to 24 weeks.

Because of their limited in vitro and in vivo activity against genotype 4, boceprevir or telaprevir should not be used as therapy for patients with HCV genotype 4 infection.

V. Genotype 5 or 6

Few data are available to help guide decision-making in patients infected with HCV genotype 5 or 6. Nonetheless, for those patients for whom immediate treatment is required, the following recommendations have been drawn from available data. No data are available to support the use of a non-PEG containing regimen for patients with HCV genotype 5 or 6 infection.

Recommended regimen for treatment-naive patients with HCV genotype 5 or 6.

Daily sofosbuvir (400 mg) and weight-based RBV (1000 mg [<75 kg] to 1200 mg [≥75 kg]) plus weekly PEG for 12 weeks is recommended for IFN-eligible persons with HCV genotype 5 or 6 infection.

Rating: Class IIa, Level B

In the Phase 3 NEUTRINO trial (Lawitz, 2013b), treatment-naive patients with genotypes 1 (n=291), 4 (n=28), 5 (n=1), and 6 (n=6) were treated with sofosbuvir (400 mg daily) plus PEG (2a) (180 µg per week) and weight-based RBV (1000 mg 1200 mg once daily) for 12 weeks. All 6 patients with HCV genotype 6 and the 1 patient with genotype 5 achieved SVR12. The adverse event profile in these patients and in the larger study population was similar to that seen with PEG/RBV therapy.

Alternative regimens for treatment-naive patients with HCV genotype 5 or 6.

Daily weight-based RBV (1000 mg [<75 kg] to 1200 mg [≥75 kg]) plus weekly PEG for 48 weeks is an acceptable regimen for persons infected with HCV genotype 5 or 6.

Rating: Class IIb, Level A

PEG/RBV for 48 weeks was the previously recommended regimen for patients infected with HCV genotype 5 or 6. Sofosbuvir has activity against genotypes 5 and 6, and when combined with PEG/RBV for 12 weeks led to SVR in the 6 patients in whom it was studied. (Lawitz, 2013b) The addition of sofosbuvir (400 mg daily) to PEG/RBV shortens duration of therapy with no apparent additional adverse effects and likely substantially increases response rates.

The following regimens are NOT recommended for treatment-naive patients with genotype 5 or 6 HCV.

Monotherapy with PEG, RBV, or a DAA

Rating: Class III, Level A

Telaprevir- or boceprevir-based regimens

Rating: Class III, Level A

Because of their limited activity in vitro and in vivo against genotypes 5 and 6, boceprevir or telaprevir should not be used as therapy for patients with genotype 5 or 6 HCV infection.

Initial Treatment Box. Summary of Recommendations for Patients Who are Initiating Therapy for HCV Infection or Who Experienced Relapse after Prior PEG/RBV Therapy, by HCV Genotype

*/

Initial Treatment Box. Summary of Recommendations for Patients Who are Initiating Therapy for HCV Infection or Who Experienced Relapse after Prior PEG/RBV Therapy, by HCV Genotype

Genotype	Recommended	Alternative	NOT Recommended
1	**IFN eligible:** SOF + PEG/RBV x 12 weeks IFN ineligible IFN ineligible is defined as one or more of the below: • Intolerance to IFN • Autoimmune hepatitis and other autoimmune disorders • Hypersensitivity to PEG or any of its components • Decompensated hepatic disease • Major uncontrolled depressive illness • A baseline neutrophil count below 1500/?L, a baseline platelet count below 90,000/?L or baseline hemoglobin below 10 g/dL • A history of preexisting cardiac disease: SOF + SMV ± RBV x 12 weeks	**IFN eligible:** SMV x 12 weeks + PEG/RBV x 24 weeks* IFN ineligible IFN ineligible is defined as one or more of the below: • Intolerance to IFN • Autoimmune hepatitis and other autoimmune disorders • Hypersensitivity to PEG or any of its components • Decompensated hepatic disease • Major uncontrolled depressive illness • A baseline neutrophil count below 1500/?L, a baseline platelet count below 90,000/?L or baseline hemoglobin below 10 g/dL • A history of preexisting cardiac disease: SOF + RBV x 24 weeks	TVR + PEG/RBV x 24 or 48 weeks (RGT) BOC + PEG/RBV x 28 or 48 weeks (RGT) PEG/RBV x 48 weeks Monotherapy with PEG, RBV, or a DAA Do not treat decompensated cirrhosis with PEG or SMV
2	SOF + RBV x 12 weeks	None	PEG/RBV x 24 weeks

			Monotherapy with PEG, RBV, or a DAA Any regimen with TVR, BOC, or SMV
3	SOF + RBV x 24 weeks	SOF + PEG/RBV x 12 weeks	PEG/RBV x 24-48 weeks Monotherapy with PEG, RBV, or a DAA Any regimen with TVR, BOC, or SMV
4	**IFN eligible:** SOF + PEG/RBV x 12 weeks IFN ineligible IFN ineligible is defined as one or more of the below: • Intolerance to IFN • Autoimmune hepatitis and other autoimmune disorders • Hypersensitivity to PEG or any of its components • Decompensated hepatic disease • Major uncontrolled depressive illness • A baseline neutrophil count below 1500/?L, a baseline platelet count below 90,000/?L or baseline hemoglobin below 10 g/dL • A history of preexisting cardiac disease: SOF + RBV x 24 weeks	SMV x 12 weeks + PEG/RBV x 24-48 weeks	PEG/RBV x 48 weeks Monotherapy with PEG, RBV, or a DAA Any regimen with TVR or BOC
5 or 6	SOF + PEG/RBV x 12 weeks	PEG/RBV x 48 weeks	Monotherapy with PEG, RBV, or a DAA Any regimen with TVR or BOC

For genotype 1a, baseline resistance testing for Q80K should be performed and alternative treatments considered if this mutation is present.

RETREATMENT OF PERSONS IN WHOM PRIOR THERAPY HAS FAILED

Expansions and notes for abbreviations used in this section can be found in Methods Table 3.

A summary of recommendations for retreatment is found in the* BOX*.

This section provides guidance on the retreatment of a person with chronic HCV infection in whom prior therapy has failed. In general, treatment responses of patients achieving an undetectable level of virus during a prior treatment course who relapse following cessation of therapy (**relapser**) are similar to those of treatment-naive persons (see Initial Treatment). Treatment responses are generally lower in prior **non-responders**, which includes null responders (those in whom serum HCV RNA levels declined less than 2 $\log_{10}$ IU/mL by week 12 during a prior treatment course) and partial responders (those with a $\geq$ 2 $\log_{10}$ IU/mL response whose virus remained detectable up to 24 weeks or the end of treatment). This section assumes that a ***decision to treat has been made*** and advises on the optimal treatment. In many instances, however, it may be advisable to delay treatment for some patients with documented early fibrosis stage (F 0-2), because waiting for future highly effective, pangenotypic, combinations in IFN-free regimens may be prudent. Potential advantages of waiting to begin to treatment will be provided in a future update to this guidance.

The level of the evidence supporting the best treatment for each patient and the corresponding confidence in the recommendation varies as does the strength of the recommendation, and is graded in the same manner as the section on initial treatment of treatment-naive patients (Methods Table 2). In addition, when treatment differs for a particular group (eg, those infected with various genotypes) specific recommendations are given. Regimens are classified as "Recommended" when it is favored for most patients or "Alternative" when it might be optimal in a particular subset of patients in that category. When a treatment is clearly inferior or should not be used, it is classified as "Not Recommended."

As always, patients receiving antiviral therapy require careful pretreatment assessment for comorbidities that may influence treatment response. All patients should have careful monitoring during treatment, particularly for anemia if ribavirin is included in the regimen.

I. Genotype 1

Recommended regimen for HCV genotype 1 PEG/RBV (without an HCV protease inhibitor) nonresponder patients:

Daily sofosbuvir (400 mg) plus simeprevir (150 mg), with or without weight-based RBV (1000 mg [<75 kg] to 1200 mg [≥75 kg]) for 12 weeks is recommended for retreatment of HCV genotype 1 infection, regardless of subtype or IFN eligibility.

Rating: Class IIa, Level B

Recommended regimen for HCV genotype 1 PEG/RBV (with an HCV protease inhibitor) nonresponder patients:

Daily sofosbuvir (400 mg) for 12 weeks plus weight-based RBV (1000 mg [<75 kg] to 1200 mg [≥75 kg]) and weekly PEG for 12 to 24 weeks is recommended for retreatment of HCV genotype 1 infection, regardless of subtype.

Rating: Class IIb, Level C

COSMOS is a phase 2a randomized trial in which participants received sofosbuvir (400 mg once daily) plus simeprevir (150 mg once daily) with or without weight-based RBV (1000 mg to 1200 mg daily) for 12 or 24 weeks (Jacobson, 2013b). Of the 80 null responders with a Metavir fibrosis stage of 2 or less included in this trial, 79% to 96% achieved SVR (79%-96% in RBV-containing arms and 93% in both RBV-free arms). Among those null responders with a Metavir fibrosis stage of 3 or 4 (n=47) who received 12 weeks of sofosbuvir and simeprevir, SVR4 was observed in 14 (93%) of 15 patients in the ribavirin-containing arm and 100% (all 7 participants) in the RBV-free arm. Although benefit from RBV is not apparent from these preliminary results, it cannot be excluded before availability of SVR12 data. Post-treatment results are not yet available for the 24-week arms. Excluding nonvirologic failures, patients with HCV genotype 1a with Q80K mutations had slightly lower numeric response rates (fibrosis stage 0-2: SVR12=89% [n=27]; fibrosis stage 3 or 4: SVR4=91% [n=11]) than genotype 1a patients without Q80K and genotype 1b (fibrosis stage 2: SVR12 100%, n=47; fibrosis stage 3 or 4: SVR4=100% [n=29]). However, because the study was not powered to assess this comparison, insufficient evidence exists on the role of testing for the Q80K mutation at this time. These regimens were well tolerated, although adverse events (eg, anemia and hyperbilirubinemia) were seen more often in patients on RBV-containing regimens. (Jacobson, 2013b)

The safety and efficacy of simeprevir have not been studied in HCV-infected patients with moderate or severe hepatic impairment (Child-Pugh Class B or C). The uncertain impact of cholestasis and the occasional association of SMV with elevated transaminases create potential for drug accumulation or impaired hepatic function during SMV use. Clinical trials with SMV have been limited to patients with compensated disease who have CTP class A, total bilirubin of 1.5 x ULN or lower, and transaminases 10 x ULN or lower. For these reasons, simeprevir use should be limited to patients with compensated liver disease. Use of simeprevir is not recommended in patients with moderate to severe hepatic impairment. The combination of PEG/RBV is contraindicated in patients with decompensated cirrhosis (moderate or severe hepatic impairment; CTP class B or C).

Alternative regimen for PEG/RBV (with or without an HCV protease inhibitor) nonresponder patients with HCV genotype 1.

Eligible to receive IFN:

Daily sofosbuvir (400 mg) for 12 weeks and weight-based RBV (1000 mg [<75 kg] to 1200 mg [≥75 kg]) plus weekly PEG for 12 to 24 weeks is an alternative for retreatment of IFN-eligible persons with HCV genotype 1 infection, regardless of subtype.

Rating: Class IIb, Level C

Ineligible to receive IFN:

Daily sofosbuvir (400 mg) for 24 weeks and weight-based RBV (1000 mg [<75 kg] to 1200 mg [≥75 kg]) for 24 weeks is an alternative for retreatment of IFN-ineligible persons with HCV genotype 1 infection, regardless of subtype.

Rating: Class IIb, Level C

NEUTRINO is an open-label, single-arm trial that evaluated 12 weeks of sofosbuvir plus PEG/RBV in treatment-naive subjects with HCV genotypes 1, 4, 5, or 6; 89% had HCV genotype 1, and 17% had cirrhosis. The SVR was 89% (261 of 292) and was somewhat lower in patients with genotype 1b than 1a (82% and 92%, respectively) and those with cirrhosis versus those without (80% versus 92%, respectively). (Lawitz, 2013a) Treatment-experienced subjects who did not respond to PEG/RBV with or without an HCV protease inhibitor were not included in this study. There are no data available to estimate the response in patients who have been previously treated with a protease inhibitor. However, among patients who were previously treated with PEG/RBV, the FDA estimates that the response rate in such patients would approximate the observed response rate in those NEUTRINO subjects with baseline factors traditionally associated with a lower response to IFN-based treatment. (US FDA, 2013a) In the NEUTRINO trial, SVR rate was 71% among participants with HCV genotype 1 with IL28B non-C/C alleles, high HCV RNA levels, and METAVIR 1 fibrosis stage F3 or F4 (37 of 52 patients). (Gilead Sciences, 2013; Sovaldi package insert)

In a prospective, multicenter trial of sofosbuvir (400 mg/day) plus RBV (ascending dose of 400 mg/day, escalating based on hemoglobin level) including treatment-experienced patients with recurrent HCV infection after liver transplantation, SVR12 was 70% in this population. (Charlton, 2013a)

Alternative regimen for PEG/RBV (without an HCV protease inhibitor) nonresponder patients with HCV genotype 1 who are eligible to receive IFN.

Daily simeprevir (150 mg) for 12 weeks plus weight-based RBV (1000 mg [<75 kg] to 1200 mg [≥75 kg]) and weekly PEG for 48 weeks is an alternative for IFN-eligible persons with HCV genotype 1 infection. (All patients with cirrhosis who are receiving simeprevir should have well compensated liver disease.)

Rating: Class IIa, Level A

Simeprevir was combined with PEG/RBV in patients who had previously failed to respond to PEG/RBV dual therapy in the Phase 2b ASPIRE trial. (Zeuzem, 2013a); (Janssen Therapeutics, 2013) (www.fda.gov; package insert). SVR24 after 48 weeks of triple therapy in the simeprevir 150 mg/day arm was 65% in patients with a previous partial response (n=23) and 53% in patients with a prior null response (n=17). Patients with HCV genotype 1a infection had inferior response rates compared with those with genotype 1b (SVR24: 47% vs 77% in patients with a partial response and 41% vs 47% in patients with a null response, respectively). Despite lower SVR in patients with HCV genotype 1a infection, SVR rates were similar with and without the presence of the Q80K mutations at baseline. SVR rates in patients with advanced fibrosis (METAVIR stage F3 or F4) treated with simeprevir (150 mg daily) plus PEG/RBV for 48 weeks were 59% in patients with a partial response (n=33) and 35% in patients with a null response (n=34). Safety in patients exposed to simeprevir was similar to that of persons in the placebo arms; however, there was a higher incidence of hyperbilirubinemia (8%) and photosensitivity/rash (5%). (Zeuzem, 2013a)

The safety and efficacy of simeprevir have not been studied in HCV-infected patients with moderate or severe hepatic impairment (Child-Pugh Class B or C). The uncertain impact of cholestasis and the occasional association of simeprevir with elevated transaminases pose potential for impaired hepatic function during simeprevir use. Clinical trials with simeprevir have been limited to patients with compensated disease who have CTP class A, total bilirubin level of 1.5 x ULN or lower, and transaminase level of 10 x ULN or lower. For these reasons, simeprevir use should be limited to patients with compensated liver disease. Use of simeprevir is not recommended in patients with moderate to severe hepatic impairment. Use of the drug in this population is not recommended at this time. The combination of PEG/RBV is contraindicated in patients with decompensated cirrhosis (moderate or severe hepatic impairment; CTP class B or C).

The following regimens are NOT recommended for PEG/RBV (with or without an HCV protease inhibitor) nonresponder patients with HCV genotype 1:

PEG/RBV with or without telaprevir or boceprevir

Rating: Class IIb, Level A

Monotherapy with PEG, RBV, or a DAA

Rating: Class III, Level A

For nonresponder patients with genotype 1 and a history of decompensated cirrhosis (moderate or severe hepatic impairment; CTP class B or C), treatment is not indicated because of the risks of PEG and boceprevir and telaprevir in this population.

Triple therapy with boceprevir plus PEG/RBV for 48 weeks may result in SVR for up to 52% of PEG/RBV partial responders (RESPOND 2; (Bacon, 2011)) and 38% of null responders (PROVIDE; (Di Bisceglie, 2013)). Similarly, telaprevir plus PEG/RBV resulted in SVR24 of 54% to 59% among partial responders and an SVR24 of 29% to 33% among null responders (REALIZE; (Zeuzem, 2011)). Due to the relatively poor efficacy, prolonged duration of therapy (48 weeks), and poor tolerability, these regimens are no longer recommended.

Monotherapy with PEG, RBV, or any of the available DAAs is ineffective; further, DAA monotherapy leads to rapid selection of resistant variants.

Patients with advanced liver disease are at increased risk for sepsis, worsening decompensation, and death when treated with dual or triple IFN-based therapy. (Crippin, 2002); (Coilly, 2014) Simeprevir is primarily metabolized by the liver and should not be used in patients with advanced cirrhosis (CTP B or C), as the AUC is increased 2.4- to 5.2-fold. (Janssen Therapeutics, 2013) (Olysio package insert, Janssen).

II. Genotype 2

Recommended regimen for genotype 2 PEG/RBV nonresponders.

Daily sofosbuvir (400 mg) and weight-based RBV (1000 mg [<75 kg] to 1200 mg [≥75 kg]) for 12 weeks is recommended for retreatment of HCV genotype 2 infection. (Patients with cirrhosis may benefit by extension of treatment to 16 weeks.)

Rating: Class I, Level A

High SVR12 rates have been demonstrated in non-cirrhotic genotype 2 treatment-experienced patients who received 12 weeks of sofosbuvir plus RBV. Limited data are available in cirrhotic genotype 2 treatment experienced patients; however, in the FUSION study, numerically higher SVR12 rates were seen with extension of therapy from 12 weeks (60%) to 16 weeks (78%). (Jacobson, 2013b) In contrast, the VALENCE trial found high SVR12 rates among HCV genotype 2-infected persons with cirrhosis after only 12 weeks of sofosbuvir plus RBV (88%). (Zeuzem, 2013b) Thus, at this time definitive recommendations on the appropriate duration of sofosbuvir and RBV for treatment-experienced, HCV genotype 2-infected persons with cirrhosis cannot be made. The decision to extend therapy to 16 weeks should be made on a case-by-case basis.

Alternative regimen for PEG/RBV nonresponder patients with HCV genotype 2 infection who are eligible to receive IFN.

Retreatment with daily sofosbuvir (400 mg) and weight-based RBV (1000 mg [<75

kg] to 1200 mg [≥75 kg]) plus weekly PEG for 12 weeks is an alternative for IFN-eligible persons with HCV genotype 2 infection.

Rating: Class IIa Level B

Recognizing the potential limitations of sofosbuvir plus RBV in harder-to-treat genotype 2 nonresponders, particularly those with cirrhosis, combination therapy with PEG has been studied. The LONESTAR-2 trial (an open-label, single site, single-arm phase 2 trial) evaluated PEG (180 ?g weekly), sofosbuvir (400 mg daily), and weight-based RBV (1000 mg to 1200 mg daily in 2 divided doses for 12 weeks) in treatment-experienced patients with HCV genotype 2 or 3. Cirrhosis was present at baseline in 61% of patients. SVR12 was achieved in 22 (96%) of 23 persons with genotype 2 HCV infection. For patients with and without cirrhosis, SVR occurred in 13 (93%) of 14 and 9 (100%) of 9, respectively. Despite the limitations of this small study (and accounting for the potential challenges inherent with IFN therapy), combination PEG plus sofosbuvir and RBV is an alternative 12-week regimen for genotype 2-infected patients with cirrhosis.

The following regimens are NOT recommended for nonresponder patients with HCV genotype 2.

PEG/RBV with or without telaprevir, boceprevir or simeprevir

Rating: Class IIb, Level A

Monotherapy with PEG, RBV, or a DAA

Rating: Class III, Level A

No HCV protease inhibitors have been approved or are indicated for the treatment of genotype 2 infection. Although PEG/RBV has been the mainstay of treatment of genotype 2, it requires a longer duration of therapy, is less efficacious, and has more adverse effects than the regimen recommended above.

III. Genotype 3

Recommended regimen for HCV genotype 3 PEG/RBV nonresponders.

Daily sofosbuvir (400 mg) and weight-based RBV (1000 mg [<75 kg] to 1200 mg [≥75 kg]) for 24 weeks is recommended for retreatment of HCV genotype 3 infection.

Rating: Class IIa, Level A

The phase 3 FUSION trial compared 12 weeks (n=103) with 16 weeks (n=98) of daily sofosbuvir (400 mg) and weight-based RBV (1000 mg to 1200 mg) in genotype 2 or 3 HCV-infected patients in whom previous PEG/RBV therapy had failed. Of patients, 63% had genotype 3; 34% of all patients had cirrhosis. Because persons who had experienced prior relapses to IFN-based therapy accounted for 75% of patients, the number of patients with a prior nonresponse in the study was limited. The SVR rate for genotype 3 patients in the 12-week arm was 30% (19% among patients with cirrhosis and 37% among those without cirrhosis). Extending therapy to 16 weeks increased the SVR rate among genotype 3 patients to 62% (61% among patients with and 63% in those without cirrhosis).

Based on results from FUSION, the phase 3 multicenter, randomized placebo-controlled VALENCE trial was amended to evaluate the effect of extending sofosbuvir plus RBV therapy to 24 weeks in all patients with HCV genotype 3. As with the FUSION study, most (65%) treatment-experienced patients had relapsed. The SVR12 rates after 24 weeks of therapy for treatment-experienced patients with genotype 3 was 79% (60% among patients with and 87% in those without cirrhosis). The increased efficacy with 24 weeks of sofosbuvir plus RBV therapy across all fibrosis stages combined with a favorable safety and tolerability profile supports the recommendation to use 24 weeks of sofosbuvir plus RBV in all genotype 3 patients despite the minimal number of patients studied to date. The response rate for HCV genotype 3-infected patients with cirrhosis treated for 24 weeks in the VALENCE trial (60%) was similar to that observed after 16 weeks of treatment in the FUSION trial (61%). Although longer treatment duration with a well-tolerated regimen may potentially be more successful in these more difficult-to-treat patients, data remain limited. Either duration of treatment is considered acceptable at this time (see below).

Alternate regimen for HCV genotype 3 PEG/RBV nonresponder patients who are eligible to receive IFN.

Retreatment with daily sofosbuvir (400 mg) and weight-based RBV (1000 mg [<75 kg] to 1200 mg [≥75 kg]) plus weekly PEG for 12 weeks is an alternative for IFN-eligible persons with HCV genotype 3 infection.

Rating: Class IIa Level B

Choice of specific regimen may be influenced by previous or anticipated tolerance to PEG or the presence of advanced fibrosis or cirrhosis. For most patients, the ease of administration and tolerability of sofosbuvir plus RBV will outweigh any potential benefit associated with the addition of PEG. However, for HCV genotype 3-infected patients who have cirrhosis, responses to sofosbuvir and RBV alone for 24 weeks were suboptimal.

In the LONESTAR-2 study, adding 12 weeks of PEG to the sofosbuvir and RBV regimen resulted in numerically higher response rates among persons with HCV genotype 3 than those obtained with sofosbuvir and RBV for 24 weeks. Of HCV genotype 3-infected patients with and without cirrhosis, 10 (83%) of 12 achieved SVR. Given the limited number of patients in this demographic in both the VALENCE and LONESTAR-2 studies, these differences in response rates should be interpreted with caution.

The following regimens are NOT recommended for nonresponder patients with HCV genotype 3 infection.

PEG/RBV with or without telaprevir, boceprevir or simeprevir

Rating: Class IIb, Level A

Monotherapy with PEG, RBV, or a DAA

Rating: Class III, Level A

No HCV protease inhibitors have been approved or are indicated for the treatment of genotype 3 HCV infection. Although PEG/RBV has been the mainstay of treatment of genotype 3 HCV, it is less efficacious and has more adverse effects than the recommended regimens.

IV. Genotypes 4, 5, and 6

***Recommended regimen for HCV genotype 4, PEG/RBV nonresponder patients*.**

Daily sofosbuvir (400 mg) for 12 weeks and daily weight-based RBV (1000 mg [<75 kg] to 1200 mg [≥75 kg]) plus weekly PEG for 12 weeks is recommended for retreatment of IFN-eligible persons with HCV genotype 4 infection

Rating: Class IIa, Level C

***Alternate regimen for HCV genotype 4, PEG/RBV nonresponder patients*.**

Daily sofosbuvir (400 mg) and weight-based RBV (1000 mg [<75 kg] to 1200 mg [≥75 kg]) for 24 weeks is recommended for retreatment of HCV genotype 4 infection.

Rating: Class IIa, Level B

The following regimens are NOT recommended for nonresponder patients with genotype 4

HCV infection.

PEG/RBV with or without telaprevir or boceprevir

Rating: Class IIb, Level A

Monotherapy with PEG, RBV, or a DAA

Rating: Class III, Level A

Recommended regimen for HCV genotype 5 or 6, PEG/RBV nonresponder patients.

Daily sofosbuvir (400 mg) for 12 weeks and daily weight-based RBV (1000 mg [<75 kg] to 1200 mg [≥75 kg]) plus weekly PEG for 12 weeks is recommended for retreatment of IFN-eligible persons with HCV genotype 5 or 6 infection.

Rating: Class IIa, Level C

Alternate regimen for PEG/RBV nonresponder patients with HCV genotype 5 or 6.

None

The following regimens are NOT recommended for nonresponder patients with HCV genotype 5 or 6.

PEG/RBV with or without telaprevir or boceprevir

Rating: Class IIb, Level A

Monotherapy with PEG, RBV, or a DAA

Rating: Class III, Level A

In the NEUTRINO trial, high SVR rates were seen in small numbers of treatment-naive patients with HCV genotypes 4, 5, and 6 treated with sofosbuvir plus PEG/RBV for 12 weeks (genotype 4: n=28, SVR=96%; genotype 5: n=1, SVR=100%; and genotype 6: n=6, SVR=100%). (Lawitz, 2013a) In a pilot study of treatment-experienced HCV genotype 4 patients of Egyptian ancestry, SVR12 was 59% in patients treated with sofosbuvir plus RBV for 12 weeks; SVR4 was 93% in patients treated for 24 weeks. In this cohort, 24% to 27% of patients had cirrhosis. (Ruane, 2013) The only available data with simeprevir for treatment-experienced patients with genotype 4 come from the ongoing RESTORE trial, in which patients (n=50) are receiving treatment with daily simeprevir 150 mg for 12 weeks plus PEG/RBV for a total of 48 weeks (10 prior partial responders, 40 prior null responders). Interim analysis revealed a 40% to 49% RVR rate using this regimen. Final SVR results are pending. (Moreno, 2013) Given the relative paucity of data, expert consultation is needed to determine optimal duration of therapy in patients with genotype 4, 5, or 6 treated with sofosbuvir.

Explanations of highlighted changes made on March 21, 2014 are available here.

Retreatment Box. Summary of Recommendations for Patients in Whom Previous Treatment Has Failed

Retreatment Box. Summary of Recommendations for Patients in Whom Previous Treatment Has Failed[†]

Genotype	Recommended	Alternative	NOT Recommended
Patients in whom previous PEG/RBV has failed*			
1	SOF + SMV ± RBV x 12 weeks	SOF x 12 weeks + PEG/RBV x 12-24 weeks SOF + RBV x 24 weeks SMV x 12 weeks + PEG/RBV x 48 weeks**	PEG/RBV ± telaprevir or boceprevir Monotherapy with PEG, RBV, or a DAA Do not treat decompensated cirrhosis with PEG or SMV
2	SOF + RBV x 12 weeks	SOF + PEG/RBV x 12 weeks	PEG/RBV ± telaprevir or boceprevir Monotherapy with PEG, RBV, or a direct-acting antiviral agent Do not treat decompensated cirrhosis with PEG

*Failure (non response) is defined as partial or null response to treatment with PEG/RBV. Relapse to prior therapy should be treated the same as treatment-naive (see Initial Treatment section)

**For genotype 1a, baseline resistance testing for Q80K should be performed and alternative treatments considered if this mutation is present

*** Failure (non response) is defined as partial or null response to treatment with PEG/RBV plus telaprevir or boceprevir. Relapse to prior therapy should be treated the same as treatment naive (see Initial Treatment section)

† Consideration should be given to postponing treatment, pending release of new drugs for patients with

limited (F 0-2) hepatic fibrosis

†† A recommendation for simeprevir use for patients with previous telaprevir or boceprevir exposure not provided due to potential risk of preexistant resistance to protease inhibitor treatment.

††† Given the lack of prior approval of protease inhibitor therapy for genotypes 2, 3, 4, 5, 6 and the lack of sufficient data, no recommendations are given for these genotypes at this time

‡IFN ineligible

‡‡IFN eligible

MONITORING PATIENTS WHO ARE STARTING HEPATITIS C TREATMENT, ARE ON TREATMENT, OR HAVE COMPLETED THERAPY

Expansions and notes for abbreviations used in this section can be found in Methods Table 3.

A summary of recommendations for monitoring is found in the BOX.

This section provides guidance on monitoring patients with chronic hepatitis C who are starting treatment, are on treatment, or have completed treatment, and is divided into 3 parts: pretreatment and on-treatment monitoring, post-treatment follow-up for persons in whom treatment has failed to clear virus, and post-treatment follow-up for those who achieved a sustained virologic response (SVR; virologic cure).

Recommended assessments prior to starting antiviral therapy

Assessment of potential drug-drug interactions with concomitant medications is recommended prior to starting antiviral therapy.

Rating: Class I, Level C

The following laboratory tests are recommended within 6 weeks prior to starting antiviral therapy:

- **Complete blood cell (CBC) count; international normalized ratio (INR)**
- **Hepatic function panel (albumin, total and direct bilirubin, alanine aminotransferase, aspartate aminotransferase, and alkaline phosphatase levels)**
- **Thyroid-stimulating hormone (TSH; if IFN is used)**
- **Calculated glomerular filtration rate (GFR)**

Rating: Class I, Level B

The following laboratory test is recommended within 12 weeks of starting antiviral therapy:

- **HCV genotype and quantitative HCV viral load**

Rating: Class I, Level B

Recommended monitoring during antiviral therapy

CBC count, creatinine level, calculated GFR, and hepatic function panel are recommended every 4 weeks during antiviral therapy. TSH is recommended every 12 weeks for patients on IFN. More frequent assessment for drug-related toxic effects (eg, CBC count for patients receiving RBV) is recommended as clinically indicated.

Rating: Class I, Level B

Quantitative HCV viral load testing is recommended after 4 weeks of therapy, at the end of treatment, and at 12 weeks following completion of therapy.

Rating: Class I, Level B

Quantitative HCV viral load monitoring at 4 weeks is recommended, but discontinuation of treatment because this test result is missing is NOT recommended.

Rating: Class III, Level C

Recommended monitoring for pregnancy-related issues prior to and during antiviral therapy that includes RBV

Women of childbearing age should be cautioned not to become pregnant while receiving RBV-containing antiviral regimens, and for up to 6 months after stopping.

Rating: Class I, Level C

Serum pregnancy testing is recommended for women of childbearing age prior to beginning treatment with a regimen that includes RBV.

Rating: Class I, Level C

Assessment of contraceptive use and of possible pregnancy is recommended at appropriate intervals during (and for 6 months after) RBV treatment for women of childbearing potential, and for female partners of men who receive RBV treatment.

Rating: Class I, Level C

Treatment with RBV is NOT recommended for pregnant women or for women who are unwilling to adhere to use of adequate contraception, who are either receiving RBV themselves or who are sexual partners of male patients who are receiving RBV.

Rating: Class III, Level C

Female patients and sexual partners of male patients who have received RBV should NOT become pregnant for at least 6 months after stopping RBV.

Rating: Class III, Level C

Pretreatment and On-Treatment Monitoring

The pretreatment testing described here assumes that a decision to treat with antiviral medications has already been made and that the testing involved in deciding to treat, including testing for HCV genotype and assessment of hepatic fibrosis, has already been completed [see **Whom and When to Treat**].

Individuals receiving antiviral therapy for chronic HCV infection should have careful monitoring for toxic effects, virologic response, and adherence to therapy. The assessment of HCV viral load at week 4 of therapy is useful to determine adherence or futility, and the end of treatment viral load will help to differentiate potential viral breakthrough versus relapse. Although HCV-RNA testing is recommended at week 4 of treatment, the absence of testing results at week 4 is not a reason to discontinue treatment. Some may choose to forego end of treatment viral load testing given the high rates of viral response with the newer regimens but to focus on the week 12 post-treatment viral load.

The availability of IFN-free treatment regimens has simplified hepatitis C therapy with shorter-duration, all-

oral therapy for many patients. However, PEG/RBV-based regimens are still recommended for some patients and these require specific monitoring for the toxic effects (eg, anemia or neutropenia) associated with PEG or RBV use. (RBV prescribing information, 2014); (PEG prescribing information, 2014) In patients without history of cardiovascular disease, RBV dose reduction to 600 mg per day is recommended for those with hemoglobin (Hgb) level below 10 g/dL and discontinuation for those with Hgb below 8.5 g/dL. In addition, although the newer all-oral regimens are generally well tolerated, adverse effects do occur. Expansion of therapy into a large population of patients may reveal toxic effects that are not apparent in registration trials. Furthermore, drug-drug interactions are possible. Thus, the pretreatment evaluation should explore potential drug-drug interactions (eg, http://www.hep-druginteractions.org/) for the selected antiviral medications, address potential drug adverse effects, and include laboratory testing. The purpose of on-treatment monitoring is to document viral response, evaluate for possible drug toxic effects, and assess adherence to the regimen.

RBV is reported to cause fetal death and fetal abnormalities in animals and thus it is imperative for persons of childbearing potential who receive the drug to use at least 2 reliable forms of effective contraception during treatment and for a period of 6 months thereafter. The safety of newer antivirals during pregnancy is unknown. The education of patients and caregivers about potential adverse effects and their management is an integral component of treatment and is important for a successful outcome.

Monitoring patients who have completed treatment

Patients who do not achieve an SVR, because of failure of the treatment to clear or maintain clearance of HCV infection with relapse after treatment completion, have ongoing HCV infection and the possibility of continued liver injury. Such patients should be monitored for progressive liver disease and considered for retreatment when alternative treatments are available. Patients who have undetectable HCV RNA in the serum, when assessed by a sensitive polymerase chain reaction (PCR) assay, 12 or more weeks after completing treatment, are deemed to have achieved an SVR. In these patients, hepatitis C-related liver injury stops, although the patients remain at risk for non-HCV related liver disease, such as fatty liver disease or alcoholic liver disease.

Recommended monitoring for patients in whom treatment failed to achieve an SVR

Disease progression assessment every 6 months to 12 months with a hepatic function panel, CBC count, and INR is recommended.

Rating: Class I, Level C

Surveillance for hepatocellular carcinoma with ultrasound testing every 6 months is recommended for patients with more advanced fibrosis (ie, Metavir F3 or F4).

Rating: Class I, Level C

Endoscopic surveillance for esophageal varices is recommended if cirrhosis is present.

Rating: Class I, Level A

Evaluation for retreatment is recommended as effective alternative treatments become available.

Rating: Class I, Level C

Monitoring for HCV drug resistance-associated variants (RAVs) on and after therapy is NOT recommended.

Rating: Class III, Level C

Patients in whom treatment failed to achieve an SVR remain at risk for ongoing liver injury and progression of liver fibrosis. (Dienstag, 2011) Thus, patients in whom treatment fails should be monitored for signs and symptoms of cirrhosis. There is currently no conclusive evidence to suggest that failure of antiviral treatment results in more severe liver injury or more rapidly progressive liver disease than would have occurred if the patient had not received treatment.

A small number of patients in whom an initial antiviral treatment failed have achieved SVR when treated with the same drugs for a longer duration, or when treated with alternative antiviral regimens. (Lawitz, 2014) Thus, patients in whom treatment has failed to achieve an SVR should be considered for treatment when alternative antiviral regimens are available. Advice from a physician experienced in HCV treatment may be beneficial when considering retreatment after antiviral therapy failure.

Patients in whom antiviral therapy failed to achieve an SVR may harbor viruses that are resistant to 1 or more of the antivirals at the time of virologic “breakthrough.” (Lawitz, 2014); (Schneider, 2014) However, there is no evidence to date that the presence of RAVs results in more progressive liver injury than would have occurred if the patient did not have resistant viruses. Furthermore, RAVs are often not detectable with routine (population sequencing) detection methods, nor with more sensitive tests of HCV variants, after patients are followed up for several months. (Schneider, 2014) Subsequent retreatment with combination antivirals, particularly regimens containing antiviral drugs that have a high barrier to resistance, such as nonstructural protein 5B nucleotide polymerase inhibitors (eg, sofosbuvir), may overcome the presence of resistance to 1 or more antivirals. Certain telaprevir- and boceprevir-associated resistant mutations may impact simeprevir activity in vitro. However, there are currently no data on SVR rates when patients are retreated with sofosbuvir plus simeprevir after emergence of telaprevir- or boceprevir-associated resistance mutations. With the exception of testing for Q80K polymorphism at baseline in patients with HCV genotype 1a before treatment with simeprevir plus PEG/RBV, testing for RAVs prior to repeat antiviral treatment is not recommended. If in doubt, consultation with an expert in the treatment of HCV infection may be useful.

Recommended follow-up for patients who achieve an SVR

For patients who do not have advanced fibrosis (ie, those with Metavir F0, F1, or F2), recommended follow-up is the same as if they were never infected with HCV.

Rating: Class I, Level B

Assessment for HCV recurrence or reinfection is recommended only if the patient has ongoing risk for HCV infection or otherwise unexplained hepatic dysfunction develops. In such cases, a quantitative HCV RNA assay rather than an anti-HCV serology test is recommended to test for HCV recurrence or reinfection.

Rating: Class I, Level A

Surveillance for hepatocellular carcinoma with twice yearly ultrasound testing is recommended for patients with advanced fibrosis (ie, Metavir F3 or F4), who achieve an SVR.

Rating: Class I, Level C

A baseline endoscopy is recommended to screen for varices if cirrhosis is present. Patients in whom varices are found should be treated and followed up as indicated.

Rating: Class I, Level C

Assessment of other causes of liver disease is recommended for patients who develop persistently abnormal liver tests after achieving an SVR.

Rating: Class I, Level C

Routine assessment for regression in liver fibrosis after achieving SVR is NOT recommended.

Rating: Class III, Level C

With the advent of highly effective HCV antiviral regimens, the likelihood of achieving an SVR among adherent, immunologically competent, treatment-naive patients with compensated liver disease generally

exceeds 90%. Of patients who achieved an SVR with PEG/RBV treatment, more than 99% have remained free of HCV infection when followed up for 5 years after completing treatment. (Manns, 2013) Thus, achieving an SVR is considered a virologic cure of HCV infection.

SVR typically aborts progression of liver injury with regression of liver fibrosis in most but not all treated patients. (Morisco, 2013); (Morgan, 2010); (George, 2009); (Morgan, 2013); (Singal, 2010) Because of lack of progression, patients without advanced liver fibrosis (ie, Metavir F0, F1, or F2) who achieve an SVR should receive standard medical care that is recommended for patients who were never infected with HCV.

Among patients with advanced liver fibrosis (ie, Metavir F3 or F4) who achieve an SVR, decompensated liver disease (with the exception of hepatocellular carcinoma) rarely develops during follow-up, and overall survival is prolonged. (Morisco, 2013); (Morgan, 2010); (George, 2009); (Morgan, 2013); (Singal, 2010) Patients who have advanced fibrosis or cirrhosis continue to be at risk for development of hepatocellular carcinoma after achieving an SVR, although the risk in these patients is lower than the risk in persistently viremic patients. (Morisco, 2013); (Morgan, 2010); (George, 2009); (Morgan, 2013); (Singal, 2010) Patients with cirrhosis who achieve SVR experience increased survival (compared with patients with cirrhosis who are untreated or fail to respond), but still may be at some risk of hepatocellular carcinoma; thus, they should continue to undergo regular surveillance for hepatocellular carcinoma despite the lowered risk that results after viral eradication. (Bruix, 2011) The risk of hepatocellular carcinoma among patients with advanced fibrosis prior to treatment but who have regression to minimal fibrosis after treatment is not known. In the absence of data to the contrary, such patients remain at some risk for hepatocellular carcinoma and should be monitored at least annually for hepatocellular carcinoma.

Liver fibrosis and liver function test results improve in most patients who achieve an SVR. (Morisco, 2013); (Morgan, 2010); (George, 2009); (Morgan, 2013); (Singal, 2010) Bleeding from esophageal varices is rare after an SVR. (Morisco, 2013); (Morgan, 2010); (George, 2009); (Morgan, 2013); (Singal, 2010) Patients with cirrhosis should receive routine surveillance endoscopy for detection of esophageal varices if not previously done and these should be treated or followed up as indicated. (Garcia-Tsao, 2007)

There is no evidence that monitoring for liver fibrosis regression after an SVR provides clinical benefit.

Patients in whom an SVR is achieved but who have another potential cause of liver disease (eg, excessive alcohol use, metabolic syndrome with or without proven fatty liver disease, or iron overload) remain at risk for progression of fibrosis. It is recommended that such patients be educated about the risk of liver disease and monitored for liver disease progression with periodic physical examinations, blood tests, and potentially, tests of liver fibrosis by a liver disease specialist.

Testing patients with ongoing risk for HCV infection (eg, illicit drug use, high-risk sexual exposure) periodically for HCV reinfection is recommended. Flares in liver enzyme test results should prompt evaluation of possible de novo re-infection with HCV through a new exposure (see **Management of Acute HCV Infection**). Antibody to HCV (anti-HCV) remains positive in most patients following an SVR. Thus, it is recommended that testing for reinfection with HCV be performed with an assay that detects HCV RNA (eg, a quantitative HCV RNA test).

Monitoring for HCV during chemotherapy and immunosuppression

Prospective monitoring for HCV recurrence among patients who achieved an SVR and who are receiving immunosuppressive treatment (eg, systemic

corticosteroids, antimetabolites, chemotherapy, etc.) is NOT routinely recommended.

Rating: Class III, Level C

In patients with inactive or past hepatitis B virus (HBV) infection, reactivation of infection and clinically apparent hepatitis during immunosuppressive treatment or chemotherapy can occur. Although some patients with active HCV infection, primarily those with hematologic malignancy, may have a flare in their liver enzymes during chemotherapy, this is unusual. (Mahale, 2012) Reactivation of past HCV infection, such as after SVR or spontaneous clearance, is not anticipated since there is no residual reservoir for the virus. Thus, routine testing of HCV RNA during immunosuppressive treatment, or prophylactic administration of antivirals during immunosuppressive treatment, is not routinely recommended. However, acute liver injury is common among patients receiving chemotherapy or potent immunosuppressive agents; quantitative HCV RNA testing should be included in the laboratory assessment of the cause of liver injury.

Monitoring Box. Summary of the Recommendations for Monitoring Patients Who Are Starting HCV Treatment, Are On Treatment, Or Have Completed Therapy

Recommended assessments prior to starting antiviral therapy

Assessment of potential drug-drug interactions with concomitant medications is recommended prior to starting antiviral therapy.

Rating: Class I, Level C

The following laboratory tests are recommended within 6 weeks prior to starting antiviral therapy:

- **Complete blood cell (CBC) count; international normalized ratio (INR)**
- **Hepatic function panel (albumin, total and direct bilirubin, alanine aminotransferase, aspartate aminotransferase, and alkaline phosphatase levels)**
- **Thyroid-stimulating hormone (TSH; if IFN is used)**
- **Calculated glomerular filtration rate (GFR)**

Rating: Class I, Level B

The following laboratory tests are recommended within 12 weeks prior to starting antiviral therapy:

HCV genotype and quantitative HCV viral load

Rating: Class I, Level B

Recommended monitoring during antiviral therapy

CBC count, creatinine level, calculated GFR, and hepatic function panel are recommended every 4 weeks during antiviral therapy. TSH is recommended every 12 weeks for patients on IFN. More frequent assessment for drug-related toxic effects (eg, CBC count for patients receiving RBV) is recommended, as clinically indicated.

Rating: Class I, Level B

Quantitative HCV viral load testing is recommended after 4 weeks of therapy, at the end of treatment, and at 12 weeks following completion of therapy.

Rating: Class I, Level B

Quantitative HCV viral load monitoring at 4 weeks is recommended, but discontinuation of treatment because this test result is missing is NOT recommended.

Rating: Class III, Level C

Recommended monitoring for pregnancy-related issues prior to and during antiviral therapy that includes RBV.

Women of child bearing age should be cautioned not to become pregnant while receiving RBV-containing antiviral regimens, and for up to 6 months after stopping.

Rating: Class I, Level C

Serum pregnancy testing is recommended for women of child bearing age prior to beginning treatment with a regimen that includes RBV.

Rating: Class I, Level C

Assessment of contraceptive use and of possible pregnancy is recommended at appropriate intervals during (and for 6 months after), RBV treatment for women of child bearing potential, and for female partners of men who receive RBV treatment.

Rating: Class I, Level C

Treatment with RBV is NOT recommended for pregnant women or for women who are unwilling to adhere to use of adequate contraception, who are either receiving RBV themselves or who are sexual partners of male patients who are receiving RBV.

Rating: Class III, Level C

Female patients and sexual partners of male patients who have received RBV should NOT become pregnant for at least 6 months after stopping RBV.

Rating: Class III, Level C

Recommended monitoring for patients in whom treatment failed to achieve an SVR

Disease progression assessment every 6 months to 12 months with a hepatic function panel, CBC count, and INR is recommended.

Rating: Class I, Level C

Surveillance for hepatocellular carcinoma with ultrasound testing every 6 months is recommended for patients with more advanced fibrosis (ie, Metavir F3 or F4).

Rating: Class I, Level C

Endoscopic surveillance for esophageal varices is recommended if cirrhosis is present.

Rating: Class I, Level A

Evaluation for retreatment is recommended as effective alternative treatments become available.

Rating: Class I, Level C

Monitoring for HCV drug resistance-associated variants (RAVs) on and after therapy is NOT recommended.

Rating: Class III, Level C

Recommended follow-up for patients who achieve an SVR

For patients who do not have advanced fibrosis (ie, those with Metavir F0, F1, or F2), recommended follow-up is the same as if they were never infected with HCV.

Rating: Class I, Level B

Assessment for HCV recurrence or reinfection is recommended only if the patient has ongoing risk for HCV infection or otherwise unexplained hepatic dysfunction develops. In such cases, a quantitative HCV RNA assay rather than an anti-HCV serology test is recommended to test for HCV recurrence or reinfection.

Rating: Class I, Level A

Surveillance for hepatocellular carcinoma with twice yearly ultrasound testing is recommended for patients with advanced fibrosis (ie, Metavir F3 or F4), who achieve an SVR.

Rating: Class I, Level C

A baseline endoscopy is recommended to screen for varices if cirrhosis is present. Patients in whom varices are found should be treated and followed up as indicated.

Rating: Class I, Level C

Assessment of other causes of liver disease is recommended for patients who develop persistently abnormal liver tests after achieving an SVR.

Rating: Class I, Level C

Routine assessment for regression in liver fibrosis after achieving SVR is NOT recommended.

Rating: Class III, Level C

Monitoring for HCV during chemotherapy and immunosuppression

Prospective monitoring for HCV recurrence among patients who achieved an SVR and who are receiving immunosuppressive treatment (eg, systemic corticosteroids, antimetabolites, chemotherapy, etc.) is NOT routinely recommended.

Rating: Class III, Level C

UNIQUE PATIENT POPULATIONS

Expansions and notes for abbreviations used in this section can be found in Methods Table 3.

1. Patients with HIV/HCV Coinfection

The summary of recommendations for HIV-coinfected patients is in the BOX.

Recommended regimen(s) for treatment-naive and prior relapser HIV/HCV-coinfected patients with genotype 1 infection who are eligible to receive IFN:

Sofosbuvir (400 mg once daily) and weight-based RBV (1000 mg [<75 kg] to 1200 mg [≥75 kg] daily) plus weekly PEG for 12 weeks is recommended for IFN-eligible persons with HCV genotype 1 infection, regardless of subtype.

Rating: Class I, Level B

Recommended regimen(s) for treatment-naive and prior relapser HIV/HCV-coinfected patients with genotype 1 who are ineligible or unwilling to receive IFN.

Sofosbuvir (400 mg once daily) and weight-based RBV (1000 mg [<75 kg] to 1200 mg [≥75 kg] daily) for 24 weeks is recommended for treatment-naive HIV/HCV-coinfected patients with HCV genotype 1 infection.

Rating: Class I, Level B

Sofosbuvir (400 mg once daily) plus simeprevir (150 mg once daily), with or without weight-based RBV (1000 mg [<75 kg] to 1200 mg [≥75 kg] daily) for 12 weeks is recommended for treatment-naive and prior PEG/RBV relapser HIV/HCV-coinfected patients with genotype 1 infection. Simeprevir should only be used with antiretroviral drugs with which it does not have significant interactions: raltegravir, rilpivirine, maraviroc, enfuvirtide, tenofovir, emtricitabine, lamivudine, and abacavir.

Rating: Class IIa Level C

Recommended regimen(s) for treatment-experienced patients with HCV genotype 1 with a history of PEG/RBV nonresponse, regardless of IFN eligibility

Sofosbuvir (400 mg once daily) plus simeprevir (150 mg once daily) with or without weight-based RBV (1000 mg [<75 kg] to 1200 mg [≥75 kg] daily) for 12 weeks is recommended for prior PEG/RBV nonresponder, HIV/HCV-coinfected patients with genotype 1 infection. Simeprevir should only be used with antiretroviral drugs with which it does not have significant interactions: raltegravir, rilpivirine, maraviroc, enfuvirtide, tenofovir, emtricitabine, lamivudine, and abacavir.

Rating: Class IIa, Level C

Recommended regimen(s) for treatment-experienced patients with HCV genotype 1 with a history of PEG/RBV plus telaprevir or boceprevir nonresponse

Treat as recommended for HCV-monoinfected individuals.

Recommended regimen(s) for treatment-naive and treatment-experienced HIV/HCV-coinfected patients with genotype 2 and 3 infection

Use the same regimens as is recommended for persons with HCV monoinfection; specifically:

For patients with genotype 2 infection: sofosbuvir (400 mg once daily) and weight-based RBV (1000 mg [<75 kg] to 1200 mg [≥75 kg] daily) for 12 weeks is recommended for treatment-naive and treatment-experienced HIV/HCV-coinfected patients. Patients who are prior nonresponders and have cirrhosis may benefit by extension of treatment to 16 weeks.

Rating: Class I, Level B

For patients with genotype 3 infection: sofosbuvir (400 mg once daily) and weight-based RBV (1000 mg [<75 kg] to 1200 mg [≥75 kg] daily) for 24 weeks is recommended for treatment-naive and treatment-experienced HIV/HCV-coinfected patients.

Rating: Class I, Level B

Recommended regimen(s) for treatment-naive and treatment-experienced HIV/HCV-coinfected patients with genotype 4, 5, or 6 HCV:

Treat as recommended for persons with HCV monoinfection.

HIV/HCV coinfection results in increased liver-related morbidity and mortality, non-hepatic organ dysfunction, and overall mortality. Even in the potent antiretroviral era, HIV infection remains independently associated with advanced liver fibrosis and cirrhosis in patients with HCV coinfection. (Thein, 2008); (de Ledinghen, 2008); (Fierer, 2013) Similar to HCV-monoinfected patients, HIV/HCV-coinfected patients cured with PEG/RBV have lower rates of hepatic decompensation, hepatocellular carcinoma, and liver related mortality. (Berenguer, 2009); (Limketkai, 2012); (Mira, 2013) Uptake of HCV therapy is limited in the HIV/HCV-coinfected population due to historically lower response rates, patient comorbidities, patient and practitioner perception, and the adverse events associated with IFN-based therapy. (Mehta, 2006); (Thomas, 2008) Due to the special population designation, the first 2 approved DAAs, telaprevir and boceprevir, remain off label for use in HIV/HCV-coinfected patients, further limiting access to treatment in this population. With the availability of the DAAs sofosbuvir and simeprevir, a milestone has been reached in HIV/HCV coinfected patients. Treatment of HIV/HCV-coinfected patients requires awareness and attention to the complex drug interactions that can occur between DAA and HIV antiretroviral medications.

Pharmacokinetics and Drug Interactions

Sofosbuvir is not metabolized by the hepatic P450 enzyme complex and is a substrate (but not an inhibitor) of drug transporters, p-glycoprotein (P-gp), and breast cancer resistance protein (BCRP). It is not a substrate of OATP. Drug interaction studies with antiretroviral drugs (ie, efavirenz, tenofovir, emtricitabine, rilpivirine, darunavir/ritonavir, and raltegravir) in non-infected persons identified no clinically significant interactions (Kirby, 2013) making sofosbuvir an ideal therapy for patients with HIV/HCV coinfection. Sofosbuvir is not recommended for use with tipranavir because of the potential of this antiretroviral drug to induce P-gp (see package insert).

Simeprevir is metabolized primarily by cytochrome P450 3A4 (CYP3A4) and therefore is susceptible to drug interactions with inhibitors and inducers of the enzyme. Simeprevir is also an inhibitor of the OATP and P-gp transporters leading to additional drug interaction concerns. Drug interaction studies with antiretroviral drugs in non-infected volunteers suggested no substantial interactions with tenofovir, rilpivirine, or raltegravir; however, simeprevir concentrations were substantially decreased when dosed with efavirenz and substantially increased when dosed with darunavir/ritonavir, resulting in their exclusion from the Phase III C212 clinical trial investigating simeprevir in combination with PEG/RBV in patients with HIV/HCV coinfection. (Ouwerkerk-Mahadevan, 2012)

Ribavirin has the potential for dangerous drug interactions with didanosine resulting in mitochondrial toxicity with hepatomegaly/steatosis, pancreatitis, and lactic acidosis; thus the concomitant administration of these 2 drugs is contraindicated. (Fleischer, 2004) The combined use of RBV and zidovudine has been reported to increase the rates of anemia and the need for RBV dose reduction, and thus zidovudine is not recommended for use with RBV. (Alvarez, 2006)

Sofosbuvir (400 mg once daily) as part of a triple-therapy regimen with PEG (180 ?g weekly) and weight-based RBV (1000 mg to 1200 mg daily given in divided doses) is safe and efficacious in patients with HCV monoinfection, with an overall SVR12 of 89% in HCV genotype 1 patients. The P7977-1910 study was a single-center, single-arm trial (N=23) investigating this same 12-week triple therapy regimen in HIV-infected patients coinfected with HCV genotypes 1, 2 3, or 4. (Rodriguez-Torres, 2013) Allowable

antiretrovirals included either efavirenz, atazanavir/ritonavir, darunavir/ritonavir, raltegravir, or rilpivirine in combination with tenofovir/emtricitabine. Of patients with HCV genotype 1 (N=19), 89% achieved SVR12; 2 patients discontinued the study early due to adverse events (ie, anemia and altered mood). This regimen is therefore recommended for persons with HIV/HCV genotype 1 coinfection who are eligible to receive IFN and are either treatment-naive or have had prior PEG/RBV relapse.

The Phase III PHOTON-1 study enrolled 182 treatment-naive patients with HIV/HCV coinfection (n=114 with genotype 1; n=26 with genotype 2; n=42 with genotype 3) in a single-arm clinical trial investigating sofosbuvir (400 mg once daily) plus weight-based RBV (1000 mg to 1200 mg daily given in divided doses) for 24 (genotype 1) or 12 (genotypes 2 and 3) weeks. (Sulkowski, 2013c) The population had well-controlled HIV with mean CD4 counts of 559 to 636 cells/?L. The same ARVs were allowed as those in the P7977-1910 study. Of participants, 90% completed treatment and 3% discontinued treatment due to adverse events. SVR12 was achieved in 76%, 88%, and 67% of participants with HCV genotypes 1, 2, and 3, respectively. For the combination of sofosbuvir plus RBV, genotype 1b subtype was a predictor of poorer response. Cirrhosis and African American race also exhibited trends toward lower SVR12. Based on the potential for lower response in HIV/HCV-coinfected patients with cirrhosis, the use of sofosbuvir plus PEG/RBV should be considered over sofosbuvir plus RBV. This regimen is otherwise recommended for HIV/HCV genotype 1-coinfected patients who are treatment naive or have relapsed after receipt of PEG/RBV and are ineligible for IFN.

The combination of simeprevir plus sofosbuvir with or without RBV has been studied in the phase II COSMOS trial in patients with HCV monoinfection. (Jacobson, 2013b) This study is the basis for the recommendation supporting the use of this all-oral combination as an alternative regimen for patients with HCV monoinfection who cannot tolerate the recommended regimens. Although sofosbuvir plus simeprevir has been used anecdotally in patients with HIV/HCV coinfection, this drug combination has never been studied in this population. Despite the absence of data, this regimen may be considered for the treatment of HCV genotype 1 infection in patients with HIV infection who are not eligible for IFN and who are receiving antiretroviral therapy that may be coadministered with simeprevir (ie, raltegravir, rilpivirine, maraviroc, enfuvirtide, tenofovir, emtricitabine, lamivudine, and abacavir).

Similarly, no data exist for the combination of sofosbuvir plus simeprevir for the (re)treatment of HCV infection in HIV-infected patients. However, preliminary results obtained in HCV-monoinfected patients, including those with prior treatment failure and advanced fibrosis, support the expectation that this regimen will be highly effective in coinfected patients receiving compatible antiretroviral therapy as described above (see Retreatment of HCV Monoinfected Patients). (Jacobson, 2013b) Given the lack of clinical data in this population, it may be prudent to reserve this regimen for the treatment of persons with advanced fibrosis in whom a delay of therapy may lead to adverse clinical outcomes.

No data with sofosbuvir currently exist to guide retreatment recommendations for coinfected patients with HCV genotype 2 or 3 HCV infection. The ongoing PHOTON-1 study enrolled 41 treatment-experienced patients coinfected with HCV genotype 2 or 3, receiving sofosbuvir (400 mg once daily) plus weight-based RBV (1000 mg to 1200 mg daily given in divided doses) for 24 weeks. (Sulkowski, 2013b) Results are expected in early 2014. In the absence of data, current recommendations for the retreatment of HIV patients coinfected with HCV genotype 2 or 3 are the same as those for HCV-monoinfected patients. Data also are lacking regarding use of sofosbuvir among patients coinfected with HCV genotype 4, 5, or 6 and HIV. Similarly, with no current data on the use of sofosbuvir in patients with genotype 4, 5, or 6 HCV and HIV coinfection, but given evidence of safety and efficacy of sofosbuvir-based regimens in this population, the recommended regimens for treatment in treatment-naive and treatment-experienced patients with HIV/HCV coinfection are the same as those for HCV-monoinfected patients.

Alternative regimen(s) for treatment-naive or treatment-experienced (prior PEG/RBV relapse) HIV/HCV- coinfected patients with genotype 1 who are eligible to receive IFN

Simeprevir (150 mg once daily) for 12 weeks and weight-based RBV (1000 mg [<75 kg] to 1200 mg [≥75 kg] daily) plus weekly PEG for 24 weeks (for treatment-naive and treatment-experienced with prior relapse to PEG/RBV) is an acceptable regimen for IFN-eligible HIV/HCV-coinfected persons with either (1) HCV genotype 1b or (2) HCV genotype 1a infection in whom the Q80K polymorphism is not detected prior to treatment. Simeprevir can only be used with the following antiretroviral drugs: raltegravir, rilpivirine, maraviroc, enfuvirtide tenofovir, emtricitabine, lamivudine, and abacavir.

Rating: Class IIa, Level B

Alternative regimen(s) for treatment-experienced (PEG/RBV nonresponders) HIV/HCV-coinfected patients with genotype 1 who are eligible for IFN

Sofosbuvir (400 mg once daily) and weight-based RBV (1000 mg [<75 kg] to 1200 mg [≥75 kg] daily) plus weekly PEG for 12 weeks is an acceptable regimen for IFN-eligible persons with HCV genotype 1 infection, regardless of subtype.

Rating: Class IIb, Level C

Alternative regimen(s) for treatment-naive and PEG/RBV relapser HIV/HCV-coinfected patients with genotype 1 who are ineligible or unwilling to receive IFN.

None

Alternative regimen(s) for treatment-experienced (PEG/RBV nonresponder) HIV/HCV-coinfected patients with genotype 1 who are ineligible to receive IFN.

Sofosbuvir (400 mg once daily) and weight-based RBV (1000 mg [<75 kg] to 1200 mg [≥75 kg] daily) for 24 weeks is an acceptable regimen for treatment-experienced (nonresponder) HIV/HCV-coinfected patients with HCV genotype 1 infection.

Rating: Class IIb, Level C

Alternative regimen(s) for treatment-naive and PEG/RBV relapser, HIV/HCV-coinfected patients with genotype 2 or 3 infection.

None

Alternative regimen(s) for treatment-experienced (PEG/RBV nonresponder) HIV/HCV-coinfected patients with genotype 2 or 3 infection who are eligible to receive IFN.

Sofosbuvir (400 mg once daily) and weight-based RBV (1000 mg [<75 kg] to 1200 mg [≥75 kg] daily) plus weekly PEG for 12 weeks is an acceptable regimen for treatment-experienced IFN-eligible persons with HCV genotype 2 or 3 infection.

Rating: Class IIa, Level C

Alternative regimen(s) for treatment-naive and treatment-experienced HIV/HCV-coinfected patients with HCV genotype 4, 5, or 6 infection.

None

The TMC435-C212 is a Phase III, open-label, single-arm study investigating simeprevir plus PEG/RBV (fixed-dose ribavirin) in treatment-naive and treatment-experienced patients coinfected with HCV genotype-1 and HIV. (Dieterich, 2013) The study used an RGT design for treatment-naive and prior PEG/RBV relapsers; prior partial and null responders and all patients with cirrhosis (regardless of treatment history) received 48 weeks of therapy (SMV x 12 weeks plus PEG/RBV x 48 weeks). The primary analysis reported an overall SVR12 of 74% (treatment naive: 79%; prior relapsers, 87%: prior partial responders: 70%; prior null responders: 57%). Most (89%) eligible patients met criteria for RGT and were able to shorten therapy to 24 weeks, after which time 78% achieved SVR12. Lower SVR12 was reported in several clinically relevant subgroups: genotype 1a (71% vs 89% in genotype 1b); genotype 1a with the Q80K mutation at baseline (67%); advanced fibrosis or cirrhosis (64%); IL28B unfavorable genetic polymorphisms (68% and 61% for the CT and TT variants vs 96% for the favorable CC variant); high baseline HCV RNA (70% for >800,000 IU/mL or 93% for <800,000 IU/mL); and patients not receiving antiretroviral therapy (62% vs 75% in subjects on antiretroviral drugs). As with patients with HCV monoinfection, baseline resistance testing for the Q80K polymorphism should be performed in all patients harboring the genotype 1a subtype and a different regimen considered if the polymorphism is present. Virologic failures occurred; most failures (79%) were associated with the emergence of resistant-associated mutations.

The adverse event profile was similar to that of patients with HCV monoinfection, with a higher frequency of pruritus, rash, photosensitivity, and increased bilirubin than is observed in patients receiving PEG/RBV alone. Due to the complexity of antiretroviral drug-associated drug interactions with simeprevir, the longer course of PEG/RBV, the adverse effect profile, and the risk of resistance emergence with treatment failure,

simeprevir plus PEG/RBV is considered an alternative regimen for treatment-naive and prior PEG/RBV relapse patients with HIV coinfection with genotype HCV who cannot tolerate the recommended regimens. This regimen is not recommended in prior nonresponders or patients with cirrhosis because of observed lower response rates seen and the poor tolerability of 48 weeks of PEG/RBV. Due to diminished activity in vitro (for genotype 2 and 3) and insufficient data (for genotype 4) this regimen cannot be recommended for these genotypes.

Sofosbuvir plus PEG/RBV has not been studied in patients with HIV/HCV genotype 1 coinfection in whom previous IFN-based HCV therapy has failed. However, in a study of a limited number of patients (n=19), the efficacy of this regimen in treatment-naive subjects with HIV/HCV genotype 1 coinfection was equivalent to that in patients with HCV monoinfection. (Rodriguez-Torres, 2013) An exploratory FDA analysis estimated the SVR rate of this regimen to be 78% among a treatment-experienced population with HCV monoinfection, including 71% in those with multiple poor pretreatment response predictors. (US FDA, 2013b) These data, along with the absence of antiretroviral drug limitations, support inclusion of this regimen as a recommended option for treatment-experienced patients with HIV/HCV coinfection.

Sofosbuvir plus RBV has not been studied in prior HCV treatment-experienced patients with HIV/HCV genotype 1 coinfection. This regimen yielded an SVR12 rate of 76% among treatment-naive HIV/HCV genotype 1-coinfected patients. (Sulkowski, 2013b) However, responses to this regimen are expected to be lower in treatment-experienced coinfected subjects based on limited data in treatment-experienced HCV-monoinfected patients treated for 12 weeks with sofosbuvir (400 mg once daily) plus weight-based RBV (1000 mg to 1200 mg daily in divided doses). (Gane, 2013a) Further, response rates are expected to be lower than those associated with the recommended and alternative regimens. This regimen should be reserved for coinfected patients who cannot tolerate IFN and do not have antiretroviral regimen options compatible with simeprevir. These patients require expert consultation with careful consideration of fibrosis stage; in some cases, deferral of therapy may be a more appropriate action.

Sofosbuvir plus PEG/RBV has not been studied in patients with HIV/HCV genotype 2 or 3 coinfection in whom previous IFN-based HCV therapy has failed. However, recognizing the potential limitations of sofosbuvir plus RBV in more difficult to treat genotype 2 and 3 patients, particularly those with prior nonresponse and cirrhosis, the addition of IFN to the regimen can be considered for those patients who are eligible. The LONESTAR-2 (open-label, single-site, single-arm phase 2 trial) evaluated PEG (180 & #956;g weekly), sofosbuvir (400 mg once daily), and weight-based RBV (1000 mg to 1200 mg daily in divided doses) for 12 weeks in HCV-monoinfected treatment-experienced patients with genotype 2 or 3 infection. Cirrhosis was present at baseline in 55% of patients. Overall, SVR12 was achieved in 96% (22 of 23) of those with genotype 2 infection. SVR occurred in 93% (13/14) and 100% (9 of 9) of patients with and without cirrhosis, respectively. Because sofosbuvir is safe and effective when used to treat HIV/HCV-coinfected patients, the combination of sofosbuvir plus PEG/RBV for 12 weeks can be considered for appropriate genotype 2 and 3 HIV/HCV-coinfected patients.

The following regimens are NOT recommended for treatment-naive or treatment-experienced HIV/HCV-coinfected patients

PEG/RBV with or without telaprevir or boceprevir for 24 to 48 weeks

Rating: Class IIb, Level A

Monotherapy with PEG, RBV, or a DAA

Rating: Class III, Level A

Due to its prolonged treatment course, adverse effects, and poor response rates, PEG/RBV is no longer recommended for the treatment of patients with HCV genotypes 1, 2, 3, or 4 who are coinfected with HIV. Neither telaprevir nor boceprevir is approved for use in patients with HIV/HCV coinfection. However, when combined with PEG/RBV and used for 48 weeks, these drugs have reported efficacy and safety in patients with HIV/HCV genotype 1 coinfection similar to that in patients with HCV genotype 1 monoinfection. (Sulkowski, 2013d); (Sulkowski, 2013a) Ongoing Phase III trials will investigate the use of RGT for select patient groups. Telaprevir and boceprevir are each substrates and inhibitors of CYP3A4 and thus have substantial drug interactions with antiretroviral drugs. (van Heeswijk, 2011a); (van Heeswijk, 2011b); (Kakuda, 2012); (Johnson, 2013); (Kasserra, 2011); (Hulskotte, 2013); (Garraffo, 2013); (de Kanter, 2012); (Hammond, 2013); (Vourvahis, 2013) Due to the adverse effect profile, prolonged required course of PEG/RBV, and substantial drug interactions, these agents are no longer recommended for HIV/HCV-coinfected patients.

Because of their limited activity in vitro and in vivo against HCV genotypes 2 and 3, boceprevir, telaprevir, and simeprevir should not be used as therapy for HIV/HCV-coinfected patients with HCV genotype 2 or 3 infection. Boceprevir and telaprevir also have limited activity against HCV genotype 4 and should not be used as therapy for HIV/HCV coinfected patients with HCV genotype 4 infection. There are currently not enough data to support a recommendation for the use of simeprevir for genotype 4 infection in HIV/HCV-coinfected patients.

2. Patients with Cirrhosis

The summary of recommendations for patients with cirrhosis is in the BOX.

Compensated Cirrhosis

Treatment-naive patients with compensated cirrhosis, including those with hepatocellular carcinoma, should receive the same treatment as recommended for patients without cirrhosis.

Rating: Class I, Level A

This statement is supported by a number of studies (described above) that included patients with compensated cirrhosis who were evaluated in sub-group analyses.

Decompensated Cirrhosis

Patients with decompensated cirrhosis (moderate or severe hepatic impairment; CTP class B or C) ***should be referred to a medical practitioner with expertise in that condition (ideally***

in a liver transplant center).

Rating: Class I, Level C

If the decision to treat has been made, the recommended regimen for patients with any HCV genotype who have decompensated cirrhosis (moderate or severe hepatic impairment; CTP class B or C***) who may or may not be candidates for liver transplantation, including those with hepatocellular carcinoma. This regimen should be used only by highly experienced HCV providers***

Daily sofosbuvir (400 mg) plus weight-based RBV (with consideration of the patient's creatinine clearance and hemoglobin level) for up to 48 weeks

Rating: Class IIb, Level B

In one study, 61 patients with HCV infection and hepatocellular carcinoma meeting MILAN criteria for liver transplant were treated with sofosbuvir plus RBV for up to 48 weeks. (Curry MP, 2013) At the time of treatment initiation, the median MELD score was 8 (range: 6-14), and 17 patients had CTP scores of 7 or 8 (CTP Class B). To date, 44 patients have undergone liver transplantation, of whom 41 (93%) had HCV RNA below the lower limit of quantification. At 12 weeks post-transplant, 23 of 37 (62%) had no detected HCV RNA consistent with prevention of recurrent HCV infection. In the post-transplant period, 10 patients experienced recurrent HCV infection. Among the 10 patients who experienced recurrent graft infection, 9 had HCV RNA not detected for less than 30 days pretransplant. The most common adverse effects were fatigue, anemia, and headache; adverse effects led to treatment discontinuation for 2 patients (3%).

In a sofosbuvir compassionate-use program for patients with severe recurrent HCV infection following liver transplantation who were predicted to have a less than 6-month survival, (Forns, 2013b) 44 patients were treated with sofosbuvir plus RBV 32 patients were also given PEG. At treatment initiation, the median MELD score was 16 (range: 6-43), and fibrosing cholestatic hepatitis was documented in 20 patients. After week 12 of treatment, 91% of patients treated with sofosbuvir plus RBV and 75% of those treated with the addition of PEG achieved HCV RNA less than the lower limit of quantification. Of 27 patients evaluated at 12 weeks post-treatment, 15 patients (56%) achieved SVR. Overall, 75% had improved or stable clinical liver disease including improvement in hyperbilirubinemia and coagulopathy as well as decrease in MELD score. In this very sick population, 8 patients died, most from liver disease progression.

The following regimens are NOT recommended for patients with decompensated cirrhosis (moderate or severe hepatic impairment; CTP class B or C***)***:

Any IFN-based therapy

Rating: Class III, Level A

Monotherapy with PEG, RBV, or a DAA

Rating: Class III, Level A

Telaprevir-, boceprevir-, or simeprevir-based regimens

Rating: Class III, Level A

IFN should not be given to patients with decompensated cirrhosis (moderate or severe hepatic impairment; CTP class B or C) because of the potential for worsening hepatic decompensation. Neither telaprevir nor boceprevir should be used for this population because they must be coadministered with PEG/RBV. Very minimal data exist for the use of simeprevir in patients with decompensated cirrhosis. Until additional data become available, simeprevir should not be used in patients with decompensated cirrhosis.

3. Patients Who Develop Recurrent HCV Infection Post-Liver Transplantation

The summary of recommendations for patients who develop recurrent HCV infection post-liver transplantation is in the BOX.

Recommended regimen for treatment-naive patients with HCV genotype 1 in the allograft liver, including those with compensated cirrhosis

Daily sofosbuvir (400 mg) plus simeprevir (150 mg), with or without RBV (initial dose 600 mg/day, increased monthly by 200 mg/day as tolerated to weight-based dose of 1000 mg [<75 kg] to 1200 mg [≥75 kg] 1200 mg), for 12 weeks to 24 weeks is recommended for patients with compensated allograft HCV genotype 1 infection.

Rating: Class IIb, Level C

Recommended regimen for treatment-naive patients with HCV genotype 2 or 3 in the allograft liver, including those with compensated cirrhosis

Daily sofosbuvir (400 mg) and RBV (initial dose 600 mg/day, increased monthly by 200 mg/day as tolerated to weight-based dose of 1000 mg [<75 kg] to 1200 mg [≥75 kg] 1200 mg) with consideration of the patient's CrCl value and hemoglobin level for 24 weeks is recommended for patients with compensated allograft HCV genotype 2 or 3 infection.

Rating: Class IIb, Level C

Alternate regimen for treatment-naive patients with genotype 1 HCV in the allograft liver, including those with compensated cirrhosis.

Daily sofosbuvir (400 mg) and RBV (initial dose 600 mg/day, increased monthly by 200 mg/day as tolerated to weight-based dose of 1000 mg [<75 kg] to 1200 mg [≥75 kg] 1200 mg) with consideration of the patient's CrCl value and hemoglobin level, with or without PEG (in the absence of contraindication to its use), for 24 weeks is recommended for patients with compensated allograft HCV genotype 1 infection.

Rating: Class IIb, Level C

Simeprevir has not been studied with sofosbuvir in the posttransplant setting. The coadministration of single-dose cyclosporine with simeprevir resulted in a 19% increase in cyclosporine concentrations and no change in simeprevir concentrations (see simeprevir package insert). However, in an interim analysis of an ongoing study (TMC435HPC3016), concomitant use of simeprevir (plus daclastavir and RBV) with cyclosporine at steady state resulted in an approximately 6-fold increase in plasma concentrations of simeprevir compared with historical data of simeprevir in the absence of cyclosporine (personal communication). This interaction may be due to inhibition of OATP1B1, P-gp and CYP3A by cyclosporine. Although the current FDA labeling does not recommend against the coadministration of simeprevir and cyclosporine, given these new findings, simeprevir should not be coadministered with cyclosporine.

The coadministration of single-dose tacrolimus with simeprevir did not result in a significant change of tacrolimus concentrations (see simeprevir package insert). In an ongoing study, concomitant use of simeprevir with tacrolimus also resulted in a 2-fold increase in plasma concentrations of simeprevir compared with historical data (personal communication). Based on phase I studies, a 2-fold increase in simeprevir concentrations is unlikely to be clinically significant.

Clinicians may consider the use of sofosbuvir plus simeprevir in patients receiving tacrolimus with therapeutic drug monitoring, particularly in those expected to have difficulty tolerating RBV (eg, patients with impaired renal function and anemia). Consideration should be given to pretreatment resistance testing for the Q80K polymorphism in genotype 1a-infected patients.

In addition to the sofosbuvir compassionate use program (Forns, 2013a), 40 patients with recurrent HCV [illegible] were reported. Discontinued therapy due to adverse events. No deaths, graft loss, or episodes of rejection.

The addition of PEG to sofosbuvir plus RBV may also be considered in the absence of contraindications.

The following regimens are NOT recommended for treatment-naive patients with compensated allograft hepatitis C virus infection.

Monotherapy with PEG, RBV, or a DAA

Rating: Class III, Level A

Telaprevir- or boceprevir- based regimens should not be used for patients

with compensated allograft hepatitis C virus infection.

Rating: Class III, Level A

Telaprevir or boceprevir should not be used in the post-liver transplant population because of surrounding toxicity and drug interactions with calcineurin inhibitors**.**

Decompensated Cirrhosis

Treatment-naive patients with decompensated allograft HCV infection should receive the same treatment as recommended for patients with decompensated cirrhosis (moderate or severe hepatic impairment; CTP class B or C).

Rating: Class I, Level C

4. Patients with Renal Impairment, Including Severe Renal Impairment (CrCl <30 mL/min) or ESRD Requiring Hemodialysis or Peritoneal Dialysis

Summary of Recommendations for Patients with Renal Impairment Including, Severe Renal Impairment (CrCl <30 mL/min) or ESRD Requiring Hemodialysis or Peritoneal Dialysis is found in the BOX.

When using sofosbuvir to treat or retreat HCV infection in patients with appropriate genotypes, no dosage adjustment is required for patients with mild to moderate renal impairment (CrCl ≥30 mL/min). Sofosbuvir is not recommended in patients with severe renal impairment/ESRD (CrCl <30 mL/min) or those who require hemodialysis, because no dosing data are currently available for this patient population.

Rating: Class IIa, level B

Sofosbuvir enters the hepatocyte, where it is metabolized to its active form, GS-461203. The downstream inactive nucleoside metabolite GS-331007 is almost exclusively eliminated from the body renally, mediated through a combination of glomerular filtration and active tubular secretion. Results of phase 2 and 3 sofosbuvir clinical trials have excluded patients with serum Cr level above 2.5 and/or CrCl level below <60 mL/min. The pharmacokinetics of a single dose of sofosbuvir 400 mg was assessed in persons not infected

with HCV (study P7977-0915) with mild (estimated glomerular filtration rate [eGFR] ≥50 and <80 mL/min/1.73m^2), moderate (eGFR ≥30 and <50 mL/min/1.73m^2), severe renal impairment (eGFR <30 mL/min/1.73m^2) and persons with ESRD requiring hemodialysis. Relative to persons with normal renal function (eGFR>80 mL/min/1.73m^2), the sofosbuvir AUC(0-inf) was 61%, 107%, and 171% higher in subjects with mild, moderate, and severe renal impairment, respectively. The GS-331007 AUC(0-inf) was 55%, 88%, and 451% higher, respectively. No safety signals have been seen under similar conditions. In subjects with ESRD (relative to subjects with normal renal function), sofosbuvir and GS-331007 AUC (0-inf) was 28% and 1280% higher, respectively, when sofosbuvir was dosed 1 hour before hemodialysis, compared with 60% and 2070% higher, respectively, when sofosbuvir was dosed 1 hour after hemodialysis. No dose adjustment is required for patients with mild or moderate renal impairment. The safety of sofosbuvir has not been established in patients with severe renal impairment or ESRD. Therefore, a dose recommendation cannot be provided for these populations at this time, although a dedicated study to evaluate optimal dosing of sofosbuvir in HCV-infected patients with severe renal impairment or ESRD on hemodialysis is currently underway.

When using simeprevir in treatment/retreatment of HCV-infected patients, no dosage adjustment is required for patients with mild to moderate to severe renal impairment. Simeprevir has not been studied in patients with ESRD, including those requiring hemodialysis.

Rating: Class IIa, level B

Simeprevir is primarily metabolized by liver CYP3A4, and renal clearance plays an insignificant role (<1%) in the elimination of simeprevir and its metabolites.

Simeprevir 150 mg daily for 7 days has been studied in non-HCV infected patients with severe renal impairment (eGFR<30 mL/min/1.73m^2) and healthy volunteers (eGFR> mL/min/1.73 m^2). For persons with severe renal impairment, simeprevir C_{min}, C_{max}, and AUC(24 hour) were 71%, 34%, and 62% higher, respectively, compared with matched healthy controls. Simeprevir exposure was higher in patients with severe renal impairment (steady-state by day 7), but no significant difference was observed in simeprevir plasma protein binding. Simeprevir was generally safe and well tolerated in subjects with severe renal impairment. Therefore, no dose adjustment of simeprevir is required in these patients. No clinically significant differences in pharmacokinetics were observed in HCV-uninfected participants with mild, moderate, or severe renal impairment. CrCl level was not identified as a significant covariate of simeprevir population pharmacokinetics in HCV-infected patients.Simeprevir has not been evaluated in patients receiving hemodialysis.

In patients with renal impairment/ESRD/HD, dosing of PEG and RBV should follow updated FDA recommendations or package insert recommendations based on calculated GFR. Caution should be used in administering RBV to these patients, and close monitoring of hemoglobin is required.

Rating: Class IIa, level B

HCV infection is a major health problem in patients with ESRD. The incidence of acute HCV infection during maintenance dialysis is much higher than that in the general population because of the risk for nosocomial transmission. The kidney is important for the catabolism and filtration of both IFN and RBV, and therefore, reduced doses of both PEG and RBV are warranted in patients with ESRD.

Impaired excretion of RBV occurs in patients with chronic kidney disease, as RBV is mostly eliminated by the kidney. Very little RBV is removed via dialysis. Thus, the drug can accumulate, exacerbating hemolysis in the dialysis population already at substantial risk for anemia. If a decision is made to use RBV in patients on maintenance hemodialysis, it should be used only after the implementation of several safety precautions, including (1) administering very low doses of RBV (200 mg daily), (2) monitoring hemoglobin levels on a weekly basis, (3) titrating epoetin alfa to treat anemia, and (4) providing intravenous iron supplementation to boost erythropoietin activity.

Dose adjustments needed for patients with renal impairment are summarized in the Renal Impairment Table.

Unique Patient Populations: HIV/HCV Coinfection Box. Summary of Recommendations for HIV/HCV Coinfected Patients Who are Being Treated for HCV, by Genotype

*For genotype 1a, baseline resistance testing for Q80K should be performed and alternative treatments should be considered if this mutation is present.

Unique Patient Populations: Cirrhosis Box. Summary of Recommendations for Patients with Cirrhosis

Unique Patient Populations: Cirrhosis Box. Summary of Recommendations for Patients with Cirrhosis

Treatment-naive patients with compensated cirrhosis, including those with hepatocellular carcinoma, should receive the same treatment as recommended for patients without cirrhosis.

Rating: Class I, Level A

Patients with decompensated cirrhosis (moderate or severe hepatic impairment; CTP class B or C) should be referred to a medical practitioner with expertise in that condition (ideally in a liver transplant center).

Rating: Class I, Level C

The recommended regimen for patients with any HCV genotype who have decompensated cirrhosis (moderate or severe hepatic impairment; CTP class B or C) who may or may not be candidates for liver transplantation, including those with hepatocellular carcinoma. This regimen should be used only by highly experienced HCV providers

Daily sofosbuvir (400 mg) plus weight-based RBV (with consideration of the patient's creatinine clearance and hemoglobin level) for up to 48 weeks

Rating: Class IIb, Level B

The following regimens are NOT recommended for patients with decompensated cirrhosis (moderate or severe hepatic impairment; CTP class B or C):

Any IFN-based therapy

Rating: Class III, Level A

Monotherapy with PEG, RBV, or a DAA

Rating: Class III, Level A

Telaprevir-, boceprevir-, or simeprevir-based regimens

Rating: Class III, Level A

Unique Patient Populations: Post-Liver Transplantation Box. Summary of Recommendations for Patients Who Develop Recurrent HCV Infection Post-Liver Transplantation

Unique Patient Population: Post-Liver Transplantation Box. Summary of Recommendations for Patients Who Develop Recurrent HCV Infection Post-Liver Transplantation

Recommended regimen for treatment-naive patients with HCV genotype 1 in the allograft liver, including those with compensated cirrhosis

Daily sofosbuvir (400 mg) plus simeprevir (150 mg), with or without RBV (initial dose 600 mg/day, increased monthly by 200 mg/day as tolerated to weight-based dose of 1000 mg [<75 kg] to 1200 mg [≥75 kg] 1200 mg), for 12 weeks to 24 weeks is recommended for patients with compensated allograft HCV genotype 1 infection.

Rating: Class IIb, Level C

Recommended regimen for treatment-naive patients with HCV genotype 2 or 3 in the allograft liver, including those with compensated cirrhosis

Daily sofosbuvir (400 mg) and RBV (initial dose 600 mg/day, increased monthly by 200 mg/day as tolerated to weight-based dose of 1000 mg [<75 kg] to 1200 mg [≥75 kg] 1200 mg) with consideration of the patient's CrCl value and hemoglobin level for 24 weeks is recommended for patients with compensated allograft HCV genotype 2 or 3 infection.

Rating: Class IIb, Level C

Alternate regimen for treatment-naive patients with genotype 1 HCV in the allograft liver, including those with compensated cirrhosis.

Daily sofosbuvir (400 mg) and RBV (initial dose 600 mg/day, increased monthly by 200 mg/day as tolerated to weight-based dose of 1000 mg [<75 kg] to 1200 mg [≥75 kg] 1200 mg) with consideration of the patient's CrCl value and hemoglobin level,

with or without PEG (in the absence of contraindication to its use), for 24 weeks is recommended for patients with compensated allograft HCV genotype 1 infection.

Rating: Class IIb, Level C

The following regimens are NOT recommended for treatment-naive patients with compensated allograft hepatitis C infection

Monotherapy with PEG, RBV, or a DAA

Rating: Class III, Level A

Telaprevir- or boceprevir- based regimens should not be used for patients with compensated allograft hepatitis C infection.

Rating: Class III, Level A

Treatment-naive patients with decompensated allograft HCV infection should receive the same treatment as recommended for patients with decompensated cirrhosis (moderate or severe hepatic impairment; CTP class B or C).

Rating: Class I, Level C

Unique Patient Populations: Renal Impairment Table. Dose Adjustments Needed for Patients with Renal Impairment

Unique Patient Populations: Renal Impairment Table. Dose Adjustments Needed for Patients with Renal Impairment

Renal Impairment	eGFR/CrCl level (mL/min/ 1.73 m^2)	Interferon	Ribavirin	Sofosbuvir	Simeprevir
Mild	50-80	180 µg PEG (2a); PEG (2b) 1.5 µg/kg	Standard	Standard	Standard
Moderate	30-50	180 µg PEG (2a); PEG alfa-2b1 µg/kg or 25% reduction	Alternating doses 200 and 400 mg every other day	Standard	Standard
Severe	<30	135 µg PEG (2a); PEG (2b)1 µg/kg or 50% reduction	200 mg/d	Data not available	Standard
ESRD/HD		PEG (2a) 135 µg/wk or PEG (2b) 1 µg/kg/wk or standard IFN 3 mU 3x/wk	200 mg/d	Data not available	Data not available

Unique Patient Populations: Renal Impairment Box. Summary of Recommendations for Patients with Renal Impairment Including Severe Renal Impairment (CrCl <30 ML/min) or ESRD Requiring Hemodialysis or Peritoneal Dialysis

Renal Impairment Box. Summary of Recommendations for Patients with Renal Impairment, Including Severe Renal Impairment (CrCl <30 ML/min) or ESRD Requiring Hemodialysis or Peritoneal Dialysis

When using sofosbuvir to treat or retreat HCV infection in patients with appropriate genotypes, no dosage adjustment is required for patients with mild to moderate renal impairment (CrCl ?30 mL/min). Sofosbuvir is not recommended in patients with severe renal impairment/ESRD (CrCl <30 mL/min) or those who require hemodialysis, because no dosing data are currently available for this patient population.

Rating: Class IIa, level B

When using simeprevir in treatment/retreatment of HCV-infected patients, no dosage adjustment is required for patients with mild to moderate to severe renal impairment. Simeprevir has not been studied in patients with ESRD, including those requiring hemodialysis.

Rating: Class IIa, level B

In patients with renal impairment/ESRD/HD, dosing of PEG and RBV should follow updated FDA recommendations or package insert recommendations based on calculated GFR. Caution should be used in administering RBV to these patients, and close monitoring of hemoglobin is required.

Rating: Class IIa, level B

UNIVERSITY OF BIRMINGHAM

NHS National Institute for Health Research

National Horizon Scanning Centre

Transient elastography (FibroScan) for evaluating liver fibrosis

April 2008

This technology summary is based on information available at the time of research and a limited literature search. It is not intended to be a definitive statement on the safety, efficacy or effectiveness of the health technology covered and should not be used for commercial purposes.

The National Horizon Scanning Centre Research Programme is part of the National Institute for Health Research

Transient elastography (FibroScan) for evaluating liver fibrosis

Target group

- All patients with chronic liver disease in particular those with suspected liver fibrosis associated with hepatitis B and C, non-alcoholic steatohepatitis (NASH), alcoholic steatohepatitis (ASH) and non-alcoholic fatty liver disease (NAFLD).

Technology description

FibroScan is an active medical diagnostic aid, which makes non-invasive, painless and immediate measurements of the stiffness (or elasticity) of the hepatic parenchyma. A FibroScan test is conducted by placing a probe in an intercostal space over the patient's liver triggering a shear wave, which is tracked through the liver using the ultrasound element of the probe (FibroScan is currently of limited use in obese patients). FibroScan can be performed by trained medical or paramedical staff. Each test typically takes less than 15 minutes in total. The acquisition speed is very high and the acquisitions are therefore not biased by cardiac or respiratory movements as they are with ultrasound imaging. FibroScan can be used as an initial screening tool to reduce the number of patients requiring liver biopsy and also to measure ongoing response to treatment. In some patients the initial screening results may be sufficiently well-defined to provide a confident assessment of the patient's stage of liver fibrosis.

Innovation and/or advantages

Unlike with a needle biopsy of the liver no anaesthetic is needed with FibroScan and the patient can be discharged immediately. No special infrastructure or specialist consumables are required for FibroScan. Whilst many patients will still require a biopsy, the company believe that a reduction in biopsies of between 40 to 60% may be observed when FibroScan is employed.

The most significant advantage of FibroScan may be that many more patients could be assessed at much more frequent intervals compared with liver biopsies[a]. The patient cohorts who would most benefit may be those with recurrent disease (whatever the aetiology) post-transplant and those with viral hepatitis[a].

Developer

EchoSens (Artemis Medical Ltd. are the UK distributor).

Availability, launch or marketing dates, and licensing plans:

CE marked. Currently installed in 12 NHS hospitals. Most of the systems in use within the NHS have been funded by either pharmaceutical companies and/or charity donations. The company predict that the initial uptake is likely to be in the major hepatology centres (approximately 35 systems). The second phase requirement would be into DGHs with gastroenterology departments. Expert opinion suggests that national guidelines regarding the use of FibroScan are needed.

NHS or Government priority area:

No NHS or government priority area was identified.

[a] Expert opinion

Relevant guidance

- The Centre for Evidence-based Purchasing (CEP) is currently conducting an evidence review of FibroScan (publication date not known).

NICE Technology Appraisals

- Hepatitis B (chronic) – tenofovir disoproxil fumarate. Proposed 17th wave.
- Hepatitis B (chronic) – adefovir dipivoxil and pegylated interferon alpha-2a. 2006[1] (review date February 2009).
- Hepatitis C – peginterferon alfa and ribavirin. 2006[2] (review date being considered). This is an extension of Hepatitis C – pegylated interferons, ribavirin and alfa interferon. 2004.

NICE Interventional Procedures

- Extracorporeal albumin dialysis for acute-on-chronic liver failure
- Laparoscopic liver resection
- Living-donor liver transplantation
- Radiofrequency-assisted liver resection

- Haute Autorité de Santé[b]. Guidelines for the diagnosis of uncomplicated cirrhosis. 2007[3].
- SIGN. Management of hepatitis C. A national clinical guideline. 2006[4].
- British Society for Gastroenterology. Guidelines on the use of liver biopsy in clinical practice. 2004[5].
- The Canadian Agency for Drugs and Technologies in Health (CADTH). Transient elastography (FibroScan) for non-invasive assessment of liver fibrosis. 2006[6].

  Stated that the diagnostic performance of FibroScan is good for identifying severe fibrosis or cirrhosis, but is less accurate for milder presentations. FibroScan is a promising technology, but large multi-centre trials comparing a range of emerging non-invasive fibrosis staging technologies are required.
- The Australia and New Zealand Horizon Scanning Network (ANZHSN). MR and transient elastography for the non-invasive assessment of liver fibrosis. 2006[7].

  Stated that elastography (magnetic resonance and transient) appears to be a reliable technique for diagnosing severe liver fibrosis. For conditions such as viral hepatitis however, antiviral therapy should ideally begin in the early stages of fibrosis. Given the low quality of evidence outlining the ability of elastography to detect mild or moderate fibrosis, it is recommended that the technology be archived[c].

Clinical need and burden of disease

Hepatitis C

Liver fibrosis is associated with significant morbidity and mortality. The major cause is hepatitis C. Hepatitis C virus (HCV) causes chronic hepatitis in about 80% of those infected. Recent estimates suggest that approximately 200,000 to 500,000 people are infected with HCV in England and Wales[2]. In 2005 the Department of Health estimated that only 47,000 people with HCV infection had been diagnosed and only 7,000 had been treated.

People infected with HCV are often asymptomatic, but about 20% will develop overt hepatitis. The rate of progression of the disease is slow but variable, usually taking about

[b] French National Authority for Health.
[c] The company have received enquiries from Australia regarding FibroScan.

20–50 years from the time of infection. About 30% of those who are infected develop cirrhosis within 20–30 years, and a small percentage of these people are at a high risk of developing hepatocellular carcinoma. A third may never progress to cirrhosis or will not progress for at least 50 years.

Hepatitis B

The Department of Health estimates that about 180,000 people in the UK have chronic hepatitis B[1]. There are about 7,700 new cases of chronic hepatitis B each year. Of these, around 300 people were infected within the UK; the remainder (mainly immigrants to the UK) were infected abroad, generally in areas of high prevalence where the virus is frequently transmitted from mother to child.

People with active chronic hepatitis B are at increased risk of liver cirrhosis and primary liver cancer.

Alcoholic Liver Disease (ALD)

In 2005, 4,160 people died in England and Wales from alcoholic liver disease, an increase of 37% since 1999[8]. The process is initially silent, but when liver disease has developed it presents as an acute illness with a 25-50% immediate mortality rate. In England, around 39,180 people are admitted to hospital with alcoholic liver disease each year.

There are three main stages of ALD: minimal change, or fatty liver; alcoholic hepatitis; and cirrhosis. Severe alcoholic steatohepatitis (ASH) is the major complication of advanced ALD and has a high mortality even when treated with corticosteroids.

Non-alcoholic fatty liver disease (NAFLD)

The prevalence of NAFLD is approximately 20-30% in western countries[9], which would approximate to between 10.7 – 16.1M people in England and Wales. It covers a number of conditions, including non-alcoholic steatohepatitis (NASH). Severe obesity, type 2 diabetes, hypertension and/or dyslipidaemia are major risk factors. NASH is usually benign and very slowly progressive but can result in the development of fibrosis in up to 40% of patients, or cirrhosis in 5-10% of patients.

Existing comparators and treatments

The gold standard for the assessment of fibrosis in chronic liver conditions is currently a liver biopsy. Liver biopsies, which are associated with a degree of sampling error, are generally performed under local anaesthesia and require a short hospital stay. Liver biopsy is an invasive technique with a risk of serious adverse events due to bleeding and other complications and therefore should only be performed if the benefits outweigh the risks (in terms of altering treatment or disease outcome).

An alternative for liver biopsy is the non-invasive prediction of the severity of liver disease using combinations of clinical and biochemical parameters. Recent SIGN guidelines[4] recommend that:

- biochemical markers should not be used as an alternative to liver biopsy for the staging of intermediate grades of fibrosis
- biochemical tests may be used as an alternative to liver biopsy to diagnose cirrhosis or to direct screening for complications of fibrosis.

Guidelines from France recommend that once a patient has been referred to a specialist, and a firm diagnosis cannot be made from the clinical and biological observations, a liver

biopsy or a non-invasive test has to be carried out[3]. The recommended first-line test for the chronic untreated hepatitis C patient with no comorbidities is a non-invasive procedure (either FibroTest[d] or FibroScan)[3].

Hepatitis C

The decision to treat a person with hepatitis C does not depend on a liver biopsy, however the clinician may recommend a biopsy for other reasons or if a strategy of watchful waiting is chosen.

Hepatitis B

The hepatitis B surface antibody (anti-HBs) is the most common test for hepatitis B. Other tests detect the presence of viral antigens. Liver biopsy is an accepted part of the diagnosis and management of patients with chronic hepatitis B and can be used for grading fibrosis and inflammation.

Alcoholic Liver Disease (ALD)

If ALD is suspected, liver function tests, blood counts, and hepatitis serology are performed. No specific test exists for alcoholic liver disease. The role and timing of liver biopsy in patients with suspected ALD remains uncertain. In patients with evidence of liver damage and a history of alcohol excess, a liver biopsy is helpful in determining the degree of liver damage.

Non-alcoholic fatty liver disease (NAFLD)

NAFLD is often asymptomatic, and may be identified through abnormal liver function tests (LFTs) or by abdominal ultrasound. The role of liver biopsy for this indication is not clearly established. Histology remains the gold standard for making the important distinction between simple steatosis (which is generally non-progressive and readily reversible) and NASH.

Efficacy and safety

There are numerous published trials, conference presentations, ongoing trials and several non-systematic reviews pertaining to FibroScan. Two systematic reviews were identified, which included 4 studies[10] and 9 studies[11] respectively (see table for details of the latter review) – these reviews had 3 studies in common.

Title	Ultrasound-based transient elastography for the detection of hepatic fibrosis
Status	Published 2007[11]
Design	Systematic review and meta-analysis
Description of study	Studies reporting accuracy of ultrasound-based transient elastography compared with liver biopsy were identified through (i) search of PubMed (MEDLINE), EMBASE, Cochrane Library, Database of Abstracts of Reviews of Effects, Web of Science, SCOPUS, American College of Physicians Journal Club, Google Scholar databases from database inception to January 2007, and (ii) review of abstracts and proceedings from the American Association for the Study of Liver Disease, European Association for the Study of the Liver, and Digestive Disease Week annual meetings between 2003-2006. N=9 studies (2,083 patients) identified.
Primary outcome	Diagnostic test performance of ultrasound-based transient elastography for the detection of cirrhosis (stage IV fibrosis) vs no cirrhosis (stages 0-III fibrosis) compared

[d] FibroTest combines the variables of age and gender with 5 biomarkers. Reported to ACTS in January 2004 for Hepatitis C and updated for chronic liver conditions in July 2005 (ACTS decided the topic did not meet the selection criteria).

	with the reference standard of liver biopsy.
Secondary outcomes	Diagnostic test performance of ultrasound-based transient elastography for detecting stages II-IV fibrosis vs stage 0-I fibrosis.
Key results	For patients with stage IV fibrosis (9 studies), the pooled estimates for sensitivity were 87% (95% CI, 84%-90%), specificity 91% (95% CI, 89%-92%), positive likelihood ratio 11.7 (95% CI, 7.9-17.1), and negative likelihood ratio 0.14 (95% CI, 0.10-0.20). For patients with stages II-IV fibrosis (7 studies), the pooled estimates for sensitivity were 70% (95% CI, 67%-73%), specificity 84% (95% CI, 80%-88%), positive likelihood ratio 4.2 (95% CI, 2.4-7.2), and negative likelihood ratio 0.31 (95% CI, 0.23-0.43). Diagnostic threshold (or cut-off value) bias was identified as an important cause of heterogeneity for pooled results in both patient groups.

Estimated cost and cost impact

FibroScan has an initial capital cost of £49,950 (+VAT) plus an annual maintenance cost of £3,000 (+VAT) from year 2 onwards. The cost per test will vary depending on the usage of the machine. The more the machine is used the lower the cost per patient.

In patients younger than 70 without complications the cost for an inpatient biopsy (HRG code G05) is £710 (elective spell) and £2,213 (non-elective spell)[12].

Potential or intended impact – speculative

Patients

☐ Reduced morbidity	☐ Reduced mortality or increased survival	☑ Improved quality of life for patients and/or carers
☑ Quicker, earlier or more accurate diagnosis or identification of disease	☐ Other:	☐ None identified

Services

☑ Increased use	☐ Service reorganisation required	☑ Staff or training required – FibroScan assessments generally undertaken by existing staff. Training is typically 3-4 hrs per operator.
☐ Decreased use	☐ Other:	☐ None identified

Costs

☐ Increased unit cost compared to alternative	☐ Increased costs: more patients coming for treatment	☑ Increased costs: capital investment needed
☐ New costs:	☑ Savings: FibroScan permits assessments to be performed in many more patients than alternative means would realistically allow. Once purchased, the cost per patient is primarily only that of the operator	☐ Other:

Issues in Emerging Health Technologies

Transient Elastography (FibroScan) for Non-invasive Assessment of Liver Fibrosis

Issue 90 • September 2006

Summary

- ✓ **Liver fibrosis is associated with significant morbidity and mortality. The major cause is hepatitis C, which affects 240,000 Canadians.**
- ✓ **Assessing the degree of liver fibrosis is critical to its management. Liver biopsy, an invasive procedure, is considered to be the diagnostic gold standard.**
- ✓ **FibroScan is a rapid, non-invasive technology that uses low frequency vibration and ultrasound to assess the stiffness of liver tissue.**
- ✓ **The diagnostic performance of FibroScan is good for identifying severe fibrosis or cirrhosis, but it is less accurate for milder presentations.**
- ✓ **FibroScan is a promising technology, but large multi-centre trials comparing a range of emerging non-invasive fibrosis staging technologies are required.**

The Technology

Fibrosis of the liver, which is associated with significant morbidity and mortality, occurs as a result of an exaggerated healing response triggered by chronic insults to the liver, such as injury, infection, and inflammation. Fibrosis of the liver develops when scar tissue replaces normal liver tissue. It can be localized or diffuse, and it can progress to cirrhosis, which increases the risk of developing liver cancer. Liver function is impaired. Assessing the degree of fibrosis is important when making decisions about starting treatment, assessing treatment response, and screening for liver cancer.[1-3]

FibroScan (EchoSens, Paris, France) is a non-invasive test that draws on the physics of transient elastography to assess liver fibrosis. A specialized ultrasound transducer placed over the liver transmits a mild amplitude, low frequency vibration. The vibration creates an elastic shear wave that moves through the underlying liver tissue. Its velocity is measured using pulse-echo ultrasound. Shear waves propagate more quickly in stiff tissue, and fibrotic tissue is stiff. FibroScan takes <5 minutes to perform, and produces immediate, operator-independent results.[4]

Regulatory Status

FibroScan is not currently licensed for use in Canada (Kathleen Savage, Health Canada, Ottawa: personal communication, 2006 May 3).

Patient Group

Liver fibrosis can be caused by many diseases, but most of the studies examining the effectiveness of FibroScan have focused on patients infected with hepatitis C (HCV). Up to 3% of the world's population are infected with HCV, and hepatitis C becomes chronic in 85% of infected adults.[5] In the US, HCV accounts for more cases of chronic liver disease than any other single cause.[6] In Canada, about 240,000 people are infected with HCV, with a prevalence estimated at 0.8% of the population.[7]

Current Practice

Liver biopsy is the gold standard for assessing the degree of fibrosis. Biopsy is recommended, but not mandated, in practice guidelines addressing the management of HCV.[8-10] No information on the proportion of HCV patients who receive a liver biopsy is available, but it is likely to be a subset of the HCV population. The clinical progression of HCV is typically slow, and infected persons may be asymptomatic for ≥20 years.[5,6] Furthermore, a biopsy may be unnecessary for HCV genotypes 2 and 3, which respond well to treatment.[8]

Liver biopsy is not easily accepted by patients. Pain is reported by one-third, complications occur in three per 1,000 biopsies, and death occurs in three per 10,000 biopsies. In addition, liver biopsy is subject to sampling error, because the typical biopsy specimen represents only 1/50,000 of the total liver volume, and discrepancies of ≥1 fibrosis stage have been identified in 33% of the samples taken from the right and left lobes of the same patient. There can also be significant intra- and inter-pathologist variation in the interpretation of biopsy samples.[11]

The Evidence

Seven observational studies address the relative performance of FibroScan, blood tests, or combinations thereof versus liver biopsy. Most of these were conducted in France.[12-18] There is overlap in the authorship of five of the seven studies.[12,14,15,17,18] Four studies[12,13,16,18] include ≤75 patients in the statistical analysis, while the others include 183 to 711 participants.[14,15,17] Most[12-16] include only HCV patients, one[17] includes patients with chronic liver disease of any origin, and one[18] includes only patients who are HIV and HCV co-infected.

The studies suggest that FibroScan results are reproducible across operators and time.[12,13] All the studies report that FibroScan's diagnostic performance is good, with Colletta *et al.*[16] indicating that it agrees perfectly with liver biopsy. This finding has sparked debate.[3,19] Five studies[12,14,15,17,18] present AUROC (area under the receiver operating characteristic curve) values, a commonly used index of diagnostic accuracy where values close to 1.0 represent high diagnostic accuracy. In terms of FibroScan's ability to discriminate degrees of fibrosis, as staged on the Metavir scale (F0 to F4 where F0=no fibrosis, and F4=cirrhosis), the AUROC ranges across the studies were F≥2, 0.72 to 0.88; F≥3, 0.90 to 0.91; and, F=4, 0.95 to 0.99. These results suggest that FibroScan performs well in identifying severe fibrosis or cirrhosis, but is less accurate in identifying lesser degrees of fibrosis. This is important because F2 is a threshold for initiating treatment.[9,10]

Two studies consider the performance of FibroScan relative to or with blood tests.[15,16] Castera *et al.*[15] reported that the diagnostic accuracy of FibroScan, FibroTest®, (BioPredictive, Paris, France) and APRI (aspartate transaminase to platelets ratio index) are of the same order, and that diagnostic accuracy is maximized when FibroScan and FibroTest are used in tandem. Colletta *et al.*[16] found FibroScan to be superior to FibroTest among HCV patients with normal aminotransferases.

These are early results, so more research is needed. Most of the studies conducted to date are small, focus on a subset of patients with chronic liver disease, fail to consider the full range of non-invasive tests, and arrive at differing thresholds for discriminating among the degrees of fibrosis. It is also unclear whether the studies were independent of industry involvement.

Adverse Effects

FibroScan is a non-invasive test, and no adverse effects have been reported.

Administration and Cost

FibroScan can be performed by trained medical or paramedical staff. No studies have addressed the optimal frequency of testing. The only available cost figures for FibroScan were published in 2004. Estimates include equipment costs of €71,760 (C$100,464), annual maintenance contract costs of €5,400 (C$7,560), and negligible costs for consumables. Although details of the calculations are not provided, it is estimated that at 20 and 150 examinations annually, the cost per examination would be €1,000 (C$1,400) and €100 (C$140) respectively.[20] These estimates focus on equipment-related expenditures, and seem to exclude staffing or indirect costs.

Liver biopsy costs are reported to range from €703 to €1,566 (C$984 to C$2,192) in European centres, and US$1,032 to US$2,745 (C$1,146 to C$3,047) in US centres, depending on whether complications occur.[11,21,22] Canadian costs may be lower; two large British Columbia health care organizations report direct costs of C$334 and C$337, and total costs of C$432 and C$472 respectively for liver biopsy (Larry Okotinsky, Fraser Health, Surrey, BC: personal communication, 2006 May 15; Chris Haack, Providence Health Care, Vancouver: personal communication, 2006 May 15).

Concurrent Development

Laboratory tests for liver fibrosis, based on direct and indirect serum markers, continue to be evaluated. Opinions about the reliability of these tests are mixed, but their development is seen as promising.[11,23,24] Another development is magnetic resonance elastography, which may offer an opportunity to assess a larger volume of the liver, and provide three-dimensional information.[25]

Rate of Technology Diffusion

FibroScan is not widely diffused in any jurisdiction, but if its effectiveness is confirmed, the technology will probably diffuse rapidly, largely on the basis of its low capital cost, widespread providers' familiarity with ultrasound technologies, and consumer demand.

The pattern of diffusion may be irregular, because the geographic prevalence of HCV varies significantly. The economics of FibroScan will be most favourable in centres that perform a significant volume of liver biopsies.

Morbid obesity or narrow intercostal spaces (the area between the ribs) preclude the use of FibroScan in 5% to 8% of patients.[14,15] This has led to speculation that the rate of uncompleted tests will be higher in jurisdictions such as the US, where the average body mass index is high.[3,14,23] This might affect diffusion, but the manufacturer is developing transducers for use in patients who are obese, or who have narrow intercostal spaces.[4,14]

Implementation Issues

The potential for non-invasive fibrosis staging is promising, but which technology or combination of technologies will be most useful is unclear. Once licensed, FibroScan could enter the Canadian health care system, as none of its features pose a significant barrier to uptake.

Although it might be argued that FibroScan does not need to be used more often than liver biopsy, it could be compelling to use FibroScan more frequently based on its rapid and non-invasive nature. This would be true for baseline fibrosis evaluations, but might also extend to ongoing monitoring, despite the lack of proof for FibroScan's utility for this purpose. If other non-invasive tools for assessing fibrosis gain acceptance, the market for FibroScan may be fragmented. Such scenarios might negatively affect the economics of FibroScan, or where non-invasive technologies are used in tandem, increase the total volume of tests conducted. This situation would be compounded if the indications for FibroScan expand beyond liver fibrosis due to HCV. This trend is evident in the literature.[17]

The degree to which FibroScan can replace liver biopsy is still unclear. Ziol *et al.*[14] and Castera *et al.*[15] indicate that the use of FibroScan alone or in tandem with another test would have permitted 42% and 77% of their respective study populations to avoid biopsy. Given the lack of information about who receives biopsy and for what reason, it is impossible to extrapolate their findings to clinical practice. Any shift to non-invasive testing will affect the system's capacity to perform liver biopsies, and perhaps require a concentration of such specialized services.

Elastography for the diagnosis of severity of fibrosis in chronic liver disease: A meta-analysis of diagnostic accuracy

E.A. Tsochatzis[1], K.S. Gurusamy[2], S. Ntaoula[1], E. Cholongitas[1], B.R. Davidson[2], A.K. Burroughs[1,*]

[1]*The Royal Free Sheila Sherlock Liver Centre and Division of Surgery, Royal Free Hospital, London NW3 2QG, UK;* [2]*University Department of Surgery, Royal Free Hospital, London NW3 2QG, UK*

Background & Aims: Transient elastography is a non-invasive method, for the assessment of hepatic fibrosis, developed as an alternative to liver biopsy. We studied the performance of elastography for diagnosis of fibrosis using meta-analysis.

Methods: MEDLINE, EMBASE, SCI, Cochrane Library, conference abstracts books, and article references were searched. We included studies using biopsy as a reference standard, with the data necessary to calculate the true and false positive, true and false negative diagnostic results of elastography for a fibrosis stage, and with a 3-month maximum interval between tests. The quality of the studies was rated with the QUADAS tool.

Results: We identified 40 eligible studies. Summary sensitivity and specificity was 0.79 (95% CI 0.74–0.82) and 0.78 (95% CI 0.72–0.83) for F2 stage and 0.83 (95% CI 0.79–0.86) and 0.89 (95% CI 0.87–0.91) for cirrhosis. After an elastography result at/over the threshold value for F2 or cirrhosis ("positive" result), the corresponding post-test probability for their presence (if pre-test probability was 50%) was 78%, and 88% respectively, while, if values were below these thresholds ("negative" result), the post-test probability was 21% and 16%, respectively. No optimal stiffness cut-offs for individual fibrosis stages were validated in independent cohorts and cut-offs had a wide range and overlap within and between stages.

Conclusions: Elastography theoretically has good sensitivity and specificity for cirrhosis (and less for lesser degrees of fibrosis); however, it should be cautiously applied to everyday clinical practice because there is no validation of the stiffness cut-offs for the various stages. Such validation is required before elastography is considered sufficiently accurate for non-invasive staging of fibrosis.

Introduction

Liver fibrosis represents the final common outcome of chronic liver injury and is often progressive, eventually evolving into cirrhosis [1]. Cirrhosis is the severest form of fibrosis with the worst clinical outcomes.

Currently, histological examination of a liver biopsy specimen is the reference standard for the diagnosis, staging, and monitoring of liver fibrosis [2]. However, it is invasive and can lead to fatal bleeding [2].

Transient elastography is a non-invasive method of quantifying fibrosis developed as an alternative to liver biopsy. Ultrasound elastography analyses ultrasound frequency waves which are related to the elasticity (deforming capacity) of the liver. It is simple, highly reproducible, and can be completed in 10 min in an outpatient setting with no significant expertise [3]. Magnetic resonance elastography involves measuring the elasticity of liver tissues using complex algorithms [4]. An increasing number of studies have evaluated the accuracy of elastography in the staging of fibrosis and compared it to liver biopsy.

In the present study, we used meta-analysis to assess the performance of elastography in the diagnosis of severity of liver fibrosis using liver biopsy as the reference standard.

Methods

Criteria for the selection of studies

We included full papers and abstracts, without language restrictions that (1) evaluated elastography in the diagnosis of severity of liver fibrosis or monitoring thereof, using liver biopsy as the reference standard, and (2) reported on data necessary to calculate the true positive false positive, true negative and false negative diagnostic results of elastography for the diagnosis of a fibrosis stage based on a defined cut-off point for liver stiffness. If such data were unavailable, the corresponding author was contacted via e-mail to provide them; if he/she failed to reply, the study was excluded. We also excluded studies reporting on <10 patients, or in which the maximum time interval between performing elastography and liver biopsy was >3 months.

Literature search

MEDLINE (Pubmed), Embase, Science Citation Index expanded, and The Cochrane Hepato-Biliary Group Controlled Trials Register, the Cochrane Central Register of Controlled Trials in The Cochrane Library were searched until May 2009. Conference abstracts from the American Association for the Study of Liver Diseases (AASLD) and the European Association for the Study of the Liver (EASL) were manually searched from 2007 to 2009. Reference lists of identified studies and reviews were also hand-searched. Search terms for each database are shown in the Appendix.

A Meta-analysis of Transient Elastography for the Detection of Hepatic Fibrosis

Justin Stebbing, MA, MRCP, FRCPath, PhD, Lavanta Farouk, MD, George Panos, MD, Mike Anderson, MD, FRCP, Long R. Jiao, MD, FRCS, Sundhiya Mandalia, PhD, Mark Bower, MD, FRCP, FRCPath, PhD, Brian Gazzard, MD, FRCP, and Mark Nelson, MD, MRCP

Objectives: The use of transient elastography to assess liver stiffness measurement (LSM) has now become widely available for the diagnosis of liver fibrosis as a rapid, noninvasive test (it is still not approved for use in the United States). It has previously been showed as an accurate method of representing the state of liver fibrosis with concomitant evaluation of liver biopsy and the histologic scoring system METAVIR. We performed a meta-analysis to further assess its use in comparisou with liver biopsy.

Methods: Studies from the literature were analyzed with a median liver stiffness value in kilopascal given for fibrosis stages according to histopathologic findings on biopsy and best discriminant cutoff levels in kilopascals for significant fibrosis ($\geq$ F2) and cirrhosis (F4).

Results: A total of 22 studies were selected comprising 4430 patients; chronic hepatitis C infection was the most common etiology of fibrosis. The pooled estimates for significant fibrosis ($\geq$ F2) measured 7.71 kPa (LSM cutoff value) with a sensitivity of 71.9% [95% confidence interval (CI): 71.4%-72.4%] and specificity of 82.4% (95% CI: 81.9-82.9%), whereas for cirrhosis (F4) the results showed a cutoff of 15.08 kPa with a sensitivity of 84.45% (95% CI: 84.2-84.7%) and specificity of 94.69% (95% CI: 94.3%-95%).

Conclusions: Further evaluation of transient elastography to assess LSM is required in prospective studies to potentially increase the sensitivity and establish its clinical utility.

Key Words: transient elastography, liver stiffness measurement, liver fibrosis, meta-analysis

(*J Clin Gastroenterol* 2010;44:214–219)

Liver fibrosis is characterized by the accumulation of an extracellular matrix that distorts the liver architecture. The major etiologies of liver fibrosis are chronic liver disease such as viral hepatitis, alcohol abuse, nonalcobolic steatobepatitis, and autoimmune disease. The progression of liver fibrosis increases the stiffness of the liver and the resistance of liver blood flow.[1] Insufficiency of liver blood flow results in liver failure with eventual cirrhosis—at which stage liver transplantation may be the only therapy to avoid a fatal outcome.[2] For this reason, an accurate assessment of liver fibrosis is vital in predicting the prognosis and the timing of commencing appropriate treatment to prevent disease progression.

Liver biopsy remains the gold standard method for assessing liver fibrosis. However, it is often difficult to undertake on a repeated basis because of the invasive nature and associated complications such as pain and bleeding. In addition, tissue samples are often too small and diagnostic opinions may differ among pathologists. Histologic quantification of liver fibrosis is also difficult because of diagnostic variability.[3] Consequently, new methods for the assessment of liver fibrosis are required.

Transient elastography (TE, FibroScan) for assessing liver stiffness measurement (LSM) has become available for the evaluation of liver fibrosis as a rapid, noninvasive method. It has been previously shown to accurately represent the state of liver fibrosis as concomitantly evaluated by the histologic scoring system METAVIR on liver biopsy.[4] FibroScan findings are generally more accurate than serum markers at predicting liver fibrosis,[5–14] the only exception being showed in one study[5] in which the combined use of TE and FibroTest offered the best diagnostic performance, both for significant fibrosis and cirrhosis.

To investigate the use of TE further, we performed a meta-analysis/systematic review to assess the validity of previously published studies in the detection of hepatic fibrosis.

METHODS

We searched medical databases (MEDLINE, Current Contents, PubMed, Cochrane library, Google Scholar), textbooks, and medical reports (UN, WHO) for relevant articles (English language). We also scanned the bibliographies of studies, reviewed abstract books/CDs for conferences and contacted individuals for personal opinions and up-to-date information. Search terms included "liver fibrosis and transient elastography," "hepatic fibrosis and transient elastography," and the terms were also interchanged—"transient elastography" to "elastography" or "fibroscan" or "elastometry" and "liver/hepatic fibrosis" to only "fibrosis."

All studies that reported data required for meta-analyses were identified and included—information providing

Liver Stiffness Is Associated With Risk of Decompensation, Liver Cancer, and Death in Patients With Chronic Liver Diseases: A Systematic Review and Meta-analysis

SIDDHARTH SINGH,[*] LARISSA L. FUJII,[*] MOHAMMAD HASSAN MURAD,[‡] ZHEN WANG,[‡] SUMEET K. ASRANI,[§] RICHARD L. EHMAN,[||] PATRICK S. KAMATH,[*] and JAYANT A. TALWALKAR[*]

This article has an accompanying continuing medical education activity on page e89. Learning Objective—At the end of this activity, the successful learner will be able to summarize the prognostic utility of liver stiffness in predicting risk of clinically relevant, liver-related events in patients with chronic liver disease.

BACKGROUND & AIMS: **Liver stiffness measurement (LSM), using elastography, can independently predict outcomes of patients with chronic liver diseases (CLDs). However, there is much variation in reporting and consistency of findings. We performed a systematic review and meta-analysis to evaluate the association between LSM and outcomes of patients with CLDs.**

METHODS: **We performed a systematic review of the literature, through February 2013, for studies that followed up patients with CLDs prospectively for at least 6 months and reported the association between baseline LSM and subsequent development of decompensated cirrhosis or hepatocellular carcinoma (HCC), as well as mortality. Summary relative risk (RR) estimates per unit of LSM and 95% confidence intervals (CIs) were estimated using the random effects model.**

RESULTS: **Our final analysis included 17 studies, reporting on 7058 patients with CLDs. Baseline LSM was associated significantly with risk of hepatic decompensation (6 studies; RR, 1.07; 95% CI, 1.03–1.11), HCC (9 studies; RR, 1.11; 95% CI, 1.05–1.18), death (5 studies; RR, 1.22; 95% CI, 1.05–1.43), or a composite of these outcomes (7 studies; RR, 1.32; 95% CI, 1.16–1.51). We observed considerable heterogeneity among studies—primarily in the magnitude of effect, rather than the direction of effect. This heterogeneity could not be explained by variations in study locations, etiologies and stages of CLD, techniques to measure liver stiffness, adjustment for covariates, or method of imputing relationship in the meta-analysis.**

CONCLUSIONS: **Based on a meta-analysis of cohort studies, the degree of liver stiffness is associated with risk of decompensated cirrhosis, HCC, and death in patients with CLDs. LSM therefore might be used in risk stratification.**

Keywords: Elastography; Prognosis; Outcomes; Cirrhosis; Cancer.

Cirrhosis is the eighth leading cause of mortality worldwide and is associated with significant morbidity.[1,2] Two distinct stages of cirrhosis with different prognostic implications have been defined: compensated cirrhosis (stage 4 fibrosis with or without esophageal varices) and decompensated cirrhosis (variceal bleeding, hepatic encephalopathy, ascites, spontaneous bacterial peritonitis, and/or hepatorenal syndrome).[3] Most of the morbidity and mortality in patients with cirrhosis is attributable to transitioning to a decompensated state. In addition, the presence of cirrhosis increases the risk of hepatocellular carcinoma (HCC). Liver transplantation (LT) is the only effective treatment modality once these outcomes develop for highly selected candidates. Hence, early recognition of patients with chronic liver disease (CLD) at high risk for developing these outcomes in a noninvasive manner is warranted to allow implementation of optimal preventative management strategies that may modify the natural course of disease.[4]

Unfortunately, objective markers of hepatic synthetic function that accurately predict an individual's risk of transitioning to a decompensated state are lacking.[5] Hepatic venous pressure gradient (HVPG) is a potential prognostic

Abbreviations used in this paper: CI, confidence interval; CLD, chronic liver disease; HCC, hepatocellular carcinoma; HCV, hepatitis C virus; HR, hazard ratio; HVPG, hepatic venous pressure gradient; LSM, liver stiffness measurement; LT, liver transplantation; MELD, model for end-stage liver disease; MRE, magnetic resonance elastography; RR, relative risk; TE, transient elastography.

Aetna considers transient elastography (e.g., FibroScan) medically necessary for distinguishing hepatic cirrhosis from noncirrhosis in persons with hepatitis C or other chronic liver diseases. Performance of transient elastography more than twice per year is considered not medically necessary. Performance of transient elastography within six months following a liver biopsy is considered not medically necessary. Transient elastography is considered experimental and investigational for all other indications.

Aetna considers serum marker tests (e.g., FibroMAX, FibroSpect, FibroTest-ActiTest, HCV-FibroSure, HepaScore, and NASH FibroSure) experimental and investigational for detecting or monitoring hepatic fibrosis in persons with hepatitis C or other chronic liver diseases (e.g., non-alcoholic fatty liver disease) because their effectiveness for these indications has not been established.

Background

Serum Markers of Hepatic Fibrosis:

Biochemical marker combinations are being developed as alternatives to liver biopsy in patients with chronic hepatitis C and other chronic liver diseases, including chronic hepatitis B, alcoholic liver disease, or non-alcoholic steatosis. Non-invasive tests are being developed to replace liver biopsy, and thus avoid the risk of biopsy-related adverse events. Non-invasive tests also have the potential to avoid limitations of liver biopsy, including the risk of sampling errors and inter- and intra-pathologist variability.

The FibroSpect II (Prometheus Laboratories, San Diego, CA) is a non-invasive diagnostic panel to assist in the detection of liver fibrosis. The FibroSpect II uses a combination of components in the fibrogenic cascade, such as hyaluronic acid, TIMP-1 (tissue inhibitor of metalloproteinase), and alpha-2-macroglobulin. The test is intended to differentiate mild fibrosis from more severe disease. The manufacturer's website provides "performance data" on the FibroSpect II Test, but this information is unpublished.

The FibroTest (Biopredictive, Houilles, France) and the ActiTest (Biopredictive, Houilles, France), marketed in the United States as the HCV-FibroSure Test (LabCorp, Burlington, NC), are the most thoroughly studied serum biochemical test for the assessment of fibrosis and necroinflammatory activity, respectively. The HCV-FibroSure Test includes the following five markers, as well as age and gender: alpha2-macroglobulin, haptoglobin, gamma-glutamyl transpeptidase (GGT), total

bilirubin, apolipoprotein A1, plus alanine aminotransferase (ALT). Rossi et al (2003) reported on the results of FibroTest scores of 125 patients with hepatitis C. Of these, 57 had FibroTest scores either less than 0.1 (indicating no fibrosis) or greater than 0.6 (indicating significant fibrosis). Although 33 of the 125 patients had FibroTest scores of less than 0.1 and were therefore deemed unlikely to have fibrosis, 6 (18 %) had significant fibrosis. Conversely, of the 24 patients with scores of greater than 0.6 who were likely to have significant fibrosis, 5 (21 %) had mild fibrosis. The investigators concluded that, "[o]f the 125 patients in the cohort, 57 (46 %) could have avoided liver biopsy"; but discrepant results were recorded in 11 of those 57 (19 %). In other words, discrepancies with the biopsy gold standard were found in one-fifth of patients. There are no prospective clinical outcome studies of the HCV-FibroSure in the management of patients with hepatitis C or other chronic liver diseases.

An National Institutes of Health Consensus Statement on Management of Hepatitis C (NIH, 2002) concluded that liver biopsy is useful in defining baseline abnormalities of liver disease and in enabling patients and healthcare providers to reach a decision regarding antiviral therapy. The NIH Consensus Statement concludes that noninvasive tests are not adequate substitutes for liver biopsy.

Various noninvasive tests of hepatic fibrosis have been examined for monitoring patients with chronic hepatitis C virus (HCV) infection. These include routinely available laboratory tests, such as liver- associated chemistries, platelet count, and prothrombin time, as well as specific serum markers of fibrosis and inflammation not currently widely available or well validated. No single test or panel of serologic markers can provide an accurate assessment of intermediate stages of hepatic fibrosis. Similarly, quantitative tests of liver function and radiologic imaging of the liver are sensitive for diagnosing advanced cirrhosis but are not useful in assessing hepatic fibrosis and early cirrhosis.

In a review on newer markers for hepatocellular carcinoma, Marrero and Lok (2004) stated that there is a scarcity of longitudinal studies evaluating the ability of biomarkers to detect pre-clinical disease. There is an urgent need for novel biomarkers for the detection of early hepatocellular carcinoma.

Suzuki et al (2005) stated that “use of an accurate serum marker for severe hepatic fibrosis may also improve accuracy of non-invasive diagnostic models. Hyaluronic acid, a serum marker for severe hepatic fibrosis, has been reported to have a high diagnostic performance in assessing the severity of hepatic fibrosis in patients with alcoholic liver disease. In this issue, a non-invasive diagnostic model including hyaluronic acid was shown to have excellent performance in excluding the presence of medium to large esophageal varices in severe alcohol abusers. Based on current evidence, the strategy of using a non-invasive diagnostic model together with a serum marker for severe hepatic fibrosis may improve cost-benefit in the prevention of variceal hemorrhage among patients with alcoholic liver disease. The independent verification of such diagnostic models is needed”.

Evidence based guidelines on the management of hepatitis C from the American Association for the Study of Liver Diseases (Strader et al, 2004) stated: "Although liver fibrosis markers are commercially available, they are currently insufficiently accurate to support their routine use. Until sensitive serum markers can be developed that will define all stages of fibrosis and mirror the information derived from liver biopsy, the procedure remains the only means of defining the severity of damage from HCV infection in many patients".

Serum gamma glutamyltransferase (GGT) is elevated in individuals with acute and chronic alcohol toxicity. Serum GGT assay may be useful in evaluating patients when heavy drinking is suspected but the patient denies it (NIAAA, 2005).

Wilson et al (2006) stated that although most HCV infections are acquired by injection drug use, prospective data on the progression of liver fibrosis are sparse. In this study, baseline liver biopsies were obtained on a random sample of 210 out of 1,667 HCV-positive injection drug users (IDUs). Subjects were followed biannually, with a second biopsy offered to those eligible. Paired biopsies were scored 0 to 6 (modified Ishak score), significant fibrosis was defined as score 3 or greater, and

progression of fibrosis was defined as an increase 2 or more units or clinical evidence of end-stage liver disease. Predictive values of blood markers (FibroSure, aspartate aminotransferase-to-platelet-ratio index (APRI) and alanine aminotransferase (ALT)) were assessed for detection of contemporaneous and future liver fibrosis. Among 119 prospectively followed IDUs, 96 % were African American; 97 % HCV genotype 1a/b; 27 % HIV-infected, and median age was 42 years. Most (90.7 %) did not have significant liver fibrosis at first biopsy. Although predictive value for detecting insignificant fibrosis at first biopsy was greater than 95 % for FibroSure, APRI, and ALT, specificities were 88.9 %, 72.7 %, and 72.7 %, respectively. After 4.2 years median follow-up, 21 % had progression of fibrosis, which was significantly associated with serum level of HCV RNA and ALT. No serological test had predictive value greater than 40 % for contemporaneous or future significant fibrosis. Even initial biopsy result had only a 30.4 % value for predicting future significant fibrosis. The authors concluded that significant liver fibrosis and progression were detected in some, but not most, IDUs in this cohort. In this setting with low fibrosis prevalence, FibroSure, ALT, and APRI tests predict insignificant fibrosis; however, further work is needed to find non-invasive markers of significant liver fibrosis.

Nourani and Pockros (2007) noted that biochemical markers are a potentially useful alternative to liver biopsy in patients with chronic hepatitis C aged 65 years and older. Furthermore, Rossi et al (2007) stated that an obstacle to widespread adoption of serum marker models (e.g., FibroSpect) for assessing liver fibrosis has been the lack of uniform performance indicators, such as diagnostic odds ratios and likelihood ratios. At present, serum marker models are not considered sufficiently reliable to replace liver biopsy in patients with chronic liver disease.

Shaheen and Myers (2008) performed a systematic review and meta-analysis of the diagnostic accuracy of fibrosis marker panels in patients with HIV/hepatitis C coinfection. Random effects meta-analyses and areas under summary receiver operating characteristics curves (AUC) examined test accuracy for detecting significant fibrosis (F2 to F4) and cirrhosis. Heterogeneity was explored using meta-regression. Five studies (n = 574) including 4 fibrosis measures (APRI [n = 4 studies], Forns' [n = 2], FibroTest [n = 1], SHASTA [n = 1]) met the inclusion criteria. The prevalence of significant fibrosis and cirrhosis were 51 % and 16 %, respectively. For the prediction of significant fibrosis, the summary AUC was 0.82 (95 % confidence interval [CI]: 0.78 to 86) and diagnostic odds ratio was 7.8 (5.1 to 11.9). For cirrhosis, these figures were 0.83 (0.69 to 0.97) and 11.0 (4.6 to 26.2), respectively. Meta-regression including study factors (methodological quality and biopsy adequacy), patient characteristics (age, gender, CD4 count), and fibrosis measure failed to identify important predictors of accuracy. The authors concluded that available fibrosis marker panels have acceptable performance for identifying significant fibrosis and cirrhosis in HIV/HCV-coinfected patients but are not yet adequate to replace liver biopsy. They noted that additional studies are needed to identify the optimal measure.

Smith and Sterling (2009) reviewed non-invasive measures and their ability to replace biopsy for assessing hepatic fibrosis in patients with chronic HCV. A systematic review of PUBMED and EMBASE was carried out through 2008 using the following search terms: HCV, liver, elastography, hepatitis, Fibroscan, SPECT, non-invasive liver fibrosis, ultrasonography, Doppler, MRI, Fibrotest, Fibrosure, Actitest, APRI, Forns and breath tests, alone or in combination. These investigators identified 151 studies: 87 using biochemical, 57 imaging and 7 breath tests either alone or in combination. The authors concluded that great strides are being made in the development of accurate non-invasive methods for determination of fibrosis. Although no single non-invasive test or model developed to date can match that information obtained from actual histology (i.e., inflammation, fibrosis, steatosis), combinations of 2 modalities of non-invasive methods can reliably differentiate between minimal and significant fibrosis, and thereby avoid liver biopsy in a significant percentage of patients.

Carlson and colleagues (2009) evaluated the clinical and economic outcomes of non-invasive testing strategies in the diagnosis of significant liver fibrosis (Metavir score greater than or equal to 2) compared with liver biopsy. These researchers developed a decision analytic model of non-invasive testing strategies in a hypothetical patient population with genotype 1 hepatitis C virus infection, with no contraindications to liver biopsy. The testing strategies included a testing algorithm using the Fibrosure test, a non-invasive measure of fibrosis, followed by liver biopsy for

patients with indeterminate results, Fibrospect II, and Fibroscan. The primary outcomes were sensitivity, specificity, diagnostic accuracy (true positive + true negatives/total patients), and costs, evaluated from the health-care payer perspective. The testing algorithm using Fibrosure was the most accurate non-invasive strategy with a sensitivity, specificity, and overall accuracy of 84 %, 87 %, and 86 %, respectively. In comparison with liver biopsy alone, there was a cost savings of approximately $770/person with the Fibrosure testing algorithm, but a net decrease in accuracy of 14 %. Fibrospect II and Fibroscan had poorer accuracy (decreases of 12 % and 4 %, respectively) and lower costs (-$138 and -$357, respectively) compared with the Fibrosure algorithm. In uncertainty analyses in which biopsy sampling error was considered, the Fibrosure algorithm remained consistently less accurate (5 to 14 % decrease). The authors concluded that the results of this study suggested that compared with liver biopsy, non-invasive testing algorithms can result in short-term cost savings, but the consequences of misdiagnosis in terms of health outcomes and treatment costs might out-weigh the short-term gains in cost and convenience.

Adams (2011) stated that fibrosis prediction is an essential part of the management of patients with chronic liver disease. Serum biomarkers offer a number of advantages over the traditional standard of fibrosis assessment of liver biopsy, including safety, cost-savings and wide spread accessibility. Current biomarker algorithms include indirect surrogate measures of fibrosis, including aminotransaminases and platelet count, or direct measures of fibrinogenesis or fibrinolysis such as hyaluronic acid and tissue inhibitor of metalloproteinase-1. A number of algorithms have now been validated across a range of chronic liver disease including chronic viral hepatitis, alcoholic and non-alcoholic fatty liver disease. Furthermore, several models have been demonstrated to be dynamic to changes in fibrosis over time and are predictive of liver-related survival and overall survival to a greater degree than liver biopsy. Current limitations of biomarker models include a significant indeterminate range, and a predictive ability that is limited to only a few stages of fibrosis. Utilization of these biomarker models requires knowledge of patient co-morbidities which may produce false positive or negative results in a small proportion of individuals. Furthermore, knowledge of the underlying prevalence of fibrosis in the patient population is required for interpretation of the positive or negative predictive values of a test result. Novel proteins identified by proteomic technology and genetic polymorphisms from genome association studies offer the possibility for further refinement and individualization of biomarker fibrosis models in the future.

Sebastiani and associates (2011) examined the effect of etiology and stages of hepatic fibrosis on the performance of fibrosis biomarkers. A total of 2,411 patients with compensated chronic liver disease (CLD) (hepatitis C virus [HCV] = 75.1 %, hepatitis B virus [HBV] = 10.5 %, non-alcoholic steato-hepatitis [NASH] = 7.9 %, HIV/HCV = 6.5 %) were consecutively enrolled in 9 centers. APRI, Forns'index, Lok index, AST-to-ALT ratio, Fib-4, platelets and Fibrotest-Fibrosure were tested against liver biopsy, considered the gold standard. The effect of the stages of hepatic fibrosis to diagnose significant fibrosis and cirrhosis (greater than or equal to F2 and F4, respectively) was investigated through difference between advanced and non-advanced fibrosis stages (DANA). Performance was expressed as observed area under the ROC curve (ObAUROC) and AUROC adjusted for DANA (AdjAUROC). Performance of APRI and Fibrotest-Fibrosure was higher than other biomarkers. In all etiologies, AdjAUROC was higher than ObAUROC. APRI showed its best performance in HCV mono-infected cases, with an AdjAUROC of 0.77 and 0.83 for greater than or equal to F2 and F4, respectively. In HBV and NASH patients, its performance was poor (AdjAUROC < 0.70). Performance of Fibrotest-Fibrosure was good in all etiologies for both greater than or equal to F2 and F4 (AdjAUROC > 0.73), except for greater than or equal to F2 in NASH (AdjAUROC = 0.64). Performance of all biomarkers was reduced in HCV cases with normal ALT. The authors concluded that etiology is a major factor influencing the performance of liver fibrosis biomarkers. Even after correction for DANA, APRI and Fibrotest-Fibrosure exhibit the best performance. However, liver biopsy is not replaceable, especially to diagnose greater than or equal to F2 and in HCV carriers with normal ALT.

Adams et al (2005) stated that staging hepatic fibrosis by liver biopsy guides prognosis and treatment of hepatitis C, but is invasive and expensive. These researchers sought to create an algorithm of serum markers that accurately and reliably predict liver fibrosis stage among hepatitis C patients. A total of 10 biochemical markers were measured at time of liver biopsy in 117 untreated hepatitis C patients (training set). Multi-variate logistic regression and receiver-operating

characteristic (ROC) curve analyses were used to create a predictive model for significant fibrosis (METAVIR F2, F3, and F4), advanced fibrosis (F3 and F4), and cirrhosis (F4). The model was validated in 104 patients from other institutions. A model (HepaScore) of bilirubin, gamma-glutamyltransferase, hyaluronic acid (HA), alpha(2)-macroglobulin, age, and sex produced areas under the ROC curves (AUCs) of 0.85, 0.96, and 0.94 for significant fibrosis, advanced fibrosis, and cirrhosis, respectively. In the training set, a score greater than or equal to 0.5 (range of 0.0 to 1.0) was 92 % specific and 67 % sensitive for significant fibrosis, a score of less than 0.5 was 81 % specific and 95 % sensitive for advanced fibrosis, and a score of less than 0.84 was 84 % specific and 71 % sensitive for cirrhosis. Among the validation set, the AUC for significant fibrosis, advanced fibrosis, and cirrhosis were 0.82, 0.90, and 0.89, respectively. A score greater than or equal to 0.5 provided a specificity and sensitivity of 89 % and 63 % for significant fibrosis, whereas scores less than 0.5 had 74 % specificity and 88 % sensitivity for advanced fibrosis, respectively. The authors concluded that a model of 4 serum markers plus age and sex provides clinically useful information regarding different fibrosis stages among hepatitis C patients.

Stevenson et al (2012) evaluated the diagnostic accuracy, cost-effectiveness, and effect on patient outcomes of 4 non-invasive tests for liver fibrosis [the Enhanced Liver Fibrosis (ELF) test (Siemens Healthcare Diagnostic Inc., Tarrytown, NY), FibroTest (BioPredictive, Paris, France), FibroMAX (BioPredictive, Paris, France) and transient elastography (FibroScan; produced by EchoSens, Paris, France and distributed in the United Kingdom. by Artemis Medical Ltd, Kent, UK)] in patients suspected of having ALD. A systematic review was undertaken to identify studies reporting the diagnostic and prognostic accuracy of the ELF test, FibroTest, FibroMAX, and FibroScan for the identification of liver fibrosis and associated conditions in patients with suspected ALD. The following databases were searched in January 2010: MEDLINE (from 1950 to January 2010), MEDLINE In-Process & Other Non-Indexed Citations (from 1950 to January 2010), EMBASE (from 1980 to January 2010), Cochrane Database of Systematic Reviews (from 1996 to January 2010), Cochrane Central Register of Controlled Trials (from 1898 to January 2010), Cochrane Methodology Register (from 1904 to January 2010), Database of Abstracts of Reviews of Effects (from 1995 to January 2010), HTA Database (from 1995 to January 2010), NHS Economic Evaluation Database (from 1995 to January 2010), Cumulative Index to Nursing and Allied Health Literature (from 1982 to January 2010), Web of Knowledge and Science Citation Index (from 1969 to January 2010). Study quality was assessed using the QUADAS (Quality Assessment of Diagnostic Accuracy Studies) checklist. Owing to the heterogeneity of the studies, no formal meta-analysis was undertaken. A de novo mathematical model was constructed to estimate the incremental costs and incremental quality-adjusted life-years (QALYs) associated with alternative strategies compared with a biopsy-all strategy. The tests were assessed first as a replacement for liver biopsy, and secondly as an additional test prior to liver biopsy. A total of 36 scenarios were assessed for each non-invasive test strategy, which varied the sensitivity of biopsy, the anxiety associated with biopsy, sensitivity and specificity values and whether or not the biopsy was percutaneous or transjugular. For each scenario, threshold levels were reported where biopsying all patients was more cost-effective than the strategy for 2 parameters (the decreased level of abstinence associated with the strategy compared with biopsying all and the level of incidental QALY gain associated with biopsy). No studies were identified that specifically assessed the ELF test, although a study was identified that evaluated the diagnostic accuracy of the European Liver Fibrosis Test (essentially, the ELF test with the addition of age to the algorithm) compared with biopsy. Three studies of FibroTest, no relevant studies of FibroMAX, and 6 studies of FibroScan assessing accuracy compared with biopsy in patients with known or suspected alcohol-related liver disease were identified. In all studies, the number of patients with suspected ALD was small, meaning that the estimated sensitivities and specificities were not robust. No conclusive estimate of the cost per QALY of each non-invasive test could be provided. Scenarios exist in which each of the strategies analyzed is more cost-effective than biopsying all patients and, in contrast, scenarios exist in which each strategy is less cost-effective than biopsying all patients. The authors concluded that no conclusive result can be provided on the most cost-effective strategy until further data are available. A large number of parameters require data; however, the following were selected as being of most importance: (i) the sensitivity and specificity of each non-invasive liver test (NILT) against biopsy at validated and pre-selected cut-off thresholds; (ii) the influence of potential confounding variables such as current drinking behavior and the degree of hepatic

inflammation on the performance of NILTs; and (iii) the likelihood, and magnitude, of decreases in abstinence rates associated with a diagnosis of significant ALD by diagnostic modality and the incidental gains in QALYs that may be associated with biopsy.

Sebastiani and Alberti (2012) chronic hepatitis C represents a major cause of progressive liver disease that can eventually evolve into cirrhosis and its end-stage complications. Formation and accumulation of fibrosis in the liver is the common pathway that leads to evolutive liver disease. Precise staging of liver fibrosis is essential for patient management in clinical practice because the presence of bridging fibrosis represents a strong indication for anti-viral therapy, while cirrhosis requires a specific follow-up. Liver biopsy has always represented the standard of reference for assessment of hepatic fibrosis, but it has limitations: it is invasive, costly and prone to sampling errors. Recently, blood markers and instrumental methods have been proposed for the non-invasive assessment of liver fibrosis in hepatitis C. However, international guidelines do not recommend the widespread use of non-invasive methods for liver fibrosis in clinical practice. This is because of, in some cases, unsatisfactory accuracy and incomplete validation of others. Some studies suggested that the effectiveness of non-invasive methods for assessing liver fibrosis may increase when they are combined, and a number of sequential and synchronous algorithms have been proposed for this purpose, with the aim of reducing rather than substituting liver biopsies. This may represent a rational and reliable approach for implementing noninvasive assessment of liver fibrosis in clinical practice. It could allow more comprehensive first-line screening of liver fibrosis in hepatitis C than would be feasible with liver biopsy alone.

Usluer et al (2012) compared the results of 9 non-invasive serum biomarkers with liver biopsies to predict liver fibrosis stage. HCV-RNA-positive, HCV genotype 1, treatment-naive patients with chronic HCV infections were included from 14 centers (n = 77). The platelet count, AST/ALT ratio (AAR), cirrhosis discriminate score (CDS), FIB4, APRI, age-platelet (AP) index, Goteborg University cirrhosis index (GUCI), FibroTest, and ActiTest were calculated and compared to histologic findings. All serum biomarkers, except AAR, were weakly or moderately correlated with liver biopsy results (ISHAK fibrosis score). The mean scores of FibroTest, FIB4, APRI, and AP index were significantly different between F0-F2 and F3-F4 groups and the NPVs of the F3-F4 group were 95 %, 85 %, 85 %, and 8 3%, respectively, for these serum biomarkers. The authors concluded that these findings suggested that serum biomarkers may help to diagnose significant fibrosis but inadequate to detect fibrosis in early stages.

Bhogal and Sterling (2012) noted that several blood tests, algorithms, and imaging tests have been studied as non-invasive markers to stage fibrosis in hepatitis C. In patients without suspicion for cirrhosis, 2 non-invasive methods can be used to predict presence of absence of significant liver fibrosis; however, liver biopsy remains the gold standard.

Chladek et al (2012) compared the results of serial measurements of serum fibrosis markers during the remission-induction phase of treatment with methotrexate (MTX) to those of patients on biological therapy and long-term MTX therapy (greater than 2 years). Serum concentrations of HA, N-terminal propeptide of collagen type III (PIIINP) and the results of 2 multi-test algorithms FibroTest and HepaScore were evaluated in patients with chronic plaque psoriasis (n = 24, age: 28 to 79 years, baseline Psoriasis Area Severity Index [PASI] 13.5, range of 2.2 to 33) at baseline and weeks 16 and 26 after the start of pharmacokinetically-guided therapy with MTX (Group A). Patients on established therapy with biologics (n = 15, Group B) and long-term MTX users (n = 10, Group C) with the mean baseline PASI scores of 0.9 and 1.2 were studied in parallel cohorts. At baseline, HA, HepaScore and PIIINP were correlated with PASI of Group A patients. At weeks 16 and 26, HA decreased by 48 % and 40 % ($p < 0.001$) and HepaScore by 31 ($p < 0.01$) and 20 % ($p < 0.05$) respectively. PASI75 (greater than or equal to 75 % improvement from baseline PASI) was observed in 76 % of Group A patients by week 26 and the absolute decreases in PASI and both fibrosis markers were correlated (HA: $r = 0.49$, $p = 0.018$, HepaScore: $r = 0.47$, $p = 0.022$). In contrast, no significant within-group differences were found in HA and HepaScore results of patients in the groups B and C. PIIINP and FibroTest were stable in all groups. The authors concluded that the fibrosis markers HA and HepaScore (the multiple test algorithm that includes HA) are less liver specific and more prone to reflect psoriasis activity than PIIINP and FibroTest.

Chou and Wasson (2013) stated that many blood tests have been proposed as alternatives to liver biopsy for identifying fibrosis or cirrhosis. These investigators evaluated the diagnostic accuracy of blood tests to identify fibrosis or cirrhosis in patients with HCV infection. Data sources included MEDLINE (1947 to January 2013), the Cochrane Library, and reference lists. Studies that compared the diagnostic accuracy of blood tests with that of liver biopsy were selected. Investigators abstracted and checked study details and quality by using pre-defined criteria. A total of 172 studies evaluated diagnostic accuracy. For identifying clinically significant fibrosis, the platelet count, age-platelet index, APRI, FibroIndex, FibroTest, and Forns index had median positive likelihood ratios of 5 to 10 at commonly used cut-offs and areas under the ROC curve (AUROCs) of 0.70 or greater (range of 0.71 to 0.86). For identifying cirrhosis, the platelet count, age-platelet index, APRI, and HepaScore had median positive likelihood ratios of 5 to 10 and AUROCs of 0.80 or greater (range of 0.80 to 0.91). The GUCI and the Lok index had slightly lower positive likelihood ratios (4.8 and 4.4, respectively). In direct comparisons, the APRI was associated with a slightly lower AUROC than the FibroTest for identifying fibrosis and a substantially higher AUROC than the aspartate aminotransferase-alanine aminotransferase ratio for identifying fibrosis or cirrhosis. The authors concluded that many blood tests are moderately useful for identifying clinically significant fibrosis or cirrhosis in HCV-infected patients. Drawbacks of this study included only English-language articles were included, and most studies had methodological limitations, including failure to describe blinded interpretation of liver biopsy specimens and inadequate description of enrollment methods.

Rossi et al (2013) noted that serum HA and biochemical models that require HA analysis are commonly used as predictors of liver fibrosis in patients with chronic liver disease, however biological variation data for HA are deficient. Four serial serum samples were obtained at weekly intervals from healthy volunteers and patients with chronic hepatitis B, chronic hepatitis C and NAFLD (20 in each group). The within-individual week-to-week variation (CVI) and reference change values for HA, αâ,,-macroglobulin and HepaScore were obtained. HepaScore was calculated from HA, α2-macroglobulin, bilirubin and γ-glutamyltransferase activity. Hyaluronic acid displayed large within-individual variation, the CVI values were 62 % in healthy subjects, 38 % in hepatitis C, 37 % in hepatitis B, and 36 % in NAFLD patients. HepaScore CVIs were 43 % in healthy subjects, 24 % in hepatitis C, 28 % in hepatitis B, and 39 % in NAFLD patients. Moreover, αâ,,-Macroglobulin was much less variable with CVIs ranging from 4.4 % to 7.6 %. Bland-Altman plots of week-to-week variations showed rates of significant disagreement for samples collected in any 2 successive weeks varied from 5 % in NAFLD patients to 8.3 % in healthy subjects. The authors concluded that when using non-fasting serum samples, HA and to a lesser extent, the HepaScore model displayed large within-individual variations in both health and chronic liver disease. This information is critical for interpreting the significance of both single measurements and changes in serial measurements.

Grattagliano et al (2013) stated that the diagnostic utilities of ultrasonography (US), fatty liver index (FLI) and an algorithm of 9 serum markers (FibroMAX) were evaluated in family practice to non-invasively characterize patients with NAFLD. A multi-center study was conducted by enrolling 259 consecutively observed patients (age of 51 +/- 10 years) with clinical and ultrasonographic features of NAFLD. Patients had mild (16.2 %), moderate (69.9 %), or severe (13.9 %) liver steatosis and 60.2 % had hyper-transaminasemia. The percent of patients with overweight, obesity, diabetes, hypertension, and dyslipidemia were 42.7 %, 46.5 % (4.2 % severe obesity), 24.7 %, 40.9 %, and 56.4 %, respectively. Lean patients (10.8 %) had normal transaminases in 2/3 of the cases. A multi-variate logistic regression (including age greater than 50 years, BMI greater than 30 kg/m2, homeostasis model assessment [HOMA] greater than 3, and hyper-transaminasemia) identified 12.3 % of patients at risk for steatohepatitis. With a sensitivity of 50 % and specificity of 94.7 %, FibroMAX identified 34 patients (13.1 %) with likely advanced fibrosis and found that over 28 % of patients with moderate (ultrasonographic) steatosis were likely to be carrying severe steatosis. Steatotest score was significantly associated with BMI, waist circumference, ALT, triglycerides, and FLI. FibroTest correlated only with ALT. Fatty liver index identified 73.4 % of patients as likely to be carrying a fatty liver. The authors concluded that NAFLD should be systematically searched and characterized in all patients with metabolic disturbances and cardiovascular risk. Asymptomatic subjects at risk also should be screened for NAFLD. They stated that FibroMAX is

a promising non-invasive diagnostic tool in family medicine for identifying patients at risk for NAFLD who require targeted follow-up.

Furthermore, an UpToDate review on "Tests used for the noninvasive assessment of hepatic fibrosis" (Curry and Afdhal, 2013) states that "While tremendous progress has been made in improving the accuracy of serum markers of hepatic fibrosis, they cannot yet supplant direct analysis of the liver. The ideal fibrosis marker is one that is specific, biologically based, noninvasive, easily repeated in all patients, correlates well with disease severity and outcome, and is not confounded by co-morbidities or drugs. Although this ideal has nearly been reached, no serum test has emerged as the perfect marker of fibrosis; all the serum tests have limitations …. Overall, the serum assay approaches remain promising, in part because these tests may represent an integrated readout of liver activity, rather than a minute sampling of the type obtained by conventional liver biopsy".

Transient Elastography:

Transient elastography (FibroScan) is a rapid, non-invasive, bedside method to evaluate liver fibrosis by measuring liver stiffness. This device is based on 1-dimensional transient elastography, a technique that uses both ultrasound (5 MHz) and low-frequency (50 Hz) elastic waves, whose propagation velocity is directly related to elasticity. In cirrhotic patients, liver stiffness measurements range from 12.5 to 75.5 kPa (kPa). However, the clinical relevance of these values is unknown.

In a prospective study, de Ledinghen et al (2006) evaluated the accuracy of liver stiffness measurement for the detection of fibrosis and cirrhosis in HIV/hepatitis C virus (HCV)-coinfected patients and compared its accuracy with other non-invasive methods. These researchers studied 72 consecutive HIV patients with chronic hepatitis C who had a simultaneous liver biopsy and liver stiffness measurement by transient elastography (FibroScan; Echosens, Paris, France) for the assessment of liver fibrosis. Liver stiffness values ranged from 3.0 to 46.4 kPa. Liver stiffness was significantly correlated to fibrosis stage (Kendall tau-b = 0.48; $p < 0.0001$). The area under the receiver operating characteristic (AUROC) curve of liver stiffness measurement was 0.72 for F > or = 2 and 0.97 for F = 4. For the diagnosis of cirrhosis, AUROC curves of liver stiffness measurement were significantly higher than those for platelet count ($p = 0.02$), aspartate aminotransferase/ALT ratio ($p = 0.0001$), Aspartate aminotransferase-to-Platelet Ratio Index ($p = 0.01$), and FIB-4 ($p = 0.004$). The authors concluded that liver stiffness measurement is a promising noninvasive method for the assessment of fibrosis in HIV-infected patients with chronic HCV infection. They also noted that its use for the follow-up of these patients should be further evaluated.

Foucher and colleagues (2006) assessed the accuracy of FibroScan for the detection of cirrhosis in patients with chronic liver disease. A total of 711 patients with chronic liver disease were studied. Etiologies of chronic liver diseases were hepatitis C virus or hepatitis B virus infection, alcohol, non-alcoholic steatohepatitis, other, or a combination of the above etiologies. Liver fibrosis was evaluated according to the METAVIR score. Stiffness was significantly correlated with fibrosis stage ($r = 0.73$, $p < 0.0001$). Areas under the receiver operating characteristic curve (95 % CI) were 0.80 (0.75 to 0.84) for patients with significant fibrosis (F > 2), 0.90 (0.86 to 0.93) for patients with severe fibrosis (F3), and 0.96 (0.94 to 0.98) for patients with cirrhosis. Using a cut off value of 17.6 kPa, patients with cirrhosis were detected with a positive predictive value and a negative predictive value (NPV) of 90 %. Liver stiffness was significantly correlated with clinical, biological, and morphological parameters of liver disease. With an NPV greater than 90 %, the cut off values for the presence of esophageal varices stage 2/3, cirrhosis Child-Pugh B or C, past history of ascites, hepatocellular carcinoma, and esophageal bleeding were 27.5, 37.5, 49.1, 53.7, and 62.7 kPa, respectively. The authors concluded that FibroScan is a promising non-invasive method for detection of cirrhosis in patients with chronic liver disease. They noted that its use for the follow-up and management of these patients could be of great interest and should be evaluated further.

Corpechot and associates (2006) assessed the diagnostic performance of liver stiffness measurement

(LSM) for the determination of fibrosis stage in chronic cholestatic diseases. A total of 101 patients with primary biliary cirrhosis (PBC, n = 73) or primary sclerosing cholangitis (PSC, n = 28) were prospectively enrolled in a multi-center study. All patients underwent liver biopsy (LB) and LSM. Histological and fibrosis stages were assessed on LB by two pathologists. LSM was performed by FibroScan. Efficiency of LSM for the determination of histological and fibrosis stages were determined by a ROC curve analysis. Analysis failed in 6 patients (5.9 %) because of unsuitable LB (n = 4) or LSM (n = 2). Stiffness values ranged from 2.8 to 69.1 kPa (median of 7.8 kPa). LSM was correlated to both fibrosis (Spearman's rho = 0.84, p < .0001) and histological (0.79, p < .0001) stages. These correlations were still found when PBC and PSC patients were analyzed separately. Areas under ROC curves were 0.92 for fibrosis stage (F) > or = 2, 0.95 for F > or = 3 and 0.96 for F = 4. Optimal stiffness cutoff values of 7.3, 9.8, and 17.3 kPa showed F > or = 2, F > or = 3 and F = 4, respectively. LSM and serum hyaluronic acid level were independent parameters associated with extensive fibrosis on LB. The authors concluded that FibroScan is a simple and reliable non-invasive means for assessing biliary fibrosis. They stated that it should be a promising tool to assess anti-fibrotic therapies in PBC or PSC.

The Canadian Agency for Drugs and Technologies in Health (CADTH) performed an evaluation on FibroScan for non-invasive assessment of liver fibrosis (Murtagh and Foster, 2006). It stated that the diagnostic performance of FibroScan is good for identifying severe fibrosis or cirrhosis, but it is less accurate for milder presentations. It concluded that FibroScan is a promising technology, but large multi-center studies comparing a range of emerging non-invasive fibrosis staging technologies are needed. An earlier assessment by the French Committee for Evaluation and Diffusion of Innovative Technologies (CEDIT, 2004) reached similar conclusions, stating that the absence of conclusive evidence concerning the diagnostic value of FibroScan argues against its immediate dissemination. More recently, an assessment by the French National Authority for Health (HAS, 2007) concluded that additional studies are necessary to evaluate the comparative cost-effectiveness of different methods of assessing liver fibrosis (e.g., FibroTest, FibroScan, and biopsy). A technology assessment by the Malasian Ministry of Health (Darus, 2008) reached similar conclusions about the need for additional research for the Fibroscan.

de Franchis et al (2007) stated that transient elastography (Fibroscan) might be of value for the non-invasive diagnosis of cirrhosis; however, its reproducibility needs to be further validated. Furthermore, Berrutti et al (2007) noted that FibroScan is a new, non-invasive method to evaluate liver stiffness and, consequently, the degree of liver fibrosis. Since its use in the clinical setting is of great interest, further studies should define the exact role of this procedure.

de Lédinghen et al (2007) assessed the feasibility of liver stiffness measurement and compared FibroScan, FibroTest, and APRI with liver biopsy for the diagnosis of cirrhosis in children with chronic liver diseases. A total of 116 consecutive children with chronic liver diseases were prospectively included. All except 1 child (58 boys, mean age of 10.7 years) could have non-invasive tests for fibrosis: FibroScan, FibroTest, and APRI, and, when necessary, a liver biopsy (n = 33). FibroScan, FibroTest, and APRI were correlated with clinical or biological parameters of chronic liver diseases, but the FibroScan marker correlated most with all parameters. By histology, the METAVIR fibrosis category score was F1 in 7 cases, F2 in 8 cases, F3 in 6 cases, and F4 in 12 cases. FibroScan, FibroTest, and APRI were significantly correlated with the METAVIR fibrosis score. For the diagnosis of cirrhosis, AUC was 0.88, 0.73, and 0.73 for FibroScan, FibroTest, and APRI, respectively. The authors concluded that these findings indicated that liver stiffness measurement is feasible in children and is related to liver fibrosis. A specific probe dedicated to children and slender patients has thus been developed and is currently under evaluation. The FibroScan equipped with this specific probe could become a useful tool for the management of chronic liver diseases in children.

Shaheen et al (2007) stated that the accurate diagnosis of HCV-related fibrosis is crucial for prognostication and treatment decisions. Due to the limitations of biopsy, non-invasive alternatives including FibroTest and FibroScan have beenn developed. These investigators systematically reviewed studies describing the accuracy of these tests for predicting HCV-related fibrosis. Studies comparing FibroTest or FibroScan versus biopsy in HCV patients were identified via an electronic search. Random effects meta-analyses and AUC were examined to characterize test accuracy for

significant fibrosis (F2 to F4) and cirrhosis. Heterogeneity was explored using meta-regression. A total of 12 studies were identified, 9 for FibroTest (n = 1,679) and 4 for FibroScan (n = 546). In heterogeneous analyses for significant fibrosis, the AUCs for FibroTest and FibroScan were 0.81 (95 % confidence interval [CI] 0.78 to 84) and 0.83 (0.03 to 1.00), respectively. At a threshold of approximately 0.60, the sensitivity and specificity of the FibroTest were 47 % (35 % to 59 %) and 90 % (87 % to 92%). For FibroScan (threshold approximately 8 kPa), corresponding values were 64 % (50 % to 76 %) and 87 % (80 % to 91 %), respectively. Methodological quality, the length of liver biopsy specimens, and inclusion of special populations did not explain the observed heterogeneity. However, the diagnostic accuracy of both measures was associated with the prevalence of significant fibrosis and cirrhosis in the study populations. For cirrhosis, the summary AUCs for FibroTest and FibroScan were 0.90 (95 % CI not calculable) and 0.95 (0.87 to 0.99), respectively. The authors concluded that FibroTest and FibroScan have excellent utility for the identification of HCV-related cirrhosis, but lesser accuracy for earlier stages. They noted that refinements are necessary before these tests can replace liver biopsy.

Sagir et al (2008) noted that transient elastography (also known as FibroScan) is a rapid, non-invasive, and reproducible method for measuring liver stiffness, which correlates with the degree of liver fibrosis in patients with chronic hepatitis. However, whether FibroScan is useful in the detection of pre-existing liver fibrosis/cirrhosis in patients presenting with acute liver damage is unclear. In this study, patients with acute liver damage of different etiologies were analyzed. Liver stiffness was measured during the acute phase of the liver damage and followed-up to the end of the acute phase. A total of 20 patients were included in the study. In 15 of the 20 patients, initial liver stiffness values measured by FibroScan during the acute phase of the liver damage were suggestive of liver cirrhosis. However, none of these 15 patients showed any signs of liver cirrhosis in the physical examination, ultrasound examination, or liver histology [performed in 11 of 15 (73 %) patients]. A significant difference was observed in the initial bilirubin levels (5.8 +/- 6.5 mg/dL versus 15.7 +/- 11.8 mg/dL; p = 0.042) and age (32.4 +/- 17.5 years versus 49.7 +/- 15.8 years; p = 0.042) between patients with liver stiffness below or above 12.5 kPa. Six patients with initially high liver stiffness were followed-up to abatement of the acute hepatitic phase; in all of them, liver stiffness values decreased to values below the cut-off value for liver cirrhosis. The authors concluded that transient elastography frequently yields pathologically high values in patients with acute liver damage and is unsuitable for detecting cirrhosis/fibrosis in these patients.

Han and Yoon (2008) stated that although liver biopsy is still the gold standard for assessing hepatic fibrosis, it has some technical limitations and risks. Furthermore, the dynamic process of liver fibrosis resulting from progression and regression can not be quantified by liver biopsy. Thus, alternative, simple, reliable and non-invasive tests are needed to assess the stage of fibrosis. Several non-invasive direct and indirect serum markers able to predict the presence of significant fibrosis or cirrhosis in patients with chronic liver disease with considerable accuracy have been reported. However, since most of these markers require complicated calculations, clinical application is difficult. Transient elastography (FibroScan) is a new method for the evaluation of liver stiffness. It is based on changes in tissue elasticity induced by hepatic fibrosis. The authors noted that based on accumulating clinical data, clinical applications of elastography will increase in the near future.

Sporea and colleagues (2008) stated that evaluation of liver fibrosis can be performed by FibroTest, elastography (FibroScan), and by LB, which is considered to be the "gold standard". At the present, there are 3 techniques for performing LB: percutaneous, transjugular, and laparoscopic. The percutaneous LB can be performed blind, ultrasound (US)-guided or US-assisted. There 2 two main categories of specialists who perform LB: gastroenterologists (hepatologists) and radiologists, and the specialty of the individual who performs the LB determines if the LB is performed under ultrasound guidance or not. There are 2 types of biopsy needles used for LB: cutting needles (Tru-Cut, Vim-Silverman) and suction needles (Menghini, Klatzkin, Jamshidi). The rate of major complications after percutaneous LB ranges from 0.09 % to 2.3 %, but the echo-guided percutaneous liver biopsy is a safe method for the diagnosis of chronic diffuse hepatitis (cost-effective as compared to blind biopsy) and the rate of complications seems to be related to the experience of the physician and the type of the needle used (Menghini type needle seems to be safer). The authors stated that maybe in a few years non-invasive markers of fibrosis will be used,

but at this time, most authorities in the field consider LB to be useful and necessary for the evaluation of chronic hepatopathies, despite the fact that it is not a perfect test.

Castera and associates (2008) stated that transient elastography (TE, FibroScan) is a novel non-invasive method that has been proposed for the assessment of hepatic fibrosis in patients with chronic liver diseases, by measuring liver stiffness. It is a rapid and user-friendly technique that can be easily performed at the bedside or in the outpatient clinic with immediate results and good reproducibility. Limitations include failure in approximately 5 % of cases, mainly in obese patients. So far, TE has been mostly validated in chronic hepatitis C, with diagnostic performance equivalent to that of serum markers for the diagnosis of significant fibrosis. Combining TE with serum markers increases diagnostic accuracy and as a result, LB could be avoided for initial assessment in most patients with chronic hepatitis C. These investigators stated that this strategy warrants further evaluation in other etiological types of chronic liver diseases. Transient elastography appears to be an excellent tool for early detection of cirrhosis and may have prognostic value in this setting. As TE has excellent patient acceptance it could be useful for monitoring fibrosis progression and regression in the individual case, but more data are awaited for this application. Guidelines are needed for the use of TE in clinical practice.

In a meta-analysis, Friedrich-Rust et al (2008) examined the performance of TE for the staging of liver fibrosis. Literature data bases and international conference abstracts were searched. Inclusion criteria were as follows: evaluation of TE, LB as reference, and assessment of the area under the receiver operating characteristic curve (AUROC). The meta-analysis was performed using the random-effects model for the AUROC, summary receiver operating curve techniques, as well as meta-regression approaches. A total of 50 studies were included in the analysis. The mean AUROC for the diagnosis of significant fibrosis, severe fibrosis, and cirrhosis were 0.84 (95 % CI: 0.82 to 0.86), 0.89 (95 % CI: 0.88 to 0.91), and 0.94 (95 % CI: 0.93 to 0.95), respectively. For the diagnosis of significant fibrosis a significant reduction of heterogeneity of the AUROC was found when differentiating between the underlying liver diseases ($p < 0.001$). Other factors influencing the AUROC were the scoring system used and the country in which the study was performed. Age, body mass index, and biopsy quality did not have a significant effect on the AUROC. The authors concluded that TE can be performed with excellent diagnostic accuracy and independent of the underlying liver disease for the diagnosis of cirrhosis. However, for the diagnosis of significant fibrosis, a high variation of the AUROC was found that is dependent on the underlying liver disease. A critique of this meta-analysis by the Centre for Reviews and Dissemination (CRD, 2010) stated that, although sensitivity and specificity data appeared to have been available for many of the studies included in this meta-analysis, the meta-analysis focused on pooled estimates of AUROC. The CRD noted that use of this measure of overall accuracy results in a loss of clinically important information about test performance; it was unclear how many inaccurate test results were due to false positive and how many to false negatives. The CRD critique stated that generation of summary receiver operating characteristic (SROC) curves using a bivariate of hierarchical model may have been more appropriate to this data set; the CRD noted that such models allow generation of summary estimates of sensitivity and specificity as well as potential to assess the significance of sources of heterogeneity. The CRD concluded that these limitations in the analysis mean that the conclusions of this meta-analysis should be interpreted with caution.

Abenavoli et al (2008) noted that in clinical practice there are currently 3 methods for the evaluation of liver fibrosis. First, LB is still considered as the "gold standard" method. Second, serological markers and their mathematical combination were suggested in the last years as an alternative to LB. Third, TE was proposed recently. This technique (TE) is based on the progression speed of an elastic shear wave within the liver. The authors concluded that currently, there are just a few studies capable of evaluating the effectiveness of TE in evaluating chronic liver diseases, mainly in patients infected with HCV. Its application must also be studied in the monitoring of patients suffering from chronic HCV infection and subjected to treatments that can modify their degree of liver fibrosis.

Muñoz et al (2009) evaluated the correlation between values of Fibroscan, liver biopsy, and clinical data among HCV-positive renal transplant patients. A total of 24 HCV/RNA-positive patients with a previous liver biopsy were selected to undergo Fibroscan (transient elastography) and a clinical

evaluation of liver function. Fibroscan values were expressed in kilopascals (kPa). As 2 patients were eliminated due to obesity or ascites, these investigators analyzed 22 patients. Thirteen patients (59 %) with fibrosis F0-F1 (METAVIR score) by biopsy and normal liver function showed a mean Fibroscan score of 5.2 kPa (range of 2.3 to 6.8 kPa). Three patients (13.6 %) exhibited F2 by biopsy and normal liver function with a mean Fibroscan score of 8.2 kPa (range of 7.3 to 8.9 kPa). Three patients (13.6 %) with F3 by biopsy and abnormal liver function showed a high mean Fibroscan score of 10.9 kPa (range of 10.5 to 11.6 kPa). The last 3 patients (13.6 %) with F4 (cirrhosis) by biopsy and abnormal clinical data showed the highest mean Fibroscan value of 14.2 kPa (range of 8.9 to 18 kPa). The authors concluded that among renal transplant patients with HCV, the values of Fibroscan seem to correlate with the degree of fibrosis by biopsy and with clinical liver function. Thus, Fibroscan may be useful to follow patients with LD. However, these results should be analyzed with caution due to the small number of cases and retrospective nature of the study.

Andersen and colleagues (2009) stated that liver biopsy is considered the "golden standard" for assessment of hepatic fibrosis. However, the procedure has limitations because of inconvenience and rare but serious complications as bleeding. Furthermore, sampling errors are frequent, and inter-observer variability often poses problems. Recently, transient elastography has been developed to assess fibrosis. The device measures liver elasticity, which correlates well with the degree of fibrosis. Studies have shown that transient elastography is more accurate in diagnosing cirrhosis than minor-to-moderate fibrosis. Most of the studies have been conducted on patients with chronic hepatitis but a few studies have also covered fibrosis and cirrhosis due to other etiologies, and they also demonstrated the high sensitivity and specificity. The authors concluded that transient elastography for assessment of fibrosis may turn out to be a valuable diagnostic procedure and follow-up of patients with chronic liver diseases.

Breton et al (2009) examined the feasibility and reliability of liver stiffness measurement in children with liver diseases. Liver stiffness measurements were performed on 72 children, from 4 to 18 years of age, with potential hepatic fibrosis disease. The clinical, biological, ultrasonographic, and endoscopic parameters were noted to identify children with portal hypertension syndrome. The APRI (ASAT-to-platelet ratio index) test was calculated according to the standard formula. An APRI test score higher than 1.5 indicates significant hepatic fibrosis. METAVIR scoring from 14 liver biopsies was compared to the liver stiffness using the Kappa statistic. A total of 28 patients had viral hepatitis, 20 cystic fibrosis, 16 chronic liver cholestasis, 5 autoimmune hepatitis, and 3 patients had liver fibrosis with uncertain etiology. FibroScan measurements were available in all children. There was good agreement between FibroScan and pathological studies (weighted kappa = 0.814). Only 9 children had portal hypertension syndrome with an average measurement of liver stiffness significantly higher than children without portal hypertension (26.5kPa versus 6.4kPa; $p < 0.01$). The APRI test for 6 out of 9 patients scored higher than 1.5. The authors concluded that these findings indicate that liver stiffness measurement is feasible in children and seems to be related to liver fibrosis. They stated that larger prospective studies are needed to validate this FibroScan method.

In a meta-analysis of transient elastography for the detection of hepatic fibrosis, Stebbing et al (2010) evaluated its use in comparison with liver biopsy. Studies from the literature were analyzed with a median liver stiffness value in kilopascal given for fibrosis stages according to histopathologic findings on biopsy and best discriminant cut-off levels in kilopascals for significant fibrosis (greater than or equal to F2) and cirrhosis (F4). A total of 22 studies were selected comprising 4,430 patients; chronic hepatitis C infection was the most common etiology of fibrosis. The pooled estimates for significant fibrosis (greater than or equal to F2) measured 7.71 kPa (LSM cut-off value) with a sensitivity of 71.9 % [95 % CI: 71.4 % to 72.4 %] and specificity of 82.4 % (95 % CI: 81.9 % to 82.9 %), whereas for cirrhosis (F4) the results showed a cut-off of 15.08 kPa with a sensitivity of 84.45 % (95 % CI: 84.2 % to 84.7 %) and specificity of 94.69 % (95 % CI: 94.3% to 95 %). The authors concluded that further evaluation of transient elastography to assess LSM is needed in prospective studies to potentially increase the sensitivity and establish its clinical utility.

Myers (2009) noted that non-alcoholic fatty liver disease (NAFLD) is the most common cause of

chronic liver disease, affecting about 30 % of Western populations and a frequent indication for liver transplantation. The histological spectrum of NAFLD includes simple steatosis, which has a benign prognosis, and non-alcoholic steatohepatitis, a more aggressive form of liver injury that may progress to cirrhosis and its complications. At present, the only widely accepted means of differentiating these lesions, including the severity of hepatic fibrosis, is liver biopsy. However, due to the invasiveness of this procedure, the rising prevalence of NAFLD, and the expected availability of effective therapies for this condition, the identification of non-invasive tools for the diagnosis and staging of NAFLD has emerged as a major clinical and research priority. The author summarized important advances in this field during the past decade, including the development of biomarkers of hepatic fibrosis, apoptosis, and inflammation; novel imaging techniques such as transient elastography; and high-throughput technologies including proteomics and genomics. Future studies must focus on the development of accurate, inexpensive, and reliable tools that can differentiate the major histologic determinants of NAFLD; are responsive to changes in NAFLD severity due to therapeutic intervention and time; and have prognostic significance. Until such tools are developed, liver biopsy remains an important tool in the assessment of patients with NAFLD.

Myers and co-workers (2010) determined the feasibility and performance of TE in a North American cohort of patients with chronic liver disease. Liver stiffness measurements were obtained using TE in 260 patients with chronic hepatitis B or C, or NAFLD from 4 Canadian hepatology centers. The accuracy of TE compared with liver biopsy for the prediction of significant fibrosis (Metavir fibrosis score of F2 or greater), bridging fibrosis (Metavir fibrosis score of F3 or greater) and cirrhosis (Metavir fibrosis score of F4) was assessed using area under ROC curves (AUROCs), and compared with the aspartate aminotransferase-to-platelet ratio index. The influence of ALT levels and other factors on liver stiffness was determined using linear regression analyses. Failure of TE occurred in 2.7 % of patients, while liver biopsies were inadequate for staging in 0.8 %. Among the remaining 251 patients, the AUROCs of TE for Metavir fibrosis scores of F2 and F3 or greater, and F4 were 0.74 (95 % CI: 0.68 to 0.80), 0.89 (95 % CI: 0.84 to 0.94), and 0.94 (95 % CI: 0.90 to 0.97), respectively. Liver stiffness measurement was more accurate than the aminotransferase-to-platelet ratio index for bridging fibrosis (AUROC 0.78) and cirrhosis (AUROC 0.88), but not significant fibrosis (AUROC 0.76). At a cut-off of 11.1 kPa, the sensitivity, specificity, and positive and negative predictive values for cirrhosis (prevalence 11 %) were 96 %, 81 %, 39 % and 99 %, respectively. For significant fibrosis (prevalence 53 %), a cut-off of 7.7 kPa was 68 % sensitive and 69 % specific, and had a positive predictive value of 70 % and a negative predictive value of 65 %. Liver stiffness was independently associated with ALT, body mass index and steatosis. The optimal LSM cut-offs for cirrhosis were 11.1 kPa and 11.5 kPa in patients with ALT levels lower than 100 U/L and 100 U/L or greater, respectively. For fibrosis scores of F2 or greater, these figures were 7.0 kPa and 8.6 kPa, respectively. The authors concluded that the major role of TE is the exclusion of bridging fibrosis and cirrhosis. However, TE can not replace biopsy for the diagnosis of significant fibrosis. Because liver stiffness may be influenced by significant ALT elevation, body mass index and/or steatosis, tailored liver stiffness cut-offs may be necessary to account for these factors.

Cholongitas et al (2010) systematically reviewed the literature regarding non-invasive tests (NIT) following liver transplantation. These investigators identified 14 studies evaluating NIT based on serum markers and/or liver imaging techniques: 10 studies assessed NIT in recipients with recurrent HCV infection for fibrosis and 4 studies evaluated predictors of progression of fibrosis in recurrent HCV. Transient Elastography had good discrimination for significant fibrosis (median AUROC: 0.88). Among the serum NIT, APRI had good performance (median AUROC: 0.75). Trnasient elastography performed better than serum (direct and indirect) NIT for significant fibrosis with median AUROC 0.88 (versus 0.66, $p < 0.001$), median sensitivity 0.86 (versus 0.56, $p = 0.002$), median NPV 0.90 (versus 0.74, $p = 0.05$) and median PPV 0.80 (versus 0.63, $p = 0.02$). Transient elastography compared to indirect serum NIT, had better performance, but was not superior to APRI score. Finally, direct, compared to indirect NIT, were not significantly different except for specificity: median: 0.83 versus 0.69, respectively, $p = 0.04$. The authors concluded that NIT could become an important tool in clinical management of liver transplant recipients, but whether they can improve clinical practice needs further evidence. Their optimal combination with

liver biopsy and assessment of collagen content requires investigation.

Stebing et al (2010) performed a meta-analysis to further assess the use of TE in comparison with liver biopsy. Studies from the literature were analyzed with a median liver stiffness value in kilopascal given for fibrosis stages according to histopathologic findings on biopsy and best discriminant cutoff levels in kilopascals for significant fibrosis (greater than or equal to F2) and cirrhosis (F4). A total of 22 studies were selected comprising 4,430 patients; chronic hepatitis C infection was the most common etiology of fibrosis. The pooled estimates for significant fibrosis greater than or equal to F2) measured 7.71 kPa (LSM cut-off value) with a sensitivity of 71.9 % [95 % CI: 71.4 % to 72.4 %] and specificity of 82.4 % (95 % CI: 81.9 % to 82.9%), whereas for cirrhosis (F4) the results showed a cut-off of 15.08 kPa with a sensitivity of 84.45 % (95 % CI: 84.2 % to 84.7 %) and specificity of 94.69 % (95 % CI: 94.3 % to 95 %). The authors concluded that further evaluation of TE to assess LSM is needed in prospective studies to potentially increase the sensitivity and establish its clinical utility.

Thabut et al (2011) noted that severe portal hypertension is responsible for complications and death. Although measurement of the hepatic venous pressure gradient is the most accurate method for evaluating the presence and severity of portal hypertension, this technique is considered invasive and is not routinely performed in all centers. Several non-invasive techniques have been proposed to measure portal hypertension. Certain methods evaluate elements related to the pathogenesis of portal hypertension through the measurement of hyperkinetic syndrome, or they examine the development of hepatic fibrosis through the measurement of increased intra-hepatic vascular resistance. Other methods assess the clinical consequences of portal hypertension, such as the presence of esophageal varices or the development of porto-systemic shunts. Methods evaluating increased hepatic vascular resistance are fairly accurate and primarily involve the detection of hepatic fibrosis by serum markers and transient elastography. The radiological assessment of hyperkinetic syndrome probably has value but is still under investigation. The assessment of severe portal hypertension by the presence of varices may be performed with simple tools such as biological assays, computed tomography, and esophageal capsules. More sophisticated procedures seem promising but are still under development. Screening tools for large populations must be simple, whereas more complicated procedures could help in the follow-up of already diagnosed patients. Although most of these non-invasive methods effectively identify severe portal hypertension, methods for diagnosing moderate portal hypertension need to be developed; this shows that further investigation is needed in this field.

Tsochatzis et al (2011) studied the performance of elastography for diagnosis of fibrosis using meta-analysis. MEDLINE, EMBASE, SCI, Cochrane Library, conference abstracts books, and article references were searched. These investigators included studies using biopsy as a reference standard, with the data necessary to calculate the true- and false-positive, true- and false-negative diagnostic results of elastography for a fibrosis stage, and with a 3-month maximum interval between tests. The quality of the studies was rated with the QUADAS tool. These researchers identified 40 eligible studies. Summary sensitivity and specificity was 0.79 (95 % CI: 0.74 to 0.82) and 0.78 (95 % CI: 0.72 to 0.83) for F2 stage and 0.83 (95 % CI: 0.79 to 0.86) and 0.89 (95 % CI: 0.87 to 0.91) for cirrhosis. After an elastography result at/over the threshold value for F2 or cirrhosis ("positive" result), the corresponding post-test probability for their presence (if pre-test probability was 50 %) was 78 %, and 88 %, respectively, while, if values were below these thresholds ("negative" result), the post-test probability was 21 % and 16 %, respectively. No optimal stiffness cut-offs for individual fibrosis stages were validated in independent cohorts and cut-offs had a wide range and overlap within and between stages. The authors concluded that elastography theoretically has good sensitivity and specificity for cirrhosis (and less for lesser degrees of fibrosis); however, it should be cautiously applied to everyday clinical practice because there is no validation of the stiffness cut-offs for the various stages. They stated that such validation is required before elastography is considered sufficiently accurate for non-invasive staging of fibrosis.

An UpToDate review on "Epidemiology, clinical features, and diagnosis of nonalcoholic steatohepatitis" (Sheth and Chopra, 2012) states that "A potentially useful non-invasive method for excluding advanced fibrosis is measurement of liver stiffness with transient elastography.

However, the approach is not widely available and has not been extensively studied in NASH".

Poca et al (2011) stated that prognostic markers of compensated cirrhosis should mainly investigate factors involved with progression to decompensation because death in cirrhosis is related with decompensation. Portal hypertension plays a crucial role in the pathophysiology of most complications of cirrhosis. Accordingly, hepatic venous pressure gradient (HVPG) monitoring has strong prognostic value. An HVPG of greater than or equal to 10 mm Hg determines a significantly higher risk of developing decompensation. Esophageal varices also can develop when the HVPG is greate than or equal to 10 mm Hg, although an HVPG greater than or equal to 12 mm Hg is required for variceal bleeding to occur. Monitoring the changes induced by the treatment of portal hypertension on HVPG, provides strong prognostic information. In compensated cirrhosis hemodynamic response is appropriate when the HVPG decreased to less than 10 mm Hg or by less than 10 % from baseline, because the incidence of complications such as bleeding or ascites significantly decrease when these targets are achieved. Whether serum markers, such as the FibroTest, may be valuable to predict decompensation should be established. Transient elastography is a promising technique that has shown an excellent accuracy to detect severe portal hypertension. However, whether it can adequately determine clinically significant portal hypertension, and risk of developing varices and decompensation, should be established. Magnetic resonance elastography is also promising.

Pesce and co-workers (2012) noted that portal hypertension has been reported as a negative prognostic factor and a relative contraindication for liver resection. These researchers considered a possible role of fibrosis evaluation by transient elastography (FibroScan) and its correlation with portal hypertension in patients with cirrhosis, and discussed the use of this technique in planning therapeutic options in patients with hepato-cellular carcinoma (HCC). A total of 77 patients with cirrhosis, 42 (54.5 %) of whom had HCC, were enrolled in this study during 2009 to 2011. The group included 46 (59.7 %) men. The mean age of the sample was 65.2 years. The principle etiology of disease was HCV-related cirrhosis (66.2 %). Liver function was assessed according to Child-Pugh classification. In all patients liver stiffness (LS) was measured using FibroScan. The presence of portal hypertension was indirectly defined as: (i) esophageal varices detectable on endoscopy; (ii) splenomegaly (increased diameter of the spleen to greater than or equal to 12 cm), or (iii) a platelet count of less than 100,000 platelets/mm(3). Median LS in all patients was 27.9 kPa. Portal hypertension was recorded as present in 37 patients (48.1 %) and absent in 40 patients (51.9 %). Median LS values in HCC patients with and without portal hypertension were 29.1 kPa and 19.6 kPa, respectively ($r = 0.26$, $p < 0.04$). Liver stiffness was used to implement the Barcelona Clinic Liver Cancer algorithm in decisions about treatment. The authors concluded that the evaluation of liver fibrosis by transient elastography may be useful in the follow-up of patients with cirrhosis and a direct correlation with portal hypertension may aid in the evaluation of surgical risk in patients with HCC and in the choice of alternative therapies.

In a multi-center study, Barbero-Villares et al (2012) evaluated the presence of significant liver fibrosis by transient elastography (FibroScan) in inflammatory bowel disease (IBD) patients treated with methotrexate. Cross-sectional study including IBD patients treated with methotrexate from different hospitals. Clinical and analytical data, duration of treatment, and cumulative dose of methotrexate were obtained. Liver stiffness was assessed by FibroScan. The cut-off value for significant liver fibrosis (according to METAVIR) was F greater than or equal to 2: 7.1 kPa. In the study, 46 patients were included, 30 women (65 %), with a mean age of 43 +/- 10 years; 31 patients had Crohn's disease (67.4 %), 13 ulcerative colitis (28.3 %), and 2 indeterminate colitis (4.3 %). The mean cumulative dose of methotrexate was 1,242 +/- 1,349 mg, with a mean treatment duration of 21 +/- 24 months. The mean value of liver stiffness was 4.7 +/- 6.9 kPa. There were 35 patients (76.1 %) with F01, 8 patients (17.4 %) with F = 2, and 3 patients with F greater than or equal to 3 (6.5 %). There were no differences in liver stiffness depending on sex, age, type of IBD, or cumulative dose of methotrexate. The authors concluded that (i) development of advanced liver fibrosis in IBD patients treated with methotrexate is exceptional, (ii) there were no differences in liver stiffness depending on the type of IBD or the cumulative dose of methotrexate, and (iii) FibroScan may be potentially useful for evaluation and follow-up of liver fibrosis in methotrexate-treated patients.

Lee and colleagues (2013) evaluated and compared the ability of serum HA and human cartilage glycoprotein-39 (YKL-40) values, as well as TE findings, to predict advanced hepatic fibrosis in a cohort from a single pediatric center. Subjects who underwent liver biopsy analysis within 12 months before enrollment were eligible for this prospective study. Hyaluronic acid and YKL-40 measurements were obtained within 1 month of TE. A METAVIR score of F3 or F4 was considered to indicate advanced fibrosis. A total of 128 patients (51 % males) aged 1.4 months to 27.6 years (22 % aged less than 2 years) were enrolled. Thirty-one subjects had data on HA and YKL-40; and 97 subjects had data on both blood tests and TE. For the prediction of advanced fibrosis, the AUC values were 0.83 for TE, 0.72 for HA, and 0.52 for YKL-40. The AUC of 0.83 for TE was statistically significantly greater than the AUCs for HA ($p = 0.03$) and YKL-40 ($p < 0.0001$). Optimal cut-off points for predicting F3-F4 fibrosis were 8.6 kPa for TE ($p < 0.0001$), 43 ng/ml for HA ($p < 0.0001$), and 26.2 ng/ml for YKL-40 ($p = 0.85$). The combination of TE and HA was not better than TE alone for predicting advanced fibrosis ($p = 0.15$). The authors concluded that in this study, which evaluated TE, HA, and YKL-40 to predict liver fibrosis in children in the United States, YKL-40 had no predictive value and TE was superior to HA, but the addition of HA did not improve the performance of TE. They stated that these findings suggested that TE and HA may be useful non-invasive tools for assessing liver fibrosis in children.

Guidelines on the management of hepatiis C from the American Association for the Study of LIver Disease (2014) state that "[n]on-invasive methods frequently used to estimate liver disease severity include a liver-directed physical exam (normal in most patients), routine blood tests (eg, serum alanine transaminase, albumin, bilirubin, international normalized ratio levels, and complete cell blood counts with platelets), serum fibrosis marker panels, liver imaging (eg, ultrasound, computed tomography scan), and liver elastography. . . . Liver elastography can provide instant information regarding liver stiffness at the point-of-care but can only reliably distinguish cirrhosis from non-cirrhosis."

CPT Codes / HCPCS Codes / ICD-9 Codes

Transient elastography (e.g., FibroScan):

CPT codes covered if selection criteria are met:

0346T

Serum marker tests:

CPT codes not covered for indications listed in the CPB:

83520

83883

Other CPT codes related to the CPB:

47000

47001

47100

82977

ICD-9 codes covered if selection criteria are met:

070.44	Chronic hepatitis C with hepatic coma
070.54	Chronic hepatitis C without mention of hepatic coma
571.0 - 571.9	Chronic liver disease and cirrhosis
V42.7	Organ or tissue replaced by transplant, liver

ICD-9 codes not covered for indications listed in the CPB:

070.0 - 070.43, 070.49 - 070.53, 070.59 - 070.9	Viral hepatitis
155.0	Malignant neoplasm of liver, primary [hepatocellular carcinoma]

Assessing Corneal Hysteresis Using the Ocular Response Analyzer

Charles W. McMonnies*

ABSTRACT

Purpose. An examination of studies that have assessed corneal biomechanical performance using the Ocular Response Analyzer (ORA: Reichert Ophthalmic Instruments, Depew, NY) raises some questions regarding the influence of measurement variables and the interpretation of the findings obtained with this instrument. This analysis of those questions describes additional factors which do or may contribute to the assessment of corneal hysteresis (CH).

Methods. Using key words CH and ORA, English language articles relevant to this analysis were selected after a PubMed search with the addition of some articles referenced in the selected publications.

Results. Corneal thickness, the level of edema, intraocular pressure, and corneal temperature as well as the area, location, rate, duration, and sequence of corneal unloading and loading may need to be considered as significant variables when assessing CH.

Conclusions. CH values may be specific to measurement method and conditions rather than representing an unequivocal corneal property. Consideration of the uncontrolled variables involved may help explain some of the findings obtained with the ORA. That a CH measurement might vary with the sequence of unloading and loading suggests that the ORA CH finding may not represent the CH, but instead represents a hysteresis value better described as central, applanation-derived hysteresis, which is based on a very short unloading/loading sequence. The potential for the ORA to contribute to improved clinical management appears to be considerable but so does the need for better understanding and further development of its functions and applications.

(Optom Vis Sci 2012;89:E343–E349)

Key Words: biomechanics, hysteresis, cornea, ocular response analyzer

For earlier forms of non-contact tonometry (NCT; Reichert Ophthalmic Instruments, Depew, New York), the instruments are calibrated to indicate intraocular pressure (IOP) according to the time taken to achieve applanation (1 to 3 ms).[1] The time taken to achieve applanation, in response to a non-linearly increasing air pressure, increases with baseline IOP and corneal rigidity[1] and the air pressure force required varies accordingly. The air pressure switches off soon after applanation but corneal indentation subsequent to applanation and then recovery to normal convexity are not relevant to measurement of IOP with earlier models of the non-contact tonometer. For measurements using an Ocular Response Analyzer (ORA) (Reichert Ophthalmic Instruments, Depew NY),[2] a modification of the NCT, milliseconds after the first applanation, the air pump generating the air pulse also shuts down and the air pressure applied to the eye decreases in an inverse-time, symmetrical fashion (Fig. 1).[2] However, before the decrease, the cornea is indented significantly as the air pressure reaches a peak about 3 ms after applanation (Fig. 1). As the pressure decreases from its peak, the cornea passes through a second applanated state while returning from indentation to its normal convex curvature.[2] The inward and outward applanation responses during the short stressor exposure to air puff pressure are monitored with a laser, which detects each corneal applanation as a peak in the reflected signal intensity (Fig. 1).[2]

In material science, a difference in the displacement history of a material during loading and unloading (adding stress followed by relief from that stress) is called hysteresis.[3] Hysteresis is the tendency for a device such as a shock absorber to rebound with less force than was required to deform it. An elastic bounce does not absorb energy but a viscoelastic bounce involves energy absorption, with a loss or dissipation of energy (as heat) and a slower rebound. Similarly, because of a dissipative or damping capacity in viscoelastic tissue, there is a delay in the response to and the recovery from a loading stressor.[3] Thus, energy adsorption during rapid corneal deformation delays the occurrence of the inward and outward

Correlations between corneal hysteresis, intraocular pressure, and corneal central pachymetry

David Touboul, MD, Cynthia Roberts, PhD, Julien Kérautret, MD, Caroline Garra, Sylvie Maurice-Tison, MD, Elodie Saubusse, Joseph Colin, MD

PURPOSE: To analyze the correlation between corneal hysteresis (CH) measured with the Ocular Response Analyzer (ORA, Reichert) and ultrasonic corneal central thickness (CCT US) and intraocular pressure measured with Goldmann applanation tonometry (IOP GA).

SETTING: Bordeaux 2 University, Ophthalmology Department, Bordeaux, France.

METHODS: This study comprised 498 eyes of 258 patients. Corneal hysteresis, corneal resistance factor (CRF), and IOP corneal-compensated (IOPcc) were provided by the ORA device; CCT US and IOP GA were also measured in each eye. The study population was divided into 5 groups: normal (n = 122), glaucoma (n = 159), keratoconus (n = 88), laser in situ keratomileusis (LASIK) (n = 78), and photorefractive keratectomy (n = 39). The Pearson correlation was used for statistical analysis.

RESULTS: Corneal hysteresis was not strongly correlated with IOP or CCT US. The mean CH in the LASIK (8.87 mm Hg) and keratoconus (8.34 mm Hg) groups was lower than in the glaucoma (9.48 mm Hg) and normal (10.26 mm Hg) groups. The lower the CH, the lower its correlation with IOPcc and IOP GA. A CH higher than the CRF was significantly associated with the keratoconus and post-LASIK groups.

CONCLUSIONS: Corneal hysteresis, a new corneal parameter, had a moderate dependence on IOP and CCT US. Weaker corneas could be screened with ORA parameters, and low CH could be considered a risk factor for underestimation of IOP. The CCT US should continue to be considered a useful parameter.

J Cataract Refract Surg 2008; 34:616–622 © 2008 ASCRS and ESCRS

Knowledge of corneal biomechanical properties is important in the fields of intraocular pressure (IOP) measurement, corneal pathology, and corneal refractive surgery. The Ocular Response Analyzer (ORA, Reichert) is the first simple device able to provide an in vivo dynamic measurement of the corneal viscoelastic parameter called corneal hysteresis (CH).

Ophthalmologists know that central corneal thickness (CCT) is an important concern in estimating the true IOP with applanation tonometric systems.[1] Until recently, CCT was the only available parameter to correlate IOP measurements by applanation in different corneas.[2,3] However, it was recently theoretically shown that corneal properties, specifically the elastic modulus, have a greater impact on IOP measurement error in applanation tonometry than corneal thickness or curvature.[4] We hypothesize that viscoelastic properties are also important to evaluate in IOP measurement, as well as in corneal pathology and surgery. In addition, pachymetry may influence viscoelasticity. Corneal hydration, properties of corneal layers, and the biomechanical nature of the stroma are important to evaluate. Because of its dynamic time-measurement concept, the ORA may allow us to improve our understanding in this field.[5]

The aim of the current study was to define the relationships between different parameters: ORA data for CH, corneal resistance factor (CRF), corneal-compensated IOP (IOPcc), and Goldmann-correlated IOP (IOPg) as well as Goldmann applanation tonometry (IOP GA), ultrasonic CCT (CCT US), and age. The main objective was to evaluate CH and CRF as new corneal parameters and to clarify their relationship with IOP and CCT US.

SURVEY OF OPHTHALMOLOGY VOLUME 52 • SUPPLEMENT 2 • November 2007

What Biomechanical Properties of the Cornea Are Relevant for the Clinician?

Aachal Kotecha, PhD

Glaucoma Research Unit, Moorfields Eye Hospital, and Department of Optometry, City University, London, United Kingdom

Abstract. Although the effects of central corneal thickness and corneal curvature on intraocular pressure measurement are well known, it has only recently become possible to measure the biomechanical properties of the cornea in vivo. This article reviews the structural and material properties of the cornea and considers the effects of corneal parameters, including biomechanics, on IOP measurement. The role of corneal biomechanics as a potential indicator of the structural integrity of the globe will also be discussed. Current evidence suggests that the importance of corneal biomechanics to the glaucoma clinician rests primarily with its effects on IOP measurement. However, the possibility that corneal biomechanics may give an indication of the structural integrity of the optic nerve head cannot be completely excluded. Further population and longitudinal studies are needed to clarify whether current in vivo measures of corneal biomechanical properties, including corneal hysteresis, prove to be independent predictors of glaucoma susceptibility. (**Surv Ophthalmol 52**:S109–S114, 2007. © 2007 Elsevier Inc. All rights reserved.)

Key words. biomechanics • central corneal thickness • cornea • glaucoma • hysteresis

The effects of central corneal thickness (CCT) and corneal curvature (K) on intraocular pressure (IOP) measurement are well known, such that true IOP will be overestimated in eyes with thick or steep corneas and be underestimated in those with thin or flat corneas.[3] However, although the linear relationship between these corneal parameters and IOP measurement is statistically significant, the reported values of the coefficient of determination (the r^2 value) suggest that only a small fraction of the variance in IOP measurements is explained by variations of CCT or K. Although some of the variability in measured IOP will be due to inter-subject differences in true IOP, it is likely that corneal biomechanical properties other than CCT or K will have an important influence on the accuracy of IOP measurements.

The biomechanics of the cornea may also have a role as an indicator of overall globe biomechanics. Thus, an understanding of the differences in corneal biomechanics between individuals may explain why some optic nerve heads are more susceptible to damage by variations in IOP.

The purpose of this article is to review the current literature regarding the relevance of corneal biomechanics to the glaucoma clinician.

Corneal Structure

Collagen is the primary structural component of both the cornea and sclera. It has a high tensile strength and provides a resilient, protective coat to the globe. Corneal collagen is contained primarily in Bowman's layer and the stroma, the latter region constituting 90% of the total thickness of a hydrated cornea. The corneal stroma has a highly organized arrangement of collagen fibrils of small diameter that are braced apart by a proteoglycan matrix that maintains uniform, inter-fibrillar spacing.[21] These fibrils are further organized into flat bundles, or lamellae, that vary in number across the cornea, from approximately 300 centrally to 500 at the limbus.[16] Anterior stroma lamellae run obliquely and randomly across the cornea, often starting at

1. Aetna considers the ocular blood flow tonometer, which has been used in the screening, diagnosis, and monitoring of glaucoma, experimental and investigational because there is a lack of evidence in the peer-reviewed published medical literature proving that measurement of pulsatile ocular blood flow significantly improves outcomes by enhancing the screening, diagnosis or management of glaucoma.

2. Aetna considers the ocular Blood Flow Analyzer (BFA) experimental and investigational for screening, diagnosis and monitoring of glaucoma and for all other indications because of insufficient evidence of its effectiveness.

3. Aetna considers measurement of corneal hysteresis experimental and investigational for the screening, diagnosis and monitoring of glaucoma and for all other indications because of insufficient evidence of its effectiveness.

4. Aetna considers continuous monitoring of intraocular pressure experimental and investigational for management of glaucoma and other indications because its effectiveness has not been established.

5. Aetna considers genotyping for the screening, diagnosis and monitoring of glaucoma experimental and investigational because of insufficient evidence of its effectiveness.

6. Aetna considers multi-focal visual evoked potential for the diagnosis and early detection of glaucomatous field defects experimental and investigational because of insufficient evidence of its effectiveness.

Background

Glaucoma is a leading cause of blindness, affecting over 60 million people worldwide. Open-angle glaucoma, the most common subtype of the disease, affects over 2.5 million people in the United States. On behalf of the American Academy of Ophthalmology,

Jampel et al (2011) reviewed the published literature to summarize and evaluate the effectiveness of visual function tests in diagnosing glaucoma and in monitoring progression. Literature searches of the PubMed and Cochrane Library databases were conducted last on May 7, 2010, and were restricted to citations published on or after January 1, 1994. The search yielded 1,063 unique citations. The first author reviewed the titles and abstracts of these articles and selected 185 of possible clinical relevance for further review. The panel members reviewed the full text of these articles and determined that 85 met inclusion criteria. They conducted data abstraction of the 85 studies, and the panel methodologist assigned a level of evidence to each of the selected articles. One study was rated as level I evidence. The remaining articles were classified broadly as providing level II evidence. Studies deemed to provide level III evidence were not included in the assessment. Standard white-on-white automated perimetry remains the most commonly performed test for assessing the visual field, with the Swedish interactive threshold algorithm (SITA) largely replacing full-threshold testing strategies. Frequency-doubling technology and its refinement into Matrix perimetry, as well as short-wavelength automated perimetry, now available with SITA, have been evaluated extensively. Machine learning classifiers seem to be ready for incorporation into software to help distinguish glaucomatous from non-glaucomatous fields. Other technologies, such as multi-focal visual-evoked potential and electro-retinography, which were designed as objective measures of visual function, provide testing free of patient input, but issues prevent their adoption for glaucoma management. The authors concluded that advances in technology and analytic tools over the past decade have provided us with more rapid and varied ways of assessing visual function in glaucoma, but they have yet to produce definitive guidance on the diagnosis of glaucoma or its progression over time. They stated that further research on an objective measure of visual function is needed.

An Agency for Healthcare Research and Quality review on "Screening for Glaucoma: Comparative Effectiveness" (Ervin et al, 2012) summarized evidence linking glaucoma screening to health outcomes. It found insufficient evidence to address whether glaucoma screening is effective in improving vision-related outcomes and concluded that more research is needed to address the association between screening and quality of life outcomes.

Ocular Blood Flow Tonometer:

The ocular blood flow (OBF) tonometer measures not only intra-ocular pressure (IOP) but also pulsatile OBF. According to the manufacturer, taking the IOP and OBF test results together increases the detection rate for glaucoma when compared to traditional tonometry, which measures only average IOP. In addition, the manufacturer claims that the OBF tonometer can be used to provide ongoing analysis of the effectiveness of glaucoma treatment. The manufacturer explains that the OBF applanation tonometer has a resolution of 0.01 mm Hg, and automatically takes 200 readings per second, continuously analyzing the pulsatile variations in IOP. These data are analyzed by a computer, which calculates the OBF. The OBF tonometer records the complete IOP waveform and prints out of the average, maximum, and minimum values in a group of chosen pulses.

To date, the OBF tonometer has been studied primarily as a research tool. The evidence published to date on the OBF tonometer provides comparisons of IOP measurements to standard tonometers. There are no prospective clinical studies, however, demonstrating that measurement of waveforms and calculation of pulsatile OBF improves the management of glaucoma patients or glaucoma suspects, such that clinical outcomes are improved.

Neither the American Academy of Ophthalmology's Preferred Practice Patterns on Glaucoma nor the American Optometric Association's Clinical Practice Guidelines on Glaucoma mention any role for the OBF tonometer in the evaluation and management of patients with glaucoma.

There is no adequate evidence that OBF tonometers offer any clinically significant benefits over conventional applanation or indentation tonometers for screening, diagnosing or monitoring glaucoma.

Bhan et al (2003) examined the repeatability of OBF pneumotonometry and its agreement with Goldmann tonometry. Intra-ocular pressure was measured by 1 experienced ophthalmologist in both eyes of 10 healthy female subjects on 10 different occasions at the same time of day. The 2 methods were performed by alternate allocation, and laterality was chosen by random order. The authors concluded that the repeatability of the OBF pneumotonometer was worse than that of the Goldmann tonometer. This casts doubt on the value of the OBF pneumotonometer as a tool for measuring IOP. The agreement plots indicate that the OBF pneumotonometer may produce significant numbers of false-positive results in screening programs.

Furthermore, pulsatile OBF assessment is used to measure the choroidal circulation and provides diagnostic value to certain ocular diseases such as glaucoma. This technique assumes a constant ocular rigidity and is influenced by axial length, diurnal variation, and age. Lam et al (2003) investigated the effect of age on pulsatile OBF, with consideration of the above factors (n = 118). Ocular blood supply in the ophthalmic artery was also determined using color Doppler ultrasonography. These investigators found that the reduction in pulsatile OBF with age was significant. Although aging affects scleral rigidity and systemic blood pressure, multiple regression analysis indicates that the most influential factor affecting pulsatile OBF is aging.

Also, Gunvant et al (2004) ascertained the effect of central corneal thickness and corneal curvature on IOP measurements using the pulsatile OBF tonograph and the Goldmann applanation tonometer, and assessed the agreement between the pulsatile OBF tonograph and the Goldmann applanation tonometer in IOP measurement (n = 479). The IOP measurements obtained with both the Goldmann applanation tonometer and the pulsatile OBF tonograph varied with central corneal thickness and mean keratometric reading. IOP measured using the Goldmann applanation tonometer increased by 0.027 mm Hg per micro m increase in central corneal thickness. IOP measured using the pulsatile OBF tonograph increased by 0.048 mm Hg per microm increase in central corneal thickness. For an increase of 1 mm of mean corneal curvature there was rise in IOP of 1.14 mm Hg measured by the Goldmann applanation tonometer and of 2.6 mm Hg measured by the pulsatile OBF. When compared to the Goldmann applanation tonometer, the pulsatile OBF tonograph under-estimated at low IOP and over-estimated at higher IOP. The authors concluded that central corneal thickness and corneal curvature affected measurements obtained with the pulsatile OBF tonograph more than they affected measurements obtained with the Goldmann applanation tonometer.

Tonnu et al (2005) compared the inter-method agreement in IOP measurements made with 4 different tonometric methods: (i) the Goldmann applanation tonometer (GAT), (ii) Tono-Pen XL, (iii) OBF tonograph, and (iv) Canon TX-10 non-contact tonometer (NCT) in a randomized order in 1 eye of each of 105 patients with ocular hypertension or glaucoma. A total of 3 measurements were made with each method, and by each of 2 independent GAT observers. GAT inter-observer and tonometer inter-method agreement was assessed by the Bland-Altman method. The outcome measures were 95 % limits of agreement for IOP measurements between GAT observers and between tonometric

methods, and 95 % confidence intervals for intra-session repeated measurements. The authors reported that there was good inter-observer agreement with the GAT and moderate agreement between the NCT and GAT. The differences between the GAT and OBF tonograph and between the GAT and Tono-Pen probably preclude the OBF tomography and Tono-Pen from routine clinical use as objective methods to measure IOP in normal adult eyes.

The ocular Blood Flow Analyzer (BFA) (Paradigm Medical Industries, Inc., Salt Lake City, UT) is an electronic pneumotonometer that measures IOP 200 times per second over a period of 5 to 15 seconds and automatically measures OBF. Ocular pressure rises and falls with each heartbeat and a pressure waveform is created when the bolus of blood from each heartbeat passes through the ocular choroid. The systolic increase and diastolic decrease in IOP caused by the pulsatile OBF is recorded by the BFA. The data are then analyzed by an on board computer in real time and a resultant OBF is calculated. Six test parameters are taken per eye with a calculated average mean value in microliters/second. Measurements for each pulse with a calculated average are given for IOP (tonometry) and pneumoplethysmographic vascular activity including: pressure, pulse amplitude, systole and diastole duration, pulse rate, and OBF rate. The BFA is fundamentally an OBF tonometer, using a pneumatic mode of operation.

Resch and colleagues (2011) stated that little information is available regarding the relationship between glaucomatous visual field defects, morphological changes of the optic disc and OBF. In this study, OBF parameters were correlated with parameters of optic nerve head (ONH) morphology and visual field performance in a cross-sectional study. A total of 103 patients with primary open angle glaucoma were included. Choroidal and ONH blood flow was assessed using laser Doppler flowmetry. Retinal blood velocities and retinal vessel diameters were measured with laser Doppler velocimetry and a Retinal Vessel Analyzer, respectively. To evaluate the ONH morphology, fundus photographs were taken and confocal laser scanning tomography was performed. Among all measured ocular hemodynamic parameters, the ONH blood flow was most strongly correlated to structural parameters of ONH damage and visual field loss. Reduced retinal vessel diameters were only slightly correlated with the degree of glaucomatous damage. The authors concluded that reduced blood flow in the ONH was associated with increasing amount of visual field defect and morphological changes of the ONH. Retinal vessel diameters were only marginally associated with glaucomatous optic nerve damage. Based on retinal vessel diameter determination alone, it is not possible to evaluate if reduced retinal blood flow is causative or secondary in glaucoma.

In a case-control study, Hwang et al (2012) examined the relationship among visual field, neural structural, and blood flow measurements in glaucoma. A total of 47 eyes of 42 patients with perimetric glaucoma were age-matched with 27 normal eyes of 27 patients. All patients underwent Doppler Fourier-domain optical coherence tomography to measure retinal blood flow and standard glaucoma evaluation with visual field testing and quantitative structural imaging. Linear regression analysis was performed to analyze the relationship among visual field, blood flow, and structure, after all variables were converted to logarithmic decibel scale. Retinal blood flow was reduced in glaucoma eyes compared to normal eyes ($p < 0.001$). Visual field loss was correlated with both reduced retinal blood flow and structural loss of rim area and retinal nerve fiber layer (RNFL). There was no correlation or paradoxical correlation between blood flow and structure. Multi-variate regression analysis revealed that reduced blood flow and structural loss are independent predictors of visual field loss. Each dB decrease in blood flow was associated with at least 1.62 dB loss in mean deviation (p â‰¤ 0.001), whereas each dB decrease in rim area and RNFL was associated with 1.15 dB and 2.56 dB loss in mean deviation, respectively (p â‰¤ 0.03). The authors concluded that there is a close link

between reduced retinal blood flow and visual field loss in glaucoma that is largely independent of structural loss. They stated that further studies are needed to elucidate the causes of the vascular dysfunction and potential avenues for therapeutic intervention. Blood flow measurement may be useful as an independent assessment of glaucoma severity.

Ocular Reponse Analyzer for Corneal Hysteresis:

Central corneal thickness has become an important biometric factor and is an essential part of the evaluation of glaucoma. Goldmann applanation tonometry is the most widely used method of measuring IOP, but it is well known that corneal parameters affect the accuracy of this instrument (Herndon, 2006). Corneal pachymetry is used to measure central corneal thickness, and is an adjunct to applanation tonometry for screening and diagnosis of glaucoma. In addition to central corneal thickness, there are probably further biomechanical properties that play a role in IOP measurement (Hager et al, 2007).

A new measure of corneal biomechanics, called corneal hysteresis, assesses corneal resistance to deformation. The Ocular Response Analyzer (ORA, Reichert Ophthalmic Instruments, Depew, NY) is a new instrument that measures corneal hysteresis, the corneal biomechanical response to rapid indentation by an air jet (Kotecha et al, 2006). Corneal hysteresis is the difference in applanation pressures between the rising and falling phases of the air jet.

Current evidence for measurement of corneal hysteresis has focused on its potential use in glaucoma, and has focused on correlations between corneal hysteresis and IOP, corneal thickness, and other ocular measurements. There are no studies demonstrating that measurement of corneal hysteresis alters clinical management such that clinical outcomes are improved.

Kotecha (2007) stated that current evidence suggests that the importance of corneal biomechanics to the glaucoma clinician rests primarily with its effects on IOP measurement. However, the possibility that corneal biomechanics may give an indication of the structural integrity of the optic nerve head can not be completely excluded. The author noted that further population and longitudinal studies are needed to clarify whether current in vivo measures of corneal biomechanical properties, including corneal hysteresis, prove to be independent predictors of glaucoma susceptibility.

Genotyping for Glaucoma:

Gibson et al (2012) stated that primary open angle glaucoma (POAG) is a characteristic optic neuropathy which progresses to irreversible vision loss. Few genes have been detected that influence POAG susceptibility and other genes are therefore likely to be involved. These researchers analyzed carefully characterized POAG cases in a genome-wide association study (GWAS). They performed a GWAS in 387 POAG cases using public control data (WTCCC2). They also investigated the quantitative phenotypes, cup:disc ratio (CDR), central corneal thickness (CCT), and intra-ocular pressure (IOP). Promising single nucleotide polymorphisms (SNPs), based on various prioritization criteria, were genotyped in a cohort of 294 further POAG cases and controls. These investigators found 2 GWAS significant results in the discovery stage for association, one of which had multiple evidence in the gene neural precursor cell expressed, developmentally down-regulated 9' (NEDD9; rs11961171, p = 8.55E-13) and the second on chromosome 16 with no supporting evidence. Taking into account all the evidence from risk and quantitative trait ocular phenotypes these researchers chose 86 SNPs for replication in an independent sample. Their most significant SNP was not replicated (p =

0.59). They found 4 nominally significant results in the replication cohort, but none passed correction for multiple testing. Two of these, for phenotypes CDR (rs4385494, discovery p = 4.51x10-5, replication p = 0.029) and CCT (rs17128941, discovery p = 5.52x10-6, replication = 0.027), show the consistent direction of effects between the discovery and replication data. These investigators also assessed evidence for previously associated known genes and found evidence for the genes 'transmembrane and coiled-coil domains 1' (TMCO1) and 'cyclin-dependent kinase inhibitor 2B' (CDKN2B). The authors concluded that although they were unable to replicate any novel results for POAG risk, they did replicate 2 SNPs with consistent effects for CDR and CCT, though they do not withstand correction for multiple testing. There has been a range of publications in the last couple of years identifying POAG risk genes and genes involved in POAG related ocular traits. The authors found evidence for 3 known genes (TMCO1, CDKN2B, and S1 RNA binding domain 1 [SRBD1]) in this study. Novel rare variants, not detectable by GWAS, but by new methods such as exome sequencing (also known as targeted exome capture) may hold the key to unraveling the remaining contribution of genetics to complex diseases such as POAG.

Ulmer et al (2012) noted that central corneal thickness (CCT) is associated with POAG. Using SNP data from the GLAUGEN and NEIGHBOR consortia, these researchers investigated the effects of CCT-associated variants on POAG risk. They performed a replication analysis of previously reported CCT SNPs in their CCT dataset (n = 1,117) and tested these SNPs for association with POAG using the full dataset (n = 6,470). They performed a CCT GWAS, selected top SNPs from this analysis, and tested these for association with POAG. They generated cDNA libraries from fetal and adult brain and ocular tissue samples for candidate gene expression analysis. They replicated association with 1 of 20 previously published CCT SNPs: rs12447690, near the ZNF469 gene (p = 0.001; beta = -5.08 microns/allele). None of these SNPs was significantly associated with POAG. In the CCT GWAS, no SNPs reached genome-wide significance. After testing 50 candidate SNPs for association with POAG these investigators identified rs7481514 within the NTM gene that was significantly associated with POAG in a low tension subset (p = 0.00099; OR = 1.28). Additionally, SNPs in the CNTNAP4 gene showed suggestive association with POAG (top SNP = rs1428758; p = 0.018; OR = 0.84). They found evidence of NTM and CNTNAP4 gene expression in ocular tissues. The authors concluded that these findings suggested that previously reported CCT loci are not significantly associated with POAG susceptibility. By performing a quantitative analysis of CCT and a subsequent analysis of POAG, they identified SNPs in 2 cell adhesion molecules, NTM and CNTNAP4, which may increase POAG susceptibility in a subset of cases.

Gemenetzi et al (2012) noted that most of the molecular mechanisms leading to POAG development are still unknown. Gene mutations in various populations have been identified by genetic studies and a genetic basis for glaucoma pathogenesis has been established. Linkage analysis and association studies are genetic approaches in the investigation of the genetic basis of POAG. Genome-wide association studies are more powerful compared with linkage analysis in discovering genes of small effect that might contribute to the development of the disease. POAG links to at least 20 genetic loci, but only 2 genes identified in these loci, myocilin and optineurin, are considered as well-established glaucoma-causing genes, whereas the role of other loci, genes, and variants implicated in the development of POAG remains controversial. Gene mutations associated with POAG result in retinal ganglion cell death, which is the common outcome of pathogenetic mechanisms in glaucoma. The authors stated that if the sensitivity and specificity of genotyping increases, it may be possible to screen individuals routinely for disease susceptibility.

Guidelines from the Australian National Health and Medical Research Council (2010) state that mutations in transcription factor genes have been found to be responsible for developmental disorders associated with childhood glaucoma. The guidelines list the following genetic syndromes associated with childhood glaucoma: Nail Patella Syndrome with the LMX1B gene, Axenfeld Rieger Syndrome/Anterior segment dysgenesis with the PITX2 and FOXC1 genes and Aniridia with the PAX6 gene. Patients with these syndromes or mutations are usually followed closely for glaucoma. The guidelines note that there is some evidence that adult-onset POAG is linked to mutations in the same genes. The guidelines state that the situation is complex and it is likely that multiple mutations in more than one gene may be involved, given that POAG is likely to be inherited as a complex trait. The guidelines note that current research has identified more than 30 mutations of the myocilin gene alone, with connections to POAG in different ethnic groups. The guidelines conclude that there is "evolving evidence" for genetic screening for glaucoma.

Multi-Focal Visual Evoked Potential:

Multi-focal visual evoked potential (mfEVP) has been studied for the diagnosis and early detection of glaucomatous field defects. However, its effectiveness for this indication has not been established.

The National Collaborating Center for Acute Careâ€™s clinical guideline on â€œGlaucoma. Diagnosis and management of chronic open angle glaucoma and ocular hypertensionâ€ (2009) did not mention the use of mfVEP. The American Academy of Ophthalmologyâ€™s report on â€œAssessment of visual function in glaucomaâ€ (Jampel et al, 2011) stated that technologies, such as mfVEP and electro-retinography, which were designed as objective measures of visual function, provide testing free of patient input, but issues prevent their adoption for glaucoma management. The U.S. Preventive Services Task Forceâ€™s recommendation statement on â€œScreening for glaucomaâ€ (2013) listed tonometry, visual field measurement, dilated ophthalmoscopy and slit lamp examination as screening tests for (POAG). The USPSTF statement noted that â€œDiagnosis of POAG is based on a combination of tests showing characteristic degenerative changes in the optic disc and defects in visual fields (often loss in peripheral vision). Although increased IOP was previously considered an important part of the definition of this condition, it is now known that many persons with POAG do not have increased IOP and not all persons with increased IOP have or will develop glaucoma. Therefore, screening with tonometry alone may be inadequate to detect all cases of POAG. Measurement of visual fields can be difficult. The reliability of a single measurement may be low; several consistent measurements are needed to establish the presence of defects. Specialists use dilated ophthalmoscopy or slit lamp examination to evaluate changes in the optic disc; however, even experts have varying ability to detect glaucomatous progression of the optic disc. In addition, no single standard exists to define and measure progression of visual field defects. Most tests that are available in a primary care setting do not have acceptable accuracy to detect glaucomaâ€ .

Mousa et al (2104) stated that mfVEP is a newly introduced method used for objective visual field assessment. Several analysis protocols have been tested to identify early visual field losses in glaucoma patients using the mfVEP technique, some were successful in detection of field defects, which were comparable to the standard automated perimetry (SAP) visual field assessment, and others were not very informative and needed more adjustment and research work. These researchers implemented a novel analysis approach and evaluated its validity and whether it could be used effectively for early detection of visual field defects in glaucoma. Three groups were tested in this study: (i) normal controls (38 eyes), (ii) glaucoma patients (36 eyes) and (iii) glaucoma suspect patients (38

eyes). All subjects had a 2 standard Humphrey field analyzer (HFA) test 24-2 and a single mfVEP test undertaken in 1 session. Analysis of the mfVEP results was done using the new analysis protocol; the hemifield sector analysis (HSA) protocol. Analysis of the HFA was done using the standard grading system. Analysis of mfVEP results showed that there was a statistically significant difference between the 3 groups in the mean signal-to-noise ratio (ANOVA test, $p < 0.001$ with a 95 % confidence interval). The difference between superior and inferior hemispheres in all subjects were statistically significant in the glaucoma patient group in all 11 sectors (t-test, $p < 0.001$), partially significant in 5 / 11 (t-test, $p < 0.01$), and no statistical difference in most sectors of the normal group (1 / 11 sectors was significant, t-test, $p < 0.9$). Sensitivity and specificity of the HSA protocol in detecting glaucoma was 97 % and 86 %, respectively, and for glaucoma suspect patients the values were 89 % and 79 %, respectively. The authors concluded that the new HSA protocol used in the mfVEP testing can be applied to detect glaucomatous visual field defects in both glaucoma and glaucoma suspect patients. Using this protocol can provide information about focal visual field differences across the horizontal midline, which can be utilized to differentiate between glaucoma and normal subjects. They stated that sensitivity and specificity of the mfVEP test showed very promising results and correlated with other anatomical changes in glaucoma field loss. Well-designed studies are needed to establish the clinical value of mfVEP for the diagnosis of glaucoma.

Furthermore, UpToDate reviews on â€œOpen-angle glaucoma: Epidemiology, clinical presentation, and diagnosisâ€ (Jacobs, 2014) and â€œAngle-closure glaucomaâ€ (Weizer, 2014) do not mention the use of mfVEP as a diagnostic tool.

CPT Codes / HCPCS Codes / ICD-9 Codes

CPT codes not covered for indications listed in the CPB:

Multi-focal visual evoked potential:

No specific code

0181T	Corneal hysteresis determination, by air impulse stimulation, bilateral, with interpretation and report
0198T	Measurement of ocular blood flow by repetitive intraocular pressure sampling, with interpretation and report
0329T	Monitoring of intraocular pressure for 24 hours or longer, unilateral or bilateral, with interpretation and report

ICD-9 codes not covered for indications listed in the CPB (not all-inclusive):

365.0 - 365.9	Glaucoma
V80.1	Special screening for glaucoma

Diagnosis and Treatment of Secondary Lymphedema

May 28, 2010

Prepared for:

Agency for Healthcare
Research and Quality
540 Gaither Road
Rockville, Maryland 20850

This report may be used, in whole or in part, as the basis for development of clinical practice guidelines and other quality enhancement tools, or as a basis for reimbursement and coverage policies. AHRQ or U.S. Department of Health and Human Services endorsement of such derivative products may not be stated or implied.

None of the investigators has any affiliations or financial involvement related to the material presented in this report.

Acknowledgments

We would like to thank Dr. Pasqualina Santaguida and Dr. Cynthia Balion for their helpful insights and guidance during the development of this report.

We also thank our librarian, Maureen Rice, for her thorough management of search terms and project methodology. We would also like to thank the following people who assisted with screening and data extraction: Sameer Rawal, Connie Freeborn, Maureen Rice, Mary Gauld, and Lynda Booker. Thank you to Mary Gauld for her assistance with project coordination and to Karen Siegel for being our Task Order Officer.

Thank you to our editorial staff, Cecile Royer, Roxanne Cheeseman, and Maureen Rice for providing invaluable input into this document, as well as to Rashmi D'Mello for her assistance managing data.

SLNB group and 16 percent in the SLNB/ALND group.[6] The Royal Australian College of Surgeons conducted an international, multicenter, randomized controlled trial (RCT) that examined SLNB versus axillary dissection in women with breast cancer. The study found that women receiving SLNB had less lymphedema, less pain, and less arm dysfunction.[7]

Lymphedema is typically diagnosed by clinical history and physical examination.[2] When imaging tests are required to assist in diagnosis, lymphoscintigraphy is often the test of first choice.[3] When lymphoscintigraphy is not available, magnetic resonance imaging (MRI) and computed tomography (CT) can also be used.[3]

The U.S. Food and Drug Administration (FDA) regulates the marketing and use of medical devices in the United States. The FDA does not specifically mention the use of lymphoscintigraphy, MRI, ultrasound, or CT to diagnose lymphedema.

There are several nonpharmacological and nonsurgical treatments for lymphedema, including: compression techniques (e.g., multilayer bandaging techniques, self adherent wraps, compression garments at prescribed pressure gradients); intermittent pneumatic compression (IPC); decongestive therapy (also known as complex or complete decongestive therapy or complex decongestive therapy [CDT]); manual lymphatic drainage; exercise; laser treatment; ultrasound, and aquatherapy. No single treatment is considered usual care for lymphedema. Treatments are typically administered by physical or occupational therapists, though massage therapists, nurses, and physicians may also perform certain kinds of lymphedema treatment.

Methods

Literature Review

The following electronic databases were searched by exploding the subject heading 'lymphedema' and searching it as a textword (lymphedema or lymphoedema). Terms for complete decongestive therapy, manual lymphatic drainage, and intermittent pneumatic compression were included in the search. There were no language limitations for this search.

1. MEDLINE® (1990 – January 19, 2010);
2. EMBASE® (1990 – January 19, 2010);
3. Cochrane Central Register of Controlled Trials® (1990 – January 19, 2010);
4. AMED (1990 – January 19, 2010); and
5. CINAHL (1990 – January 19, 2010).

Further searches were conducted of reference lists of recently published review articles[2,8-11] and bibliographies of extracted articles.

Inclusion/exclusion criteria. For the diagnostic section, we included articles published in the English language that examined the sensitivity and specificity, or psychometric properties (e.g., reliability, validity, responsiveness) of diagnostic tests for lymphedema. Included articles had to contain an evaluation of the diagnostic test(s) on subjects with secondary lymphedema. For the treatment section, we included articles published in the English language, provided they were RCTs or observational studies with comparison groups (e.g., cohort, case control). We included studies of pediatric and adult patients who received any treatment for secondary lymphedema (except drug therapy or surgery) following any form of illness with the exception of filariasis infection.

Although rarely identified as gold standards, the frequency of use of different measures of limb volume or circumference would suggest that these measures are the de facto gold standards for diagnosing secondary lymphedema.

d) What is the sensitivity and specificity of tests used to diagnose lymphedema?

In the eight studies that contained examinations of the sensitivity and specificity of diagnostic tests for secondary lymphedema, sensitivities ranged from 5 to 100 percent (most were at least 40 or 50 percent or above) and specificities ranged from 71 to 100 percent.

e) What are the psychometric properties (reliability, validity, responsiveness) of these diagnostic methods?

Reliability. There is consistent evidence to indicate that lymphedema can be reliably measured using circumferential measures or volume displacement (although volume displacement calculated using Sitzia's method tended to produce the lowest intraclass correlation coefficients, which are measures of reliability). There is too little evidence to draw conclusions about the reliability of other tests such as tonometry, ultrasound, lymphoscintigraphy, or bioimpedance.

Validity. Based on consistently high correlation coefficients, there is strong evidence that limb volume and circumference are interchangeable among one another.

Responsiveness. Only two of the studies included in this report evaluated the responsiveness to change of diagnostic tests for secondary lymphedema. The dearth of evidence on this topic prohibits one from drawing firm conclusions about responsiveness.

f) How frequently and for how long should patients be measured for the development of lymphedema or its subclinical precursor? Does this vary with the diagnostic test method?

There is no evidence to answer these key questions as none of the included diagnostic studies were intended to address either question.

g) Does the diagnostic test method influence the choice of lymphedema treatment or patient outcome? What outcomes were measured in studies of diagnostic tests of lymphedema?

There is no evidence in the 41 diagnostic testing studies to answer either of these questions.

Treatment

Question 2. What were the patient selection criteria in the studies (inclusion and exclusion criteria)? Did they differ by treatment modality?

The major selection criterion in most of the 36 treatment studies was that persons had to have lymphedema secondary to breast cancer. Some studies contained specification that participants had to be in remission, have no relapse, or have no metastases. Various studies defined lymphedema as 'mild', 'chronic', or 'moderate to severe'; other definitions included categorization of lymphedema by excess volume in the affected limb, degree of swelling and excess volume, or degree of swelling alone. There was no evidence to suggest that patient selection criteria differed by treatment modality.

Question 7: Were there any treatments, combinations of treatment methods, or sequence of treatments shown to be more effective or ineffective for any type of lymphedema along the continuum, or patient characteristics (e.g., demographics or comorbidities)? Of particular interest: Is there evidence that the use of compression sleeves or low stretch bandaging is effective in maintaining reductions in lymphedema achieved through the use of other modalities (e.g., IPC, manual lymphatic drainage, exercise)?

There is no evidence to answer either part of this question. In no group of studies were the populations defined or the results reported in such a degree of detail that it was possible to identify groups of patients for whom these treatments are more, or less, effective. No studies were designed to examine the role of sleeve or bandaging in maintaining the benefits of initial treatment.

Question 8: What comparators were used in the studies? Are these comparators consistent with usual care for lymphedema?

Many treatments have been suggested to provide benefit for patients with lymphedema. Despite this, no single treatment has emerged as a gold standard in clinical trials. Due to this, there appears to be no agreement on a standard comparator for RCTs.

Question 9: What outcomes were measured in studies of lymphedema therapy? How effective were these treatment methods in reducing lymphedema?

Multiple outcomes were used in these reports (e.g., changes in limb volume or circumference, subjective symptoms [e.g., pain], range of joint motion, intra and extra cellular fluid levels through bioimpedance). Objective measurements, usually relating to some sort of assessment of limb volume, were the most frequently reported outcomes.

Question 10: Did any studies show that the time of treatment initiation (single modality or combination therapy) relative to symptom onset, any other lymphedema characteristics, or any patient characteristics influenced or predicted treatment outcome?

As few studies were sufficiently powered to detect a difference in the primary outcome (often defined as a reduction in lymphedema swelling over time), most trials were limited in their ability to detect differences in patient subgroups which were predictive for response. Few trials randomized patients with a stratification scheme or performed adjusted analyses to allow for detection of predictive factors.

Question 11: What was the length of followup in studies of lymphedema therapy? How long were the benefits of treatment maintained?

Considering the chronicity of lymphedema, very few trials performed long term followup in their study populations. Treatment benefits were shown to persist for up to 12 weeks in some studies with short term followup periods. Only eight of 36 studies reported outcomes at 6 months or more, with benefits shown to last for up to one year in some cases, provided there was use of maintenance therapy (i.e., elastic sleeve).

Question 12: What harms have been reported associated with the various treatments for lymphedema? Do any patient characteristics (e.g., demographics, comorbidities) or etiology of lymphedema increase the risk of these harms?

Conclusion

Although a great deal of research into the diagnosis and treatment of secondary lymphedema has already been undertaken, there is no evidence to suggest an optimal diagnostic testing protocol, an optimal frequency or duration of treatment, the most efficacious treatment combinations (including the use of maintenance therapy), the length of time for which persons should be tested or treated for lymphedema, and whether certain tests or treatments may benefit some types of patients more than others. The field of research into secondary lymphedema is ripe for advancement and the contents of this report may serve as a springboard to guide future scientific endeavors in this domain.

compression with calibrated gradient pressure) more effective in reducing lymphedema than another for any type of lymphedema along the continuum, or patient characteristic (e.g., demographics, comorbidities)?

b. Did the studies of IPC for lymphedema in patients with comorbidities such as wounds, arterial and/or venous insufficiency, diabetes, congestive heart failure, infection, etc., report the need to modify their treatment protocols? Did it affect treatment outcome?
c. Did the timing of an IPC application and/or the sequence of use of the various IPC device types (either alone or in combination with other therapies) influence outcomes either positively or negatively?

6. What protocols for single modality treatments resulted in the best outcomes of lymphedema therapy? Consider parameters such as usage schedules and characteristics of treatment such as intensity, duration, frequency and setting (self administered at home vs. professionally applied in a medical clinic), and if applicable pumping times/cycles and pressures.
7. Were there any treatments, combinations of treatment methods, or sequence of treatments shown to be more effective or ineffective for any type of lymphedema along the continuum, or patient characteristics (e.g., demographics, comorbidities)? Of particular interest: Is there evidence that the use of compression sleeves or low stretch bandaging is effective in maintaining reductions in lymphedema achieved through the use of other modalities (e.g., IPC, manual lymphatic drainage, exercise)?
8. What comparators were used in the studies? Are these comparators consistent with usual care for lymphedema?
9. What outcomes were measured in studies of lymphedema therapy? How effective were these treatment methods in reducing lymphedema?
10. Did any studies show that the time of treatment initiation (single modality or combination therapy) relative to symptom onset, any other lymphedema characteristics, or any patient characteristics influenced or predicted treatment outcome?
11. What was the length of followup in studies of lymphedema therapy? How long were the benefits of treatment maintained?
12. What harms have been reported associated with the various treatments for lymphedema? Do any patient characteristics (e.g., demographics, comorbidities) or etiology of lymphedema increase the risk of these harms?

Background

The human circulatory system is comprised of two interacting closed systems: the arterial-venous system and the lymphatic system. The lymphatic system is a network of vessels (lymphatics) which transport lymph. Lymph is a clear fluid that contains cells and proteins and originates as interstitial fluid (fluid that occupies space between cells). The lymphatic system drains lymph into the venous blood.[17]

Lymphedema is a pathological condition of the lymphatic system. The normal lymphatic system has three major functions, namely to transport lymph from the periphery of the body to the large veins of the chest and neck, to maintain homeostasis, and to regulate immunity.[18] Lymph flow occurs from peripheral lymphatics to the lymph nodes (distal to proximal). Peripheral lymphatics are dead ended and they originate in the distal-most tissues of the skin,

Secondary lymphedema. The exact pathophysiology of secondary lymphedema depends on its etiology. Globally, the most prevalent cause of secondary lymphedema is from infection with the nematode *Wusheria Bancrofti*, which leads to lymphatic filariasis. The filarial larvae enter the human host when a mosquito bites and then grow into adult worms that damage the lymphatic system, leading to a disruption of lymphatic flow. It has been estimated that more than 14 million people worldwide suffer from lymphedema and elephantiasis of the leg caused by lymphatic filariasis.[20] Filariasis is not endemic to the United States (U.S.) and thus incident cases of lymphatic filariasis are rare and occurrences can usually be traced back to a visit to an endemic country.

In the U.S., the most common cause of secondary lymphedema is malignancies and their related treatment (i.e., surgery, radiation). If a malignancy or tumor is present in the lymphatic system, then it can act as a physical block to lymph flow, thereby leading to lymphedema. When lymph nodes are removed during the treatment of cancer, scarring and adhesions may develop that decrease or block lymph flow. Radiation therapy over the lymph nodes can cause further damage and scarring, which may impair lymph flow and lead to lymphedema.

Less common causes of secondary lymphedema include trauma, chronic venous insufficiency, nonfilariasis infection, and obesity. Trauma can destroy lymphatic structures contained in the skin, resulting in impaired lymph flow (e.g., severe burns).[3] In chronic venous insufficiency, there is usually longstanding damage to the veins and their valves. Valve failure results in a continual backflow of blood in the veins, which increases pressure on the veins and damages the delicate surrounding lymphatic structures. When the lymphatic structures are damaged, lymphedema ensues.[3] Infection in the lymphatics from a variety of sources, including possibly venipuncture, can cause lymphedema. For this reason, patients recovering from cancer treatment must be vigilant about skin care and the prevention of infection.[2]

Obesity has also been shown to impede the flow of lymph, leading to the accumulation of protein rich fluid in the subcutaneous tissue.[1]

The Incidence of Secondary Lymphedema in Both the Upper and Lower Extremities in the United States

The incidence of secondary lymphedema for all diagnostic categories is generally poorly documented. There is great variability in the incidence rates, which results from the variety of measurement techniques and definitions used in studies that evaluate the rates of lymphedema, as well as a general lack of literature on the incidence of secondary lymphedema.[2]

Filariasis. The incidence of filariasis in the U.S. is essentially zero percent as filariasis is not endemic to the U.S. The rare cases that are recorded can be traced back to travel and exposure in an endemic country.[21]

Upper extremity lymphedema. Breast cancer accounts for the majority of upper extremity secondary lymphedema in the U.S.[2] Rates of lymphedema after mastectomy have been reported between 24 to 49 percent.[2] A 5 year, population based, prospective study of female U.S citizens with incident breast cancer documented a 42 percent cumulative incidence of lymphedema following treatment for breast cancer.[22] Axillary node clearance and radiation therapy to the axilla have been shown to increase the incidence of lymphedema after breast cancer treatment, especially when radiation therapy is used adjunctively.[2,20] Conversely, sentinel node biopsies have been shown to decrease the incidence of secondary lymphedema compared to axillary dissection.[2,6]

Contrast lymphography is rarely used today as it requires surgery and has been associated with complications such as wound infection and damage to the lymphatic vessels.[23] On the other hand, lymphoscintigraphy (isotope lymphography) involves the injection of a radioisotope labeled colloid into the interdigital region of the affected limb. A gamma camera is then used to track the flow of colloid as it moves towards the proximal lymph nodes. Lymphoscintigraphy is superior to contrast lymphography as it allows the practitioner to measure lymph flow and carries less risk of complications.[23] Though lymphoscintigraphy is often recommended as the test of first choice for the detection of lymph flow abnormalities,[3] the test lacks universal standards of application.[24,25] Thus further research is warranted to refine the standards of application. When lymphoscintigraphy is not available or desired, magnetic resonance imaging (MRI) and computed tomography (CT) can be used. Both MRI and CT image lymphedema as a subcutaneous honeycomb pattern, though MRI is seen as superior to CT because it also detects excess fluid.[3] Ultrasound can also be used for evaluation of lymphedema and has been used to correlate subcutaneous tissue thickness with lymphedema and fibrosis progression.[26]

During physical examination for lymphedema of the extremities, various methods of limb volume measurement may be employed to determine if a volume increase is present in the affected limb. These methods include limb circumference measurement, water displacement (volumetry), and perometry. Volume measurements are compared with the unaffected limb and lymphedema is often defined as a 2 cm or greater difference in girth, a 200 ml or greater difference in volume or a 10 percent or greater difference in limb volume.[27] Tonometry and tissue dielectric constant may also be used to assess whether lymphedema is present in the limb.

Limb circumference measurement is used to calculate limb volume. A flexible non elastic measuring tape is employed to measure limb circumference at various anatomical landmarks or at given distances from the fingertips or toes.[27-29] Limb volume is then calculated using the frustrum sign method (volume of a truncated cone) or the disk model method (summed truncated cones).[30] The volume of a truncated cone is calculated by taking the circumference of the limb at two different points and using the distance between the two points to calculate volume. The disk model method divides the arm into 10 disks, each with a height of 5 cm. The volume of each disk is then calculated and all 10 volumes summed.[30] On the upper limb, the typical points of measurement are at the hand, wrist and above and below the lateral epicondyle. The advantages to limb circumference measurement is that it is fairly easy to perform in a clinical setting, has a low cost and has good reliability.[30,31] A drawback to limb circumference is the inability to accurately measure the volume of the hand due to its irregular shape.[32]

Volumetry is used to calculate limb volume by having subjects submerge their swollen limb into a cylinder filled with a known amount of water. The amount of water that is displaced by the limb is equal to its volume. To measure the amount of displaced water, one can weigh the water or measure the volume. Water displacement is a reliable method of measuring limb volume[30,31] though its use is not very practical in a clinical setting because of water spillage and space considerations.

Perometry, also known as infrared optoelectric volumetry, uses infra red light to measure the volume of a limb. The limb is placed in a solid frame and the perometer scans the limb taking volume measurements at multiple segments. Limb volume is then calculated by summing the volumes of elliptical segments using a special computer program.[28,30] Perometry for the upper limb using Volometer® (Bosl Medizintechnik, Aschen Germany) was shown to have excellent intrarater and interrater reliability (ICC = 0.997).[30] Though shown to be reliable, perometry is expensive, which may limit its clinical application.

CT. CT scan is 510k cleared for medical use, though highly regulated by the FDA due to radiation risk. The FDA does not specifically mention the use of CT for the diagnosis of lymphedema.

Ultrasound. Ultrasound, which is sometimes used to help with the diagnosis of lymphedema, has been 510k cleared by the FDA for medical imaging. There is no specific mention of the use of ultrasound in the diagnosis of lymphedema.[38]

Bioimpedance devices. Certain bioelectrical impedance devices have 510k clearance from the FDA. Impedimed Imp SFB7 Body Composition Analyzer has been cleared by the FDA as has the Impedimed L-Dex U400 BIS extracellular fluid analysis. The L-Dex U400 BIS has been cleared specifically for lymphedema use.[39,40]

Perometer. No evidence has been found for whether perometry is considered a device or if it has been cleared, either in general or specifically for lymphedema.

Tonometer. A search of the devices product classification database yielded no results for whether tonometry is considered a device or if it has been cleared, either in general or specifically for lymphedema.

Tissue dielectric constant. A search of the devices product classification database yielded no results for whether tonometry is considered a device or if it has been cleared, either in general or specifically for lymphedema.

Nonpharmacologic/Nonsurgical Methods of Treatment for Lymphedema

Compression techniques (including multilayer bandaging techniques, self adherent wraps, and compression garments at prescribed pressure gradients). Compression techniques consist of bandaging and compression garments. Both act to restore hydrostatic pressure in the limb and improve lymph flow.[41] Bandaging is performed with low stretch bandages designed to maintain a constant pressure at rest and an increased pressure with exercise, thus assisting the muscle pump effect. High stretch bandages are not recommended because their application pressure may be difficult to control at rest, thereby increasing the potential for impaired circulation. During exercise, there may be decreases in the pressure exerted by high stretch bandages, thus preventing an increase in lymph flow via the muscle pump effect.[41,42]

Compression garments are fitted to the individual patient and constructed with the intent of exerting a prescribed pressure on the limb. They can be of use to patients who are unable to self wrap with bandages.

Intermittent pneumatic compression. Intermittent pneumatic compression (IPC) is used in the treatment of lymphedema, as well as arterial disease, DVT, and chronic venous insufficiency.[43]

IPC devices consist of pneumatic cuffs connected to a pump that, when applied to human limbs, mimics the muscle pump effect that naturally occurs when muscles contract around the peripheral lymphatics.[43] It is thought that compression may empty terminal lymphatics, thereby allowing drainage of fluid from the interstitium and possibly facilitate fluid flow from the interstitium to the lymphatics. It is still not known if IPC assists protein clearance from tissue.[43]

With IPC, a pumping action on the limb is created by an air filled bladder that fills and exerts pressure on the limb. Most pumps are electrically driven and the timing of the IPC application varies significantly between devices. Cycle time can be as short as 2 seconds or as long as 2

650-1000nm in a scanning or spot laser form.[10] It has been suggested that the mechanism of action of LLLT encourages formation of lymphatic vessels (lymphangiogenesis), promotes lymph flow and stimulates the immune system.[10,33] LLLT has also been shown to break down scar tissue.[49]

Ultrasound (US). At present there is very little literature examining the use of US for lymphedema management. It is thought that US promotes lymph flow by way of wave propagation at the cellular level, which modifies cell metabolism and microcirculation.[50] The efficacy and safety of US remains to be established.

Aquatherapy. Aquatherapy, which consists of slow water based exercises, has been tried as a therapy for lymphedema.[51] The physiological rationale for the use of aquatherapy is based on the concepts of hydrostatic pressure, water temperature, and water viscosity. Hydrostatic pressure increases with the depth of water and lymphedematous limbs are thought to benefit from this pressure gradient through the direction of interstitial fluid toward the trunk.[51] Aquatherapy is performed in warm water to prevent capillary vasodilatation and decreased flow that can occur at lower temperatures. Water viscosity provides resistance to movement, which is believed to assist lymph flow via the muscle pump effect and promotes muscle strengthening. At present there is very little literature examining the use or efficacy of aquatherapy for lymphedema management.

What Method(s) of Treatment is Considered Usual Care for Lymphedema Management?

No single treatment is considered usual care for lymphedema. At present CDT, which is a combination of therapies, is suggested as the main method of conservative care for lymphedema.[2,41,44] CDT includes MLD, application of compression low stretch bandages, exercise, and skin care. IPC devices are sometimes used to supplement CDT.[41,44]

Who are the Health Care Professionals That Administer These Treatments? Are any Training or Certification Standards Required?

Typically, physical or occupational therapists administer lymphedema treatments, though massage therapists, nurses and physicians may also perform certain kinds of lymphedema treatment.[52] Health care professionals do not require any specific training prior to administering lymphedema treatment other than a valid license to practice their profession. This being said, many practitioners seek out additional specialized training in lymphedema management. Several schools exist to offer specialized training in lymphedema care. The Lymphology Association of North America (LANA) is a non-profit corporation that offers certification exams for practitioners of lymphedema care in an attempt to regulate and improve lymphedema management.[52]

inclusion criteria were advanced to the next level. Citations were also advanced if there was insufficient information to determine whether the inclusion criteria were satisfied. The complete, published manuscript was retrieved for all citations that passed through title and abstract screening. Once retrieved, the complete manuscript was screened to determine if the inclusion criteria were met (level three – full text – screening). At this stage, the raters assigned the studies to the key question or questions to which they applied.

At every stage of screening, agreement was required from both raters for a study to be promoted to the next level. Discrepancies were resolved by consensus. If consensus could not be reached, then a neutral third party reviewed the study in question and made a final decision.

Studies that passed the full text screening phase proceeded to full data extraction. The following information was extracted from each diagnosis article: type of diagnostic test, study design, sample size, inclusion and exclusion criteria, sensitivity/specificity, psychometric properties of test, and outcomes. The following information was extracted from each treatment article: type of treatment, study design, sample size, inclusion and exclusion criteria, criteria used to start and stop therapy, time of treatment initiation, time of lymphedema onset, provider of treatment, comparators in study, parameters of treatment, outcomes, length of followup, and reporting of harms.

The authors of this report reviewed the extracted data to confirm the accuracy of the work.

Non English Language Studies

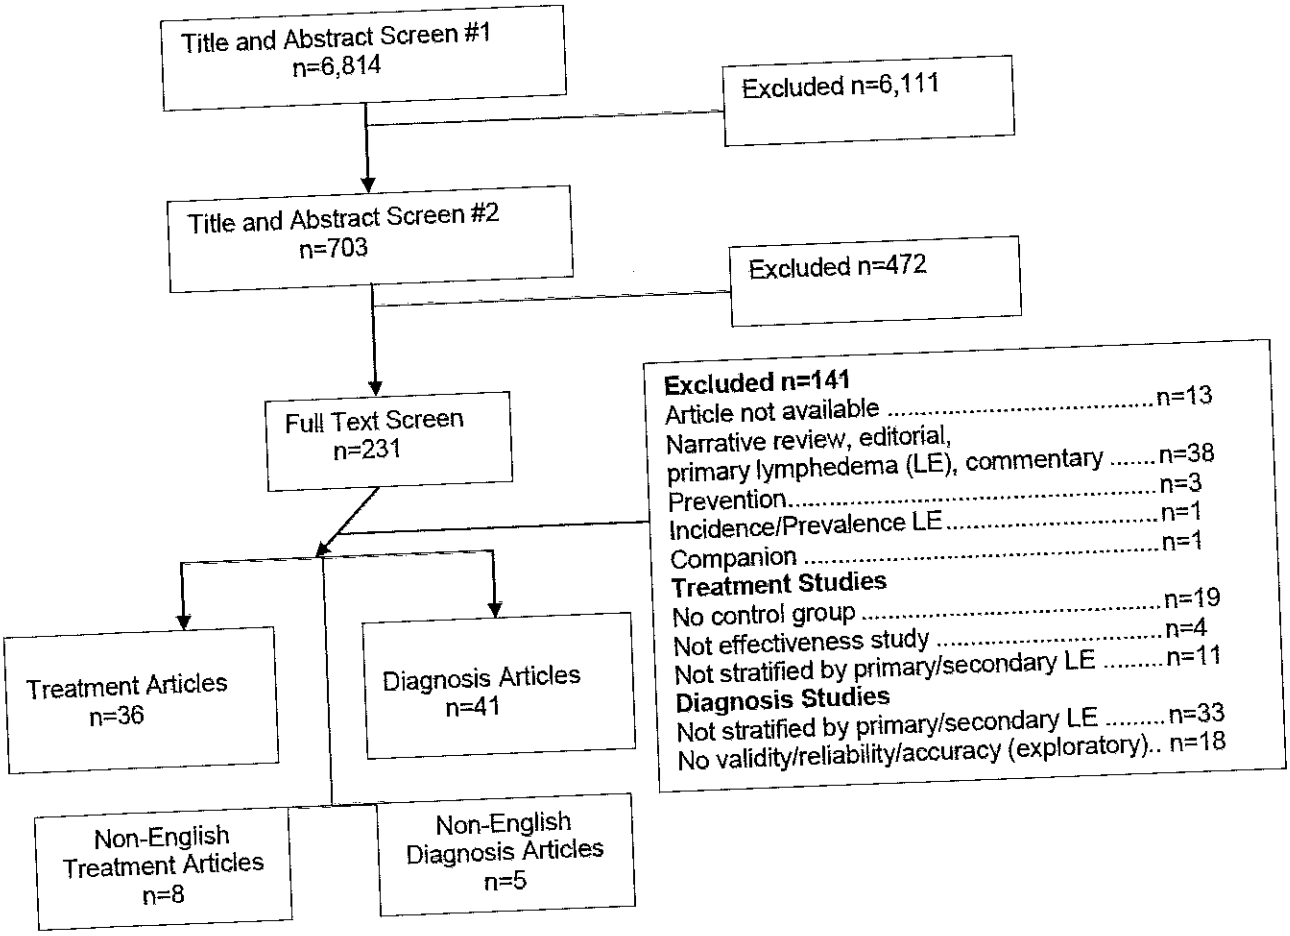
In response to peer review of the draft report, we reran the literature search a second time to identify non English language articles, which were screened at three levels as described above. The purpose was to examine whether the non English language literature was substantively different from the English language literature. We did not extract data from the non English language articles that survived the screening process. Rather, we provided a written summary of the main contents of these articles and discussed whether (and how) they differed from the English language literature.

Quality Assessment of Included Studies

Following data extraction of English language studies, two raters independently assessed the quality of these studies. Discrepancies were resolved by consensus or third party review. The quality of diagnostic studies was assessed using the Quality Assessment of Diagnostic Accuracy Studies (QUADAS) scale.[12] The QUADAS scale contains 14 questions that examine potential sources of bias in diagnostic studies. Response options are 'yes', 'no', or 'unclear'. The general domains covered by the questions include representativeness of subjects, clear selection criteria, and appropriateness of the reference standard test. Unlike many quality instruments, the QUADAS does not award points for answers that signify 'good quality', nor is there a summary score.

The quality of treatment studies was assessed using two scales, the modified Jadad scale for RCTs and the Newcastle-Ottawa Scale (NOS) for cohort and case control studies. The modified Jadad scale[13,14] contains six questions covering the following domains: randomization, double blinding, tracking of withdrawals and adverse effects, use of statistics, and inclusion and exclusion criteria. One point is awarded for each 'yes' response; zero points for 'no' responses.

Figure 1. Flow diagram showing the numbers of articles processed at each level



possibility exists that patient withdrawals were minimal or nonexistent in most of these studies due to the limited number of assessments (usually one or two conducted on the same day) and purpose of the assessments (to examine the utility of diagnostic tests rather than to administer a treatment). The reporting of intermediate results may in fact be irrelevant to most diagnostic studies because the intent was to compare the results of different tests, rather than to follow a cohort of persons over time. Given the intent of diagnostic accuracy studies, the authors may not have thought it necessary to use limited journal space to describe the selection and training of raters. Thus, many of the 'fair' studies may have been rated as such due to reporting or relevancy issues rather than due to fundamental flaws in the research. Certainly, one limitation of quality assessment is that reviewers essentially examine the quality of what was reported in the published article rather than what was actually done in the study.[102]

More problematic in terms of quality was the fact that four of nine reliability studies[28,67,92,100] did not contain reports of whether appropriate intervals were used between administrations of the tests of interest. While this may be a reporting rather than a quality issue, a fundamental aspect of any reliability study is to ensure that repeated administrations of the test occur in a timeframe where the underlying condition of interest has not changed, (e.g., the severity of a person's lymphedema remains constant). It will not be possible to assess test-retest or interrater reliability if the underlying condition changes between administrations of the diagnostic test. Authors of reliability studies should comment on the timeframe of their test administrations. In addition, none of the 30 validity studies reported whether the results of the index test were interpreted without knowledge of the results of the reference standard. To prevent the results of the first test from biasing the interpretation of results from the second test, different persons should assess the test results in a blinded fashion. Authors of validity studies should report whether the test results were interpreted in a blinded fashion.

Tables 2 to 4 contain a summary of the quality assessment of the diagnostic accuracy studies.

Treatment

Of the 36 studies that looked at treatments for secondary lymphedema, 30 were randomized controlled trials (RCTs)[33,47,48,103-129] and six were observational (cohort) studies.[50,130-134] The majority of the RCTs were of 'fair' quality and there was an even split between 'good' and 'fair' quality observational studies (Figure 3).

not specify how these conditions were defined or measured. Thus, there is no way to determine whether the ascertainment of adverse effects may have been biased in the extracted clinical trials.

Turning to the observational studies, the major quality issue was a lack of addressing the comparability of the exposed and unexposed groups in the design or analysis of the studies. In the absence of randomization, control of confounding in observational studies requires techniques such as matching, stratification, or use of multivariable regression analysis. Four of the six studies[130,131,133,134] did not contain reports of whether methods were used to control for confounding. The authors of the other two studies[50,132] indicated that the exposed and unexposed groups were matched on severity of lymphedema.

Tables 5 and 6 contain a summary of the quality assessment of the treatment studies.

Diagnosis Studies

Question 1. What is the performance of diagnostic tests for preclinical and/or clinically significant lymphedema?

a) What inclusion criteria (including patient demographics, signs, and symptoms) were used in studies evaluating the performance of diagnostic tests of lymphedema?

Of the 41 diagnosis studies contained in the review, 35 included persons who had breast cancer (Table 7).[27,28,30,31,36,67,68,70,71,73-79,81-87,89-99,101] Other disease related inclusion criteria were melanoma tumor removal,[69] AIDS and Kaposi's Sarcoma,[72] or lymphedema diagnosis.[66,73,77,79,80,88,90,99] Miscellaneous criteria included subjects who had a traumatic accident[79] or who lived within a certain radius of the study site.[68,74,95] For comparative purposes, many diagnostic studies also included nondiseased persons such as clinic staff,[28,91] healthy patients,[71,90,97] or medical students and surgical residents.[91,93] Most studies had liberal age requirements (e.g., 18 years or more,[27,71,77,78,97] less than 75 years[68,74]) and wide ranges of ages of included persons (e.g., 35 to 67 years,[82] 40 to 83 years[88]). Mean and median ages of included persons tended to lie above 50 years.[30,67,73,80,83,85,89,92,93,98] Time since diagnosis or treatment of the primary condition (e.g., cancer) was an inclusion criterion in three studies.[67,69,74] Timeframes in these studies were variable: six months or less,[74] more than six months,[69] and at least 12 months.[67] Three studies excluded persons with concomitant skin disease;[31,75,76] three studies excluded pregnant women.[97,98,100]

b) Is there any "gold standard" method to formally grade or measure the severity of lymphedema?

Only three articles pertaining to diagnostic testing for lymphedema included a measure of severity (Table 7). In a study comparing self reported lymphedema (i.e., patient questionnaire about whether limbs are a different size and whether the differences are noticeable) to physical therapists' measures of arm circumference, the severity of lymphedema was assessed by comparing the circumferential differences between the affected and unaffected arms.[83] Differences of ≤2 cm signified mild lymphedema, >2 or <5 cm indicated moderate lymphedema, and ≥5 cm or more suggested severe lymphedema. This severity scale was developed by the two physical therapists who were involved in the study. The authors did not provide any details about the validity of this classification. The authors also compared self-report on the questionnaire to a 'rule based' assessment of circumferential differences: ≤1 cm meant no lymphedema, >1 cm and ≤2 cm indicated mild lymphedema, >2 cm and <5 cm signified moderate lymphedema, and ≥5

bioimpedance. Sensitivity and specificity were 42 percent and 88 percent for arm circumference and 61 percent and 59 percent for self report, compared to bioimpedance.

Another study contained measures of whole limb volume perometry and arm circumference on persons diagnosed with lymphedema following melanoma.[69] Perometry changes of at least 15 percent and circumference changes of at least 7 percent signified lymphedema. The test of interest was patient self assessment of whether lymphedema was moderate or severe. Sensitivity and specificity were 56 percent and 95 percent for perometry and 50 percent and 100 percent for arm circumference, compared to self assessment. The authors of another study, conducted with persons suffering from lymphedema following breast cancer, compared an abbreviated number of circumferential measurements to a more extensive number of measurements.[78] For the abbreviated regimen, two measurements were taken, one above and one below the elbow. The comparator test involved measurements taken across the palm of the hand, at the wrist, at 10 cm intervals proximal to the wrist, and at the elbow. Sensitivity and specificity were 37 percent and 92 percent for the abbreviated measurement regimen when a 10 percent change in circumference versus the preoperative state was defined as lymphedema. When the threshold change was lowered to 5 percent, sensitivity was 80 percent and specificity was 71 percent.[78]

Persons with breast cancer were included in a study where the tests of interest involved differences in the sum of arm circumference between the treated and untreated arms.[74] Circumferential differences to diagnose lymphedema were established at $\geq$5 cm and $\geq$10 cm. A self report test was also evaluated in the study. Self report contained one question asking patients if they experienced swelling after the diagnosis of lymphedema (response: yes or no). The test of interest was multifrequency bioimpedance. For differences of $\geq$5 cm versus bioimpedance, sensitivity was 35 percent and specificity was 89 percent; for differences of $\geq$10 cm versus bioimpedance, sensitivity was 5 percent and specificity was 100 percent; for self report compared to bioimpedance, sensitivity was 65 percent and specificity was 77 percent.

Bioimpedance was again used diagnostically in a study of 102 persons with breast cancer.[95] Bioimpedeance measures were taken prior to surgery, one month postsurgery, and then at two month intervals until 24 months following surgery. Clinical diagnosis of secondary lymphedema was established through measures of limb volume. The sensitivity of bioimpedance compared to limb volume was 100 percent and the specificity was 98 percent.

A self report served as the test of interest in a study involving persons with breast cancer.[83] This self report contained two questions asking patients whether they noticed if and to what extent their limbs were a different size. The comparator was assessment by a physiotherapist, which was either rule based (i.e., measured changes in circumferential measurement) or clinical observation. Sensitivity comparisons to the rule based and clinical assessments ranged from 93 to 96 percent; specificity comparisons ranged from 69 to 75 percent.

In a study composed of persons with AIDS-related Kaposi's Sarcoma, the tests of interest were a ^{99m}Tc-hexakis-2-methoxy isobutyl isonitrate scan (scintigraphy) and an undefined clinical examination.[72] Forty persons were included in the study and 18 were diagnosed with lymphedema using the scan and 12 were diagnosed using the clinical examination.

The final study assessed sensitivity and specificity for multiple cut off points using volumetry and perometry taken together as a joined set of measurements.[70] The comparator test was unclear. Sensitivity ranged from 73 to 90 percent; specificity ranged from 69 to 78 percent.

A study without limb volume or circumference was a comparison of lymphoscintigraphy and clinical assessment (see Question 1b) to stage lymphedema on a five-point scale.[92] The weighted kappa of 0.77 indicated excellent agreement on staging between these methods. A 4-item questionnaire on truncal swelling was compared to caliper-based skinfold measures of truncal swelling in a study of 12 persons.[86] The questionnaire was developed by the authors and there was no report of whether it was validated prior to use in the study. The correlation between caliper measures of 'creep' (i.e., skin deformations over time) and the questionnaire score (score range is 0 to 8, with higher scores indicating more swelling) was 0.75. The final validity study without a measure of limb volume or circumference compared the torsional rigidity of normal versus lymphedema-affected skin in a group of persons with secondary lymphedema.[75] The authors found that the power to rotate normal skin exceeded the power to rotate diseased skin by 46.3 percent, although the difference was not statistically significant at the 5 percent level ($p = 0.13$).

Two validity studies compared perometer to tape measure. Correlation coefficients between measures were 0.98 for legs and 0.96 for arms in one study[66] and 0.99 for arms in the other study.[91]

Seven studies measured water displacement and made comparisons with limb circumference. In one of these studies, limb circumference was measured using frustrum calculation and tape measure.[79] In frustrum calculation, the limb is viewed as a geometric shape (usually a cone) and specialized formulae are used to measure circumference. In three other studies, limb circumference was calculated using tape measure alone[28,89] or an unexplained method.[90] Correlation coefficients ranged from 0.88 to 0.99. In the fifth study, inverse water volumetry was compared to limb circumference expressed as a ratio between the affected and unaffected limbs and the ICCs ranged from 0.89 to 0.91.[73] In the sixth study, water displacement was compared to Sitzia's method (a specific formula for frustrum calculation[137]) of measuring arm circumference (at 4 or 8 cm intervals) and ICCs ranged from 0.71 to 0.87.[77] Comparison of arm circumference measures at 4 cm with measures at 8 cm yielded ICCs of 0.80 for one rater and 0.92 for a second rater. The seventh study compared interstitial fluid pressure with arm volume ($r = 0.29$ after outlier removal).[88]

The focus of one study was entirely on different interval measures of arm circumference.[84] Intervals of 10 cm were compared to intervals of 3.81 cm (1.5 inches) and the correlation between measures was calculated to be 0.94 or greater.

One study was undertaken to compare two types of physiotherapists' assessments of arm circumference (see Question 1b) to a self report questionnaire.[83] The self report questionnaire asked respondents to indicate whether their affected and unaffected limbs were a different size and whether the differences were noticeable. Weighted kappa's ranged from 0.70 to 0.84, primarily depending on the type of assessment. The lowest kappa's were estimated when the rule-based assessment of arm circumference was compared to the questionnaire (kappa's of 0.70 and 0.76).

Five studies involved bioimpedance and a group of other tests: perometer alone,[80,98] tape measure alone,[85,87] or the combination of perometer, tape measure, and the Lymphedema Breast Cancer Questionnaire (LBCQ).[71] In three of these five studies,[71,80,87] correlation coefficients between all tests ranged from 0.61 to 0.99, with lows of 0.61 between bioimpedance and perometer[80] and 0.70 between bioimpedance and arm circumference assessed with tape measure.[87] Statistically significant correlations between symptoms on the LBCQ and other tests were limited to two domains, namely swelling and firmness/tightness (correlation coefficients

resistance.[31] Differences were 75 mL for water displacement, 0.46 to 1.02 cm for limb circumference measurement, and 0.32 to 1.01 mm for tissue resistance. In the second study, a standard error of the mean of less than or equal to 150 mL was found to be measurement error in an investigation of limb circumference measurement and water displacement.[28] Both studies recruited persons with breast cancer, although one study also included an undefined control group.[28]

f) How frequently and for how long should patients be measured for the development of lymphedema or its sub-clinical precursor? Does this vary with the diagnostic test method?

Fifteen of the 41 diagnostic studies included in this report involved a single assessment of patients (Table 7).[30,31,67,69,71,72,74,87-91,96,98,99] The authors of one of these studies reported that two of 40 patients received a repeat ^{99m}Tc-hexakis-2-methoxy isobutyl isonitrate scan,[72] but no reason was given for performing the second test. None of the authors provided a rationale for limiting their assessments to a single point in time.

The remaining 26 studies involved two or more assessments. In four studies, there were repeat assessments without a clear rationale to explain why.[66,68,78,136]

Seven of the 26 studies contained multiple assessments to permit the study of test-retest or interrater reliability.[28,73,77,79,82,83,100] These repeat assessments were typically performed two or three times, usually on the same day, 1 week apart, or 4 weeks apart.

In six studies, two assessments were conducted to assess the validity of various tests: lymphoscintigraphy versus clinical examination,[92] lymphoscintigraphy versus arm volume,[81] torsional rigidity on swollen and non-swollen arms,[75] ultrasound versus arm circumference,[76] LBCQ versus arm circumference,[36] and 10 cm versus 3.81 cm (1.5 inches) measures of arm volume.[84]

One study, on truncal lymphedema, contained two sets of two assessments to examine the test-retest reliability of skinfold caliper measurements and the validity of caliper measurements versus a 4-item questionnaire about truncal swelling.[86]

More than two assessments were done in seven of the 26 studies: a mean of two assessments to compare single frequency bioimpedance and bioimpedance spectroscopy;[97] four assessments to compare a single measure of tissue dielectric constant with the mean of three measures of tissue dielectric constant;[93,94] five quarterly assessments to examine the calculation of incidence of lymphedema over time using each of four methods (i.e., 200 mL difference in limb volume, 10 percent change in limb volume, 2 cm change in limb volume, or self reported limb swelling or heaviness);[27] five assessments (baseline, once weekly for 3 weeks, and 1 month post-baseline) to study the correlation of bioimpedance and perometry over time;[80] seven assessments of volumetry versus perometry at different cut off points;[70] and a maximum of 14 assessments to examine the diagnostic capability of bioimpedance.[95]

In the last of the 26 studies, measures of limb circumference and bioimpedance were taken daily for 4 weeks as part of the treatment protocol for a larger study being done to investigate a self-management program for lymphedema.[85]

In the 26 studies with multiple assessments, all except eight studies[75,86,92-94,97,99,136] included either limb volume or limb circumference as a diagnostic test. None of the 26 studies contained recommendations for the length of time that patients should be measured for the development of lymphedema, nor was there any evidence of variance based on type of test.

In the five observational studies included in the review, four were conducted in breast cancer survivors,[50,130,133,134] with the fifth in persons suffering from Kaposi's Sarcoma[132] and the sixth in persons with various cancers.[131] The observational studies generally had fewer inclusion and exclusion criteria than the RCTs (one observational study excepted[133]), but these criteria did not appreciably differ from the criteria used in the RCTs.

The inclusion and exclusion criteria were spread across the 36 studies. There was no grouping of similar criteria attached to any specific treatment modality.

Question 3. What were the criteria used to initiate treatment for lymphedema? When was treatment initiated compared to the time of onset of the lymphedema? What were the criteria used to stop therapy? Did these criteria vary with treatment modality?

In the 23 RCTs with Jadad scores between 4 and 8, the criterion used to initiate treatment was a diagnosis of secondary lymphedema. Details are shown in Table 11. This basic condition was specified as an inclusion criterion in all of the trials. In seven of these 23 RCTs, the authors specified general timeframes for recruitment compared to the time of onset of lymphedema: at least 3 months[104,118] or greater than 3 months,[114] a median of 9 to 10.5 months,[109] less than 1 year,[112] less than or equal to 2 years,[119] or 0 to 5 years.[113] Eleven studies contained reports of the time of recruitment following surgical or chemotherapy treatment for cancer: 3 to 6 weeks,[121] at least 3 months,[108] at least 4 months,[115,129] at least 6 months,[47,110] at least 12 months,[116,117,124] between 1 month and 1 year,[111] or at least 4 years.[120] In five RCTs, there was no report of when treatment was initiated compared to time of onset of lymphedema or treatment for cancer.[33,122,123,127,128] One study reported that subjects had a history of breast cancer 1 to 15 years before study entry.[48]

A single study reported that treatment was initiated for hospitalized patients only because a precondition of study entry was the failure of previous outpatient treatment for lymphedema.[124]

Only five studies contained criteria to stop therapy. Four of these studies were RCTs that scored in the 4 to 8 range on the Jadad scale. Two RCTs specified stoppage in the event of adverse effects.[47,112] Other stopping rules included a change of 25 percent change or more in the circumference of the lymphedema-affected arm versus the contralateral arm[110] or completion of the therapeutic regimen.[116] A single observational study contained criteria to stop therapy. Patients were not included in the second phase of treatment if there was less than a 10 percent volume difference between their abnormal and normal arm.[133]

The RCTs with Jadad scores between 0 and 3, as well as the six observational studies, did not exhibit characteristics that were vastly different from what was described above for the 18 RCTs with Jadad scores greater than 3. The exceptions were two RCTs in the Jadad 0 to 3 range that reported 'extreme' recruitment times of 2 days after surgery[106] or 5 years after surgery.[105]

Question 4. Who provided the treatments in the studies? What information was provided on their professional training or certification in lymphedema care?

Fifteen out of the 23 RCTs with a Jadad score between 4 and 8 reported the profession of the person who provided the lymphedema treatment. Some trials contained more than one type of professional.[47,48,113,116,117,123] The authors of nine trials reported that a physiotherapist provided treatment.[47,109,113-115,119,120,123,128] For four of these RCTs, the trial publication indicated that the physiotherapists had been trained in the Vodder technique for the provision of MLD.[109,114,115,123] In two other RCTs, the authors wrote that the person who delivered the treatment was trained in the Vodder technique, but they did not mention whether the person was a physiotherapist.[108,111]

randomized to one-to-one or three-to-one compression cycles, as well as to single-chamber or three-chamber sleeves, with no statistically significant differences found between groups when looking at the absolute extent of edema reduction.[125] The typical measure of efficacy was a change in arm volume or circumference.

None of the studies contained breakdowns of treatment efficacy by patient characteristics.

Question 5b. Did the studies of IPC for lymphedema in patients with comorbidities such as wounds, arterial and/or venous insufficiency, diabetes, congestive heart failure, infection, etc., report the need to modify their treatment protocols? Did it affect treatment outcome?

The need to modify protocols was not discussed by the authors of 10 of the 12 studies that included IPC therapy[50,103,104,108-113,128] (see Table 12). In one RCT, compression pressure was established for each patient based on the consistency of the edema: lower compression pressures for solid edema and higher pressures for soft edema. Pressures were always kept lower than diastolic blood pressure and ranged from 30 to 50mmHg.[125] The authors of one observational study wrote that lower levels of pressure were permitted in some patients treated with compression stockings, but they did not report the number of patients affected by the reductions, the mean decrease in pressure, nor how the reductions may have affected the comparisons with IPC.[130] The authors of the observational study indicated that the potential for pressure decreases was offered to participants as a means of increasing compliance, thereby suggesting a protocol modification. However, there was no discussion in either the RCT or the observational study of whether the compliance issue was related to comorbidity.

Question 5c. Did the timing of IPC application and/or the sequence of use of the various IPC device types (either alone or in combination with other therapies) influence outcomes either positively or negatively?

Six of the 12 studies involving IPC contained reports of the timing of the treatment.[104,108,109,111-113] IPC applied within 1 year of onset of lymphedema was not statistically significantly different from skin care and prophylaxis (cleaning wounds, gloves during gardening, avoidance of weight gain and venipuncture, prolonged sun exposure and carrying heavy weights),[112] but it was better as a supplement to MLD and compression garment when applied an average of 60 mths (3-480 mths) after lymphedema onset[111] (see Table 12). In two studies, IPC was applied within 5 years following lymphedema onset, showing better results versus massage as an adjunct to compression garment and showing no difference versus MLD.[109,113] One study had IPC applied at least 12 weeks following cancer treatment and results were better when IPC was added to MLD and compression bandaging versus MLD and bandaging alone.[108]When IPC was applied to patients who had arm lymphedema for at least 3 months, it performed statistically significantly worse than laser.[104]

Six studies did not report the precise timing of IPC application, with IPC performing statistically significantly better than massage (followed by elastic bandage),[103] no difference versus ultrasound,[50] no different when added to an elastic sleeve versus the sleeve alone,[110] no different when added to compression stockings versus the stockings alone,[130] and no different based on compression cycles or single versus triple sleeves, except for a relative edema reduction in the comparison of three-to-one compression cycles using single versus three-chamber sleeves ($p = 0.04$).[125] In the sixth study, IPC was given to both treatment groups as part of a multimodal therapy.[128]

receive any treatment. The difference in arm volume between groups, favoring the active treatment group, was 12.6 mL ($p = 0.04$).

One RCT ($n = 47$) compared laser to IPC over 12 weeks of followup.[104] Laser was delivered in three sessions per week for 4 weeks with a total of 1.5 Joules/cm^2 per session; IPC was given in five sessions per week for 4 weeks at 60mmHg per session. The change in arm circumference between affected and unaffected limbs was greater for laser than IPC over 12 weeks of followup ($p = 0.02$), but there were no differences on pain or grip strength measures.

A single RCT compared IPC to providing patients with guidelines on skin care for the affected limb.[112] IPC was delivered in two cycles lasting 2 weeks each, with a 5-week separation between the cycles. Each cycle consisted of five sessions per week at 60mmHg. Eighty patients were followed over 9 weeks, and no differences were shown in arm circumference between the groups.

The first exercise trial lasted 12 weeks and involved 32 persons.[47] Randomization was to a group that received 20 supervised, aerobic or resistance exercise sessions or to a group that was instructed to continue with habitual activities. No differences in reduction of lymphedema were found between the groups. The second exercise trial involved a semi-supervised weight-lifting program versus a fitness center membership with partial supervision. After 1 year, there were no statistically significant differences between groups in terms of the proportions of women with at least a 5% change in limb swelling.[48] The weight-lifting group reported reduced severity of lymphedema symptoms, improved upper- and lower-body strength, and fewer incidences of exacerbations of lymphedema.

An observational study examined the use of below-knee, custom-made stockings versus no treatment for lymphedema in a study of 65 persons that lasted for a mean of 5 to 6 months.[132] Differences in limb volume were highly significant between the groups and favored the stockings.

An RCT examining high (44 to 50mmHg) versus low (20 to 30mmHg) pressure bandages found statistically significant within group edema reductions after 24 hours, but no statistically significant between group differences.[124]

A trial comparing kinesiology taping versus MLD in persons who received limb-lengthening surgery reported that the taping was statistically significantly better than MLD.[126] However, the authors did not provide quantitative intergroup results (just intragroups results).

Question 7: Were there any treatments, combinations of treatment methods, or sequence of treatments shown to be more effective or ineffective for any type of lymphedema along the continuum, or patient characteristics (e.g., demographics, comorbidities)? Of particular interest: Is there evidence that the use of compression sleeves or low stretch bandaging is effective in maintaining reductions in lymphedema achieved through the use of other modalities (e.g., IPC, manual lymphatic drainage, exercise)?

There were 27 articles that addressed this question. Pneumatic compression was used as a study treatment in nine randomized trials. Six of those trials received a Jadad score of 4-8.[108-113] Three trials received a lower score.[103,104,125] Of the nine trials, IPC was shown superior to some form of massage-based treatment in three,[103,108,113] inferior to laser in one,[104] and equivalent to MLD with or without bandaging,[109,111] elastic sleeve,[110] and skin care.[112]

In one IPC study, a three-chamber sleeve was more efficacious than a single-chamber sleeve, using a three-to-one compression cycle, in reducing the relative extent of edema in women who had breast cancer.[125]

demonstrated long term volume reduction without the use of maintenance therapy. None of these studies was designed to examine the role of sleeve or bandaging in maintaining benefits of the initial treatment. No trials were identified which compared sleeve or bandage to no treatment in the volume reduction phase of a study.

Question 8: What comparators were used in the studies? Are these comparators consistent with usual care for lymphedema?

In five non-randomized studies, which included a comparator group, all five used different treatments as their comparator. These comparator treatments were pneumatic compression, bandaging, elastic compression garment, stocking and MLD, or no active treatment.[50,130,132-134]

Several RCTs did not clearly identify the treatments that were considered experimental or control. For purposes of this report, it was assumed that the more conservative therapy was the comparator.

There appeared to be little difference between the comparators chosen for higher or lower quality RCTs. The most common comparator used in nine randomized trials was a group of strategies loosely defined as either "usual care", sham treatment or no treatment.[33,47,107,112,116-118,121,130] The most commonly reported active therapies used as a comparator were some form of decongestive therapy,[105,108,111] or elastic sleeve.[110,115,130] Less commonly used study comparators were self-massage,[113] bandaging alone,[123,124] therapies reported as "simple lymphatic drainage".[114,122] Comparators used in some trials included IPC,[104] manual lymphatic drainage,[120,126] and physiotherapy.[106] In two randomized trials involving sequential pneumatic compression vs. MLD[103,109] it was difficult to interpret which of the two treatments was intended as experimental and which was the control. In one RCT, the comparator was a 1-year fitness membership with partially supervised instruction.[48] See Table 11 for details.

Question 9: What outcomes were measured in studies of lymphedema therapy? How effective were these treatment methods in reducing lymphedema?

A multiplicity of outcomes was used to detect benefit in the trials. The vast majority included some form of measurement related to volume of the affected area, although a few simply recorded changes in limb circumferences without reporting volumes.[103,104,110,112,118,121] Other outcomes included subjective symptoms such as pain, heaviness or tension,[104,105,109,118,120,121,133] range of motion in joints (usually shoulder),[33,108,109,115,118,120,129] grip strength,[104,109] measurements of intra- and extra-cellular fluid levels through bioimpedance,[33,47] skin-fold thickness,[116,117] and skin tonicity using tonometry.[33,108,111] Finally, several studies attempted to correlate results of lymphedema treatment with changes in quality of life.[107,113]

The six observational studies examined a mixed group of patients and treatments. One study reported on the use of ultrasound and pneumatic pressure therapy in breast cancer patients. For reasons that are not clear only 96 of 150 study patients contributed data to the final analysis. The authors found that both groups experienced a reduction in arm circumference over baseline values, but that there was no difference between the two treatment groups.[50] Another study of breast cancer patients included some patients with active disease. The reduction in lymphedema volume was 22 percent regardless of disease status but p values were not reported.[131] A study in breast cancer patients looked at the value of adding group talks and exercise sessions to a regimen including MLD and compression stocking. Outcomes in this study were measured using 'psychic well-being' and 'physical complaints' scales, with better psychic well-being shown in the talk/exercise group versus the comparator group ($p<0.05$). No between-group difference was

Therapy with a Deep Oscillation machine in addition to MLD was found to provide initial benefit to women who experienced swelling of the breast following surgery but this was not apparent at study end. Shoulder mobility was improved in the control group. This was the only study of breast, as opposed to arm, lymphedema in women with breast cancer.[120]

Lower quality trials were more likely to suggest benefit in the study group. Two involving pneumatic compression reported significantly more reduction in arm circumferences when compared to MLD,[103] but less than seen following laser.[104] A study of bone marrow stromal cell (BMSC) transplantation versus decongestive therapy reported greater reductions in excess arm volumes with transplant (81% vs. 55%; $p<0.001$) by study end. Both groups experienced a reduction in pain. The hypothesis for the transplant study was that BMSCs would promote the regeneration and reconstitution of lymphatic vessels.[105] A study of adding exercise as a method of reducing arm volumes did not suggest any improvement.[107] A further study examined the use of manual drainage in addition to physiotherapy in patients who had recently undergone ankle surgery.[106] The authors reported improved lymphedema volume loss with the addition of MLD (6.4%) over physiotherapy alone (0.1%; $p = 0.01$).

Question 10: Did any studies show that the time of treatment initiation (single modality or combination therapy) relative to symptom onset, any other lymphedema characteristics, or any patient characteristics influenced or predicted treatment outcome?

A minority of publications (8/36) commented on factors predictive for response to therapy.[48,112,113,115,119,123,131,132] With only two exceptions,[131,132] studies reporting on predictive factors were RCTs. No RCTs with a low quality score commented on predictive factors.

Pretreatment lymphedema volume was the most commonly reported factor, with contradictory findings. One study of massage and bandaging suggested a greater percentage response in those patients with mild, as opposed to moderate, cases.[123] Another similar study, however, suggested opposite results but did not provide any supporting statistics.[119] A third study suggested that pretreatment volumes were "predictive of treatment response" but did not report the direction of this association.[113] A fourth study examining pneumatic compression reported no influence of lymphedema severity on response.[112] One study also reported a non-significant trend toward better responses in those patients who had been diagnosed with lymphedema for less than 1 year.[123] Another reported no such difference with respect to duration.[112]

One study of MLD suggested that compliance with the use of elastic compression sleeves predicts for a better treatment response.[115]

Two non-randomized studies reported predictive factors on very specific patient populations in which active disease was allowed in the study groups. One report found no difference in the response to decongestive therapy, regardless of the presence or absence of active disease.[131] A further study found that those patients with leg lymphedema from Kaposi's sarcoma had a similar response to elastic stockings, regardless of chemotherapy use.[132]

Across all studies, several factors were not found to predict treatment response, including a history of prior radiation, prior chemo therapy, type of previous surgery, a history of prior infection, age, body mass index (BMI), and gender. The authors of an RCT where weight-lifting was the active treatment adjusted their results for cancer stage, number of cancer nodes, race, physical activity, diet, and BMI, and found no effects on the unadjusted results.[48]

visits, personal reasons, or refusal of therapy. Overall, 36 of 616 patients (6.0%) were reported as not receiving therapy as intended.[116,117 33,104,106,112,118,122,123] Unfortunately, it was not possible to discern whether refusal of therapy was due to adverse events in these situations.

Other adverse events more specifically addressed were much rarer. Because the majority of trials addressed lymphedema in patients with cancer, more specifically breast cancer, the most common finding reported was recurrence of malignant disease. Overall, 11 patients (2%) were found to have recurrent disease during or shortly after the study period.[33,47,112,116,117,119] Adverse events which may have been specific to therapy were less common, occurring in less than 1 percent of patients, such as infection, "skin reaction"/ dermatitis,[33,123] arm thrombosis,[33,117] headache with elevated blood pressure,[108] and arm pain.[123]

In a trial evaluating bandages, subjects getting high pressure bandages reported more pain and discomfort than subjects receiving low pressure bandages, although the assessment was done using an author developed scale.[124] A similar scale was used in an RCT comparing kinesiology tape with short stretch bandaging: subjects reported greater wound development from usage of the tape relative to the bandage ($p = 0.013$).[128]

Author	Study Type (reliability, validity, Sensitivity/ Specificity)	Sample Size	Question #1a Inclusion/ Exclusion Criteria	Question #1b Measure of Severity of LE	Question #1f Frequency of Assessment for LE	Question #1g Outcomes
Ward[87] 1992 Australia	Validity	LE n=15 Control n=15	Women with LE following BCa treatment; average age 53 years; duration of LE 1.5 months (average) Female controls from clinical staff/investigative team	Grade 2 LE (on 1-6 scale)	Single assessment	NR
Ward[98] 2009 Australia	Validity	LE n=45 Control n=21	Women clinically diagnosed with unilateral arm LE after BCa. Healthy control group, no history LE or BCa	NR	2 assessments each device to measure validity	NR
York[99] 2009 Australia	Validity	Arm LE n=28 Leg LE n=16 Healthy controls n=28	Women with arm LE post BCa Women with leg LE secondary to Ca Controls, no history of LE or surgery to axilla	NR	Single assessment	NR

Table 8. Psychometric properties of diagnostic studies (continued)

Author	Test(s)	Sample Size	Reliability	Validity	Responsiveness
Chen[31] 2008 Taiwan	Water displacement Circumference measurement Tonometry	Total n=31 Trial 1: Water displacement and circumference n=14 Trial 2: Tonometry n=17	ICCs for test-retest and interrater reliability ranged from 0.69 to 0.88	NR	Defined as smallest difference detectable 75 ml for water displacement 0.46 to 1.02 cm for limb circumference measurement 0.32 to 1.01mm for tissue resistance
Cornish[85] 2001 Australia	Index Test: MFBIA Reference Test: Limb circumference	n=102 LE patients n=60 healthy control	NR	NR	NR
Cornish[85] 1996 Australia	Bioimpedance daily measurements vs. circumferential measurements taken daily throughout 4 weeks of lymphedema treatment	n=20 LE Patients n=20 Control	NR	Bias scores decreased from 31% to 15% between 1 and 26 days of followup. Lower bias scores indicate better agreement	NR
Czerniec[100] 2010 Australia	Limb circumference, perometry, bioimpedance spectroscopy (BIS) and self report of LE	n=33 LE patients n=18 control	ICCs for intrarater reliability 0.95 to 1.00 for the three physical measures and 0.50 for visual analogue scale; interrater reliability, calculated for the physical measures only, ranged from 0.98 to 1.00	High agreement between limb circumference, perometry and BIS (r = 0.89- 0.99) Moderate agreement between physical measures and self-report (r= 0.65-0.71)	NR
Damstra[73] 2006 Netherlands	Inverse water volumetry vs. circumferential measurements (Herpertz method)	n=25	NR	ICCs ranged from 0.89 to 0.91	NR

Table 8. Psychometric properties of diagnostic studies (continued)

Author	Test(s)	Sample Size	Reliability	Validity	Responsiveness
Halaska[90] 2006 Prague	Multifrequency bioelectrical impedance, circumferential measurements, subgroup with water displacement	Total n=101 Group A n=60 (circumference & MFBIA):subgroups A1 n=7 (circumference & MFBIA 1-100kHz & water displacement), A2 n=20 (& MFBIA 200kHZ) Group B n=5 (circumference & MFBIA); Group C n=36 (circumference & MFBIA)	NR	Correlation between circumferential measurements and water displacement was 0.94	NR
Hayes[74] 2005 Australia	Index Test: Multifrequency bioelectrical impedance Reference Test: Sum of arm circumference and self report	Total n=294 Clinical component n=218 Data complete n=176	NR	NR	NR
Hayes[68] 2008 Australia	Index Test: Bioimpedance spectroscopy (BIS) Reference Test: Comparator: Sum of arm circumference and self report	n=287	NR	NR	NR
Karges[79] 2003 U.S.	Volumetric measurements taken with a volumeter minus fingers (UE-F) circumferential measures taken with a tape measure, calculated volume formula using truncated cone formula	n=14	NR	Correlation coefficient for volumetric measurements and tape measure was 0.98	NR

Table 8. Psychometric properties of diagnostic studies (continued)

Author	Test(s)	Sample Size	Reliability	Validity	Responsiveness
Meijer[77] 2004 Netherlands	Indirect volume determination (Sitzia's method) vs. water displacement	n=30	Intrarater reliability for water displacement ranged from 0.95 to 0.98 Intrarater reliability for Sitzia's method ranged from .90 to .99 with one low ICC of .62	Comparing Sitzia's method to water displacement: ICCs ranged from 0.71 to 0.87 Comparison of arm circumference measures at 4 cm with measures at 8 cm ICCs of 0.80 for one rater and 0.92 for a second rater	NR
Mellor[76] 2004 U.K.	Dermascan ultrasound	n=10	NR	Ultrasound strongly correlated with arm circumference, r=0.95	NR
Mirnajafi[75] 2004 Australia	Torsional rigidity of skin	n=17	NR	Power to rotate normal skin exceeded power to rotate diseased skin by 46.3%. Not significant (p=0.13)	NR
Moseley[67] 2002 Australia	Bioimpedance vs. Tonometry	n=12 healthy volunteers n=12 LE patients	Covariance for bioimpedance ranged from 0.002 to 0.0086 Covariance for tonometry ranged from 0.0129 to 0.0325	NR	NR

Table 8. Psychometric properties of diagnostic studies (continued)

Author	Test(s)	Sample Size	Reliability	Validity	Responsiveness
Roberts[86] 1995 U.K.	Modified Harpenden Skinfold Calipers Arm volume measurements	n=14 LE patients n=1 Healthy subject	Coefficient of standard variation of 5%	Correlation between caliper measures and questionnaire scores was 0.75	NR
Sagen[90] 2009 Norway	Simplified water displacement instrument (SWDI) vs. Cross sectional area (CSA) by computed tomography	n= 23	NR	Correlation of SWDI and total CSA of upper arm was r=0.904; correlation of SWDI and CSA of subcutaneous tissue r=0.867; correlation of SWDI and CSA of muscle tissue r=0.725	NR
Spillane[89] 2008 Australia	Index Test: Infrared Opto-electronic perometer technique Reference Test: circumference measurements, brief questionnaire	n=66	NR	NR	NR
Stanton[91] 1997 U.K	Opto-electronic limb volumeter (Perometer) and limb circumference	n=12	NR	Correlation of 0.988 between Perometer and limb circumference in patients with LE	NR
Szuba[61] 2002 U.S.	Quantitative radionuclide lymphoscintigraphy	n=19	NR	Correlation of outcome of therapy with pre-therapeutic axillary radioactivity level r=0.5	NR

Table 9. Sensitivity and specificity studies

Author	Study Design	Sample Size	Inclusion/Exclusion Criteria	Index Test	Reference Test	Sensitivity/Specificity
Bland[78] 2003 U.S.	Sensitivity/Specificity	n=90	≥18 years, male or female eligible. New diagnosed resectable BCa. Scheduled for mastectomy or lumpectomy, with lymph node sampling, dissection, or sentinel node biopsy, or breast conservation therapy followed by radiation therapy. Participants average age was 53.7 years, all female, half of patients had RT	Percent change in circumferential measurements above and below the elbow	10% change or more in volume. 1 cm change in circumference at any site	Sensitivity 37% and Specificity 92% for a 10% change in circumference above and below elbow Sensitivity 80% and Specificity 71% for a 5% change in circumference above and below elbow
Cornish[95] 2001 Australia	Sensitivity/Specificity	n=102 n=60 control	Dx BCa, living within 50 km of Brisbane pathological confirmation of tumor malignancy Axillary dissection	Bioimpedance (BI)	Limb volume	Sensitivity BI vs. limb Volume=100% Specificity BI=98%
Godoy[70] 2007 Brazil	Sensitivity/Specificity	n= 90	Women with LE following surgery for BCa Mean age 54.8 ± 11.7 yrs	Perometry	Volumetry	Comparator test was unclear; Sensitivity ranged from 73 to 90%; specificity ranged from 69 to 78 percent

Abbreviations: AIDS-KS=Acquired Immune Deficiency Syndrome-Karposi's Sarcoma, BCa=Breast Cancer, BI=Bioimpedance, BIS=Bioimpedance Spectroscopy, Dx=Diagnosis LE=Lymphedema, MFBIA=Multifrequency Bioelectrical Impedance, Rx=treatment, SOAC=Sum of Arm Circumference

Table 9. Sensitivity and specificity studies (continued)

Author	Study Design	Sample Size	Inclusion/Exclusion Criteria	Index Test	Reference Test	Sensitivity/Specificity
Spillane[69] 2008 Australia	Sensitivity/Specificity	n=66	Patients who had previously undergone an inguinal or ilio-inguinal dissection for melanoma >6 months previous, 31 male, 35 female, median age 44.2 (20-95) years range (20-95 years), 9 received RT	Infrared Opto-electronic perometer technique	Arm circumference Self assessment questionnaire	Sensitivity 56% and Specificity 95% for perometry vs. self assessment Sensitivity 50% and Specificity 100% for perometry vs. arm circumference

Table 10. Treatment basic study data (continued)

Study	Study Design	Type of Treatment	Sample Size	Cause of Lymphedema	Definition of Lymphedema	Co-morbidities	Other Inclusion/Exclusion Criteria
RCT							
Carati[33] 2003 Australia	RCT crossover plus within group comparison of one cycle vs. two cycle	LLLT one cycle vs. LLLT two cycles	n=37 n=27	LE secondary to BCa treatment	>200 ml difference between arms or ≥2 cm difference in arm circumference	NR	Inclusion: - female Exclusion: - presence of co-morbidities - significant change to the arm in past 3 months - inability to abduct arm for measurement - presence of primary LE of lower limbs
Damstra[124] 2009 Netherlands	RCT	Compression therapy: low vs. high pressure bandaging	n=18 low pressure n=18 high pressure	LE following BCa	Patients with moderate to severe LE as defined by ISL	NR	Inclusion: -female ->18 years of age -12 months post BCa Rx without signs of reoccurrence Exclusion: -allergy to materials -systemic diseases -arterial or venous disease

Table 10. Treatment basic study data (continued)

Study	Study Design	Type of Treatment	Sample Size	Cause of Lymphedema	Definition of Lymphedema	Co-morbidities	Other Inclusion/Exclusion Criteria
RCT							
Hayes[47] 2009 Australia	RCT	Mixed exercise program (aerobic and resistance)	n=16 Exercise n=16 Control	LE secondary to BCa treatment	Upper limb LE diagnosed by a health professional	NR	Inclusion: - women <76 years with completed Rx for unilateral BCa ≥6 months prior - able to travel to clinic for exercise for 12 weeks
Hou[105] 2008 China	RCT	Bone Marrow Stromal Cell Transplantation or Complex Decongestive Therapy	n=15 BMSC n=35 CDT	Lymphedema secondary to BCa	NR	NR	Exclusion: - radiotherapy
Irdesel[129] 2007 Turkey	RCT	Compression garment and exercise	n=10 exercise n=11 exercise + compression	LE secondary BCa	NR	NR	Exclusion: -BCa operation <4 months ago -recurrence or bilateral BCa -elephantiasis -congestive heart failure -deep vein thrombosis -acute infection -stage 4 BCa

Table 10. Treatment basic study data (continued)

Study	Study Design	Type of Treatment	Sample Size	Cause of Lymphedema	Definition of Lymphedema	Co-morbidities	Other Inclusion/Exclusion Criteria
RCT							
Johansson[109] 1998 Sweden	RCT	MLD vs. sequential pneumatic compression	n=14 MLD n=14 SPC	Unilateral LE after BCa surgery with axillary nodal dissection	>10% difference in LE affected arm vs. unaffected arm	NR	Exclusion: - previous contralateral breast disease - intercurrent disease affecting the swollen arm - difficulty participating for reasons such as dementia - treatment within the last 6 mths (except for wearing compression sleeve) - resolution of LE during initial use compression sleeve by all participants
Kaviani [118] 2006 Iran	RCT	LLLT	n=4 LLLT n=4 Control	LE secondary to BCa treatment	≥2 cm swelling in affected arm	NR	Inclusion: - no contraindications to laser therapy Exclusion: - metastatic disease
Kessler[106] 2003 Switzerland	RCT	Standard physiotherapy plus manual lymphatic drainage	n=11 SP and MLD n=12 SP	LE following hindfoot surgery	Clinically diagnosed post-operative swelling	NR	- Age: 18-75 yrs - good physical condition - no contraindications for lymph drainage

Table 10. Treatment basic study data (continued)

Study	Study Design	Type of Treatment	Sample Size	Cause of Lymphedema	Definition of Lymphedema	Co-morbidities	Other Inclusion/Exclusion Criteria
RCT							
Lau[127] 2009 China	RCT	LLLT vs. no Rx	n=11 LLLT n=10 control	LE secondary to BCa treatment	Arm volume difference of more 200 ml	NR	Inclusion: -18+ years -unilateral mastectomy + chemo and/or radiation Exclusion: -metastases -Hx of severe trauma to arm -kidney, heart or lung disorder -medications that alter body fluids -primary LE of lower limb -decrease shoulder ROM -cellulitis past 3 months
Maiya[121] 2008 India	RCT	LLLT and exercise	n=10 LLLT + exercise n=10 control (compression + exercise)	LE secondary to BCa treatment	circumference of UE 2 cm at any 2 points compared to normal limb	NR	Inclusion: - mastectomy for BCa - completion of RT Exclusion: - primary LE - infection of the limb
McKenzie[107] 2003 Canada	RCT	Exercise (resistance training plus arm ergometer)	n=7 Exercise n=7 Control	LE secondary to BCa	LE >2 cm and <8 cm at 1 measurement point	NR	Exclusion: - stage III LE - bilateral disease - medication that effects swelling

Table 10. Treatment basic study data (continued)

Study	Study Design	Type of Treatment	Sample Size	Cause of Lymphedema	Definition of Lymphedema	Co-morbidities	Other Inclusion/Exclusion Criteria
RCT							
Schmitz[48] 2009 U.S *companion Schmitz[138]	RCT	Weight lifting vs. no weight lifting	n= 141 intervention n=71 control n=70	LE secondary to BCa	Difference in volume or circumference of 10% or more affected vs. unaffected arm	NR	Inclusion: -1-15 years since BCa Dx -unilateral LE -BMI less 50 -not actively trying to lose weight -no evidence of cancer -no medical conditions that would limit exercise -no history of weight lifting in past year -at least one lymph node removed
Shaw [116] 2007 U.K.	RCT	Weight reduction program along with conventional treatment with compression hosiery	n=21 intervention n=11 control n=10	Arm LE following surgery for BCa	Affected arm volume ≥15% larger than unaffected	May or may not have been receiving hormone treatment	Inclusion: - remission from Ca - BMI ≥25 kg/m²
Shaw [117] 2007 U.K.	RCT	Diet intervention plus multilayer bandaging then compression hosiery or hosiery alone	n=19 weight reduction n=17 low fat diet n=15 control	Arm LE secondary to BCa treatment	≥20% greater volume than unaffected arm	NR	Inclusion: - Ca remission

diagnose lymphedema. However, few of the extracted studies included ultrasound or lymphoscintigraphy; studies that included these imaging tests did not consider them to be gold standards. Rather, these tests were evaluated as index tests (the tests under investigation).

d) What is the sensitivity and specificity of tests used to diagnose lymphedema?

In the eight studies that contained examinations of the sensitivity and specificity of diagnostic tests for secondary lymphedema, sensitivities ranged from 5 to 100 percent and specificities ranged from 71 to 100 percent. However, it was not possible to rank order the tests in terms of performance because there were too few studies from which to permit generalization, persons with three different underlying conditions were the subject of the studies (breast cancer, melanoma, Kaposi's Sarcoma), a mix of different tests were used (changes in circumference with different cut points, self reports, imaging), and several different reference standards were also used. Researchers must use a common reference standard as a first step to providing a clearer picture of the sensitivity and specificity of tests in persons with secondary lymphedema.

e) What are the psychometric properties (reliability, validity, responsiveness) of these diagnostic methods?

Reliability. There is consistent evidence to indicate that lymphedema can be reliably measured using circumferential measures or volume displacement. It should be noted that these studies were conducted in breast cancer patients with secondary lymphedema primarily in the upper extremities. One study pertained to the trunk of the body.[86] The excellent reliability of these measures might not be transferable to situations where lymphedema occurs in other parts of the body, or to cases where lymphedema occurs secondarily to other diseases besides breast cancer.

There is too little evidence to draw conclusions about the reliability of other tests such as tonometry, ultrasound, lymphoscintigraphy, or bioimpedance.

Validity. Twenty-three of the 30 validity studies involved some use of volume displacement or limb circumference as a diagnostic test for secondary lymphedema. Based on consistently high correlation coefficients, there is strong evidence that displacement and circumference are interchangeable amongst one another in terms of results. This interchangeability applies despite the various means of measuring displacement or circumference.

Tests involving bioimpedance show good validity when compared to tape measured circumference or perometry, although the correlation coefficients were not as high as the coefficients in the displacement-circumference comparisons. Self reported symptoms on the Lymphedema and Breast Cancer Questionnaire (LBCQ) also show good validity in comparison to bioimpedance, perometer, and tape measure, although the evidence is limited to a single study and correlation coefficients were also lower than the ones calculated for the displacement-circumference comparisons.[71]

The validity of ultrasound, lymphoscinitgraphy, CT scan, or MRI was evaluated in four studies. There is little evidence for the validity of these tests owing to the limited number of studies, small sample sizes, a questionable reference standard in one study,[92] and questionable means of scoring lymphoscinitgraphy in two studies.[81,92]

Given the limited extent to which the LBCQ has been examined as a diagnostic tool for secondary lymphedema, and the lower correlation coefficients found in the bioimpedance studies, the evidence suggests that volume displacement or limb circumference are the most valid means of diagnosing secondary lymphedema. Most of the validity studies included breast cancer

Treatment

Question 2. What were the patient selection criteria in the studies (inclusion and exclusion criteria)? Did they differ by treatment modality?

There were multiple inclusion and exclusion criteria spread across the 36 studies. There was no grouping of criteria attached to any specific treatment modality. Consequently, there is no evidence to suggest that patient selection criteria differed by treatment modality.

Question 3. What were the criteria used to initiate treatment for lymphedema? When was treatment initiated compared to the time of onset of the lymphedema? What were the criteria used to stop therapy? Did these criteria vary with treatment modality?

In all 36 treatment studies extracted for this report, a diagnosis of lymphedema was the only specific criteria used to initiate treatment. Only seven studies reported the approximate time of recruitment following onset of lymphedema. All except one of these studies began recruitment within 1 year of onset, but there was a wide range of recruiting times within this 1 year period. It should be noted that these are recruitment times following onset of lymphedema, not the times to initiation of treatment. Although it is likely that lymphedema treatment was initiated soon after recruitment, the time frame between recruitment and initiation was not reported in any article. Therefore, no evidence exists to provide a clear answer to the question about time of treatment initiation.

Only five studies reported specific criteria to stop treatment.[47,110,112,116,133] This number is too small to assess whether stopping criteria varied with treatment modality in the 36 studies that were extracted for this report.

Question 4. Who provided the treatments in the studies? What information was provided on their professional training or certification in lymphedema care?

The authors of 17 of the 36 treatment studies did not detail who provided the lymphedema treatment. Except in the case of patient self-massage, the provision of lymphedema treatment requires a trained professional such as a physiotherapist or a technician familiar with the operation of an IPC device. To enhance reporting, as well as to facilitate judgments about the generalizability of published studies, authors of future studies in the domain of lymphedema treatment should report on the professional status and qualifications of the persons delivering lymphedema therapy.

Question 5a. Was one type of pneumatic compression device and sleeve (e.g., non-segmented compression device, sequential segmented compression, or segmented compression with calibrated gradient pressure) more effective in reducing lymphedema than another for any type of lymphedema along the continuum, or patient characteristic (e.g., demographics, comorbidities)?

Twelve studies included IPC treatment.[50,103,104,108-113,130] There was no evidence from which to determine whether one type of IPC device and sleeve were more effective than others were across the continuum. The lack of evidence was partly a result of the fact that there were simply too few studies from which to conduct meaningful comparisons. Comparison was mainly inhibited by the degree of heterogeneity between articles: nine different types of IPC were investigated against multiple comparators. Comparators included MLD,[108,109,111] compression

There is no evidence to address whether the timing of the IPC application might have influenced the study outcomes. Six of the studies did not contain reports on timing.[50,103,104,110,125,128,130] In the other six studies, the treatment regimens were too heterogeneous to allow for the isolation of any potential effect of timing. For sequence of use, the conclusion is the same: the mix of different treatments does not permit the isolation of the effect of sequence. Hence, there is no evidence for sequence as well. Additionally, there are simply too few studies from which to establish definitive patterns about timing or sequence.

Question 6. What protocols for single modality treatments resulted in the best outcomes of lymphedema therapy? Consider parameters such as usage schedules and characteristics of treatment such as intensity, duration, frequency and setting (self-administered at home versus professionally administered applied in a medical clinic), and if applicable pumping times/cycles and pressures.

There were 12 studies that examined single modality treatments for lymphedema. This reflects the fact that most lymphedema treatment is delivered as some form of combination therapy. Most of the studies adopted unrealistic comparators to maintain the 'single modality' distinction. For example, it is unlikely that persons with secondary lymphedema would be treated in standard clinical practice with only a booklet on healthy eating[116] or instructions to continue with usual activities,[47,117] or no treatment whatsoever.[127,132] By the same token, the use of sham laser[33,118] is questionable because there is no actual treatment given to patients. Ideally, the comparator should be the standard, medically-accepted treatment for lymphedema in the locality where researchers are conducting the study.

Notwithstanding the above, there was no evidence from which to ascertain whether certain treatment protocols would lead to better outcomes. Certainly this was the case for exercise[47,48,129] and elastic stockings,[132] where too few studies of each treatment negated any ability to compare protocols. For the other treatments (diet, laser, IPC, bandage, tape), the number of studies of each treatment was also not sufficient to investigate the effect of protocol differences on outcomes.

To address the effect of protocol on outcome, a series of studies with nearly identical samples, lengths of followup, comparator therapies, and outcomes would need to be constructed, with the only difference being the protocol used to deliver the treatment of interest. In the diet, laser, and IPC studies, there was little standardization in most of these areas (with the exception of the definition of outcome). Additionally, epidemiologic and statistical issues such as bias and power would have to be addressed in the design and analysis of the studies to increase the confidence in results. In one RCT, placebo patients were allowed to cross over to the active treatment group and analyses were conducted with these 'crossovers' included in both groups. Also, all of the studies except one[48] had fewer than 100 participants. From a methodological perspective, there is simply too much noise from which to tease out the signal of a protocol effect on outcome.

Question 7: Were there any treatments, combinations of treatment methods, or sequence of treatments shown to be more effective or ineffective for any type of lymphedema along the continuum, or patient characteristics (e.g., demographics, comorbidities)? Of particular interest: Is there evidence that the use of compression sleeves or low stretch bandaging is effective in maintaining reductions in lymphedema achieved through the use of other modalities (e.g., IPC, manual lymphatic drainage, exercise)?

Question 9: What outcomes were measured in studies of lymphedema therapy? How effective were these treatment methods in reducing lymphedema?

Multiple outcomes were used in these reports. Objective measurements, usually relating to volume were most reported.

Many studies reported that treatment brought about a reduction in lymphedema volume. However, relative benefit is difficult to appreciate in that despite studies including comparator groups, some provided pre- and post-treatment assessments of each group but did not provide between group comparisons.[111,131] Other studies provided p values for comparisons but did not report point estimates in differences of benefit[110,112,130,132] leaving clinicians to question the clinical benefit of treatment. Even in those studies that did, report point estimates of benefit, the specific outcomes reported varied such that cross comparisons were difficult to make. For instance, arm measurements may have resulted in reporting of circumference differences,[103] percent volume loss,[122] absolute volume loss,[109] or proportion of patients achieving a pre-specified degree of benefit.[48,110]

Question 10: Did any studies show that the *time* of treatment initiation (single modality or combination therapy) relative to symptom onset, any other lymphedema characteristics, or any patient characteristics influenced or predicted treatment outcome?

Since few studies were sufficiently powered to detect a difference in the primary outcome, most trials were did not have power to detect differences in patient subgroups which were predictive for response. Few trials randomized patients with a stratification scheme or performed adjusted analyses to allow for detection of predictive factors. One RCT with 141 subjects specifically looked at differences according to cancer severity, race, physical activity, diet, and BMI and found no effect.[48]

Question 11: What was the length of followup in studies of lymphedema therapy? How long were the benefits of treatment maintained?

Considering the chronicity of lymphedema, very few trials performed long term followup in their study population. Only eight trials reported outcomes at 6 months or beyond.[48,50,104,105,110,111,115,132] One study reported outcomes at week 30 of the study, but this was only 12 weeks from the last treatment.[33] There was no consistent evidence regarding the length to which treatment benefits could be maintained.

Question 12: What harms have been reported associated with the various treatments for lymphedema? Do any patient characteristics (e.g., demographics, comorbidities) or etiology of lymphedema increase the risk of these harms?

Due to the nature of these studies, it was not always possible to delineate which patients were in which treatment group, preventing readers from drawing conclusions about the relative harms of various treatments. The majority of withdrawals and adverse events were related to treatment scheduling or disease recurrence, neither of which would be the direct result of therapy. Adverse events likely related to study therapy were all rare.

Even if all adverse events were in the treatment groups, their infrequency would be unlikely to result in statistical significance if formally tested. No studies reported on factors which may increase the risk of harms associated with treatment. There was no evidence in the extracted studies to answer this question.

Overall, the 5 non English diagnosis studies did not contribute substantive new information to the TA. The studies were conducted in the familiar population of breast cancer patients and the tests had all been evaluated in English language publications. The correlation between ultrasound and arm circumference in one non English study[142] was lower than many of the reported correlations in the English literature, but this could be a function of the specifics of one study rather than an indication of a new and important finding. Another non English study[141] addressed two key questions that were not covered in the English literature; however no general conclusions can be drawn from a single observational study of only two diagnostic tests.

Treatment

The 8 treatment studies were observational, with sample sizes ranging from 30[144,145] to 440.[146] Lengths of followup, in the studies where authors reported such information, ranged from 28 days[144] to 10 years.[146] All 8 studies involved breast cancer survivors with upper limb lymphedema. The authors of only one report specified the type of individual who provided therapy, i.e., a 'kinesiology therapist'.[147]

Three studies examined single modality treatments. The first study compared an education program for self administered MLD against an unspecified control treatment over 6 weeks of followup. Arm function, measured using a vaguely described questionnaire, was better in the treated group over the entire followup period ($p<0.05$).[148] In the second study, three groups were compared over 28 days: MLD via the 'Asdonk standard' for 1 hour/day; non Asdonk standard MLD for 1.5 hours/day; non Asdonk standard MLD for 1 hour/day. Although the author describes the Asdonk standard method, there are no references to this method given in the published manuscript.[144] The author reports a greater reduction in arm volume in the Asdonk group versus the other groups over the course of followup, but does not provide p-values or other quantitative statistics. The third study of single modality treatments compared single chamber IPC using a Jobst machine with multi chamber IPC using a Lymph-a-mat machine. Lymphedema severity decreased within each group over an unspecified followup time (described as 'beginning' and 'end' in the published figures); however, there was no statistically significant difference between groups at the 5% level.[149]

Three studies investigated multi modal treatments. The first study compared multi layer bandaging and MLD to simplified bandaging and MLD. Simplified bandaging, which was considered the active treatment, was 2 bandages juxtaposed one over the other rather than a more complex method of wrapping multiple bandages. After 12 to 16 sessions over 4 weeks, the group treated with simplified bandaging in addition to MLD showed larger decreases in edema relative to the comparison group ($p = 0.04$).[147] The second study involved a combination treatment of MLD, IPC, and exercise in two groups, with one of the groups given additional treatment in the form of bandage. The authors provide intragroup comparisons over time, but do not provide intergroup comparisons.[145] The third study involved a 10 year followup of 440 persons assigned nonrandomly to one of four groups. Each group received IPC at 40 to 110mmHg for 15 sessions lasting 1 hour each. Treatment was limited to IPC in one group, but treatment was IPC plus electrostimulation of muscles in a second group, IPC plus magnetic therapy in a third group, and IPC plus both electrostimulation and magnetic therapy in a fourth group. Percent changes in limb volume were highest in the fourth group, with all results statistically significantly different at the 5% level.[146]

ROC curve, perhaps due to the lack of agreement on a gold standard means of diagnosing lymphedema.

There was no evidence to suggest an adequate diagnostic testing protocol. The extracted studies failed to provide an indication of suitable frequencies of testing or time spans within which testing should be done. Additionally, there was no information to suggest whether the type of diagnostic test would have an effect on the choice of treatment or on patient outcomes.

Regarding treatment for secondary lymphedema, there was no evidence concerning the optimal criteria to initiate or stop treatment. While the studies suggested that most treatments did reduce the size of the lymphatic limb, there was too much heterogeneity in terms of therapy, inclusion, and exclusion criteria, and treatment protocols to suggest the optimality of one type of treatment over another. Despite the multiplicity of inclusion and exclusion criteria, almost no studies contained reports of treatment benefits in any subgroup of patients. In fact, most studies were not designed to look for treatment benefits in subgroups.

Adverse effects were only reported in a small number of studies. The adverse effects that were reported were generally rare and mild, and unlikely to be a major clinical issue.

The methodological quality of the extracted diagnosis and treatment studies was generally 'fair'. Many quality issues may have been related to a lack of adequate reporting rather than to methodological shortcomings in the conduct of the research. However, the authors of some studies omitted the reporting of fundamental aspects of their research. For example, there were reliability articles that did not contain mention of the intervals between administrations of the tests of interest, none of the validity studies indicated whether index test results were interpreted without knowledge of reference test results, and the majority of RCTs did not include comment on whether outcome assessors were blinded. While reporting oversight may be one reason for these omissions, the fundamental nature of the omitted elements suggests a certain degree of caution should be exercised when interpreting study results. This suggestion reflects a degree of healthy skepticism in the assessment of scientific research, i.e., to assume inadequate quality unless the study authors present evidence to the contrary.[102]

Although the quality of the extracted articles suggests the need for a guarded approach to interpreting results, quality did not appear to play a major role the answers to the key questions. The articles were far too heterogeneous in terms of test, treatment, and outcome to ascertain whether studies of a certain quality tended to group around any particular test, treatment, or outcome. Indeed, most of the studies were of 'fair' quality anyway, which suggests that quality was not a major factor in the response or interpretation of the key questions.

In looking at the extracted articles as a whole, it can be concluded that there is no evidence in the literature to suggest an optimal diagnostic testing protocol, an optimal frequency or duration of treatment, the most efficacious treatment combinations (including the use of maintenance therapy), and the length of time for which persons should be tested or treated for lymphedema.

Recommendations for Future Research

Diagnostic Testing. Prior to the initiation of further research into diagnostic testing, clinicians and researchers in the field of secondary lymphedema need to agree on a uniform, gold standard, diagnostic test. Existing work suggests that limb volume or circumference has already emerged as the de facto gold standard, but a set means of measuring volume or circumference should be adopted by the clinical and research communities. Ideally, this set means should be accessible by clinical and research centers globally to promote uniformity. If the strong validity

Most of the studies extracted for this report involved lymphedema to the upper extremities. Lower limb lymphedema was not well represented in the studies, despite its high incidence from cancer treatment.[20] More RCTs should be conducted in patients with secondary lymphedema in the lower limbs.

Although a great deal of research into the diagnosis and treatment of secondary lymphedema has already been undertaken, there is no evidence to suggest the optimal diagnostic test or treatment. Similarly, there is no evidence to suggest whether certain tests or treatments may benefit some types of patients more than others may. The field of research into secondary lymphedema is ripe for advancement and the contents of this report may serve as a springboard to guide future scientific endeavors in this domain.

Full Text Screening Questions

Ref ID:_____ Name of Screener:_____

1. Is this study a narrative review, a case study (n=1), a commentary, an editorial, a study of primary lymphedema/filariasis/drug treatments for lymphedema/surgical treatments ALONE for lymphedema?

○ Yes (STOP)

2. Is this study: (Check all that apply)

□ A qualitative study (STOP)

□ A Quality of Life (QOL) assessment of subjects with lymphedema (that does not examine efficacy of a Rx intervention) (STOP)

□ An incidence/prevalence study of lymphedema following surgery for cancer (STOP)

□A study of prevention for lymphedema (ie all subjects do not have lymphedema) (STOP)

□ An investigation study of lymph flow/lymphatic system with no treatment of diagnosis of lymphedema included (STOP)

□ None of the above (continue)

3. All or some of the patients have secondary LE or suspected secondary LE and if primary and secondary patients used, results are stratified by primary and secondary LE?

○ Yes (continue)

○ No (exclude)

4. Is this study:

○ Primarily an investigative/exploratory study of a diagnostic method(s) for lymphedema? (STOP)

○ Article evaluates the Sensitivity/Specificity, Reliability, Validity or Responsiveness of a diagnostic test for LE OR gives data to calculate 2x2 table for test (STOP) (Include)

○ Not a diagnosis study (continue)

5. Is this a study focusing on the efficacy of a non-surgical/non pharmacological treatment for secondary lymphedema?

○ Yes (continue)

○ No (STOP)

6. Is this study a:

○ RCT (include)

○ A non-RCT WITH a Control group (include)

○ No control group/subjects act as their own controls (exclude)

QUALITY SCORE FOR JADAD SCALE AND FOR MODIFIED JADAD SCALE

CRITERIA	RESULT	SCORING	SCORE
Reported as randomized	☐ YES ☐ NO	1 point for YES	
Randomization is appropriate	☐ YES ☐ NO ☐ NOT DESCRIBED	1 point for YES -1 point for NO	
Double blinding is reported	☐ YES ☐ NO	1 point for YES	
Double blinding is appropriate	☐ YES ☐ NO ☐ NOT DESCRIBED	1 point for YES -1 point for NO	
Withdrawals are reported by number and reason per arm	☐ YES ☐ NO	1 point for YES	
JADAD SCORE			/5
Method used to assess adverse events is described	☐ YES ☐ NO	1 point for YES	
Methods of statistical analysis are described	☐ YES ☐ NO	1 point for YES	
Inclusion criteria reported	☐ YES ☐ NO	1 point for YES in at least one of two criteria	
Exclusion criteria reported	☐ YES ☐ NO		
MODIFIED JADAD SCORE			/8

COHORT STUDIES

Selection

10. Representativeness of the exposed cohort

- □ Truly representative of the average secondary lymphedema patient in the community
- □ Somewhat representative of the average secondary lymphedema patient in the community
- □ Selected group of users e.g. nurses, volunteers
- □ No description of the derivation of the cohort

11. Selection of the non exposed cohort

- □ Drawn from the same community as the exposed cohort
- □ Drawn from a different source
- □ No description of the derivation of the non exposed cohort

12. Ascertainment of exposure

- □ Secure record (e.g. surgical records/clinical records)
- □ Structured interview
- □ Written self report
- □ No description

13. Demonstration that outcome of interest was not present at start of study

- □ Yes
- □ No

Comparability

14. Comparability of cohorts on the basis of the design or analysis

- □ Study controls for stage of lymphedema
- □ Study controls for time of onset of lymphedema

Outcome

15. Assessment of outcome

- □ Independent blind assessment
- □ Record linkage (some other objective measure not encompassed by "independent blind assignment" see above)
- □ Self report
- □ No description

16. Was follow-up long enough for outcomes to occur

- □ Yes (6 weeks +)
- □ No (less than 6 weeks)

17. Adequacy of follow up of cohorts

- □ Complete follow up – all subjects accounted for
- □ Subjects lost to follow up unlikely to introduce bias – small number lost (> 80%follow up), or description provided of those lost
- □ Follow up rate < 80% and no description of those lost
- □ No statement

QUADAS – Quality Assessment Tool for Reliability Diagnosis papers

	Yes	No	Unclear
1. Were study patients representative of the patients who will receive the test(s) in practice?			
2. Were selection criteria for patients clearly described?			
3. Were correct statistical measures used?			
4. Was execution of test and comparator described in sufficient detail to permit replication in another study?			
5. Were withdrawals from the study explained?			
6. Were intermediate results/incomplete data reported?			
7. Did assessors have adequate professional training to perform test/measurement?			
8. How were raters selected?			
9. Was interval between test-retest appropriate?			
10. Did independent ratings take place within a time frame that would ensure the condition did not change?			
Comments:

Assessment of Bilateral Limb Lymphedema by Bioelectrical Impedance Spectroscopy

Leigh Ward, PhD,† Ann Winall, Dipl Physiol,‡ Elizabeth Isenring, PhD,§ Andrew Hills, PhD,§ Sharon Czerniec, MHlthSci,† Elizabeth Dylke, MPhty,† and Sharon Kilbreath, PhD†*

Objective: The aim of the present study was to determine if the ratio of extracellular fluid (ECF), including the lymph, to that of intracellular fluid (ICF), as measured by bioimpedance spectroscopy (BIS), could be used to assess bilateral lymphedema (LE).

Background: The presence of LE is commonly determined as an increase in tissue volume due to the presence of excess lymph relative to the volume of a comparable unaffected body region or to comparative normative data. However, in bilateral LE of the limbs, a comparable body region, the contralateral limb, is also affected, precluding normalization. An alternative is to normalize the increase in lymph volume, as ECF, to that of ICF volume.

Methods: Extracellular/intracellular fluid ratios, expressed as the ratio of intracellular impedance (R_i) to extracellular impedance (R_0), for the limbs of 277 female and 224 male controls were determined from an accumulated database of impedance data. Equivalent data were obtained for an opportunistic cross-sectional sample of 37 female and 5 male participants with bilateral LE of the legs. The ratios of R_i/R_0 in the lymphedematous legs of the affected participants were compared with the equivalent ratios in the unaffected arms of the same participants and with those of the controls using box plots and visualized as bivariate data using tolerance ellipses.

Results: Despite R_i/R_0 ratios varying with age, sex, and limb dominance, comparison of the ratio for affected legs (normalized to the ratio in the unaffected arms) with equivalent ratios observed in a control population (as bivariate tolerance plots) was capable of discriminating between 70% and 89% of the participants with LE.

Conclusions: Bioelectrical impedance spectroscopy and determination of R_i/R_0 ratios as indices of ECF/ICF ratios holds promise for the semiquantitative assessment of bilateral LE.

Key Words: Bilateral, Lymphedema, Bioelectrical impedance spectroscopy, BIS

Lymphedema (LE) will be familiar to many surgeons as a chronic debilitating condition that may occur as a consequence of axillary and inguinal surgery and/or radiotherapy to lymph nodes. The precise incidence and prevalence is uncertain, but it is reported to occur in between 9% and 55% of patients receiving inguinal or ilioinguinal dissection.[1–3] This uncertainty is due largely to the lack of a universally accepted definition for the presence of LE.[2,4] Although a staging classification for LE based primarily on clinical features has been developed to describe the progression of the condition,[5] early detection and severity of LE are commonly based on changes in the volume or circumference of an affected limb relative to that of the contralateral control.[2,5–8] Such measurements are, however, not applicable in cases of bilateral LE, common in postgynecological LE, where there is no unaffected contralateral limb to act as a control.[3,9] Attempts have been made to overcome this problem by estimating the change in volume by comparing, for example, thigh-to-foot ratios of circumferences within the same limb.[10] Clearly, such an approach will again not work where the whole limb is affected.

Bioelectrical impedance spectroscopy (BIS) has been used for the assessment of arm LE since the early 1990s.[11] Bioelectrical impedance spectroscopy is based on the principle that the magnitude of the opposition (impedance) to the flow of a low-frequency alternating electric current through the limb is inversely proportional to the volume of fluid in the tissue. Thus, the impedance at a low frequency is a measure of the ECF volume and, at least in the early stages of LE, where excess lymphatic fluid accumulates, tissue impedance decreases proportionately.[12] (Strictly, the measured impedance is that of the extracellular water, but because the total extracellular fluid is approximately 95% water, the terms fluid and water are often used interchangeably.) Because there is wide biological variation between individuals in impedance values, the impedance per se of a limb cannot discriminate between an affected limb, that is, one with excess lymph, from a normal limb.[11] The impedance of an affected limb is therefore normalized to that of the contralateral unaffected limb and expressed as a ratio; the ratio is then compared with normative values. The method has been shown to detect accurately early-stage upper limb LE and monitor treatment efficacy (see Ward et al[12] for review) and to be suitable for early detection of lower limb LE.[13]

In bilateral LE, as with volumetric measurements, normalization to the contralateral limb is not possible. In 1996, Ward et al[12] showed that the intracellular fluid volume is largely unaffected in the early stages of LE development and subsequently demonstrated that the ratio of extracellular (ECF) to intracellular fluid (ICF) volumes (as the inverse ratio of the respective resistances, R_i/R_0, where R_i and R_0 are the resistances of ICF and ECF, respectively) was a sensitive diagnostic criterion for unilateral LE posttreatment for breast cancer.[14] These authors postulated that this method could be applied to the assessment of bilateral LE, although substantiation of the technique in such cases was necessary.

The purpose of the present study was to determine the normal variation of ECF/ICF ratios (as R_i/R_0) in the limbs of a cross section of a healthy population and to determine whether this ratio could be used to discriminate individuals with clinically ascribed bilateral LE.

METHODS

Participants

The study was an opportunistic cross-sectional design with patients with clinically diagnosed bilateral LE identified from patients attending an LE treatment clinic and invited to participate in the study. Criteria to be met for inclusion were broad, with participants being excluded only if they were younger than 18 years, pregnant, fitted with a pacemaker or other electrical medical device (contraindicated for BIS measurements), or had medical conditions other than LE or were using medications that would disturb their fluid status, for example, diuretics.

Data were obtained for control subjects with no history of LE from a database of impedance data maintained at The University of Queensland. The participants had been recruited for a variety of other studies being undertaken by the authors for whom comparable impedance measurements had been obtained. These data were pooled to provide the data set used for analysis in the present study. Pooling of data was considered acceptable inasmuch as inclusion and exclusion criteria for all of the studies were similar and the impedance measurement protocols were identical in all studies.

All participants were weighed using digital scales, to the nearest 0.1 kg, and their height measured to the nearest 0.1 cm using a wall or stand-mounted stadiometer. All participants were asked to state their arm and leg dominance. The characteristics of the participants are presented in Table 1. The mean ages of the male and female controls were similar at approximately 43 years of age. This was considerably younger than the mean ages of the LE participants at 70 and 63 years for the men and women, respectively. Correspondingly, the age distribution of the LE participants was such that all the men were aged between 60 and 80 years, whereas the women's ages ranged from 25.5 to 84.1 years. The male LE participants were shorter on average by 16 cm but 4.9 kg heavier than the male controls; consequently, their body mass indices (BMIs) were higher: 33.7 kg/m^2 compared to 26.3 kg/m^2. Although the female LE participants were the same height as the female controls, they were considerably heavier: average of 94.2 kg compared to 69.0 kg, with correspondingly higher BMI: 34.7 compared to 25.4 kg/m^2. The number of cases of primary LE in men was 4-fold greater than secondary LE. The ratio was 3:1 for the female participants. There were also 7 female participants with clinically ascribed mixed lipedema-lymphedema. Ethical approvals were obtained from the relevant medical research ethics committee of the participating institutions, and all participants provided written informed consent.

Measurement of Limb Impedance

The impedance of the legs and arms of all participants was measured according to methods described in detail elsewhere.[12] Briefly, whole limb impedance (wrist to axilla and ankle to groin) was determined according to the principle of equipotentials, as this protocol has been shown to have

greater precision than a "paired electrode" approach.[12] Participants assumed a supine position on a nonconductive examination couch, arms by their side and slightly abducted from the body. All jewelry, except rings on fingers, was removed and the skin at the electrode sites cleaned with an alcohol wipe before the application of silver–silver chloride gel electrodes. The electrode locations were those recommended by the manufacturer, that is, current drive electrodes on the dorsal surface of the third metacarpal of the hand and the dorsal surface of the third metatarsal of the foot and the voltage sensing electrodes on the dorsum of the wrists midway between the styloid processes and the dorsal surface of the ankle midway between the malleoli. All measurements were performed on each limb with the exception of a cohort of 73 men and 103 women in the control group for whom only measurements on the dominant side were available.

Impedance data were obtained with 2 different impedance instruments. Data for 224 male controls and 277 female controls drawn from the database had been obtained using an SFB3 frequency-scanning bioimpedance spectrometer (range, 5-1024 kHz; SEAC-ImpediMed Ltd, Brisbane, Australia). All other data were obtained using an SFB7 bioimpedance spectrometer (ImpediMed Ltd), which scans a similar range of frequencies (3-1000 kHz). Equivalence of these instruments has been demonstrated previously (below and in Ward[15]).

Data Processing and Analysis

Data from both SFB3 and SFB7 were processed according to Cole theory[12] using the manufacturer's software (Bioimp v 4.8.0.0, ImpediMed Ltd) to provide values for R_0 and R_∞. R_0 is the resistance at zero frequency and is equal to that of ECF, whereas R_∞ is the resistance at infinite frequency equal to that of total limb water. At zero and infinite frequencies, impedance (Z) and resistance (R) are equal; therefore, for the purposes of this manuscript, these terms are used interchangeably. Generally, the default program settings were used for analyses; however, for some data sets, the analysis was optimized by adjustment of the frequency "window" used for fitting the data to the Cole model guided by minimizing the standard error of the estimate (SEE) for the curve fitting procedure.[16] The SEE for all analyses was less than 1%.

Small, less than 2.5%, but significant differences in R_0 and R_∞ values between the SFB3 and SFB7 instruments have been determined when both are tested on the participants or electronic test circuits, an observation confirmed in a small subset of the present subject group (data not presented). Therefore, to facilitate pooling of data, all SFB3 data were converted to equivalent SFB7 data using the conversion factors provided by Ward.[15]

The resistance of intracellular water (ICF), R_i, was calculated from the relationship:

$$R_i = \frac{(R_0 \times R_\infty)}{(R_0 - R_\infty)}$$

Inasmuch as resistance is inversely related to volume, the ratio of ECF/ICF is given by

$$\frac{ECW}{ICW} = \frac{R_i}{R_o},$$

assuming that the resistivities of ICF and ECF are relatively constant (see "Discussion" section). The ECF/ICF ratios were calculated for each limb.

Statistical Analysis

Participant data were summarized with parametric descriptive statistics. Individuals were classified according to group (LE/control), sex (male/female), age (<30, 30–39.9, 40–49.9, 50-59.9 and >60 years) and BMI (20, 20–24.9, 25–29.9, >30 kg/m^2). The distributions of ECF/ICF ratios, as R_i/R_0, for all limbs were then determined for subgroups.

To determine whether there were significant differences across and between subgroups, 2- and 3-way analyses of variance (ANOVA) were performed using the general linear model procedures in the statistics module of Sigmaplot Version 11.0 (Systat Software Inc, Chicago, Ill). Two-way ANOVAs were used to determine whether there were any overall differences between age strata and between dominant and nondominant limbs within each sex and limbs (arm and

leg). Three-way ANOVAs were used to determine whether there were any overall differences between age, sex, and between dominant and nondominant limbs for arms and leg separately. Post hoc pairwise comparisons were performed using the Holm-Sidak test. The effect of BMI was similarly explored in a 2-way ANOVA.

To determine whether the ratios for the affected limbs could be discriminated from those of the control group, the distribution of the ECF/ICF ratios of the legs and the arms were analyzed according to the generalized method of Hotteling.[17,18] When the ECF/ICF ratios for the arms are plotted on polar axes against the same ratios for the legs of the control population, they follow a bivariate Gaussian distribution and a confidence interval (CI) for the correlation between the 2 variables determines an ellipsoid shape. Confidence intervals of 50%, 70%, and 95% were calculated for the control data and presented as tolerance ellipses[18] against which the ECF/ICF ratios for the LE participants were then compared. Tolerance ellipses were prepared using both the data for all control subjects and those aged older than 40 years because these more closely matched the age spectrum of the LE participants (Table 1).

RESULTS

Control Subjects

The ratio of ECF to ICF in all 4 limbs, stratified for limb dominance and by age decade, for the male participants is presented in Figure 1 and for the female participants in Figure 2. The mean ECF/ICF ratios of the arms in men varied significantly ($P < 0.001$) among the different age strata after allowing for dominance. The ratios were generally similar up to the fifth decade and then increased progressively into the ninth decade in men. Post hoc analysis among the groups indicated that this was significant for the 80-year-olds versus all other groups and for the 70-year-olds versus the 30- and 40-year-olds only. Despite there being also an overall significant, but weaker, effect ($P < 0.030$) of age in the arms of the female controls, there were no individual pairwise significant differences. As for the men, there was no effect of arm dominance or a significant age-dominance interaction.

The effect of age on ECF/ICF ratios in the legs was the same and highly significant ($P < 0.001$) in both men and women. Post hoc analysis between age strata for each sex indicated that significant differences ($P < 0.001$) were present between 80-year-old subjects and all other age strata. The ECF/ICF ratios of the nondominant leg were significantly larger in both sexes ($P < 0.014$ for men and $P < 0.005$ for women). There was no significant interaction between age and dominance.

Three-way ANOVA revealed that the ECF/ICF ratios were significantly higher ($P < 0.001$) in both the arms and the legs of men compared to those of the women. However, there was no significant interaction among dominance, age, and sex.

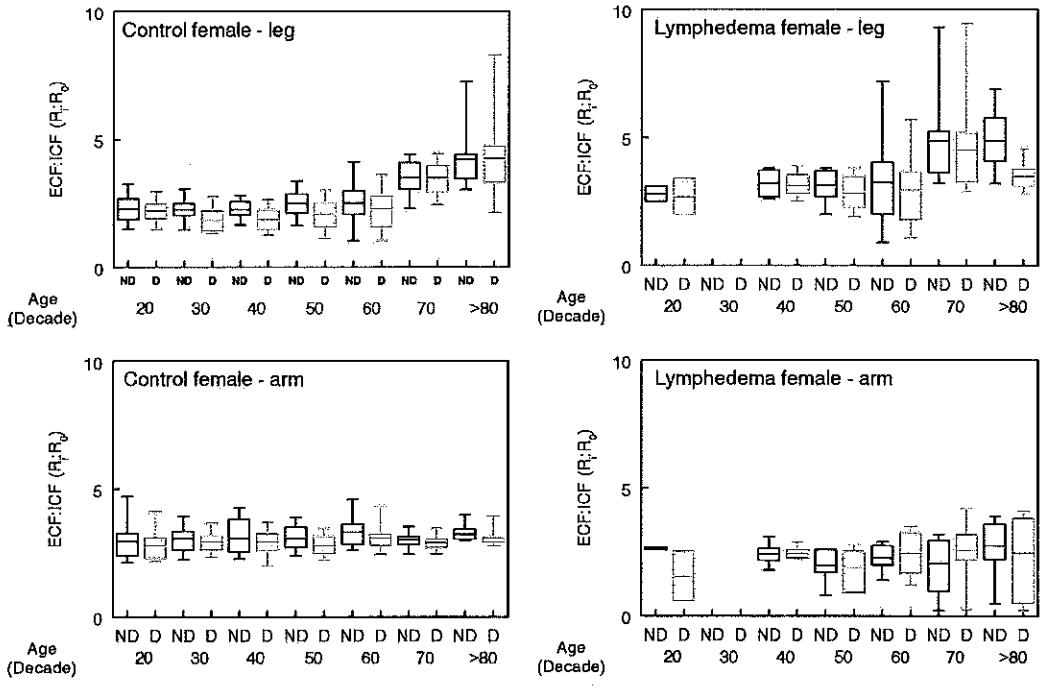

FIGURE 2. Ratio of ECF to ICF (as R_i/R_0) in the arms and legs of female controls and of female participants with bilateral lower limb LE stratified by age. Data presented as mean (line), 25th and 75th percentiles (box), and 5th and 95th percentiles (whiskers). Mean values shown for each data set. Upper left panel: affected leg to nondominant to dominant; upper right panel: control leg to nondominant to dominant; lower left panel: affected arm to nondominant to dominant; lower right panel: control arm to nondominant to dominant.

The ratios of ECF to ICF in the nondominant limbs, stratified by BMI, are presented in Figure 3, and the ratios of ECF to ICF in the dominant limbs are shown in Figure 4. Two-way ANOVA showed a significant effect ($P < 0.001$) of BMI, allowing for the effects of dominance, in the arms of men only. There was no significant effect of BMI in the legs irrespective of sex. However, as noted earlier, the ratios were significantly larger in the nondominant leg compared with the dominant leg for both men and women ($P < 0.016$ and $P < 0.001$, respectively).

Participants With Lymphedema

The small sample size of the male LE participants (n = 5 only) precluded stratification in this group by age, and the combined group data are presented in Figure 1. The ratios in the arms of the LE participants were slightly but not significantly less (6%) than those observed in the comparably aged control subjects. The ratios in the legs of the LE participants were, however, significantly greater ($P < 0.007$) than those of the comparably aged controls: 5.1 and 5.3 compared with 2.9 and 3.1 for nondominant and dominant limbs, respectively (Fig. 1).

The mean ratio in the legs of LE females was significantly greater by 29% ($P < 0.001$) than that of comparable control women at all ages and irrespective of limb dominance. Post hoc analysis indicated that the effect of the presence of LE was significant at ($P < 0.001$) for the age strata 40 to 49.9, 60 to 69.9, and older than 70 years of age; ($P < 0.010$) for the 50 to 59.9 age group but not significant in those aged younger than 30 years. This last observation is not surprising given the small number of participants in this age stratum.

The ECF/ICF ratio in the arms of the LE females was significantly lower ($P < 0.001$) by an average of 17%, compared with similarly aged controls (Fig. 2), a finding similar to that observed in the men with leg LE. However, post hoc analysis indicated no difference among age strata. There were no other significant differences or interactions among the variables studied.

Bivariate Analyses

Bivariate tolerance ellipses for control males and females with superimposed data points for the LE participants

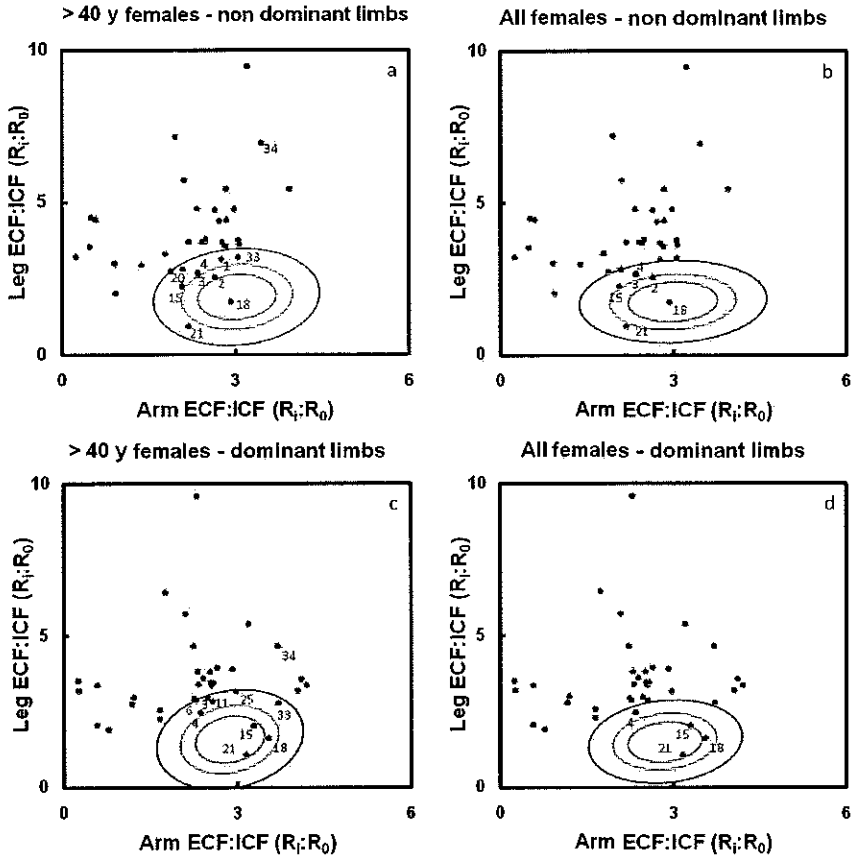

FIGURE 5. Bivariate distributions of ratio of ECF to ICF (as R_i/R_0) in the arms and legs of female controls and of participants with bilateral lower limb LE. Control data presented as tolerance ellipses: 50th (—), 75th (—), and 95th (—) percentiles. Upper left panel: nondominant arm, female participants aged older than 40 years; upper right panel: nondominant arm, female participants aged 18 to 86 years; lower left panel: dominant arm, female participants aged older than 40 years; lower right panel: dominant arm, female participants aged 18 to 86 years. FIGURE 6. Bivariate distributions of ratio of extracellular to intracellular water (as R_i/R_0) in the arms and legs of male controls and of participants with bilateral lower limb LE. Control data presented as tolerance ellipses: 50th (—), 75th (—), and 95th (—) percentiles. Upper left panel: nondominant arm, male participants aged older than 40 years; upper right panel: nondominant arm, male participants aged 18 to 86 years; lower left panel: dominant arm, male participants aged older than 40 years; lower right panel: dominant arm, male participants aged 18 to 86 years.

are presented in Figures 5 and 6, respectively. Tolerance ellipses are presented for participants older than 40 years only (left-hand panels) and for all participants (right-hand panels) in each figure. Depending on limb dominance, all but 4 (dominant) or 6 (nondominant) female LE participants fell outside the 95th percentile for all control subjects (Figs. 5B, D). If the more conservative tolerance ellipses for similarly aged control subjects are used, then 9 of the total 37 women fell within the 95th percentile. These data suggest that, depending on limb dominance and the chosen tolerance limits, between 89% and 70% of women were identified as having ECF/ICF ratios outside the reference range. For the male LE participants, except for the ECF/ICF ratio in the nondominant leg of one subject when compared to age-matched controls (Fig. 6A), all participants exhibited ratios that fell outside the 95th percentile ellipse.

DISCUSSION

The assessment of bilateral limb LE presents particular challenges to the clinician. The commonly used approach of measuring affected limb volume excess compared to the assumed normal contralateral limb is not possible. In this study, a novel approach of referencing the volume excess in a lymphedematous limb to another body region was explored. Using bivariate analysis, up to 89% of the participants with a clinically ascribed bilateral LE were correctly classified.

The approach taken was to quantify the accumulated lymph in LE as a change in the ratio of ECF to ICF in the limb. The present study is, to the authors' knowledge, the first to apply this method to the assessment of bilateral LE in the legs. We found that the ECF/ICF ratio was increased in the legs of those with leg LE compared with that of similarly aged controls but that the range of ratio values found in affected limbs overlapped with that observed in the healthy population, limiting diagnostic discrimination.

Consequently, individual variation was decreased by indexing the ECF/ICF ratio of an affected leg to the equivalent ratio of the arm. The relationship between these variables, ECF/ICF ratios in the arm and leg, of healthy control subjects is depicted as tolerance ellipses. A tolerance ellipse is a reference for a given percentile, which gives the probability that a given datum is located from the mean vector of the ellipse drawn for the reference population, that is, the probability for data from participants with LE that the loci for

© 2011 IGCS and ESGO

Copyright © 2011 by IGCS and ESGO. Unauthorized reproduction of this article is prohibited.

these data fall outside the tolerance ellipse. This procedure proved effective in classifying correctly all the male participants and up to 89% of the female participants at the 95% probability level of having LE.

Interestingly, despite the LE participants having clinically ascribed bilateral leg LE, predominantly of grades 2 and 3, comparison of ECF/ICF ratios with the reference ranges did not consistently detect this. Six LE women had both legs correctly identified as abnormal when compared with age-matched control data (Figs. 5A, C). However, participants 6, 11, and 25 presented with only the dominant leg as abnormal, whereas participants 1, 2, and 20 presented with only the nondominant leg as having an abnormal ratio despite all being clinically described as having bilateral LE. The possibility of an original misdiagnosis of bilateral LE cannot be excluded.

Another interesting observation was that for those participants whose ECF/ICF ratios fell outside the reference ranges, the loci for the ratio for each leg were not identical. For example, subject 34 exhibited a ratio of 6.9 for the nondominant leg compared to 4.6 for the dominant leg despite having similar ratios in both arms: 3.5 and 3.6, respectively (Figs. 5A, C). These results suggest that bilateral LE may not affect both limbs equally.

A number of caveats to the conclusions drawn from this study should be acknowledged. The relationship between the impedance of a given volume conductor is given by

$$V = \rho \frac{L^2}{Z},$$

where V is the volume, L is the conductor length, and ρ is the specific resistivity of the conductor.[12] Hence, the measured impedance of a conductor—in this study, either the ECF or ICF—is determined by both the resistivities of the tissue fluids and their volumes. Thus, comparison of the R_i/R_0 ratios between limbs in both the LE and control conditions to reflect accurately the volume differences assumes that the resistivities of the ICF and ECF compartments remain constant. The correctness of this assumption is unknown. Indeed, accurate knowledge of the resistivities of these fluids is lacking.[19] Resistivity is primarily determined by the concentration of electrolytes in the tissue fluids and is exquisitely sensitive to change in their concentration. Under normal physiological conditions, electrolyte balance is tightly homeostatically regulated such that resistivities remain essentially constant. Whether this is the case in LE is unknown. As LE progresses and protein or fatty infiltration of the lymph occurs, resistivity will undoubtedly alter. It is, however, noteworthy that 7 of the women with LE presented with mixed lipedema/lymphedema yet still had ratios falling outside the ellipses, suggesting that the presence of lipid had not affected adversely the diagnostic power of the method. Further research is required to determine the magnitude of such changes.

There is an assumption that effects of LE are generally confined to a specific body region. For example, secondary LE after inguinal surgery is usually considered to be confined to the legs only. The procedure for indexing the ECF/ICF ratio of an affected limb—in this case, the leg—to that of another body region is predicated on this assumption. The findings from this study challenge this assumption because the ratio was found, on average, to be significantly lower in the arms of those with LE compared with the control subjects.

Superimposition of participant's data on reference tolerance ellipses provides a simple and effective visual representation for LE assessment. It does not, however, provide an exact quantitative measure of the magnitude of the ECF volume increase. The distance of a datum locus from the ellipse is an indication of this magnitude. It may be possible, with more data, to provide better quantification by calculation of Kendall's τ statistic as has been used in other contexts.[20]

Inasmuch as it could not be assumed that the ECF/ICF ratio is constant across all healthy individuals, we attempted to determine the impact of factors such as age, dominance, and BMI, as a surrogate for adiposity, on the reference range of values. An unexpected observation was that the ratio of R_i to R_0 in the legs of older persons was increased, indicative of expansion of the ECF in these individuals. This is suggestive of a degree of edema being present and may reflect the increasing prevalence of vascular disorders in the elderly. It is also noteworthy that many of these older participants were essentially sedentary institutional residents in which pooling of ECF in the legs may occur through lowered calf muscle pump activity due to physical inactivity. With respect to LE assessment, these observations indicate that age-related reference ranges are required. Although less pronounced, a BMI effect was also noted. A further unexpected observation was the lack of effect of dominance on the ECF/ICF ratio in the arms compared with a significant effect in the legs of the control subjects. It is generally assumed that the effects of dominance, and consequently on physiology, are more pronounced in the upper limbs than in the legs. Presumably, although arm dominance is typically associated with a volume difference between the arms of up to 3%,[11] differences in composition are proportionate such that ECF/ICF ratios are unchanged. Why this seems not to be the case in the legs is unknown.

This proof of concept study has demonstrated that bioimpedance spectroscopy shows great promise for the assessment of bilateral LE. The data analytic method of tolerance ellipses provides an effective way to display these data. Further work is, however, required. Definitive normative ranges across a broader spectrum of ages, to allow age-matching of patients with controls, and body habitus in which bilateral LE commonly occurs, need to be established. A prospective study to determine the minimum change in ratio capable of detecting LE, that is, the detection threshold, should also be undertaken. The successful translation of BIS for early detection of unilateral breast cancer–related LE from a research tool to routine clinical practice,[21] however, gives hope that it may eventually be equally successful for the assessment of bilateral LE.

ACKNOWLEDGMENTS

The willing participation of the volunteers is gratefully acknowledged. The assistance of Kendall Sharpe, Jarrod Meerkin, Simon Van Rosendal, and Julia Dyer in collecting control data is also gratefully acknowledged.

Medical Policy

Subject:	Bioimpedance Spectroscopy Devices for the Detection and Management of Lymphedema		
Policy #:	MED.00105	**Current Effective Date:**	07/15/2014
Status:	Reviewed	**Last Review Date:**	05/15/2014

Description/Scope

This document addresses the use of bioimpedance spectroscopy, a device which uses impedance ratios to measure extracellular fluid volume differences between limbs to aid in the clinical assessment of lymphedema.

Note: Please see the following related document for additional information:

- CG-DME-06 Pneumatic Compression Devices for Lymphedema

Position Statement

Investigational and Not Medically Necessary:

The use of bioimpedance spectroscopy testing in the assessment, diagnosis, or management of individuals with known or suspected lymphedema is considered **investigational and not medically necessary.**

Rationale

In spite of advances in breast conserving surgical procedures and axillary dissection techniques, breast cancer survivors remain at risk for the development of secondary lymphedema, that is, excessive lymph fluid and protein accumulation in the extracellular space of the affected limb. Studies suggest that 6-40% of breast cancer survivors will develop lymphedema at some point during their lifetime (Ridner, 2009). While conventional clinical methods to diagnose and monitor lymphedema include serial measurements of limb circumference and limb volume (water displacement volumetry), multiple methods of evaluating lymphedema are under study including infrared perometry scanning (infrared light beams image the outline of the limb, which can then be used to calculate limb volume), single and multi-frequency bioelectrical impedance, ultrasound, and lymphoscintigraphy. Some of these studies have included comparisons with conventional measures of lymphedema, such as limb circumference and volume.

Bioelectrical impedance analysis has been studied in research settings for a number of years. In 2008 the U.S. Food and Drug Administration (FDA) granted 510(k) market clearance for one such device, the ImpediMED L-Dex® U400 BIS Extra Cellular Fluid Analyzer (ImpediMed Limited, San Diego CA). This device is classified as an impedance plethysomograph and was approved for the measurement of extracellular fluid volume differences between the arms to aid in the clinical assessment of unilateral lymphedema of the arm in women. FDA market clearance did not include approval of the device to either diagnose or predict the development of lymphedema of an extremity. In 2011 the FDA granted 510(k) clearance to another Extra Cellular Fluid Analyzer which is manufactured by the same company and lists the L-Dex U400 as the predicate device. The purpose of this submission was to expand the previously cleared indication to include use for legs in women and men and a clarification limiting the device to be used with humans.

Czerniec and colleagues (2010) reported on individuals with lymphedema (n=33) and individuals without lymphedema (n=18) to examine the relationship between physical methods of measuring lymphedema and self-reported swelling. The purpose of the study was to compare the reliability of the most commonly used measures of lymphedema. Measurement techniques included self-report, bioimpedance spectroscopy, truncated cone (circumference) method and infrared perometry. The study concluded that the physical measurement tools studied were reliable with high concordance (0.89 to 0.99) while self-report correlated only moderately with physical measurements (0.65-0.71) and was therefore only moderately reliable. The authors concluded that while lymphedema assessment methods showed good concordance and reliability, they were not interchangeable.

Ridner (2009) reported a feasibility study of single-frequency bioelectrical impedance to detect upper limb lymphedema in non-laboratory settings. Impedance ratios among healthy normal women and breast cancer survivors, both with and without lymphedema were compared. Ratios of healthy normal controls and breast cancer survivor without clinical evidence of lymphedema were similar with nearly complete overlap in confidence intervals. However, those values were markedly different from the values measured in the breast cancer survivor group with lymphedema ($p< 0.001$).

In a 2011 study by Czerniec, the authors sought to determine if bioimpedance spectroscopy could detect lymphedema of the arm and compare the measurements of bioimpedance spectroscopy to that of perometry. With a sample size of 29 women with known lymphedema and 11 women with no history of lymphedema, arm volume was measured by both perometry and bioimpedance spectroscopy. Both techniques were sensitive enough to detect localized lymphedema of the arm and there was a high degree of concordance between the bioimpedance spectroscopy ratio and that determined by perometry. However, sample size was small and larger studies are necessary.

Fu and colleagues (2013) reported on a study which sought to examine the reliability, sensitivity and specificity of bioimpedance spectroscopy in the detection of lymphedema. Circumferential tape measurement was used to validate the presence of lymphedema in 250 women. Bioimpedance was used to measure lymph fluid changes. The 250 women in the study included healthy females, breast cancer survivors with lymphedema, and those who were at risk for developing lymphedema. Bioelectrical impedance analysis, as indicated by L-Dex ratio, was highly reliable among healthy women (ICC=0.99; 95% CI = 0.99 - 0.99), survivors at-risk for lymphedema (ICC=0.99; 95% CI = 0.99 - 0.99), and all women (ICC=0.85; 95% CI = 0.81 - 0.87); reliability was acceptable for survivors with lymphedema (ICC=0.69; 95% CI = 0.54 to 0.80). The bioimpedance ratio correlated with limb volume by sequential circumferential tape measurement. The L-Dex ratio had a diagnostic cutoff of >+7 which missed 20% of true lymphedema cases. The authors noted that "it is important for clinicians to integrate other assessment methods (such as self-report, clinical observation, or perometry) to ensure the accurate detection of lymphedema."

A technology assessment by the Agency for Healthcare Research and Quality (AHRQ, 2010) concluded that limb volume and circumference remain the de facto 'gold standard' tests to assess the presence of secondary lymphedema. In addition, this technology assessment concluded that there is insufficient evidence to assess the reliability of other tests to measure lymphedema which are under study such as perometry, ultrasound, lymphoscintigraphy, and bioimpedance.

Currently, there is insufficient information to judge the technical and diagnostic performance of bioimpedance spectroscopy testing or its clinical utility as studies are limited to small group sizes (Jain, 2010). There is no evidence from comparative clinical trials which demonstrate an impact on clinical outcome. Further study of this technology as a tool for the diagnosis and treatment of early, subclinical lymphedema continues, but based on current evidence, the use of bioimpedance spectroscopy testing in the diagnosis or management of individuals with known or suspected lymphedema is considered investigational.

Background/Overview

Lymphedema is swelling from fluid build-up caused by improper functioning of the lymphatic system. Symptoms of lymphedema include arm swelling, heaviness, chest/breast swelling, tightness, firmness, pain, numbness, stiffness or impaired limb mobility. There are two types of lymphedema: primary lymphedema which occurs in those who have a congenital abnormality or dysfunction of their lymphatic system and secondary lymphedema which is an acquired condition caused by a disruption or obstruction of the normal lymphatic system. Individuals with breast cancer are at risk for the development of arm lymphedema. Axillary lymph node sampling compromises lymphatic drainage and lymphatic function can be further compromised by radiation delivered to the lymph node beds. Secondary lymphedema can develop days or years after treatment. Most lymphedema occurs within three years of surgery and is associated with discomfort, heaviness, functional limitations and risk of infection. Early lymphedema can be difficult to diagnose. Various methods can be used for evaluating limb volume including water displacement, circumferential measurement, infrared perometry and bioelectrical impedance.

Measurement of limb volume with water displacement requires the individual to submerge the affected limb into a cylinder filled with a known volume of water. The amount of water that is displaced can be weighed or the volume measured. Water displacement is a reliable method to measure limb volume, but it can be cumbersome and difficult to perform in the physician's office. It cannot be used for those individuals with open wounds or sores.

Circumferential measurement of limb volume involves the use of a measuring tape to measure limb circumference at various anatomical landmarks or marked distances from the fingertips or toes. A hindrance to circumferential measurement is that individuals must remove the clothing over the affected limb. There is also concern about the reliability of the measurements. Different individuals measuring the limbs may hold the tape measure tightly or loosely around the limb causing a variation in the measurements.

Infrared perometry uses infrared light to measure the limb volume. The affected limb is placed in a frame and the perometer scans the limb taking measurements at different segments. The limb volume is then calculated by a special computer program. Perometry is a quick method and it does not touch the skin so it can be used for individuals with sensitive or broken skin. Clinical application may be limited by the fact that the equipment is not portable and requires individuals to come into a clinic or facility for limb measurement.

Bioelectrical impedance involves the response of a living organism to a mild electrical current. Skin electrodes are used to pass a small alternating current through a limb and measure the opposition (impedance) to the flow of the current. The measure of the body's resistance to the current can be converted into measurements such as fluid levels. Bioimpedance spectroscopy is a direct measurement of extracellular fluid volume. The device is used to detect extracellular fluid in an individual's limb and is being studied as a tool to detect early signs of subclinical lymphedema.

Definitions

Lymphedema: A condition in which extra lymph fluid builds up in tissues and causes swelling. It may occur in an arm or leg if lymph vessels are blocked, damaged, or removed by surgery.

Coding

The following codes for treatments and procedures applicable to this document are included below for informational purposes. Inclusion or exclusion of a procedure, diagnosis or device code(s) does not constitute or imply member coverage or provider reimbursement policy. Please refer to the member's contract benefits in effect at the time of service to determine coverage or non-

coverage of these services as it applies to an individual member.

When services are Investigational and Not Medically Necessary:
When the code describes a procedure indicated in the Position Statement section as investigational and not medically necessary.

Using Nontraditional Risk Factors in Coronary Heart Disease Risk Assessment: U.S. Preventive Services Task Force Recommendation Statement

U.S. Preventive Services Task Force

Description: New recommendation from the U.S. Preventive Services Task Force (USPSTF) on the use of nontraditional, or novel, risk factors in assessing the coronary heart disease (CHD) risk of asymptomatic persons.

Methods: Systematic reviews were conducted of literature since 1996 on 9 proposed nontraditional markers of CHD risk: high-sensitivity C-reactive protein, ankle–brachial index, leukocyte count, fasting blood glucose, periodontal disease, carotid intima–media thickness, coronary artery calcification score on electron-beam computed tomography, homocysteine, and lipoprotein(a). The reviews followed a hierarchical approach aimed at determining which factors could practically and definitively reassign persons assessed as intermediate-risk according to their Framingham score to either a high-risk or low-risk strata, and thereby improve outcomes by means of aggressive risk-factor modification in those newly assigned to the high-risk stratum.

Recommendation: The USPSTF concludes that the current evidence is insufficient to assess the balance of benefits and harms of using the nontraditional risk factors studied to screen asymptomatic men and women with no history of CHD to prevent CHD events. (I statement).

Ann Intern Med. 2009;151:474-482. www.annals.org

For author affiliation, see end of text.

* For a list of the members of the USPSTF, see the **Appendix** (available at www.annals.org).

The U.S. Preventive Services Task Force (USPSTF) makes recommendations about preventive care services for patients without recognized signs or symptoms of the target condition.

It bases its recommendations on a systematic review of the evidence of the benefits and harms and an assessment of the net benefit of the service.

The USPSTF recognizes that clinical or policy decisions involve more considerations than this body of evidence alone. Clinicians and policymakers should understand the evidence but individualize decision making to the specific patient or situation.

Summary of Recommendation and Evidence

The USPSTF concludes that the current evidence is insufficient to assess the balance of benefits and harms of using the nontraditional risk factors discussed in this statement to screen asymptomatic men and women with no history of coronary heart disease (CHD) to prevent CHD events. This is an I statement.

The nontraditional risk factors included in this recommendation are high-sensitivity C-reactive protein (hs-CRP), ankle–brachial index (ABI), leukocyte count, fasting blood glucose level, periodontal disease, carotid intima–media thickness (carotid IMT), coronary artery calcification (CAC) score on electron-beam computed tomography (EBCT), homocysteine level, and lipoprotein(a) level.

See the Clinical Considerations section for suggestions for practice concerning the Insufficient Evidence statement.

See the **Figure** for a summary of the recommendation and suggestions for clinical practice.

See **Table 1** for a description of the USPSTF grades and **Table 2** for a description of the USPSTF classification of levels of certainty about net benefit.

Rationale

Importance

Coronary heart disease is the most common cause of mortality in adults in the United States. Treatment to prevent CHD events by modifying risk factors is currently based on the Framingham risk model, which sorts individuals into low-, intermediate-, or high-risk groups. If the risk model could be improved, treatment might be bet-

Preamble and Transition to ACC/AHA Guidelines to Reduce Cardiovascular Risk

The goals of the American College of Cardiology (ACC) and the American Heart Association (AHA) are to prevent cardiovascular diseases (CVD); improve the management of people who have these diseases through professional education and research; and develop guidelines, standards, and policies that promote optimal patient care and cardiovascular health. Toward these objectives, the ACC and AHA have collaborated with the National Heart, Lung, and Blood Institute (NHLBI) and stakeholder and professional organizations to develop clinical practice guidelines for assessment of cardiovascular risk, lifestyle modifications to reduce cardiovascular risk, management of blood cholesterol in adults, and management of overweight and obesity in adults.

In 2008, the NHLBI initiated these guidelines by sponsoring rigorous systematic evidence reviews for each topic by expert panels convened to develop critical questions (CQs), interpret the evidence, and craft recommendations. In response to the 2011 report from the Institute of Medicine on the development of trustworthy clinical guidelines,[1] the NHLBI Advisory Council recommended that the NHLBI focus specifically on reviewing the highest-quality evidence and partner with other organizations to develop recommendations.[2,3] Accordingly, in June 2013 the NHLBI initiated collaboration with the ACC and AHA to work with other organizations to complete and publish the 4 guidelines noted above and make them available to the widest possible constituency. Recognizing that the Expert Work Group/Work Groups did not consider evidence beyond 2011 (except as specified in the methodology), the ACC, AHA, and collaborating societies plan to begin updating these guidelines starting in 2014.

The joint ACC/AHA Task Force on Practice Guidelines (Task Force) appointed a subcommittee to shepherd this transition, communicate the rationale and expectations to the writing panels and partnering organizations, and expeditiously publish the documents. The ACC/AHA and partner organizations recruited a limited number of expert reviewers for fiduciary examination of content, recognizing that each document had undergone extensive peer review by representatives of the NHLBI Advisory Council, key federal agencies, and scientific experts. Each writing panel responded to comments from these reviewers. Clarifications were incorporated where appropriate, but there were no substantive changes because the bulk of the content was undisputed.

Although the Task Force led the final development of these prevention guidelines, they differ from other ACC/AHA guidelines. First, as opposed to an extensive compendium of clinical information, these documents are significantly more limited in scope and focus on selected CQs on each topic, based on the highest-quality evidence available. Recommendations were derived from randomized trials, meta-analyses, and observational studies evaluated for quality and were not formulated when sufficient evidence was not available. Second, the text accompanying each recommendation is succinct, summarizing the evidence for each question. The Full Panel/Work Group Reports include more detailed information about the evidence statements that serve as the basis for recommendations. Third, the format of the recommendations differs from other ACC/AHA guidelines. Each recommendation has been mapped from the NHLBI grading format to the ACC/AHA Classification of Recommendation/Level of Evidence (COR/LOE) construct (Table 1) and is expressed in both formats. Because of the inherent differences in grading systems and the clinical questions driving the recommendations, alignment between the NHLBI and ACC/AHA formats is in some cases imperfect. Explanations of these variations are noted in the recommendation tables, where applicable.

In consultation with NHLBI, the policies adopted by the writing panels to manage relationships of authors with industry and other entities (RWI) are outlined in the methods section of each panel report. These policies were in effect when this

Table 1. Applying Classification of Recommendation and Level of Evidence

ESTIMATE OF CERTAINTY (PRECISION) OF TREATMENT EFFECT	SIZE OF TREATMENT EFFECT: CLASS I *Benefit >>> Risk* Procedure/Treatment **SHOULD** be performed/ administered	CLASS IIa *Benefit >> Risk* *Additional studies with focused objectives needed* **IT IS REASONABLE** to perform procedure/administer treatment	CLASS IIb *Benefit ≥ Risk* *Additional studies with broad objectives needed; additional registry data would be helpful* Procedure/Treatment **MAY BE CONSIDERED**	CLASS III *No Benefit* or CLASS III *Harm* COR III: No benefit — Procedure/Test: Not Helpful — Treatment: No Proven Benefit COR III: Harm — Procedure/Test: Excess Cost w/o Benefit or Harmful — Treatment: Harmful to Patients
LEVEL A Multiple populations evaluated* Data derived from multiple randomized clinical trials or meta-analyses	■ Recommendation that procedure or treatment is useful/effective ■ Sufficient evidence from multiple randomized trials or meta-analyses	■ Recommendation in favor of treatment or procedure being useful/effective ■ Some conflicting evidence from multiple randomized trials or meta-analyses	■ Recommendation's usefulness/efficacy less well established ■ Greater conflicting evidence from multiple randomized trials or meta-analyses	■ Recommendation that procedure or treatment is not useful/effective and may be harmful ■ Sufficient evidence from multiple randomized trials or meta-analyses
LEVEL B Limited populations evaluated* Data derived from a single randomized trial or nonrandomized studies	■ Recommendation that procedure or treatment is useful/effective ■ Evidence from single randomized trial or nonrandomized studies	■ Recommendation in favor of treatment or procedure being useful/effective ■ Some conflicting evidence from single randomized trial or nonrandomized studies	■ Recommendation's usefulness/efficacy less well established ■ Greater conflicting evidence from single randomized trial or nonrandomized studies	■ Recommendation that procedure or treatment is not useful/effective and may be harmful ■ Evidence from single randomized trial or nonrandomized studies
LEVEL C Very limited populations evaluated* Only consensus opinion of experts, case studies, or standard of care	■ Recommendation that procedure or treatment is useful/effective ■ Only expert opinion, case studies, or standard of care	■ Recommendation in favor of treatment or procedure being useful/effective ■ Only diverging expert opinion, case studies, or standard of care	■ Recommendation's usefulness/efficacy less well established ■ Only diverging expert opinion, case studies, or standard of care	■ Recommendation that procedure or treatment is not useful/effective and may be harmful ■ Only expert opinion, case studies, or standard of care
Suggested phrases for writing recommendations	should is recommended is indicated is useful/effective/beneficial	is reasonable can be useful/effective/beneficial is probably recommended or indicated	may/might be considered may/might be reasonable usefulness/effectiveness is unknown/unclear/uncertain or not well established	COR III: No Benefit: is not recommended; is not indicated; should not be performed/ administered/ other; is not useful/ beneficial/ effective COR III: Harm: potentially harmful; causes harm; associated with excess morbidity/mortality; should not be performed/ administered/ other
Comparative effectiveness phrases†	treatment/strategy A is recommended/indicated in preference to treatment B treatment A should be chosen over treatment B	treatment/strategy A is probably recommended/indicated in preference to treatment B it is reasonable to choose treatment A over treatment B		

A recommendation with Level of Evidence B or C does not imply that the recommendation is weak. Many important clinical questions addressed in the guidelines do not lend themselves to clinical trials. Even when randomized trials are unavailable, there may be a very clear clinical consensus that a particular test or therapy is useful or effective.

*Data available from clinical trials or registries about the usefulness/efficacy in different subpopulations, such as sex, age, history of diabetes, history of prior myocardial infarction, history of heart failure, and prior aspirin use.

†For comparative-effectiveness recommendations (Class I and IIa; Level of Evidence A and B only), studies that support the use of comparator verbs should involve direct comparisons of the treatments or strategies being evaluated.

effort began in 2008 and throughout the writing process and voting on recommendations, until the process was transferred to ACC/AHA in 2013. In the interest of transparency, the ACC/AHA requested that panel authors resubmit RWI disclosures as of July 2013. Relationships relevant to this guideline are disclosed in Appendix 1. None of the ACC/AHA expert reviewers had relevant RWI (Appendix 2). See Appendix 3 for a list of abbreviations used in the guideline.

Systematic evidence reports and accompanying summary tables were developed by the expert panels and NHLBI. The guideline was reviewed by the ACC/AHA Task Force and approved by the ACC Board of Trustees, and the AHA Science Advisory and Coordinating Committee. In addition, ACC/AHA sought endorsement from other stakeholders, including professional organizations. It is the hope of the writing panels, stakeholders, professional organizations, NHLBI, and Task Force that the guidelines will garner the widest possible readership for the benefit of patients, providers, and the public health.

These guidelines are meant to define practices that meet the needs of patients in most circumstances and are not a replacement for clinical judgment. The ultimate decision about care of a particular patient must be made by the healthcare provider and patient in light of the circumstances presented by that patient. As a result, situations might arise in which deviations from these guidelines may be appropriate. These considerations notwithstanding, in caring for most patients, clinicians can employ the recommendations confidently to reduce the risks of atherosclerotic cardiovascular disease (ASCVD) events.

See Tables 2 and 3 for an explanation of the NHLBI recommendation grading methodology.

Table 2. NHLBI Grading of the Strength of Recommendations

Grade	Strength of Recommendation*
A	Strong recommendation There is high certainty based on evidence that the net benefit† is substantial.
B	Moderate recommendation There is moderate certainty based on evidence that the net benefit is moderate to substantial, or there is high certainty that the net benefit is moderate.
C	Weak recommendation There is at least moderate certainty based on evidence that there is a small net benefit.
D	Recommendation against There is at least moderate certainty based on evidence that there is no net benefit or that risks/harms outweigh benefits.
E	Expert opinion ("There is insufficient evidence or evidence is unclear or conflicting, but this is what the Work Group recommends.") Net benefit is unclear. Balance of benefits and harms cannot be determined because of no evidence, insufficient evidence, unclear evidence, or conflicting evidence, but the Work Group thought it was important to provide clinical guidance and make a recommendation. Further research is recommended in this area.
N	No recommendation for or against ("There is insufficient evidence or evidence is unclear or conflicting.") Net benefit is unclear. Balance of benefits and harms cannot be determined because of no evidence, insufficient evidence, unclear evidence, or conflicting evidence, and the Work Group thought no recommendation should be made. Further research is recommended in this area.

*In most cases, the strength of the recommendation should be closely aligned with the quality of the evidence; however, under some circumstances, there may be valid reasons for making recommendations that are not closely aligned with the quality of the evidence (eg, strong recommendation when the evidence quality is moderate, such as smoking cessation to reduce cardiovascular disease risk or ordering an ECG as part of the initial diagnostic work-up for a patient presenting with possible MI). Those situations should be limited and the rationale explained clearly by the Work Group.

†Net benefit is defined as benefits minus risks/harms of the service/intervention.

ECG indicates electrocardiogram; MI, myocardial infarction; and NHLBI, National Heart, Lung, and Blood Institute.

Table 3. NHLBI Quality Rating of the Strength of Evidence

Type of Evidence	Quality Rating*
• Well-designed, well-executed† RCT that adequately represent populations to which the results are applied and directly assess effects on health outcomes. • Meta-analyses of such studies. Highly certain about the estimate of effect. Further research is unlikely to change our confidence in the estimate of effect.	High
• RCT with minor limitations‡ affecting confidence in, or applicability of, the results. • Well-designed, well-executed nonrandomized controlled studies§ and well-designed, well-executed observational studies‖. • Meta-analyses of such studies. Moderately certain about the estimate of effect. Further research may have an impact on our confidence in the estimate of effect and may change the estimate.	Moderate
• RCT with major limitations. • Nonrandomized controlled studies and observational studies with major limitations affecting confidence in, or applicability of, the results. • Uncontrolled clinical observations without an appropriate comparison group (eg, case series, case reports). • Physiological studies in humans. • Meta-analyses of such studies. Low certainty about the estimate of effect. Further research is likely to have an impact on our confidence in the estimate of effect and is likely to change the estimate.	Low

*In some cases, other evidence, such as large all-or-none case series (eg, jumping from airplanes or tall structures), can represent high- or moderate-quality evidence. In such cases, the rationale for the evidence rating exception should be explained by the Work Group and clearly justified.

†"Well-designed, well-executed" refers to studies that directly address the question; use adequate randomization, blinding, and allocation concealment; are adequately powered; use intention-to-treat analyses; and have high follow-up rates.

‡Limitations include concerns with the design and execution of a study that result in decreased confidence in the true estimate of the effect. Examples of such limitations include but are not limited to: inadequate randomization, lack of blinding of study participants or outcome assessors, inadequate power, outcomes of interest that are not prespecified for the primary outcomes, low follow-up rates, and findings based on subgroup analyses. Whether the limitations are considered minor or major is based on the number and severity of flaws in design or execution. Rules for determining whether the limitations are considered minor or major and how they will affect rating of the individual studies will be developed collaboratively with the methodology team.

§Nonrandomized controlled studies refer to intervention studies where assignment to intervention and comparison groups is not random (eg, quasi-experimental study design).

‖Observational studies include prospective and retrospective cohort, case-control, and cross-sectional studies.

NHLBI indicates National Heart, Lung, and Blood Institute; and RCT, randomized controlled trials.

1. Introduction

1.1. Organization of the Work Group

The Risk Assessment Work Group (Work Group) was composed of 11 members and 5 ex-officio members, including internists, cardiologists, endocrinologists, and experts in cardiovascular epidemiology, biostatistics, healthcare management and economics, and guideline development.

1.2. Document Review and Approval

A formal peer review process, which included 12 expert reviewers and representatives of federal agencies, was initially completed under the auspices of the NHLBI. This document was also reviewed by 3 expert reviewers nominated by the ACC and the AHA when the management of the guideline transitioned to the ACC/AHA. The ACC and AHA Reviewers' RWI information is published in this document (Appendix 2).

This document was approved for publication by the governing bodies of the ACC and AHA and endorsed by the American Association of Cardiovascular and Pulmonary Rehabilitation, American Society for Preventive Cardiology, American Society of Hypertension, Association of Black Cardiologists, National Lipid Association, Preventive Cardiovascular Nurses Association, and WomenHeart: The National Coalition for Women With Heart Disease.

1.3. Charge to the Work Group

The Work Group was 1 of 3 work groups appointed by the NHLBI to develop its own recommendations and provide cross-cutting input to 3 Panels for updating guidelines on blood cholesterol, blood pressure (BP), and overweight/obesity. The Work Group was asked to examine the scientific evidence on risk assessment for initial ASCVD events and to develop an approach for quantitative risk assessment that could be used in practice and used or adapted by the risk factor panels (blood cholesterol, hypertension, and obesity) in their guidelines and algorithms. Specifically, the Work Group was charged with 2 tasks:

1. To develop or recommend an approach to quantitative risk assessment that could be used to guide care; and
2. To use systematic review methodology to pose and address a small number of questions judged to be critical to refining and adopting risk assessment in clinical practice.

1.4. Methodology and Evidence Review

This guideline is based on the Full Work Group Report supplement, which is provided as a supplement to the guideline. The Full Work Group Report supplement contains background and additional material related to content, methodology, evidence synthesis, rationale, and references and is supported by the NHLBI Systematic Evidence Review, which can be found at (http://www.nhlbi.nih.gov/guidelines/cvd_adult/risk_assessment/). These documents also describe the process for the development of novel, comprehensive multivariable risk equations for the prediction of 10-year risk of development of ASCVD in non-Hispanic African-American and non-Hispanic white men and women from 40 to 79 years of age. These equations were developed from several long-standing population-based cohort studies funded by the NHLBI. Ten-year risk was defined as the risk of developing a first ASCVD event, defined as nonfatal myocardial infarction or coronary heart disease (CHD) death or fatal or nonfatal stroke, over a 10-year period among people free from ASCVD at the beginning of the period.

In addition, through evaluation of evidence developed by systematic reviews of the literature, the Work Group addressed the following 2 CQs:

CQ1. "What is the evidence with regard to reclassification or contribution to risk assessment when high-sensitivity C-reactive protein (hs-CRP), apolipoprotein B (ApoB), glomerular filtration rate, microalbuminuria, family history, cardiorespiratory fitness, ankle-brachial index (ABI), carotid intima-media thickness (CIMT), or coronary artery calcium (CAC) score is considered in addition to the variables that are in the traditional risk scores?"

CQ2. "Are models constructed to assess the long-term (≥15 years or lifetime) risk of a first cardiovascular disease (CVD) event in adults effective in assessing variation in long-term risk among adults at low and/or intermediate short-term risk, whether analyzed separately or in combination?"

The evidence and recommendations in the guideline focus on the large proportion of the adult population without clinical signs or symptoms of ASCVD who merit evaluation for the primary prevention of ASCVD. They do not apply to those with clinically manifest ASCVD, who require secondary prevention approaches, or to highly-selected patient subgroups, such as those with symptoms suggestive of CVD, who require diagnostic strategies rather than risk assessment. Furthermore, these recommendations were not developed for use in specific subgroups of asymptomatic individuals at unusually high risk, such as those with genetically determined extreme values of traditional risk factors (eg, patients with familial hypercholesterolemia).

2. Risk Assessment: Recommendations

See Table 4 for a summary of the recommendations for risk assessment.

3. Approach to Risk Assessment

In addressing its charge, the Work Group recognized the need for a risk assessment approach that was based on the types of data that primary care providers could easily collect and that could be implemented in routine clinical practice. After deliberation, the Work Group endorsed the existing and widely used paradigm of matching the intensity of preventive efforts with the individual's absolute risk.[23,24] The Work Group acknowledges that none of the risk assessment tools or novel risk markers examined in the present document have been formally evaluated in randomized controlled trials of screening strategies with clinical events as outcomes. Nevertheless, this approach balances an understanding of an individual's absolute risk of CVD and potential treatment benefits against the potential absolute risks for harm from therapy. With the use of this framework, treatment can be targeted to those most likely to benefit without undue risk of harm, in the context of a "risk discussion." A risk discussion could include the assessment of the patient's risk of ASCVD, as well as potential benefits, negative aspects, risks, and patient preferences with regard to initiation of relevant preventive therapies.

By its nature, such an approach requires a platform for reliable quantitative estimation of absolute risk based on data from representative population samples. It is important to note that risk estimation is based on group averages, which are then applied to individual patients in practice. This process is admittedly imperfect; no one has 10% or 20% of a heart attack during a 10-year period. Individuals with the same estimated risk will either have or not have the event of interest, and only those patients who are destined to have an event can have their event prevented by therapy. The criticism of the risk-estimation approach to treatment decision making also applies to the alternative, and much less efficient approach, of checking the patient's characteristics against numerous and complex inclusion and exclusion criteria for a potentially large number of pertinent trials. Only a small fraction of trial participants have events, and only a fraction of these events are prevented by therapy. Using either approach, the clinician must apply the average results obtained from groups of patients to the individual patient in practice.

Given the modification and adoption of the Framingham 10-year risk score for CHD risk assessment by the Third Report of the National Cholesterol Education Program Expert Work Group on Diagnosis, Evaluation, and Treatment of High

Table 4. Summary of Recommendations for Risk Assessment

Recommendations	NHLBI Grade	NHLBI Evidence Statements	ACC/AHA COR	ACC/AHA LOE
Assessment of 10-Year Risk of a First Hard ASCVD Event				
1. The race- and sex-specific Pooled Cohort Equations* to predict 10-year risk of a first hard ASCVD event should be used in non-Hispanic African Americans and non-Hispanic whites, 40–79 years of age.	B (Moderate)	N/A	I	B[4–8]
2. Use of the sex-specific Pooled Cohort Equations for non-Hispanic whites may be considered for estimation of risk in patients from populations other than African Americans and non-Hispanic whites.	E (Expert Opinion)	N/A	IIb	C
CQ1: Use of Newer Risk Markers After Quantitative Risk Assessment				
1. If, after quantitative risk assessment, a risk-based treatment decision is uncertain, assessment of ≥1 of the following—family history, hs-CRP, CAC score, or ABI—may be considered to inform treatment decision making.	E (Expert Opinion)	Appendix 4	IIb†	B[9–17]
2. Routine measurement of CIMT is not recommended in clinical practice for risk assessment for a first ASCVD event.	N (No recommendation for or against)	Appendix 4	III: No Benefit†	B[12,16,18]
3. The contribution of ApoB, CKD, albuminuria, and cardiorespiratory fitness to risk assessment for a first ASCVD event is uncertain at present.	N (No recommendation for or against)	Appendix 4	—	—
CQ2: Long-Term Risk Assessment				
1. It is reasonable to assess traditional ASCVD risk factors‡ every 4–6 years in adults 20–79 years of age who are free from ASCVD and to estimate 10-year ASCVD risk every 4–6 years in adults 40–79 years of age who are free from ASCVD.	B (Moderate)	Appendix 5 CQ2/ES7	IIa	B[19,20]
2. Assessment of 30-year or lifetime ASCVD risk on the basis of traditional risk factors‡ may be considered in adults 20–59 years of age who are free from ASCVD and are not at high short-term risk.	C (Weak)	Appendix 5 CQ2/ES2, CQ2/ES3, CQ2/ES4, CQ2/ES5, CQ2/ES6	IIb	C[20–22]

A downloadable spreadsheet enabling estimation of 10-year and lifetime risk of ASCVD and a Web-based calculator is available at http://my.americanheart.org/cvriskcalculator and http://www.cardiosource.org/en/Science-And-Quality/Practice-Guidelines-and-Quality-Standards/2013-Prevention-Guideline-Tools.aspx.

*Derived from the ARIC (Atherosclerosis Risk in Communities) study,[8] Cardiovascular Health Study,[5] CARDIA (Coronary Artery Risk Development in Young Adults) study,[7] and Framingham original and offspring cohorts.[4,6]

†Based on new evidence reviewed during ACC/AHA update of evidence.

‡Age, sex, total cholesterol, high-density lipoprotein cholesterol, systolic BP, use of antihypertensive therapy, diabetes, and current smoking.

ABI indicates ankle-brachial index; ACC, American College of Cardiology; AHA, American Heart Association; ApoB, apolipoprotein B; ASCVD, atherosclerotic cardiovascular disease; BP, blood pressure; CAC, coronary artery calcium; CIMT, carotid intima-media thickness; CKD, chronic kidney disease; COR, Class of Recommendation; CQ, critical question, ES, evidence statement; hs-CRP, high-sensitivity C-reactive protein; LOE, Level of Evidence; NHLBI, National Heart, Lung, and Blood Institute; and —, not applicable.

Blood Cholesterol in Adults (Adult Treatment Panel III)[24] and the uptake of this algorithm by practice sites across the United States, the Work Group began by discussing the value of retaining this algorithm. In collaboration with other NHLBI panels, the Work Group decided not to use this algorithm in its 2013 recommendations because of the algorithm's derivation in an exclusively white sample population and the limited scope of the outcome (in determining CHD alone). Rather, the Work Group derived risk equations from community-based cohorts that are broadly representative of the US population of whites and African Americans, and the Work Group focused on estimation of first hard ASCVD events (defined as first occurrence of nonfatal myocardial infarction, CHD death, or fatal or nonfatal stroke) as the outcome of interest because they were deemed to be of greater relevance to both patients and providers. The focus on hard ASCVD, rather than CHD alone, is also consistent with evidence reviewed in a statement from the AHA and American Stroke Association calling for the inclusion of ischemic stroke in the outcome of interest for CVD risk assessment.[25]

Numerous multivariable risk scores and equations have been derived and published (Appendix 6; for more details, see the Full Work Group Report supplement). As part of its deliberations, the Work Group considered previously published risk scores with validation in NHLBI cohort data as one possible approach. However, several persistent concerns with existing risk equations were identified, including nonrepresentative or historically dated populations, limited ethnic diversity, narrowly defined endpoints, endpoints influenced by provider preferences (eg, elective revascularizations), and endpoints with poor reliability (eg, angina and heart failure). Given the inherent limitations of existing scores, the Work Group judged that a new risk score was needed to address some of the deficiencies of existing scores—for example, the need for a population sample that approaches, to the degree possible, the ideal sample for algorithm development and closely represents the US population.

Data are sparse on the use and impact of absolute risk scores in clinical practice in primary-prevention settings.[26]

Two systematic reviews, based on few studies, support the conclusion that risk assessment, combined with counseling, is associated with favorable but modest changes in patient knowledge and intention to change and in provider prescribing behavior and risk factor control.[27,28] No data are available on hard event outcomes. The Work Group specifically calls for research in this area (Section 8).

The Work Group notes that the "2009 ACCF/AHA Performance Measures for the Primary Prevention of Cardiovascular Disease in Adults" specifically recommended use of global CVD risk estimation in clinical practice.[29] Likewise, the US Preventive Services Task Force recommendations for aspirin,[30] the NHLBI Adult Treatment Panel III recommendations,[24] and European[31] and Canadian[32,33] guidelines for primary prevention of CVD, among others, have all recommended the use of absolute risk assessment for decision making about the intensity of lifestyle and pharmacological preventive interventions. Risk scores have been implemented in practice through paper scoring sheets and, increasingly, through Web sites and downloadable applications. The electronic medical record can be adapted to estimate absolute risks automatically by using patient data and published equations, and it is anticipated that risk estimation with this technology will become a mainstream application of the current and future risk algorithms.

4. Development of New Pooled Cohort ASCVD Risk Equations

Having made the decision to develop new equations to estimate the 10-year risk of developing a first ASCVD event, the Work Group used the best available data from community-based cohorts of adults, with adjudicated endpoints for CHD death, nonfatal myocardial infarction, and fatal or nonfatal stroke. Cohorts that included African-American or white participants with at least 12 years of follow-up were included. Data from other racial/ethnic groups were insufficient, precluding their inclusion in the final analyses. The final pooled cohorts included participants from several large, racially and geographically diverse, modern NHLBI-sponsored cohort studies, including the ARIC (Atherosclerosis Risk in Communities) study,[8] the Cardiovascular Health Study,[5] and the CARDIA (Coronary Artery Risk Development in Young Adults) study,[7] combined with applicable data from the Framingham Original and Offspring Study cohorts.[4,6]

The Work Group used state-of-the-art statistical methods to derive and internally validate the Pooled Cohort Equations, which provide sex- and race-specific estimates of the 10-year risk of ASCVD for African-American and white men and women 40 to 79 years of age. The variables that statistically merit inclusion in the risk assessment equations are age, total cholesterol, high-density lipoprotein cholesterol, systolic BP (including treated or untreated status), diabetes mellitus (diabetes), and current smoking status.

An expanded description of the derivation and validation of the Pooled Cohort Equations, as well as the means for implementing them in clinical practice, is provided in Appendix 7. Additional details are provided in the Full Work Group Report supplement. A specific clinical vignette is also provided as an example in Appendix 7. In the clinical vignette, the 10-year risk is calculated for a patient 55 years of age who is a nonsmoker without diabetes, and with total cholesterol level of 213 mg/dL, high-density lipoprotein cholesterol level of 50 mg/dL, and untreated systolic BP of 120 mm Hg. With these values used in the Pooled Cohort Equations, the predicted 10-year ASCVD risks are 2.1% for white women, 3.0% for African-American women, 5.3% for white men, and 6.1% for African-American men.

Numerous other potential risk markers were considered for inclusion in the Pooled Cohort Equations: for many, no additional utility was demonstrated when they were included; for others, data are insufficient at the present time to determine their additional value. The equations were also assessed in external validation studies with data from other available cohorts. Other than the Framingham CHD risk score (and its derivative ATP III risk assessment profile) and the European SCORE (System for Cardiac Operative Risk Evaluation) algorithm for CVD death, these equations have been subjected to more rigorous validation than other currently available equations, and they are the only risk assessment equations that include significant numbers of African Americans and that focus on estimation of 10-year risk of the clinically relevant endpoint of ASCVD. The Work Group specifically calls for further research to develop similar equations applicable to other ethnic groups, to validate the utility of the Pooled Cohort Equations in diverse primary-prevention settings, and to assess the potential benefit of novel risk markers when added to these equations, so that the equations maybe modified or expanded over time as new data become available.

4.1. Recommendations for Assessment of 10-Year Risk of a First Hard ASCVD Event

Recommendation 1. The race- and sex-specific Pooled Cohort Equations* to predict 10-year risk of a first hard ASCVD event should be used in non-Hispanic African Americans and non-Hispanic whites, 40 to 79 years of age.

NHLBI Grade: B (Moderate); ACC/AHA COR: I; LOE: B

Recommendation 2. Use of the sex-specific Pooled Cohort Equations for non-Hispanic whites may be considered for estimation of risk in patients from populations other than African Americans and non-Hispanic whites.

NHLBI Grade: E (Expert Opinion); ACC/AHA COR: IIb; LOE: C

A Web-based application enabling estimation of 10-year and lifetime risk of ASCVD is available at http://my.americanheart.org/cvriskcalculator and http://www.cardiosource.org/en/Science-And-Quality/Practice-Guidelines-and-Quality-Standards/2013-Prevention-Guideline-Tools.aspx.

5. Implications for Risk Assessment

A range of estimated 10-year risk of a first hard ASCVD event is illustrated in the Full Work Group Report supplement (Tables 8 through 11), across a broad range of risk factor burdens for

*Ten-year risk was defined as the risk of developing a first ASCVD event, defined as nonfatal myocardial infarction, CHD death, or fatal or nonfatal stroke, over a 10-year period among people free from ASCVD at the beginning of the period.

selected combinations of the risk factors in sex–race groups (African-American and white women and men). The estimated risks are specific to defined combinations of the risk factors and demonstrate how they vary over a broad spectrum of potential profiles. Risk factor levels that are more adverse than those shown in these tables should always be associated with a higher estimated risk. For example, if a given risk factor combination indicates an estimated 10-year risk of hard ASCVD of 8%, but a patient has a higher level of systolic BP or total cholesterol, or a lower level of high-density lipoprotein cholesterol, than shown for that table cell, then the estimated risk would be ≥8%. Because the estimated probabilities can become unstable when approaching the limits of the sample data, the risk probabilities are truncated at 1% and 30%. The proportions of the US adult population, 40 to 79 years of age, in selected strata of estimated 10-year risk of hard ASCVD events, are shown overall and by sex and race/ethnicity in Table 5. When compared with non-Hispanic whites, estimated 10-year risk of ASCVD is generally lower in Hispanic-American and Asian-American populations and higher in American-Indian populations;[34,35] hence, the lack of race/ethnicity-specific risk algorithms is an important gap in our efforts to understand and prevent ASCVD in these populations. Although the development of algorithms specific to these racial/ethnic groups is encouraged, in the interim, providers may consider using the equations for non-Hispanic whites for these patients. When doing so, the estimated risks may be overestimates, especially for Hispanic and Asian Americans.

6. CQs and Systematic Evidence Review

6.1. Critical Question 1

"What is the evidence with regard to reclassification or contribution to risk assessment when hs-CRP, ApoB, glomerular filtration rate, microalbuminuria, family history, cardiorespiratory fitness, ABI, CAC, or CIMT is considered in addition to the variables that are in the traditional risk scores?"

The concept of matching the intensity of risk factor management to the estimated risk of CVD has been well established since the 27th Bethesda Conference in 1996.[23] As a consequence, widespread attention has focused on the accuracy and reliability of risk assessment. Claims that a minority of the risk of CVD can be explained by the major traditional risk factors or that most patients presenting with CHD have no elevated traditional risk factors have been disproved.[36,37] Nonetheless, the desire to improve existing quantitative risk-estimation tools has helped to stimulate and maintain interest in the search for new risk markers for CVD that might further enhance risk assessment.

CQ1 was developed to address whether newer risk markers have been identified that actually improve risk assessment enough to warrant routine measurement in clinical practice. This question applies to risk assessment in the general population—that is, the typical asymptomatic adult in routine clinical practice. This question does not address other highly selected patient subgroups, such as those with symptoms suggestive of CVD.

CQ1 was addressed through 2 independent approaches. First, in the process of developing the Pooled Cohort Equations, the additional risk markers listed in CQ1 were tested for inclusion in the model if they were available in the databases and could be evaluated on the basis of at least 10 years of follow-up. A review of meta-analyses and systematic reviews published before September 19, 2013, was conducted in 2 stages. In the first stage, meta-analyses and systematic reviews published before April 2011 were identified and reviewed. In a second stage, conducted to update the evidence base before publication, additional meta-analyses and systematic reviews published before September 19, 2013, were identified and reviewed against the same criteria applied in the first stage. The reliance on published meta-analyses to evaluate novel biomarkers is a conservative approach that helps avoid the influence of positive publication bias that can occur early in the evaluation of a novel association and assures that we relied on a mature body of evidence.[38]

Members of the Work Group proposed an initial list of novel risk markers for inclusion in CQ1, which was then prioritized during several rounds of discussion. In selecting the final list, the Work Group gave priority to factors that have engendered substantial discussion in the scientific community and that could be reasonably considered as potentially feasible for widespread population use by primary care providers in routine clinical settings in the United States. In these deliberations, the Work Group considered availability, cost, assay reliability, and risks of the test or downstream testing. The final list of new risk markers to be evaluated included several blood and urine biomarkers (hs-CRP, ApoB, creatinine [or estimated glomerular filtration rate], and microalbuminuria), several measures of subclinical cardiovascular disease (CAC, CIMT, and ABI), family history, and cardiorespiratory fitness. Other novel potential screening tools maybe the subject of future guideline updates. Guidance published by Hlatky et al[39] was considered during discussion of the utility of incorporating these new risk factors into routine risk assessment. Special attention was given to the additional value these markers contributed to risk assessment in terms of discrimination, calibration, reclassification, and cost-effectiveness, in the context of any potential harm.

6.1.1. Summary of Systematic Reviews and Meta-Analyses for CQ1

Thirteen systematic review articles or meta-analyses met the inclusion/exclusion criteria.[9–18,40–42] Publication dates ranged from 2008 to 2013. The Work Group reviewed the 13 systematic reviews and meta-analyses and created a table to list their key findings (Appendix 4). None of these markers has been evaluated as a screening test in randomized controlled trials with clinical events as outcomes. On the basis of current (limited) evidence, it is the opinion of the Work Group that among the novel risk markers, assessments of family history of premature CVD, as well as measurement of hs-CRP, CAC, and ABI, show some promise for clinical utility. Table 6 provides expert opinion on thresholds of these measures that may be considered for clinical decision making.

The Work Group notes that the review by Peters et al[16] provides evidence to support the contention that measuring CAC is

*Data derived by applying the Pooled Cohort Equations to the National Health and Nutrition Examinations Surveys, 2007–2010 (*N*=5367, weighted to 100 542 000 US population).

ASCVD indicates atherosclerotic cardiovascular disease; and CVD, cardiovascular disease.

likely to be the most useful of the current approaches to improving risk assessment among individuals found to be at intermediate risk after formal risk assessment. Furthermore, the Work Group recognizes that the "2010 ACCF/AHA Guideline for Assessment of Cardiovascular Risk in Asymptomatic Adults" made recommendations for CAC testing.[43] However, the Work Group notes that the outcomes in the studies reviewed by Peters et al[16] and by Greenland et al[43] were CHD outcomes, not hard ASCVD events that included stroke; hence, uncertainty remains about the contribution of CAC assessment to estimation of 10-year risk of first hard ASCVD events after formal risk assessment with the new Pooled Cohort Equations. Furthermore,

Table 6. Expert Opinion Thresholds for Use of Optional Screening Tests When Risk-Based Decisions About Initiation of Pharmacological Therapy Are Uncertain After Quantitative Risk Assessment

Measure	Support Revising Risk Assessment Upward	Do Not Support Revising Risk Assessment
Family history of premature CVD	Male <55 years of age Female <65 years of age (first-degree relative)	Occurrences at older ages only (if any)
hs-CRP	≥2 mg/L	<2 mg/L
CAC score	≥300 Agatston units or ≥75th percentile for age, sex, and ethnicity*	<300 Agatston units and <75th percentile for age, sex, and ethnicity*
ABI	<0.9	≥0.9

*For additional information, see http://www.mesa-nhlbi.org/CACReference.aspx.

ABI indicates ankle-brachial index; CAC, coronary artery calcium; CVD, cardiovascular disease; and hs-CRP, high-sensitivity C-reactive protein.

issues of cost and radiation exposure related to measuring CAC were discussed, resulting in some uncertainty about potential risks of more widespread screening, which resulted in a decision in the present guideline to make assessment of CAC an ACC/AHA COR IIb recommendation among individuals for whom a risk-based treatment decision is uncertain after formal risk estimation. The Work Group notes that this ACC/AHA COR IIb recommendation is consistent with the recommendations in the 2010 ACCF/AHA guideline[43] for patients with a 10-year CHD risk of <10%, as well as for many other patients, because of the lower risk threshold (7.5% 10-year risk of a first hard ASCVD event) adopted by the "2013 ACC/AHA Guideline on the Treatment of Blood Cholesterol to Reduce Atherosclerotic Cardiovascular Risk in Adults"[44] for recommending initiation of statin therapy for ASCVD risk reduction.

Furthermore, it was noted that measurement of ApoB, albuminuria, glomerular filtration rate, or cardiorespiratory fitness is of uncertain value. Finally, the Work Group judged that the evidence provided by Den Ruijter et al,[18] reviewed during the ACC/AHA update period, in combination with the concerns about measurement quality, provided sufficient rationale to recommend against measuring CIMT in routine clinical practice for risk assessment for a first ASCVD event. If any of the 9 markers considered in the present report is assessed in selected patients, the use of the information to guide treatment decisions will require sound clinician judgment and should be based on shared decision making.

6.1.2. Recommendations for CQ1: Use of Newer Risk Markers After Quantitative Risk Assessment

Recommendation 1. If, after quantitative risk assessment, a risk-based treatment decision is uncertain, assessment of 1 or more of the following—family history, hs-CRP, CAC score, or ABI—may be considered to inform treatment decision making.

NHLBI Grade: E (Expert Opinion); ACC/AHA COR: IIb†, LOE: B†

†Based on new evidence reviewed during ACC/AHA update of the evidence.

Recommendation 2. Routine measurement of CIMT is not recommended in clinical practice for risk assessment for a first ASCVD event.

NHLBI Grade: N (No recommendation for or against); ACC/AHA COR III: No Benefit†, LOE: B

Recommendation 3. The contribution of ApoB, chronic kidney disease, albuminuria, and cardiorespiratory fitness to risk assessment for a first ASCVD event is uncertain at present.

NHLBI Grade: N (No recommendation for or against)

6.2. Critical Question 2

"Are models constructed to assess the long-term (≥15 years or lifetime) risk of a first CVD event in adults effective in assessing variation in long-term risk among adults at low or intermediate short-term risk, whether analyzed separately or in combination?"

Younger men (typically <50 years of age) and most women have low (eg, <5% or <10%) predicted 10-year risks of CHD and more broad CVD outcomes, even in the presence of significant risk factor burden.[45,46] However, extensive epidemiological, pathological, and basic science data indicate that the development of atherosclerosis, the precursor of ASCVD, occurs over decades and is related to long-term and cumulative exposure to causal, modifiable risk factors. Thus, a life-course perspective on risk assessment and prevention must be taken, especially among younger individuals. The primary value of risk factor measurement and quantitative long-term risk estimation in younger adults is 2-fold: first, to identify risk in individuals with extreme values of risk factors (eg, familial hypercholesterolemia); and second, to provide risk information and context for the potential benefits of lifestyle modification. When posing CQ2, the Work Group did not anticipate that long-term or lifetime risk would replace 10-year risk assessment as the foundation for absolute risk assessment and clinical decision making. Rather, longer-term risk estimates, if found to be useful, could provide adjunctive information for risk communication.

CQ2 was developed to assess the utility of long-term and lifetime risk assessment as an adjunct to short-term (10-year) risk assessment. It was recognized that there is little "disconnect" with regard to approaches to prevention when the 10-year risk estimate is high (eg, >10% predicted 10-year risk); such patients merit intensive prevention efforts and should be considered for drug therapy to reduce or modify adverse levels of causal risk factors. CQ2 was selected for evaluation to determine whether quantitative or semiquantitative long-term risk assessment would provide differential information that could be useful in risk communication, specifically to patients estimated to be at lower short-term risk. However, it is unclear what the long-term predicted and observed risks for CHD and CVD are among individuals who are at low predicted 10-year risk. CQ2 was designed to identify studies that assessed both short- and long-term risk, focusing in particular on those studies that provide long-term outcomes data for groups predicted to be at low 10-year risk. If a sufficiently large proportion of the population is at high long-term risk despite being at low short-term risk, then incorporating long-term risk assessment

into routine clinical practice might have value for informing risk discussions with patients and guiding therapeutic lifestyle counseling and other aspects of care.

6.2.1. Summary of Evidence for CQ2

Ten studies that met inclusion/exclusion criteria were identified by the systematic review performed in April 2011 and were examined.[19–22,47–52] Publication dates ranged from 1999 to 2009. All of the studies were observational. On the basis of these studies, 7 evidence statements were adopted (Appendix 5).

Multiple sources provided consistent evidence for the associations of traditional risk factors with events occurring during both short-term and long-term follow-up. The important associations are best represented and understood in the context of multivariable risk equations that reliably predict absolute risk of ASCVD events. In addition, most of these risk factors are both causal and modifiable, which indicates their central clinical importance for ASCVD prevention efforts. Given the additional evidence suggesting improved risk prediction with updated clinical covariates, the Work Group makes the following recommendations.

6.2.2. Recommendations for CQ2: Long-Term Risk Assessment

Recommendation 1. It is reasonable to assess traditional ASCVD risk factors‡ every 4 to 6 years in adults 20 to 79 years of age who are free from ASCVD and to estimate 10-year ASCVD risk every 4 to 6 years in adults 40 to 79 years of age who are free from ASCVD.

NHLBI Grade: B (Moderate); ACC/AHA COR: IIa, LOE: B

Recommendation 2. Assessment of 30-year or lifetime ASCVD risk on the basis of traditional risk factors‡ may be considered in adults 20 to 59 years of age who are free from ASCVD and are not at high short-term risk.

NHLBI Grade: C (Weak); ACC/AHA COR: IIb, LOE: C

A Web-based application enabling estimation of 10-year and lifetime risk of ASCVD is available at http://my.americanheart.org/cvriskcalculator and http://www.cardiosource.org/en/Science-And-Quality/Practice-Guidelines-and-Quality-Standards/2013-Prevention-Guideline-Tools.aspx.

Evidence was not found on the utility of lifetime risk assessment for guiding pharmacological therapy decisions, and the Work Group judged that long-term and lifetime risk information may be used more appropriately at this time to motivate therapeutic lifestyle change in younger individuals. This perspective influenced the choice of age 20 years as the starting point for long-term risk assessment, despite a threshold of age 40 years for short-term 10-year ASCVD risk assessment.

Long-term and lifetime risk estimation may be less valuable for individuals who are found to be at high short-term (10-year) risk according to multivariable equations, for whom decisions about prevention efforts may be clear. However, an understanding of long-term risk may provide a means of encouraging adherence to lifestyle or pharmacological therapies, especially for patients who might have difficulty understanding the importance of their short-term risk. Likewise, for older individuals or those with limited life expectancy, clinical considerations should dictate the intensity of risk assessment and prevention efforts.

‡Age, sex, total cholesterol, high-density lipoprotein cholesterol, systolic BP, use of antihypertensive therapy, diabetes, and current smoking.

7. Implementation Considerations for Risk Assessment

A suggested approach for incorporating these recommendations into clinical practice is shown in Figure 1. For patients 20 to 79 years of age who are free from clinical ASCVD, the first step is to assess ASCVD risk factors. Although it is reasonable to assess ASCVD risk factors in individuals younger or older than this age range, limitations of available data prevented the development of robust risk assessment algorithms in those populations. Hence, for patients outside this age range, providers should refer to applicable clinical practice guidelines (ie, pediatric[53] and adult primary prevention guidelines.[44,54,56] Risk assessment should be repeated every 4 to 6 years in persons who are found to be at low 10-year risk (<7.5%). Beginning at age 40 years, formal estimation of the absolute 10-year risk of ASCVD is recommended.[20,21] Long-term or lifetime risk estimation is recommended for all persons who are between 20 and 39 years of age and for those between 40 and 59 years of age who are determined to be at low 10-year risk (<7.5%). As shown in Figure 1, all patients should receive applicable risk information and appropriate lifestyle counseling. The 10-year risk estimates provided by the new Pooled Cohort Equations differ from those generated by the Adult Treatment Panel III algorithm in several respects,[24] as discussed in detail in the Full Work Group Report supplement. To summarize, on the basis of the risk estimation algorithm recommended by Adult Treatment Panel III, approximately 31.9% of the ASCVD-free, nonpregnant US population between 40 and 79 years of age have a 10-year risk of a first hard CHD event of at least 10% or have diabetes. On the basis of the new Pooled Cohort Equations described here, approximately 32.9% have a 10-year risk of a first hard ASCVD of at least 7.5%. The outcomes and thresholds of these 2 approaches are different, but the overlap of these 2 means of defining high-risk groups is substantial, at roughly 75%. Nonetheless, these important differences make simple linear conversions imprecise. We recommend that healthcare organizations convert to these new Pooled Cohort Equations as soon as practical (Appendix 7). A Web-based application enabling estimation of 10-year and lifetime risk of ASCVD is available at http://my.americanheart.org/cvriskcalculator and http://www.cardiosource.org/en/Science-And-Quality/Practice-Guidelines-and-Quality-Standards/2013-Prevention-Guideline-Tools.aspx.

8. Evidence Gaps and Future Research Needs

The Work Group strongly recommends continued research to fill gaps in knowledge about short- and long-term ASCVD risk assessment and outcomes in all racial/ethnic groups, across the age spectrum, and in women and men. Future research should include analyses of short- and long-term risk in diverse groups, optimal communication of ASCVD risk information, utility of short-and long-term risk assessment for motivating behavioral change and adherence to therapy, utility of short- and long-term risk assessment for influencing risk factor levels and clinical outcomes, utility of differential information

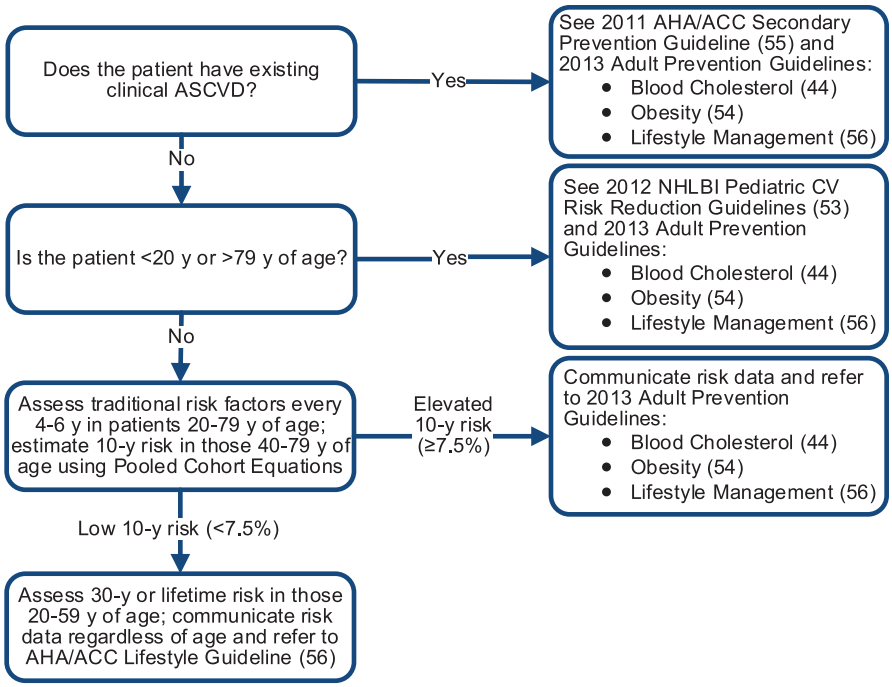

Figure 1. Implementation of Risk Assessment Work Group Recommendations. ACC indicates American College of Cardiology; AHA, American Heart Association; ASCVD, atherosclerotic cardiovascular disease; CV, cardiovascular; and NHLBI, National Heart, Lung, and Blood Institute.

conveyed by short- and long-term risk assessment, and utility of novel risk markers in short- and long-term risk assessment.

9. Conclusions

The Work Group's approach to risk assessment represents a step forward in ASCVD prevention that is large enough to justify the challenges inherent in implementing a new approach, rather than staying with the CHD risk assessment approach recommended previously. The final recommendations are summarized in Table 4 and Figure 1. Two major advantages of this approach are the ability to estimate risk for a broader-based ASCVD outcome that is more relevant to additional segments of the population, including women and African Americans, and the ability to provide risk estimates specific to African Americans. Promotion of lifetime risk estimation may represent an additional step forward in supporting lifestyle behavior change counseling efforts. Periodic updates of the guidelines should address numerous issues related to risk assessment.

This table reflects the relevant healthcare-related relationships of authors with industry and other entities provided by the panels during the document development process (2008–2012). Both compensated and uncompensated relationships are reported. These relationships were reviewed and updated in conjunction with all meetings and conference calls of the Expert Work Group during the document development process. Authors with relevant relationships during the document development process recused themselves from voting on recommendations relevant to their relationships. In the spirit of full transparency, the ACC and AHA asked Expert Work Group members to provide updates and approve the final version of this table, which includes current relevant relationships (2013). To review the NHLBI and ACC/AHA's current comprehensive policies for managing RWI, please refer to http://www.nhlbi.nih.gov/guidelines/cvd_adult/coi-rwi_policy.htm and http://www.cardiosource.org/Science-And-Quality/Practice-Guidelines-and-Quality-Standards/Relationships-With-Industry-Policy.aspx.

Per ACC/AHA policy: A person is deemed to have a significant interest in a business if the interest represents ownership of ≥5% of the voting stock or share of the business entity, or ownership of ≥$10 000 of the fair market value of the business entity; or if funds received by the person from the business entity exceed 5% of the person's gross income for the previous year. Relationships that exist with no financial benefit are also included for the purpose of transparency. Relationships in this table are modest unless otherwise noted.

*Significant relationship.

ACC indicates American College of Cardiology; AHA, American Heart Association; and NHLBI, National Heart, Lung, and Blood Institute.

Appendix 2. Expert Reviewer Relationships With Industry and Other Entities—2013 ACC/AHA Guideline on Assessment of Cardiovascular Risk

Reviewer	Employment	Representing	Consultant	Speaker's Bureau	Ownership/ Partnership/ Principal	Personal Research	Expert Witness
Ezra A. Amsterdam	University of California (Davis) Medical Center, Division of Cardiology—Professor	ACC/AHA	None	None	None	None	None
Ralph G. Brindis	University of California, San Francisco—Department of Medicine & the Phillip R. Lee Institute for Health Policy Studies—Clinical Professor of Medicine	ACC/AHA Task Force on Practice Guidelines	None	None	None	None	None
Frederick A. Masoudi	University of Colorado, Anschutz Medical Campus—Professor of Medicine (Cardiology)	ACC/AHA	None	None	None	None	None

This table represents the relationships of reviewers with industry and other entities that were self-disclosed at the time of peer review. It does not necessarily reflect relationships with industry at the time of publication. To review the NHLBI and ACC/AHA's current comprehensive policies for managing relationships with industry and other entities, please refer to http://www.nhlbi.nih.gov/guidelines/cvd_adult/coi-rwi_policy.htm and http://www.cardiosource.org/Science-And-Quality/Practice-Guidelines-and-Quality-Standards/Relationships-With-Industry-Policy.aspx.

ACC indicates American College of Cardiology; and AHA, American Heart Association.

Appendix 3. Abbreviations

ABI = ankle-brachial index
ApoB = apolipoprotein B
ASCVD = atherosclerotic cardiovascular disease
BP = blood pressure
CAC = coronary artery calcium
CHD = coronary heart disease
CIMT = carotid intima-media thickness
COR = Class of Recommendation
CQ = critical question
CVD = cardiovascular disease
hs-CRP = high-sensitivity C-reactive protein
LOE = Level of Evidence
NHLBI = National Heart, Lung, and Blood Institute
RWI = relationships of authors with industry and other entities

Appendix 4. Evidence Statements for CQ1

Evidence Statement Number	Author/Group	Factor	Evidence Statement/Conclusion
1	USPSTF[9]	hs-CRP	"Strong evidence indicates that CRP is associated with CHD events. Moderate, consistent evidence suggests that adding CRP to risk prediction models among initially intermediate-risk persons improves risk stratification." "Few studies directly assessed the effect of CRP on risk reclassification in intermediate-risk persons." hs-CRP was associated with risk, and its use resulted in some reclassification in intermediate-risk persons, but it was not clear whether this reclassification led to a net improvement in prediction. Values of receiver operating curve *C*-statistics (measures of discrimination) are mentioned but not reported; hence, no evidence on discrimination, calibration, net reclassification index, or cost-effectiveness was provided. Reports some impact on reclassification, probably modest (pp. 488–491).
2	Helfand et al, 2009[12]	hs-CRP, CAC, CIMT, ABI	With regard to risk assessment for major CHD, the authors concluded that, "The current evidence does not support the routine use of any of the 9 risk factors for further risk stratification of intermediate-risk persons." The 9 risk factors examined were: hs-CRP, CAC score as measured by electron-beam computed tomography, lipoprotein (a) level, homocysteine level, leukocyte count, fasting blood glucose, periodontal disease, ABI, and CIMT. hs-CRP was associated with CHD and led to some reclassification. The authors cite the JUPITER results to support the conclusion that hs-CRP testing may be useful in intermediate-risk patients to drive statin therapy. The Work Group recognizes that more recent individual study results have been published. Updated systematic reviews addressing discrimination, calibration, reclassification, and cost issues in the context of the newer ASCVD risk assessment model proposed in the present document are needed. CAC was associated with CHD and with some reclassification, but the size and value of this reclassification are uncertain. The document provides little evidence with regard to discrimination, calibration, and cost-effectiveness. The Work Group also is concerned about radiation and incidental findings. The Work Group recognizes that more recent individual study results have been published. Updated systematic reviews addressing discrimination, calibration, reclassification, cost, and safety issues in the context of the newer ASCVD risk assessment model proposed in the present document are needed. CIMT was associated with CHD, but the document provides little evidence for reclassification, discrimination, calibration, and cost-effectiveness. The Work Group also has concerns about measurement issues. Standardization of CIMT measurement is a major challenge. The Work Group recognizes that more recent individual study results have been published. Updated systematic reviews addressing discrimination, calibration, reclassification, cost, and measurement (standardization) issues in the context of the newer ASCVD risk assessment model proposed in this document are needed. ABI was associated with CHD and some reclassification, but the size and value of this reclassification are uncertain. Evidence suggests some improvement in discrimination, but the document provides little evidence with regard to calibration and cost-effectiveness. The Work Group members are uncertain whether more recent individual study results have been published relevant to ABI. Updated systematic reviews addressing discrimination, calibration, reclassification, and cost issues in the context of the newer ASCVD risk assessment model proposed in this document are needed.
3	Emerging Risk Factors Collaboration[13]	hs-CRP	"CRP concentration has continuous associations with the risk for coronary heart disease, ischaemic stroke, vascular mortality, and death from several cancers and lung disease that are each of broadly similar size. The relevance of CRP to such a range of disorders is unclear. Associations with ischaemic vascular disease depend considerably on conventional risk factors and other markers of inflammation." hs-CRP is associated with risk of CVD. This analysis did not directly assess value in risk prediction. No additional evidence was provided for discrimination, calibration, reclassification, or cost-effectiveness.
4	Schnell-Inderst et al, 2010[17]	hs-CRP	For MI and cardiovascular mortality, "Adding hs-CRP to traditional risk factors improves risk prediction, but the clinical relevance and cost-effectiveness of this improvement remain unclear." Absolute differences in *C*-statistics between models including and not including hs-CRP ranged from 0.00 to 0.027. Some evidence was provided to support the cost-effectiveness of hs-CRP testing in some modeling scenarios, characterized by intermediate- and higher-risk populations and lower-cost (generic) statins of at least moderate efficacy.
5	Emerging Risk Factors Collaboration[40]	ApoB	This article provided evidence of rough equivalence of associations of CVD with non–HDL-C and ApoB after multivariable adjustment (including HDL-C). See Figure 1 for CHD and the text for stroke. By inference, this finding means there would be rough equivalence between ApoB and total cholesterol with similar adjustment.

(*Continued*)

Appendix 4. Continued

Evidence Statement Number	Author/Group	Factor	Evidence Statement/Conclusion
6	Sniderman et al, 2011[42]	ApoB	ApoB was more strongly related to risk of ASCVD than either non–HDL-C or LDL-C in a substitution model that also included HDL-C. No evidence was presented pertinent to an addition model in which ApoB might be added to a model that included total cholesterol, LDL-C, or non–HDL-C. Additional models are the type of model of interest to this question. By inference, these results maymean that ApoB is more strongly related to risk than is total cholesterol. This article did not address directly the value of adding ApoB to a model with traditional risk factors. No information was presented for discrimination, calibration, reclassification, or cost. The relative risks evaluated in the meta-analysis were adjusted for various sets of covariates in the various primary reports, and the adjustments were judged to be incomplete. Furthermore, studies of varying designs and quality were included, leaving the Work Group members concerned about the validity of the evidence.
7	Kodama et al, 2009[41]	Cardiorespiratory fitness	Better cardiorespiratory fitness was associated with lower risk of all-cause mortality and CHD/CVD. According to the sensitivity analyses in Table 2, evidence of association was weaker for CHD/CVD, but still significant, when based on studies with more complete adjustment for other risk factors. The utility of assessing cardiorespiratory fitness in risk prediction was not assessed (discrimination, calibration, reclassification, and cost).
8	Ankle Brachial Index Collaboration[11]	ABI	ABI is associated with total CHD risk and leads to significant reclassification, and the pattern of reclassification is different by sex. Among men, the effect is to down-classify high-risk men. Among women, the effect is to up-classify low-risk women. Overall, the FRS, as applied by the investigators, showed relatively poor discrimination in this meta-analysis, with *C*-statistics of 0.646 (95% CI: 0.643–0.657) in men and 0.605 (0.590–0.619) in women. There was an improvement in *C*-statistic in both men (0.655 [0.643–0.666]) and women (0.658 [0.644–0.672]) when ABI was added to a model with FRS. The improvement in the *C*-statistic was greater and significant in women but was not significant in men. No evidence on calibration, net reclassification index, or cost-effectiveness was provided.
9	Empana et al, 2011[10]	Family history of CHD	"In separate models adjusted for age, gender, and study cohort, a family history of CHD, BMI, and waist circumference were all predictors of CHD. When traditional risk factors were controlled for, family history of CHD ($P<0.001$) and BMI ($P=0.03$) but not waist circumference ($P=0.42$) remained associated with CHD. However, the addition of family history of CHD or BMI to the traditional risk factors model did not improve the discrimination of the model (not shown)." This article developed a CHD risk prediction algorithm based on 4 French population studies and evaluated, among other factors, the contribution of family history to traditional risk factors. Family history of CHD was defined as the self-report of a MI in first-degree relatives (parents and siblings) in the D.E.S.I.R. and SU.VI.MAX studies, as a history of MI before age 55 years in men and before age 65 years in women in parents, siblings, and grandparents in the PRIME study, and as a death due to MI in first-degree relatives in the Three City study. No evidence on calibration, net reclassification index, or cost-effectiveness was provided.
10	Moyer et al, 2013[15]	ABI	This article is an updated review of the utility of assessing ABI for the USPSTF. "The USPSTF concludes that the current evidence is insufficient to assess the balance of benefits and harms of screening for PAD and CVD risk assessment with the ABI in adults. (I statement)" "The USPSTF found no evidence that screening for and treatment of PAD in asymptomatic patients leads to clinically important benefits. It also reviewed the potential benefits of adding the ABI to the FRS and found evidence that this results in some patient risk reclassification; however, how often the reclassification is appropriate or whether it results in improved clinical outcomes is not known." The Work Group notes that this review provides some evidence that assessing ABI may improve risk assessment; however, no evidence was found by the USPSTF reviewers pertinent to the question of whether measuring ABI leads to better patient outcomes.

(*Continued*)

Appendix 4. Continued

Evidence Statement Number	Author/Group	Factor	Evidence Statement/Conclusion
11.	Peters et al, 2012[16]	CIMT, CAC	This article is a systematic review of the literature on the contribution to risk assessment of imaging for subclinical atherosclerosis. "Published evidence on the added value of atherosclerosis imaging varies across the different markers, with limited evidence for FMD and considerable evidence for CIMT, carotid plaque and CAC. The added predictive value of additional screening may be primarily found in asymptomatic individuals at intermediate cardiovascular risk. Additional research in asymptomatic individuals is needed to quantify the cost-effectiveness and impact of imaging for subclinical atherosclerosis on cardiovascular risk factor management and patient outcomes." With regard to CIMT: "The c-statistic of the prediction models without CIMT increased from 0.00 to 0.03 when CIMT was added. In the Atherosclerosis Risk In Communities (ARIC) study, addition of CIMT to the prediction model resulted in an NRI overall of 7.1% (95% CI 2.2% to 10.6%) and an IDI of 0.007 (95% CI 0.004 to 0.010). The NRI intermediate was 16.7% (95% CI 9.3% to 22.4%). In contrast, 10 year results from the Carotid Atherosclerosis Progression Study showed that addition of CIMT to the prediction model resulted in an IDI of 0.04% and NRI overall of –1.41%. Analysis of 1,574 participants from the Firefighters and Their Endothelium study showed an NRI overall of 11.6% (P=0.044) and an NRI intermediate of 18.0% (P=0.034)." The Work Group notes that this article provides some evidence to consider assessing CIMT; however, this conclusion was not supported by the article by Den Ruijter et al described below.[18] With regard to CAC: "The c-statistic increased from 0.04 to 0.13 when CAC was added to the model. Four recently published studies also reported results on the NRI and/or the IDI. One of these studies comprised a subgroup analysis of an earlier publication in the total population in individuals without indications for statin therapy. Analyses of the MESA study showed that addition of CAC to the conventional prediction model resulted in an NRI overall of 25% (95% CI 16% to 34%) and an NRI intermediate of 55% (95% CI 41% to 69%). The IDI in the MESA study was 0.026. Results were similar in the Rotterdam study. Addition of CAC to the prediction model led to an NRI overall of 14% (P<0.01) which was mainly driven by correctly reclassifying those at intermediate risk according to the traditional prediction model. Results from the Heinz Nixdorf Recall study also showed large NRIs when CAC was added to the Framingham Risk Score. Using different thresholds to define the intermediate risk category (10%–20% or 6%–20%), the NRI overall was 22% and 20%, respectively. The NRI intermediate was 22% for intermediate risk thresholds of 10%–20% and 31% for intermediate risk thresholds of 6%–20%. In addition, the IDI was 0.0152 when the prediction models with and without CAC were compared. The NRI overall was 25.1% and the IDI was 0.0167 in individuals from the Heinz Nixdorf Recall study without indications for statin therapy." The Work Group notes that this article provides evidence to support the conclusion that assessing CAC is likely to be the most useful approach to improving risk assessment among individuals found to be at intermediate risk after formal risk assessment. Furthermore, we note that the outcomes in the studies reviewed above were CHD, not ASCVD. The Work Group discussed concerns about cost, radiation exposure, and the uncertainty of the contribution of assessing CAC to estimation of 10-year risk of hard ASCVD after formal risk assessment.
12.	Kashani et al, 2013[14]	Family history	This article is an integrative literature review on the contribution of assessing family history to risk appraisal. "The evidence demonstrates that family history is an independent contributor to risk appraisal and unequivocally supports its incorporation to improve accuracy in global CVD risk estimation." The Work Group notes that a variety of endpoints, clinical and subclinical, were included in the reviewed articles. No evidence on discrimination, calibration, net reclassification index, or cost-effectiveness was provided.
13.	Den Ruijter et al, 2012[18]	CIMT	This article is an individual-level meta-analysis of "14 population-based cohorts contributing data for 45 828 individuals. During a median follow-up of 11 years, 4007 first-time MIs or strokes occurred." "We first refitted the risk factors of the FRS and then extended the model with common CIMT measurements to estimate the absolute 10-year risks to develop a first-time MI or stroke in both models. The *C*-statistic of both models was similar (0.757; 95% CI, 0.749–0.764; and 0.759; 95% CI, 0.752–0.766). The net reclassification improvement with the addition of common CIMT was small (0.8%; 95% CI, 0.1%–1.6%). In those at intermediate risk, the net reclassification improvement was 3.6% in all individuals (95% CI, 2.7%–4.6%) and no differences between men and women." "The addition of common CIMT measurements to the FRS was associated with small improvement in 10-year risk prediction of first-time MI or stroke, but this improvement is unlikely to be of clinical importance." The Work Group judged this article to provide the strongest evidence available on the potential value of CIMT to risk assessment. The Work Group also has concerns about measurement issues. Standardization of CIMT measurement is a major challenge.

ABI indicates ankle-brachial index; ApoB, apolipoprotein B; BMI, body mass index; ASCVD, atherosclerotic cardiovascular disease; CAC, coronary artery calcium; CHD, coronary heart disease; CI, confidence interval; CIMT, carotid intima-media thickness; CRP, C-reactive protein; CVD, cardiovascular disease; FMD, flow-mediated dilation; FRS, Framingham Risk Score; HDL-C, high-density lipoprotein cholesterol; hs-CRP, high-sensitivity C-reactive protein; IDI, integrative discrimination index; JUPITER, Justification for the Use of Statins in Primary Prevention: An Intervention Trial Evaluating Rosuvastatin; LDL-C, low-density lipoprotein cholesterol; MESA, Multi-Ethnic Study of Atherosclerosis; NRI, net reclassification index; PAD, peripheral artery disease; MI, myocardial infarction; and USPSTF, US Preventive Services Task Force.

Appendix 5. Evidence Statements for CQ2

Evidence Statement Number	Evidence Statement	References
1.	We found no evidence assessing variations in long-term or lifetime risk of CVD outcomes among persons at low or intermediate short-term risk in racial/ethnic groups other than non-Hispanic whites in the United States and Europe. *Strength of Evidence: None*	—
2.	ASCVD risk factors measured in young and middle-aged adults, considered singly or jointly, generally are associated with short-term (≤10 years), long-term (≥15 years), and lifetime risk of ASCVD. *Strength of Evidence:* Low (for diabetes and metabolic syndrome) to Moderate (for BMI, cholesterol, systolic BP, and smoking).	20,21,47,48,51,52
3.	Multivariable short-term (10-year) CHD risk prediction models underestimate absolute lifetime risk of CHD but maystratify relative lifetime risk of CHD in women and older men.* *Strength of Evidence: Low* *CHD is defined as all manifestations of CHD, or as CHD death/nonfatal MI.	22
4.	Long-term (30-year) risk equations based on traditional ASCVD risk factors* provide more accurate prediction of long-term ASCVD† risk than do extrapolations of short-term (10-year) risk equations among individuals 20–59 years of age who are free from ASCVD. *Strength of Evidence: Low* *Age, sex, total cholesterol, HDL-C, systolic BP, use of antihypertensive therapy, diabetes, and current smoking. †CHD death, nonfatal MI, or fatal/nonfatal stroke; or all ASCVD.	20
5.	The presence and severity of selected traditional ASCVD risk factors* stratify absolute levels of lifetime risk of ASCVD† among non-Hispanic white adults 45–50 years of age who are free of ASCVD and not at high short-term risk. *Strength of Evidence: Low* *Risk factors were considered in 5 mutually exclusive strata encompassing the full spectrum of risk levels, as follows: 1) ≥2 major risk factors (defined as total cholesterol ≥240 mg/dL or treated, systolic BP ≥160 or diastolic BP ≥100 mm Hg or treated, or diabetes, or current smoking) and lifetime risk of ASCVD >50%; 2) only 1 major risk factor and lifetime risk of ASCVD 39%–50%; 3) ≥1 elevated risk factor (defined as untreated total cholesterol 200 to 239 mg/dL, or untreated systolic BP 140–159 mm Hg or diastolic BP 90–99 mm Hg, and no diabetes and no current smoking) and lifetime risk of ASCVD 39%–46%; 4) ≥1 risk factor at nonoptimal levels (untreated total cholesterol 180–199 mg/dL, or untreated systolic BP 120–139 mm Hg or diastolic BP 80–89 mm Hg, and no diabetes and no current smoking) and lifetime risk of ASCVD 27%–36%; and 5) all optimal levels of risk factors (defined as untreated total cholesterol <180 mg/dL, and untreated BP <120/<80 mm Hg, and no diabetes, and no current smoking) and lifetime risk of ASCVD <10%. †CHD death, MI, coronary insufficiency, angina, fatal/nonfatal atherothrombotic stroke, claudication, other CVD death.	21
6.	Long-term (≥15 years) risk prediction models based on selected traditional ASCVD risk factors* predict CHD death with good discrimination and calibration, and better in women than men, in US non-Hispanic white populations. *Strength of Evidence: Low* *Age, sex, total cholesterol, systolic BP, diabetes, and smoking.	50
7.	Measuring and updating ASCVD risk factors every 4–6 years improves short- and long-term risk prediction. *Strength of Evidence: Moderate*	19,20

ASCVD indicates atherosclerotic cardiovascular disease; BMI, body mass index; BP, blood pressure; CHD, coronary heart disease; CQ, critical question; CVD, cardiovascular disease; HDL-C, high-density lipoprotein cholesterol; MI, myocardial infarction; and —, none.

Appendix 7. Development and Steps for Implementation of the ASCVD Pooled Cohort Risk Equations

Prior experience with the development of the Framingham Heart Study 10-year *CHD* risk prediction equations[24,57] and the more recent Framingham 10-year *general CVD* risk prediction equations,[58] was used as a basis for developing the new Pooled Cohort Risk Equations. To expand the utility and generalizability of the new equations, extensive data were used from several large, racially and geographically diverse, modern NHLBI-sponsored cohort studies, including the ARIC (Atherosclerosis Risk in Communities) study,[8] Cardiovascular Health Study,[5] and the CARDIA (Coronary Artery Risk Development in Young Adults) study,[7] combined with applicable data from the Framingham Original and Offspring Study cohorts.[4,6]

A total of 11 240 white women (who experienced 902 hard ASCVD events), 9098 white men (1259 hard ASCVD events), 2641 African-American women (290 hard ASCVD events), and 1647 African-American men (238 hard ASCVD events) who met the following criteria were included: 40 to 79 years of age, apparently healthy, and free of a previous history of nonfatal myocardial infarction (recognized or unrecognized), stroke, heart failure, percutaneous coronary intervention, coronary artery bypass surgery, or atrial fibrillation. Data from the included participants were used to develop sex- and race-specific equations to predict 10-year risk of a first hard ASCVD event. Because of the growing health burden of heart failure, the Work Group examined the possibility of including heart failure as an outcome. However, study-by-study ascertainment and adjudication of heart failure varied considerably, and therefore heart failure could not be included as an outcome. Because of known substantial geographic variation in use (Dartmouth Atlas of Healthcare, http://www.dartmouthatlas.org/), self-selection, and physician recommendation biases,[64] coronary revascularization was also not included as an endpoint.

The Pooled Cohort Equations for estimating ASCVD were developed from sex- and race-specific proportional-hazards models that included the covariates of age, treated or untreated systolic BP level, total cholesterol and high-density lipoprotein cholesterol levels, current smoking status (yes/no), and history of diabetes (yes/no). A variable representing lipid treatment was considered but not retained in the final model because lipid therapy was relatively uncommon in the cohorts and statistical significance was lacking. Baseline characteristics of the participants included in the equation derivation model are shown in the Full Work Group Report Data supplement, as are details of the methods used to derive, evaluate, and validate (internally and externally) the resulting risk equations and their potential limitations. In summary, discrimination and calibration of the models were very good. *C*-statistics ranged from a low of 0.713 (African-American men) to a high of 0.818 (African-American women). Calibration chi-square statistics ranged from a low of 4.86 (non-Hispanic white men) to a high of 7.25 (African-American women). The coefficients for the equations for calculating an estimate of an individual's 10-year risk of a first hard ASCVD event are provided in Table A, along with examples based on a specific risk profile for each race–sex group. The step-by-step process for estimating the risk in the specific examples of Table A is provided in Table B. These 2 tables are intended to enable programmers to integrate these equations into electronic health records.

The Work Group also considered the inclusion of additional and novel risk markers in the risk equations. On the basis of the availability of data across cohorts at applicable examination cycles, additional risk markers were evaluated for potential inclusion if they improved model performance within the framework of Hlatky et al.[39] The additional risk markers that were evaluated included diastolic BP, family history of ASCVD, moderate or severe chronic kidney disease (defined as an estimated glomerular filtration rate of <60 mL/min per 1.73 m^2),[65] and body mass index (continuous or categorical). None of these variables significantly improved discrimination for 10-year hard ASCVD risk prediction when added to the final base models. Other risk markers (hs-CRP, ApoB, microalbuminuria, cardiorespiratory fitness, CAC score, CIMT, and ABI) could not be evaluated in creating this new model because of absence of data or lack of inclusion in the appropriate examination cycle of 1 or more of the studies. Therefore, these and the other risk markers were addressed in CQ1 as potential adjuncts to quantitative risk estimation.

Further research using state-of-the art statistical techniques (including net reclassification improvement and integrative discrimination index[66]) is needed to examine the utility of novel biomarkers when added to these new Pooled Cohort Equations in different populations and patient subgroups. Randomized clinical trials demonstrating the utility of screening with novel risk markers would represent the best evidence for their inclusion in future risk assessment algorithms. In the absence of evidence from trials, methodologically rigorous observational studies should be conducted to evaluate utility.

Table A. Equation Parameters of the Pooled Cohort Equations for Estimation of 10-Year Risk of Hard ASCVD* and Specific Examples for Each Race and Sex Group

	White			African American		
	Coefficient	Individual Example Value	Coefficient × Value†	Coefficient	Individual Example Value	Coefficient × Value†
Women (Example: 55 years of age with total cholesterol 213 mg/dL, HDL-C 50 mg/dL, untreated systolic BP 120 mm Hg, nonsmoker, and without diabetes)						
Ln Age (y)	–29.799	4.01	–119.41	17.114	4.01	68.58
Ln Age, Squared	4.884	16.06	78.44	N/A	N/A	N/A
Ln Total Cholesterol (mg/dL)	13.540	5.36	72.59	0.940	5.36	5.04
Ln Age × Ln Total Cholesterol	–3.114	21.48	–66.91	N/A	N/A	N/A
Ln HDL-C (mg/dL)	–13.578	3.91	–53.12	–18.920	3.91	–74.01
Ln Age × Ln HDL-C	3.149	15.68	49.37	4.475	15.68	70.15
Ln Treated Systolic BP (mm Hg)	2.019	—	—	29.291	—	—
Ln Age × Ln Treated Systolic BP	N/A	N/A	N/A	–6.432	—	—
Ln Untreated Systolic BP (mm Hg)	1.957	4.79	9.37	27.820	4.79	133.19
Ln Age × Ln Untreated Systolic BP	N/A	N/A	N/A	–6.087	19.19	–116.79
Current Smoker (1=Yes, 0=No)	7.574	0	0	0.691	0	0

Diabetes (1=Yes, 0=No)	0.661	0	0	0.874	0	0
Individual Sum			–29.67			86.16
Mean (Coefficient × Value)	N/A	N/A	–29.18	N/A	N/A	86.61
Baseline Survival	N/A	N/A	0.9665	N/A	N/A	0.9533
Estimated 10-y Risk of Hard ASCVD	N/A	N/A	2.1%	N/A	N/A	3.0%
Men (Example: 55 years of age with total cholesterol 213 mg/dL, HDL-C 50 mg/dL, untreated systolic BP 120 mm Hg, nonsmoker, and without diabetes)						
Ln Age (y)	12.344	4.01	49.47	2.469	4.01	9.89
Ln Total Cholesterol (mg/dL)	11.853	5.36	63.55	0.302	5.36	1.62
Ln Age × Ln Total Cholesterol	–2.664	21.48	–57.24	N/A	N/A	N/A
Ln HDL-C (mg/dL)	–7.990	3.91	–31.26	–0.307	3.91	–1.20
Ln Age × Ln HDL-C	1.769	15.68	27.73	N/A	N/A	N/A
Ln Treated Systolic BP (mm Hg)	1.797	—	—	1.916	—	—
Ln Untreated Systolic BP (mm Hg)	1.764	4.79	8.45	1.809	4.79	8.66
Current Smoker (1=Yes, 0=No)	7.837	0	0	0.549	0	0
Ln Age × Current Smoker	–1.795	0	0	N/A	N/A	N/A
Diabetes (1=Yes, 0=No)	0.658	0	0	0.645	0	0
Individual Sum			60.69			18.97
Mean (Coefficient × Value)	N/A	N/A	61.18	N/A	N/A	19.54
Baseline Survival	N/A	N/A	0.9144	N/A	N/A	0.8954
Estimated 10-y Risk of Hard ASCVD	N/A	N/A	5.3%	N/A	N/A	6.1%

*Defined as first occurrence of nonfatal myocardial infarction or CHD death, or fatal or nonfatal stroke.

†Coefficient × Value: For age, lipids, and BP, defined as the natural log of the value multiplied by the parameter estimate. When an age interaction is present with lipids or BP, the natural log of age is multiplied by the natural log of the lipid or BP, and the result is multiplied by the parameter estimate. N/A indicates that that specific covariate was not included in the model for that sex–race group; — indicates that this value was not included in the example (eg, this example used untreated systolic BP, not treated systolic BP).

ASCVD indicates atherosclerotic cardiovascular disease; BP indicates blood pressure; CHD, coronary heart disease; HDL-C, high-density lipoprotein cholesterol; Ln, natural logarithm; and N/A, not included.

Table B. Estimating an Individual's 10-Year Risk of Incident Hard ASCVD

The hypothetical profile provided in Table 5 (the "Individual Example Value" column) is identical for each race and sex group and is based on the overall sample mean. The profile assumes an individual 55 years of age (for which the Ln[Age]=4.01), with a total cholesterol of 213 mg/dL, HDL-C of 50 mg/dL, and an untreated systolic BP of 120 mm Hg. This individual is not a current smoker and does not have diabetes. For the equations, the values for age, lipids, and systolic BP are Ln transformed. Interactions between age and lipids or age and systolic BP use the natural log of each variable (eg, Ln[Age]×Ln[Total Cholesterol]).

Calculation of the 10-year risk estimate for hard ASCVD can best be described as a series of steps. The natural log of age, total cholesterol, HDL-C, and systolic BP are first calculated with systolic BP being either a treated or untreated value. Any appropriate interaction terms are then calculated. These values are then multiplied by the coefficients from the equation ("Coefficient" column of Table A) for the specific race-sex group of the individual. The "Coefficient × Value" column in the table provides the results of the multiplication for the risk profile described above.

The sum of the "Coefficient × Value" column is then calculated for the individual. For the profile shown in Table A, this value is shown as "Individual Sum" for each race and sex group.

The estimated 10-year risk of a first hard ASCVD event is formally calculated as 1 minus the survival rate at 10 years ("Baseline Survival" in Table A), raised to the power of the exponent of the "Coefficient × Value" sum minus the race- and sex-specific overall mean "Coefficient × Value" sum; or, in equation form:

$1 - S_{10}^{(\text{IndX'B}-\textit{Mean}X'\text{B})}$

Using white men as an example:

$1 - 0.9144e^{(60.69-61.18)}$

equates to a 5.3% probability of a first hard ASCVD event within 10 years.

ASCVD indicates atherosclerotic cardiovascular disease; BP, blood pressure; HDL-C, high-density lipoprotein cholesterol; and Ln, natural logarithm.

Negative Pressure Wound Therapy

Question: where should negative pressure wound therapy be located on the Prioritized List?

Issue: Negative pressure wound therapy was an excluded service for many years. It was reviewed in 2005 and 2009 and kept on the Excluded List. The Health Resources Review Commission reviewed this technology in 2010 and recommended coverage. During the discussion in 2010, the deep open wound line was identified as possibly being the only appropriate code for this type of treatment. The final decision was to place the codes for this service on the Ancillary List with a guideline.

New codes have been released for 2015 regarding negative pressure wound therapy. HERC staff review of claims data for this service found many inappropriate diagnoses on claims, including conditions for which NPWT is contraindicated (osteomyelitis, cancers, etc.). HERC staff identified a limited number of lines which would be appropriate for these codes.

CPT/HCPCS codes for negative pressure wound therapy

Code	Code Description	Current Placement
97605	Negative pressure wound therapy (eg, vacuum assisted drainage collection), utilizing durable medical equipment (DME), including topical application(s), wound assessment, and instruction(s) for ongoing care, per session; total wound(s) surface area less than or equal to 50 square centimeters	Ancillary
97606	total wound(s) surface area greater than 50 square centimeters	Ancillary
97607	Negative pressure wound therapy, (eg, vacuum assisted drainage collection), utilizing disposable, non-durable medical equipment including provision of exudate management collection system, topical application(s), wound assessment, and instructions for ongoing care, per session; total wound(s) surface area less than or equal to 50 square centimeters	New code
97608	total wound(s) surface area greater than 50 square centimeters	New code
A6550	Wound care set, for negative pressure wound therapy electrical pump, includes all supplies and accessories	Ancillary
E2402	Negative pressure wound therapy electrical pump, stationary or portable	Ancillary
G0456	Negative pressure wound therapy, (e.g. vacuum assisted drainage collection) using a mechanically-powered device, not durable medical equipment, including provision of cartridge and dressing(s), topical application(s), wound assessment, and instructions for ongoing care, per session; total wounds(s) surface area less than or equal to 50 square centimeters	Ancillary
G0457	total wounds(s) surface area greater than 50 square centimeters	Ancillary

ANCILLARY GUIDELINE A1, NEGATIVE PRESSURE WOUND THERAPY

Negative pressure wound therapy (97605, 97606) is a covered benefit only for patients who:

- Have wounds that are refractory to or have failed standard therapies;
- Are not suitable candidates for surgical wound closure; or,
- Are at high risk for delayed or non-healing wounds due to factors such as compromised blood flow, diabetic complications, wounds with high risk of fecal contamination, extremely exudative wounds, and similar situations.

Appropriate Lines for Negative Pressure Wound Therapy

Line	**Examples of appropriate diagnoses on line**
8 TYPE 1 DIABETES MELLITUS	250.61 Diabetes with neurological manifestations, type I
30 TYPE 2 DIABETES MELLITUS	250.60 Diabetes with neurological manifestations, type II (includes diabetic ulcers)
51 DEEP ABSCESSES, INCLUDING APPENDICITIS AND PERIORBITAL ABSCESS	675.13 Abscess of breast
84 INJURY TO INTERNAL ORGANS	868.10 Injury to other intra-abdominal organs with open wound into cavity, unspecified intra-abdominal organ
209 SUPERFICIAL ABSCESSES AND CELLULITIS	682.5 Cellulitis and abscess of buttock
211 DEEP OPEN WOUND, WITH OR WITHOUT TENDON OR NERVE INVOLVEMENT	879.3 Open wound of abdominal wall, anterior, complicated
239 LIMB THREATENING VASCULAR DISEASE, INFECTIONS, AND VASCULAR COMPLICATIONS	728.86 Necrotizing fasciitis
290 COMPLICATIONS OF A PROCEDURE ALWAYS REQUIRING TREATMENT	998.32 Disruption of external operation (surgical) wound
383 CHRONIC ULCER OF SKIN	707.05 Pressure ulcer, buttock
427 COMPLICATIONS OF A PROCEDURE USUALLY REQUIRING TREATMENT	998.83 Non-healing surgical wound

HERC staff recommendations:

1) Place all negative pressure wound therapy CPT codes (CPT 97605-97608) and appropriate HCPCS codes (HCPCS G0456 and G0457) on the limited number of lines from the table above
    a. Lines 8,30,51,84,209,211,239, 290, 383, 427
    b. Advise DMAP to remove CPT 97605 and 97606 and HCPCS G0456 and G0457 from the Ancillary List
2) Change the current Ancillary Guideline into a guideline note as shown below

~~**ANCILLARY GUIDELINE A1**~~ **GUIDELINE NOTE XXX, NEGATIVE PRESSURE WOUND THERAPY**

Lines 8,30,51,84,209,211,239,290,383,427

Negative pressure wound therapy (CPT 97605-97608, HCPCS G0456, G0457 ~~97605, 97606~~) is a covered benefit only for patients who:

- Have wounds that are refractory to or have failed standard therapies;
- Are not suitable candidates for surgical wound closure; or,
- Are at high risk for delayed or non-healing wounds due to factors such as compromised blood flow, diabetic complications, wounds with high risk of fecal contamination, extremely exudative wounds, and similar situations.

Arthrocentesis

Issue: the current arthrocentesis codes are one some inappropriate lines. There are new arthrocentesis codes in the 2015 CPT code set. These codes should be on consistent lines with the current codes. The current codes are on some lines with no joint diagnoses or on lines with inappropriate diagnoses (i.e. shoulder diagnosis for a small joint procedure). Some of the existing codes are missing from one or more lines with joint diagnoses.

HERC staff recommendation:

1) Placement of codes as shown in the table below (red=suggested for deletion, blue=suggested for addition)

CPT code	Code description	Current Placement	Recommended Placement
20600	Arthrocentesis, aspiration and/or injection, small joint or bursa (eg, fingers, toes); without ultrasound guidance	**50** RHEUMATOID ARTHRITIS AND OTHER INFLAMMATORY POLYARTHROPATHIES **51** DEEP ABSCESSES, INCLUDING APPENDICITIS AND PERIORBITAL ABSCESS **157** PYOGENIC ARTHRITIS **290** COMPLICATIONS OF A PROCEDURE ALWAYS REQUIRING TREATMENT **306** GOUT **422** DISORDERS OF SHOULDER, INCLUDING SPRAINS/STRAINS GRADE 3 THROUGH 6 **430** ACUTE PERIPHERAL MOTOR AND DIGITAL NERVE INJURY **468** OSTEOARTHRITIS AND ALLIED DISORDERS **509** OTHER DISORDERS OF SYNOVIUM, TENDON AND BURSA, COSTOCHONDRITIS, AND CHONDRODYSTROPHY **511** PERIPHERAL ENTHESOPATHIES **597** SYNOVITIS AND TENOSYNOVITIS **601** GANGLION **612** DISORDERS OF SOFT TISSUE	**50** RHEUMATOID ARTHRITIS AND OTHER INFLAMMATORY POLYARTHROPATHIES **157** PYOGENIC ARTHRITIS 290 COMPLICATIONS OF A PROCEDURE ALWAYS REQUIRING TREATMENT **290** COMPLICATIONS OF A PROCEDURE ALWAYS REQUIRING TREATMENT **306** GOUT **468** OSTEOARTHRITIS AND ALLIED DISORDERS **511** PERIPHERAL ENTHESOPATHIES **533** BENIGN NEOPLASM OF BONE AND ARTICULAR CARTILAGE INCLUDING OSTEOID OSTEOMAS; BENIGN NEOPLASM OF CONNECTIVE AND OTHER SOFT TISSUE **597** SYNOVITIS AND TENOSYNOVITIS

CPT code	Code description	Current Placement	Recommended Placement
20604	with ultrasound guidance	New code	**50, 157, 290, 306, 468, 511, 533, 597**
20605	Arthrocentesis, aspiration and/or injection, intermediate joint or bursa (eg, temporomandibular, acromioclavicular, wrist, elbow or ankle, olecranon bursa); without ultrasound guidance	**50** RHEUMATOID ARTHRITIS AND OTHER INFLAMMATORY POLYARTHROPATHIES **51** DEEP ABSCESSES, INCLUDING APPENDICITIS AND PERIORBITAL ABSCESS **157** PYOGENIC ARTHRITIS **290** COMPLICATIONS OF A PROCEDURE ALWAYS REQUIRING TREATMENT **306** GOUT **422** DISORDERS OF SHOULDER, INCLUDING SPRAINS/STRAINS GRADE 3 THROUGH 6 **430** ACUTE PERIPHERAL MOTOR AND DIGITAL NERVE INJURY **468** OSTEOARTHRITIS AND ALLIED DISORDERS **511** PERIPHERAL ENTHESOPATHIES **544** LESION OF PLANTAR NERVE; PLANTAR FASCIAL FIBROMATOSIS **597** SYNOVITIS AND TENOSYNOVITIS **601** GANGLION **612** DISORDERS OF SOFT TISSUE	**50** RHEUMATOID ARTHRITIS AND OTHER INFLAMMATORY POLYARTHROPATHIES **157** PYOGENIC ARTHRITIS **290** COMPLICATIONS OF A PROCEDURE ALWAYS REQUIRING TREATMENT **306** GOUT **468** OSTEOARTHRITIS AND ALLIED DISORDERS **511** PERIPHERAL ENTHESOPATHIES **533** BENIGN NEOPLASM OF BONE AND ARTICULAR CARTILAGE INCLUDING OSTEOID OSTEOMAS; BENIGN NEOPLASM OF CONNECTIVE AND OTHER SOFT TISSUE **597** SYNOVITIS AND TENOSYNOVITIS
20606	with ultrasound guidance	New code	**50, 157, 290, 306, 468, 511, 533, 597**

CPT code	Code description	Current Placement	Recommended Placement
20610	Arthrocentesis, aspiration and/or injection, major joint or bursa (eg, shoulder, hip, knee, subacromial bursa); without ultrasound guidance	**50** RHEUMATOID ARTHRITIS AND OTHER INFLAMMATORY POLYARTHROPATHIES **51** DEEP ABSCESSES, INCLUDING APPENDICITIS AND PERIORBITAL ABSCESS **145** SYSTEMIC LUPUS ERYTHEMATOSUS, OTHER DIFFUSE DISEASES OF CONNECTIVE TISSUE **157** PYOGENIC ARTHRITIS **290** COMPLICATIONS OF A PROCEDURE ALWAYS REQUIRING TREATMENT **306** GOUT **359** RHEUMATOID ARTHRITIS, OSTEOARTHRITIS, OSTEOCHONDRITIS DISSECANS, AND ASEPTIC NECROSIS OF BONE Treatment: ARTHROPLASTY/RECONSTRUCTION **422** DISORDERS OF SHOULDER, INCLUDING SPRAINS/STRAINS GRADE 3 THROUGH 6 **430** ACUTE PERIPHERAL MOTOR AND DIGITAL NERVE INJURY **435** INTERNAL DERANGEMENT OF KNEE AND LIGAMENTOUS DISRUPTIONS OF THE KNEE, RESULTING IN SIGNIFICANT INJURY/IMPAIRMENT **468** OSTEOARTHRITIS AND ALLIED DISORDERS **509** OTHER DISORDERS OF SYNOVIUM, TENDON AND BURSA, COSTOCHONDRITIS, AND CHONDRODYSTROPHY **511** PERIPHERAL ENTHESOPATHIES **533** BENIGN NEOPLASM OF BONE AND ARTICULAR CARTILAGE INCLUDING OSTEOID OSTEOMAS; BENIGN NEOPLASM OF CONNECTIVE AND OTHER SOFT TISSUE **597** SYNOVITIS AND TENOSYNOVITIS **601** GANGLION **612** DISORDERS OF SOFT TISSUE	**50** RHEUMATOID ARTHRITIS AND OTHER INFLAMMATORY POLYARTHROPATHIES **157** PYOGENIC ARTHRITIS **290** COMPLICATIONS OF A PROCEDURE ALWAYS REQUIRING TREATMENT **306** GOUT **422** DISORDERS OF SHOULDER, INCLUDING SPRAINS/STRAINS GRADE 3 THROUGH 6 **435** INTERNAL DERANGEMENT OF KNEE AND LIGAMENTOUS DISRUPTIONS OF THE KNEE, RESULTING IN SIGNIFICANT INJURY/IMPAIRMENT **468** OSTEOARTHRITIS AND ALLIED DISORDERS **511** PERIPHERAL ENTHESOPATHIES **533** BENIGN NEOPLASM OF BONE AND ARTICULAR CARTILAGE INCLUDING OSTEOID OSTEOMAS; BENIGN NEOPLASM OF CONNECTIVE AND OTHER SOFT TISSUE **597** SYNOVITIS AND TENOSYNOVITIS

CPT code	Code description	Current Placement	Recommended Placement
20611	with ultrasound guidance	New code	**50, 157, 290, 306, 422, 435, 468, 511, 533, 597**

2015 CPT Code Review Issues

Cryoablation of bone tumors (CPT 20982)

1) Minimally invasive treatment for metastatic cancer to bone; also used for primary osteosarcoma treatment
2) Similar minimally invasive treatment--radiofrequency ablation of bone tumors (CPT 20982) is Excluded. Last reviewed 2004, found to be experimental
3) Evidence
    i. **Callstrom 2013**
        1. Prospective multi-center trial of 61 patients with 1 or 2 painful bone metastases, treated with percutaneous cryoablation.
        2. Significant reduction in pain scores seen at 4, 8 and 24 weeks
        3. 1 patient developed osteomyelitis at the site as a complication
        4. CONCLUSIONS: Percutaneous cryoablation is a safe, effective, and durable method for palliation of pain due to metastatic disease involving bone.
    ii. **McMenomy 2013** (only abstract available)
        1. Retrospective study of 40 patients who underwent cryoablation of 5 or fewer musculoskeletal metastases with the goal of complete disease remission
        2. RESULTS: Local control was achieved in 45 of 52 tumors (87%; 95% confidence interval [CI], 75%-93%) at a median follow-up of 21 months (range, 4-62 mo). Median overall survival was 47 months (95% CI, 26-62 mo). Median disease-free survival was 7 months (95% CI, 5-10 mo).
4) No guidance or studies found from Cochrane, NICE, SIGN. No reviews or meta-analyses found
5) HERC staff recommendation: **Non-covered List**
    i. Experimental
    ii. Standard treatment with external beam radiation is available to patients

Cryoablation of liver tumors (CPT 47383)

1) Cryoablation of liver tumors is a minimally invasive treatment of either primary hepatocellular carcinoma or metastatic disease to the liver
2) Radiofrequency ablation of liver tumors (CPT 47382) is covered on the liver cancer line
3) Evidence
    a. **NICE 2010,** guidance for treatment of liver metastases
        i. Current evidence on the safety of cryotherapy for the treatment of liver metastases appears adequate in the context of treating patients whose condition has such a poor prognosis, but the evidence on efficacy is inadequate in quality. Therefore cryotherapy for the treatment of liver metastases should only be used with special arrangements for clinical governance, consent and audit or research.
    b. **Bala 2013**, Cochrane review of cryotherapy for liver metastases
        i. 1 RCT, with high risk of bias
            1. 123 patients, randomized to cryotherapy or conventional surgery
            2. The patients were followed for up to 10 years (minimum five months). Mortality at the last follow-up was 81% (51/63) in the cryotherapy group and 92% (55/60) in the conventional surgery group (RR 0.88; 95% CI 0.77 to 1.02); that is, no statistically significant difference was observed.
            3. Recurrence in the liver was observed in 86% (54/63) of the patients in the cryotherapy group and 95% (57/60) of the patients in the conventional surgery group (relative risk (RR) 0.9; 95% CI 0.8 to 1.01); that is, no statistically significant difference was observed.
        ii. **Authors' conclusions** On the basis of one randomised clinical trial with high risk of bias, there is insufficient evidence to conclude if in patients with liver metastases from various primary sites cryotherapy brings any significant benefit in terms of survival or recurrence compared with conventional surgery. In addition, there is no evidence for the effectiveness of cryotherapy when compared with no intervention. At present, cryotherapy cannot be recommended outside randomised clinical trials.
    c. **Awad 2009**, Cochrane review of cryotherapy for hepatocellular carcinoma
        i. No trials identified
        ii. **Authors' conclusions** At present, there is no evidence to recommend or refute cryotherapy for patients with hepatocellular carcinoma. Randomised clinical trials with low-risk of bias may help in defining the role of cryotherapy in the treatment of hepatocellular carcinoma.
4) HERC staff recommendation: **Non-covered List**
    a. Experimental for both hepatocellular carcinoma and metastatic disease

Transversus abdominis plane (TAP) block (CPT 64486-64489)

1) Definition: Transversus abdominis plane (TAP) block is a regional anesthetic technique used to block sensation to the anterior abdominal wall. This can be used for pain control after surgical procedures such as cesarean section, colorectal surgery, hysterectomy, and other abdominal surgeries.
2) Evidence
    a. **De Oliveira 2014**, meta-analysis of TAP for pain control after laparoscopic surgery
        i. N=10 studies (633 patients)
        ii. The weighted mean difference (99% confidence interval) of the combined effects favored TAP block over control for pain at rest (≤4 hours, −2.41 [−3.6 to −1.16]) and (at 24 hours, −1.33 [−2.19 to −0.48]) (0–10 numerical scale).
        iii. Postoperative opioid consumption was decreased in the TAP block group compared with control, weighted mean difference (99% confidence interval) of −5.74 (−8.48 to −2.99) mg morphine IV equivalents.
        iv. CONCLUSIONS: TAP block is an effective strategy to improve early and late pain at rest and to reduce opioid consumption after laparoscopic surgical procedures.
    b. **Champaneria 2013**, meta-analysis of TAP for pain control after hysterectomy
        i. N=5 studies (225 patients)
        ii. Study quality was moderate.
        iii. Compared with no block or saline placebo, transversus abdominis plane block provided significantly less postoperative pain at rest on a 10 cm visual analog scale at 2 h (mean difference -2.14 cm, 95% confidence interval (CI) –3.57 to -0.71) but not at 24 h postoperatively (–0.52 cm, 95% CI –1.49 to 0.45). Pain on movement showed similar results. Transversus abdominis plane block resulted in significantly less postoperative requirement for morphine use at 24 h (-11.76 mg, 95% CI -18.77 to -4.75) but not at 48 h (-16.01 mg, 95% CI -39.40 to 7.39).
        iv. Conclusions: until further robust evidence is available, anesthetists should not rush to adopt this procedure into routine practice.
    c. **Abdallah 2012**, meta-analysis of TAP for pain control after cesarean section
        i. N=5 trials (312 patients)
        ii. TAP block reduced the mean 24 h i.v. morphine consumption by 24 mg [95% confidence interval (CI) 239.65 to 27.78] when spinal morphine was not used. TAP block also reduced visual analogue scale pain scores (10 cm line where 0 cm, no pain, and 10 cm, worst pain) by 0.8 cm (95% CI 21.53 to 20.05, P¼0.01), and decreased the incidence of opioid-related side effects.
        iii. Conclusions: TAP block provides superior analgesia compared with placebo and can reduce the first 24 h morphine consumption in the setting of a multimodal analgesic regimen that excludes spinal morphine. TAP block can provide effective analgesia when spinal morphine is contraindicated or not used.
    d. HERC staff recommendation:

i. **Ancillary Codes File**
    1. Most anesthesia procedures are on the Ancillary List
    2. Appears to be an effective adjuvant pain control strategy for abdominal surgery post-operative pain

Digital breast tomosynthesis (CPT 77061-77063)

1) Definition: a new technology which acquires 3D images of the breast to assist in breast cancer screening and diagnosis. Generally, tomosynthesis is done together with traditional digital mammography.
2) Other guidelines/guidances
    a. **NCCN 2014**, breast cancer screening guideline
        i. Early studies show promise for tomosynthesis mammography. Two large trials showing a combined use of digital mammography and tomosynthesis resulted in improved cancer detection and decreased call back rates; of note, this is double the dose of radiation and is a factor in recommending this modality. Definitive studies are still pending.
        ii. Tomosynthesis is not included in their flow charts for routine breast cancer screening
3) Evidence
    a. **TEC 2014**, technology report
        i. N=6 studies
        ii. Insufficient evidence to permit conclusions on whether digital breast tomosynthesis improves detection of breast cancer or improves any health outcomes compared to conventional mammography
    b. **Houssami 2013**, systematic review
        i. N=13 studies
        ii. Authors conclusions: At present, there is insufficient evidence to justify a change from standard digital mammography to digital breast tomosynthesis however the available data strongly support investment in new large-scale population screening trials.
    c. **Rafferty 2013**, trial of tomosynthesis + digital mammography vs digital mammography alone
        i. N=1192 patients
            1. Included women scheduled for breast biopsy (i.e. not a screening population) as well as women who presented for screening
        ii. Diagnostic accuracy of tomosynthesis plus digital mammography was superior to digital mammography alone.
        iii. Recall rates for noncancerous cases for all readers decreased with the addition of tomosynthesis (range, 6%–67%; P = 0.001 for 25 readers, P = 0.03 for all readers).
        iv. The increase in the rate of sensitivity was greatest for invasive cancers: 15% and 22% in studies 1 and 2 versus 3% for in situ cancers in both studies.
        v. The authors concluded that the addition of tomosynthesis to digital mammography provides the dual benefit of significantly increased diagnostic accuracy and significantly reduced recall rates for noncancerous cases.

vi. Several authors had significant conflicts of interest; one was an employee of the company that manufactures the tomosynthesis machines and the study was funded by the manufacturer

d. **Skaane 2013**, trial of tomosynthesis tomosynthesis + digital mammography vs digital mammography alone
   i. N=12,631 patients
   ii. Detection rates, including those for invasive and in situ cancers, were 6.1 per 1000 examinations for mammography alone and 8.0 per 1000 examinations for mammography plus tomosynthesis (27% increase, adjusted for reader; *P* =.001). False-positive rates before arbitration were 61.1 per 1000 examinations with mammography alone and 53.1 per 1000 examinations with mammography plus tomosynthesis (15% decrease, adjusted for reader; *P* , .001). After arbitration, positive predictive values for recalled patients with cancers verified later were comparable (29.1% and 28.5%, respectively, with mammography alone and mammography plus tomosynthesis; *P* = .72). Twenty-five additional invasive cancers were detected with mammography plus tomosynthesis (40% increase, adjusted for reader; *P*, .001). The mean interpretation time was 45 seconds for mammography alone and 91 seconds for mammography plus tomosynthesis (*P* , .001).
   iii. Conclusion: The use of mammography plus tomosynthesis in a screening environment resulted in a significantly higher cancer detection rate and enabled the detection of more invasive cancers.
   iv. Study funded by the manufacturer and several authors had significant conflicts of interest; 2 were employees of the manufacturer

4) Other coverage policies:
   a. **BCBS 2014**: does not cover, investigational
   b. **Aetna 2014**: does not cover, investigational
5) HERC staff recommendation: **Non-covered List**
   a. Experimental, unclear what added value is for general population screening, has risk of increased radiation exposure
   b. Re-evaluate coverage when the results of a large NHS trial currently underway in the UK (TOMMY trial) and/or other large scale, definitive studies are released in a few years

Laboratory Tests

FTL3 (CPT 81246)

1) Definition: FTL3 internal tandem duplications occur in some acute myeloid leukemia cell lines
2) Evidence
    a. **Etsy 2013**, review of treatment updates for Acute Myeloid Leukemia
        i. patients with a FLT3 ITD have only a 30–40% chance of cure even after stem cell transplant. Accordingly analyses of NPM1, FLT3, and CEBPA should be part of routine evaluation
        ii. Suggests adaptations to chemotherapy regimens determined in part by FLT3 status
    b. **Port 2014**, meta-analysis of FLT3 for prognosis
        i. Meta-analysis for overall survival (OS) and relapse-free survival (RFS) showed FLT3-ITD to predict an unfavorable prognosis, with hazard ratios (HR) of 1.86 and 1.75, respectively.
3) HERC staff recommendation: Lines with acute myeloid leukemia diagnoses
        i. 97 CHILDHOOD LEUKEMIAS
        ii. 401 ACUTE PROMYELOCYTIC LEUKEMIA
        iii. 402 ACUTE MYELOID LEUKEMIA Treatment: BONE MARROW TRANSPLANT
        iv. 241 MYELOID DISORDERS
        v. Appears to affect prognosis and possibly treatment decisions, does not appear to be used in diagnosis of AML

PCA3/KLK3 ratio (CPT 81313)

1) Definition: PCA3 is a urine test which can be used for screening for prostate cancer; it can be used to determine which patient requires prostate biopsy. KLK3 is another term used for PSA (prostate specific antigen), the standard screening test for prostate cancer.
2) Evidence
    a. **Bradley 2013,** review of PCA3
        i. N=34 observations studies
        ii. PCA3 was more discriminatory than total prostate specific antigen increases (eg at an observed 50% specificity, summary sensitivities were 77% and 57%, respectively). Analyses indicated that this finding holds for initial and repeat biopsies, and that the markers were independent predictors. For all other biopsy decision making comparisons and associated health outcomes, strength of evidence was insufficient. For treatment decision making, strength of evidence was insufficient for all outcomes and comparators.
        iii. Conclusions: PCA3 had a higher diagnostic accuracy than total prostate specific antigen increases, but strength of evidence was low (limited confidence in effect estimates). Strength of evidence was insufficient to conclude that PCA3 testing leads to improved health outcomes. For all other outcomes and comparators, strength of evidence was insufficient.

a. **Choudhury 2013**, review genetic markers in prostate cancer
    iv. A PCA3 score >35 in the urine has correlated with an average sensitivity and specificity of 66% and 76%, respectively, for the diagnosis of PCa (compared to a specificity of 47% for serum PSA at the cutoff for 65% sensitivity). Elevated PCA3 scores have also been demonstrated to increase the probability of a positive repeat biopsy in men with one or two prior negative biopsy results.
    v. Conclusions: Large clinical trials involving multi-institutional collaborations will be required to prospectively validate the utility of these markers for clinical decision making.
b. **Auprich 2011**, review of role of PCA3
    i. Despite its costs, prostate cancer antigen 3 (PCA3) is superior to prostate-specific antigen (PSA) and percent free PSA in the early detection of PCa. PCA3 improves the diagnostic accuracy of externally validated nomograms among men with an elevated PSA undergoing biopsy. PCA3 independently predicts low-volume disease and pathologically insignificant PCa but is not associated with locally advanced disease and is limited in the prediction of aggressive cancer. Preliminary data demonstrate that combining PCA3 with other new biomarkers further improves diagnostic and prognostic accuracy.
    ii. Conclusions: PCA3, integrated in novel biopsy nomograms or risk stratification tools, can be used to counsel or confirm biopsy indications. If confirmed in further studies, using PCA3 together with established staging risk factors could assist clinicians in specific pretreatment decision making. So far no evidence for the usefulness of PCA3 in active surveillance programs has been presented.

3) Other policies
    a. **Aetna 2014**: Experimental
4) HERC staff recommendation: **Non-covered List**
        i. Experimental

Breast mRNA gene expression (CPT 81519)

1) Definition: Breast mRNA gene expression is marketed as Oncotype Dx Breast.
2) Evidence
    a. **AHRQ 2014**, review of oncology genetics tests
        i. Oncotype Dx breast found to have multiple studies associating the test result and prognosis
        ii. Oncotype Dx breast found to have ~30% of treatment decisions changed by the test (moderate evidence)
        iii. Conclusion: Oncotype DX assay in breast cancer [has] a sizeable body of evidence to suggest an effect on treatment decisions (resulting in fewer recommendations for chemotherapy), though not yet a clear effect on downstream outcomes.
    b. **NICE 2013**, review of gene expression profiling in oncology
        i. Oncotype DX is recommended as an option for guiding adjuvant chemotherapy decisions for people with oestrogen receptor positive (ER+), lymph node negative (LN−) and human epidermal growth factor receptor 2 negative (HER2−) early breast cancer if:
            1. the person is assessed as being at intermediate risk **and**
            2. information on the biological features of the cancer provided by Oncotype DX is likely to help in predicting the course of the disease and would therefore help when making the decision about prescribing chemotherapy **and**
            3. the manufacturer provides Oncotype DX to NHS organisations according to the confidential arrangement agreed with NICE.
3) Other policies
    a. Aetna 2014: Oncotype Dx to assess necessity of adjuvant chemotherapy in females or males with recently diagnosed breast tumors, where all of the following criteria are met:
        i. Breast cancer is nonmetastatic (node negative); *and*
        ii. Breast tumor is estrogen receptor positive; *and*
        iii. Breast tumor is HER2 receptor negative or breast tumor is HER2 receptor positive and less than 1 cm in diameter. (Rationale: adjuvant chemotherapy with trastuzumab (Herceptin) is considered to be medically necessary regardless of an Oncotype Dx score for HER2 receptor positive lesions 1 cm or more in diameter); *and*
        iv. Adjuvant chemotherapy is not precluded due to any other factor (e.g., advanced age and/or significant co-morbidities); *and*
        v. Member and physician (prior to testing) have discussed the potential results of the test and agree to use the results to guide therapy (i.e., member will forgo adjuvant chemotherapy if Oncotype Dx score is low).
4) HERC staff recommendation: line 195 CANCER OF BREAST; AT HIGH RISK OF BREAST CANCER
    a. Note: this is scheduled for review and possible coverage guidance with HTAS at their November 24th meeting. If the HTAS coverage recommendation is different than the HERC staff recommendation above, this topic will need to be re-addressed (for example, addition of a guideline for coverage specifics).

ST2 (CPT 83006)

1) Definition: Growth stimulation expressed gene 2 (ST2, Interleukin 1 receptor like-1) is a novel biomarker for heart failure (CHF)
2) Evidence
    a. **Gaggin 2013**, review of novel biomarkers for CHF
        i. Novel biomarkers, such as mid-regional pro atrial natriuretic peptide (MR-proANP),mid-regional pro adrenomedullin (MR-proADM), highly sensitive troponins, soluble ST2 (sST2), growth differentiation factor (GDF)-15 and Galectin-3, show potential in determining prognosis beyond the established natriuretic peptides, but their role in the clinical care of the patient is still partially defined and more studies are needed.
    b. **Ciccone 2013**, review of ST2 as a biomarker
        i. Conclusions: sST2 measurements in blood samples could be a clinical prognostic biomarker useful in risk stratification of patients suffering from myocardial infarction, HF and dyspnea. Further studies are needed in order to better point out the evidence for a routine use of sST2 evaluation in the clinical evaluation of a patient suffering from myocardial infarction and HF.
3) HERC staff recommendation: **Non-covered List**
    a. Experimental

Liver elastography (CPT 91200)

1) Definition: a non-invasive test to assess liver stiffness measurement (LSM) for the diagnosis of liver fibrosis. Promoted as a way to avoid liver biopsy in some patients; also may be more accurate than biopsy which can have sampling error. A device to conduct this test (Fibroscan) was FDA approved in 2012.
2) Guidances
    a. **NICE 2013**, guidance on the diagnosis and management of hepatitis C
        i. Offer transient elastography as the initial test for liver disease in adults newly referred for assessment.
        ii. Offer antiviral treatment without a liver biopsy to adults with a transient elastography score greater than or equal to 11 kPa
        iii. Consider liver biopsy to confirm the level of fibrosis in adults with a transient elastography score between 6 and 10 kPa
        iv. Offer liver biopsy to adults with a transient elastography score less than 6 kPa if they are younger than 30 years and have HBV DNA greater than 2000 IU/ml and abnormal ALT (greater than or equal to 30 IU/L for males and greater than or equal to 19 IU/L for females) on 2 consecutive tests conducted 3 months apart
        v. Do not offer liver biopsy to adults with a transient elastography score less than 6 kPa who have normal ALT (less than 30 IU/L in males and less than 19 IU/L in females) and HBV DNA less than 2000 IU/ml as they are unlikely to have advanced liver disease or need antiviral treatment
        vi. Offer an annual reassessment of liver disease using transient elastography to adults who are not taking antiviral treatment.
    b. SIGN 2013, guidance for diagnosis and management of hepatitis C
        i. Measurement of liver stiffness may be useful as a non-invasive assessment of liver fibrosis.
    c. **AASLD 2014**, management of hepatitis C
        i. Liver elastography can only reliably distinguish cirrhosis from non-cirrhosis.
        ii. Vibration-controlled transient liver elastography is a noninvasive way to measure liver stiffness and correlates well with measurement of substantial fibrosis or cirrhosis in patients with chronic HCV infection. A cutoff value of 8.7 kPa correlates with Metavir F2 or higher fibrosis stage; greater than 9.5 kPa with F3; and 14.5 or higher kPa with F4 or cirrhosis. The measurement range does overlap between stages. The most efficient approach to fibrosis assessment is to combine direct biomarkers and vibration-controlled transient liver elastography. A biopsy should be considered for any patient who has discordant results between the 2 modalities that would affect clinical decision making.
3) Evidence
    a. Cochrane has a protocol for evaluation of liver elastography
    b. **NHS 2008**, technology assessment of liver elastography
        i. FibroScan can be used as an initial screening tool to reduce the number of patients requiring liver biopsy and also to measure ongoing response to treatment. In some patients the initial screening results may be sufficiently

well-defined to provide a confident assessment of the patient's stage of liver fibrosis.

c. **Canadian Agency for Drugs and Technology in Health (CADTH) 2008**, technology assessment of liver elastography
    i. The diagnostic performance of FibroScan is good for identifying severe fibrosis or cirrhosis, but it is less accurate for milder presentations.
    ii. FibroScan is a promising technology, but large multi-centre trials comparing a range of emerging non-invasive fibrosis staging technologies are required.
d. **Tshochatzis 2013**, meta-analysis of liver elastrography accuracy
    i. N=40 studies
    ii. Summary sensitivity and specificity was 0.79 (95% CI 0.74–0.82) and 0.78 (95% CI 0.72–0.83) for F2 stage and 0.83 (95% CI 0.79–0.86) and 0.89 (95% CI 0.87–0.91) for cirrhosis. After an elastography result at/over the threshold value for F2 or cirrhosis (''positive'' result), the corresponding post-test probability for their presence (if pre-test probability was 50%) was 78%, and 88% respectively, while, if values were below these thresholds (''negative'' result), the post-test probability was 21% and 16%, respectively.
    iii. Conclusions: Elastography theoretically has good sensitivity and specificity for cirrhosis (and less for lesser degrees of fibrosis); however, it should be cautiously applied to everyday clinical practice because there is no validation of the stiffness cut-offs for the various stages. Such validation is required before elastography is considered sufficiently accurate for non-invasive staging of fibrosis.
e. **Stebbing 2012**, Meta-analysis of Transient Elastography for the Detection of Hepatic Fibrosis
    i. N=22 studies (4430 patients)
    ii. The pooled estimates for significant fibrosis (ZF2) measured 7.71 kPa (LSM cutoff value) with a sensitivity of 71.9% [95% confidence interval (CI): 71.4%-72.4%] and specificity of 82.4% (95% CI: 81.9-82.9%), whereas for cirrhosis (F4) the results showed a cutoff of 15.08 kPa with a sensitivity of 84.45% (95% CI: 84.2-84.7%) and specificity of 94.69% (95% CI: 94.3%-95%).
    iii. Conclusions: Further evaluation of transient elastography to assess LSM is required in prospective studies to potentially increase the sensitivity and establish its clinical utility.
f. **Singh 2013**, meta-analysis to determine predictive value of liver elastography
    i. N=17 studies (7058 patients) with chronic liver disease
    ii. Baseline LSM was associated significantly with risk of hepatic decompensation (6 studies; RR, 1.07; 95% CI, 1.03–1.11), HCC (9 studies; RR, 1.11; 95% CI, 1.05–1.18), death (5 studies; RR, 1.22; 95% CI, 1.05–1.43), or a composite of these outcomes (7 studies; RR, 1.32; 95% CI, 1.16–1.51).
    iii. CONCLUSIONS: Based on a meta-analysis of cohort studies, the degree of liver stiffness is associated with risk of decompensated cirrhosis, HCC,

and death in patients with CLDs. LSM therefore might be used in risk stratification

4) Other policies
    a. Aetna 2014
        i. Aetna considers transient elastography (e.g., FibroScan) medically necessary for distinguishing hepatic cirrhosis from noncirrhosis in persons with hepatitis C or other chronic liver diseases. Performance of transient elastography more than twice per year is considered not medically necessary. Performance of transient elastography within six months following a liver biopsy is considered not medically necessary. Transient elastography is considered experimental and investigational for all other indications.
5) Expert input:
    a. Dr. Atif Zaman, hepatologist at OHSU
        i. "The cost and complications of liver biopsy in HCV patients will be avoided. It (Fibroscan) has excellent performance for stage 3 and 4…it can be a part of practice and reduce liver biopsy use by at least 65%. Of note, liver biopsies cost $3-5K, which FibroScan is only at $300-500."
6) Summary: Significant controversy exists in the literature and in various guidelines regarding liver elastography. It has the potential to affect management of hepatitis B and C, and to have a significant number of patients avoid liver biopsy, which would reduce complications and costs. However, most meta-analyses conclude that further work needs to be done to increase its sensitivity and determine its clinical utility.
7) HERC staff recommendation: **Non-covered List**
    a. Unclear clinical utility. Gold standard test of liver biopsy is available.
    b. MED report is expected in the next few months. Will readdress once the MED report is available. Additionally, a Cochrane review is expected in the near future.

Corneal hysteresis determination (CPT 92145)

1) Definition: Measuring intraocular pressure (IOP) is important for the diagnosis and monitoring of glaucoma. IOP measurements can be affected by corneal thickness and other characteristics of the cornea. Corneal hysteresis (CH) was developed to measure the viscous damping in the corneal tissue in order to provide a correction to IOP measurements. Corneal hysteresis assesses corneal resistance to deformation in the cornea. The Ocular Response Analyzer (ORA, Reichert Ophthalmic Instruments, Depew, NY) is a new instrument that measures corneal hysteresis, the corneal biomechanical response to rapid indentation by an air jet.
2) Evidence:
    a. **McMonnies 2012**, review of corneal hysteresis (CH)
        i. Corneal thickness, the level of edema, intraocular pressure, and corneal temperature as well as the area, location, rate, duration, and sequence of corneal unloading and loading may need to be considered as significant variables when assessing CH.
        ii. CH values may be specific to measurement method and conditions rather than representing an unequivocal corneal property.
        iii. The potential for the ORA to contribute to improved clinical management appears to be considerable but so does the need for better understanding and further development of its functions and applications.
    b. **Touboul 2008**, study of correlation between corneal hysteresis (CH) and intraocular pressure (IOP)
        i. N=498 eyes of 258 patients
        ii. Corneal hysteresis was not strongly correlated with IOP
        iii. CONCLUSIONS: Corneal hysteresis, a new corneal parameter, had a moderate dependence on IOP
    c. **Kotecha 2007**, review of the clinical relevance of corneal measurement
        i. Further population and longitudinal studies are needed to clarify whether current in vivo measures of corneal biomechanical properties, including corneal hysteresis, prove to be independent predictors of glaucoma susceptibility.
3) Other policies
    a. **Aetna 2014**: Aetna considers measurement of corneal hysteresis experimental and investigational for the screening, diagnosis and monitoring of glaucoma and for all other indications because of insufficient evidence of its effectiveness
4) HERC staff recommendation: **Non-covered List**
    a. Experimental

Bioimpedance spectroscopy for lymphedema assessment (CPT 93702)

1) Definition: Bioimpedance has been proposed as a method of diagnosing Stage 0 lymphedema, which is difficult to detect with current diagnostic methods. Bioelectrical impedance analysis measures the body's response to an electrical current. A low level current is applied through the body and the impedance (or resistance) to flow is measured. Current flows along the path of least resistance through the body and thus follows tissues with the highest water content, thereby allowing for edema to be measured. The L-Dex U400 BIS (Impedimed LTD) has been cleared by the FDA specifically for lymphedema use.
2) Alternatives: other methods of diagnosing lymphedema include arm circumference measurements, water displacement (volumetry), perometry (infrared optoelectric volumetry), tonometry, and the Lymphedema and Breast Cancer Questionnaire (LBCQ).
3) Evidence
    a. **AHRQ 2011**, technology assessment of diagnostic tests for lymphedema
        i. There is too little evidence to draw conclusions about the reliability of tests such as…bioimpedence.
        ii. No evidence was found that tests such as bioimpedence affected treatment decisions or patient outcomes
        iii. The heterogeneity of the available evidence was too substantial to enable one to draw conclusions about the type of diagnostic test that would be most appropriate for diagnosing secondary lymphedema
        iv. It is recommended that limb volume or circumference be the de facto 'gold standard' tests from which to assess the presence of secondary lymphedema.
    b. **Ward 2011**, assessment of bioimpedence spectroscopy for diagnosis of lymphedema
        i. N=37 female patients and N=5 male patients with bilateral lower extremity lymphedema
            1. Controls: N=277 female and N=224 male controls
        ii. Results varied with age, sex, and limb dominance
        iii. comparison of the ratio for affected legs (normalized to the ratio in the unaffected arms) with equivalent ratios observed in a control population (as bivariate tolerance plots) was capable of discriminating between 70% and 89% of the participants with lymphedema
        iv. Conclusions: Bioelectrical impedance spectroscopy and determination of Ri/R0 ratios as indices of ECF/ICF ratios holds promise for the semiquantitative assessment of bilateral lymphedema.
4) Other policies:
    a. **BCBS 2013**: The use of bioimpedance spectroscopy testing in the assessment, diagnosis, or management of individuals with known or suspected lymphedema is considered investigational and not medically necessary.
5) HERC staff recommendation: **Non-covered List**
    a. Experimental

Carotid intima media thickness (CPT 93895)

1) Definition: Carotid intima-media thickness testing (CIMT or IMT) is an ultrasound-based test to determine the thickness of the intima and media, part of the carotid artery wall. This thickness can be related to prediction of risk for cardiovascular disease. This test requires a high-resolution B-mode ultrasound, which currently is only available in specialized centers
2) Evidence
    a. **USPSTF 2009**, review of non-traditional risk factors for screening for cardiovascular disease
        i. Fair-quality evidence indicates, on the basis of 1 fair and 2 good-quality population-based longitudinal studies in the United States and the Netherlands, that carotid IMT predicts CHD independent of Framingham risk factors in asymptomatic persons (1300 to 16 000 men and women who showed a relative risk of 1.19 to 3.80). Adding carotid IMT scores to a risk prediction equation based on traditional risk factors modestly improved the prediction of subsequent CHD among healthy adults, particularly for me. However, the studies that show an association of carotid IMT with CHD outcome have all been done in research settings, and the ability to conduct carotid IMT with precision in nonresearch settings has not been established. No information is available about the prevalence or applicability of carotid IMT to populations at intermediate risk for CHD events.
        ii. Lack of consensus on examination techniques and population-based standards for interpreting quantitative IMT measures.
        iii. Overall strength of evidence for prediction of CVD events by use of IMT was rated as poor
        iv. Effects on treatment decisions based on IMT independent of LDL levels unclear
        v. Usefulness of IMT in cardiac risk assessment needs to be validated in prospective, population-based cohort studies that use appropriate methods to measure other risk factors and examine the added predictive ability of carotid IMT in persons classified as intermediate-risk by the Framingham risk score.
        vi. Recommendation: The USPSTF concludes that the current evidence is insufficient to assess the balance of benefits and harms of using the nontraditional risk factors (includes IMT) studied to screen asymptomatic men and women with no history of CHD to prevent CHD events. (I statement).
    b. **Goff 2013**, ACC/AHA Guideline on the Assessment of Cardiovascular Risk
        i. Routine measurement of CIMT is not recommended in clinical practice for risk assessment for a first ASCVD event.
            1. NHLBI Grade: N (No recommendation for or against); ACC/AHA COR III: No Benefit, LOE: B
2) HERC staff recommendation: **Non-covered List**
    a. USPSTF and ACC/AHA recommend against use in clinical practice

Original Article

Percutaneous Image-Guided Cryoablation of Painful Metastases Involving Bone

Multicenter Trial

Matthew R. Callstrom, MD PhD[1]; Damian E. Dupuy, MD[4]; Stephen B. Solomon, MD[5]; Robert A. Beres, MD[6]; Peter J. Littrup, MD[7]; Kirkland W. Davis, MD[8]; Ricardo Paz-Fumagalli, MD[9]; Cheryl Hoffman, MD[10]; Thomas D. Atwell, MD[1]; J. William Charboneau, MD[1]; Grant D. Schmit, MD[1]; Matthew P. Goetz, MD[2]; Joseph Rubin, MD[2]; Kathy J. Brown[1]; Paul J. Novotny, MS[3]; and Jeff A. Sloan, PhD[3]

BACKGROUND: This study sought to describe the results of a single-arm multicenter clinical trial using image-guided percutaneous cryoablation for the palliation of painful metastatic tumors involving bone. **METHODS:** Over a 44-month period, 61 adult patients with 1 or 2 painful bone metastases with a score of 4 or more on a scale of 0 to 10 ($\geq$4/10) worst pain in a 24-hour period who had failed or refused conventional treatment were treated with percutaneous image-guided cryoablation. Patient pain and quality of life was measured using the Brief Pain Inventory prior to treatment, 1 and 4 days after the procedure, weekly for 4 weeks, and every 2 weeks thereafter for a total of 6 months. Patient analgesic use was also recorded at these same follow-up intervals. Complications were monitored. Analysis of the primary endpoint was undertaken via paired comparison procedures. **RESULTS:** A total of 69 treated tumors ranged in size from 1 to 11 cm. Prior to cryoablation, the mean score for worst pain in a 24-hour period was 7.1/10 with a range of 4/10 to 10/10. At 1, 4, 8, and 24 weeks after treatment, the mean score for worst pain in a 24-hour period decreased to 5.1/10 ($P < .0001$), 4.0/10 ($P < .0001$), 3.6/10 ($P < .0001$), and 1.4/10 ($P < .0001$), respectively. One of 61 (2%) patients had a major complication with osteomyelitis at the site of ablation. **CONCLUSIONS:** Percutaneous cryoablation is a safe, effective, and durable method for palliation of pain due to metastatic disease involving bone. ***Cancer* 2013;119:1033-41.** © *2012 American Cancer Society.*

KEYWORDS: palliation, image-guided, cryoablation, metastases, skeletal.

The bony skeleton is the most common metastatic site from cancer after lungs and liver, with prostate, breast, lung, kidney, and thyroid malignancies accounting for approximately 80% of skeletal metastases. Of the patients who develop skeletal metastases, approximately 50% of patients will develop poorly controlled pain during the course of their disease.[1-4] Unfortunately, it is often difficult to achieve adequate pain relief, and the quality of life for these patients is poor. Current standard-of-care treatments for patients who develop painful bone metastases are primarily palliative. For focal palliative pain treatment, external beam radiation and surgery are most commonly offered, whereas for diffuse metastases, a systemic approach is used including chemotherapy, hormonal therapy, radiopharmaceuticals, and bisphosphonates.

Because many patients fail to derive adequate pain relief despite use of current conventional therapies, multiple minimally invasive focal therapies have been explored as new strategies for the palliation of painful metastatic disease. Of these methods, radiofrequency (RF) ablation has been most thoroughly evaluated with results from 2 multicenter studies demonstrating significantly reduced focal pain in patients who are unresponsive to standard treatments.[5,6] Although effective at reducing a patient's pain, RF ablation has a critical limitation, which is the nonvisualization of the ablation margin with computed tomography (CT) monitoring. In contrast to RF ablation, the ablation zone of cryoablation is readily identified with CT imaging as a low-attenuation ice ball beyond which tissues are safe from thermal injury.[7] Another advantage of cryoablation relative to RF ablation is that patients treated with cryoablation do not experience increased pain during the procedure or in the immediate posttreatment period.[8]

Cryotherapy for the treatment of liver metastases

Issued: December 2010

NICE interventional procedure guidance 369

www.nice.org.uk/ipg369

NHS Evidence has accredited the process used by the NICE Interventional Procedures Programme to produce interventional procedures guidance. Accreditation is valid for three years from January 2010 and applies to guidance produced since January 2009 using the processes described in the 'Interventional Procedures Programme: Process guide, January 2009' and the 'Interventional Procedures Programme: Methods guide, June 2007'

1 Guidance

1.1 Current evidence on the safety of cryotherapy for the treatment of liver metastases appears adequate in the context of treating patients whose condition has such a poor prognosis, but the evidence on efficacy is inadequate in quality. Therefore cryotherapy for the treatment of liver metastases should only be used with special arrangements for clinical governance, consent and audit or research.

1.2 Clinicians wishing to undertake cryotherapy for the treatment of liver metastases should take the following actions.

- Inform the clinical governance leads in their Trusts.
- Ensure that patients and their carers understand that other ablative treatments are available and provide them with clear written information. In addition, the use of NICE's information for patients ('Understanding NICE guidance') is recommended.
- Audit and review clinical outcomes of all patients having cryotherapy for liver metastases (see section 3.1).

1.3 Patient selection and treatment should be carried out by a hepatobiliary multidisciplinary team with expertise in the use of ablative techniques.

Copyright © NICE 2010. All rights reserved. Last modified December 2010

2 The procedure

2.1 Indications and current treatments

2.1.1 Liver metastases are commonly caused by colorectal cancer or other primary malignancies, such as lung and gastric cancer.

2.1.2 For a minority of patients, surgical resection of liver metastases with curative intent may be possible. For most patients however, treatment is palliative and options include systemic chemotherapy, external beam radiotherapy, other thermal ablation techniques, and selective internal radiation therapy. Multiple treatment modalities may be used for individual patients.

2.2 Outline of the procedure

2.2.1 Thermal ablation procedures including cryotherapy may be used as the primary treatment for liver metastases in patients who are not considered suitable for surgery, or to treat post-resection recurrence. They may also be used as an adjunct to hepatic resection. Cryotherapy can be delivered as part of an open resection procedure (requiring general anaesthesia and intraoperative ultrasound), or percutaneously (under local or general anaesthesia, with ultrasound, computed tomography [CT] or magnetic resonance imaging guidance).

2.2.2 Cryotherapy probes (single or multiple, depending on the size of the tumour) deliver coolant at subzero temperatures directly to the tumour in freeze-thaw cycles with the aim of destroying tumour cells.

2.2.3 The maximum recommended hepatic tumour size for cryotherapy is 4 cm. Cryotherapy for larger tumours requires multiple probes and is associated with increased morbidity.

2.2.4 Various devices can be used for this procedure.

Copyright © NICE 2010. All rights reserved. Last modified December 2010

Sections 2.3 and 2.4 describe efficacy and safety outcomes from the published literature that the Committee considered as part of the evidence about this procedure. For more detailed information on the evidence, see the overview.

2.3 Efficacy

2.3.1 A randomised controlled trial (RCT) of 123 patients treated by cryotherapy and chemotherapy or by surgical resection and chemotherapy reported disease-free survival in 14% (9/63) and 5% (3/60) of patients respectively at 10-year follow-up (significance not stated).

2.3.2 A non-randomised controlled trial of 415 patients treated by surgical resection and cryotherapy (for remnant lesions) or resection alone reported median survival of 29 and 34 months respectively (p = 0.206).

2.3.3 A case series of 326 patients reported median overall survival of 29 months after cryotherapy of colorectal liver metastases, with tumour recurrence in 42% (136/326) of patients at a median of 32 months. In a subset of 280 patients who had CT imaging at baseline and during follow-up, complete response was reported in 15% (41/280), partial response in 41% (115/280), stable disease in 24% (68/280), and progressive disease in 20% (56/280) (follow-up not stated).

2.3.4 The Specialist Advisers listed key efficacy outcomes as tumour destruction with small margins of additional tissue destruction, and survival.

2.4 Safety

2.4.1 A non-randomised controlled study of 223 patients reported no significant difference in perioperative mortality between the cryotherapy group (2% [1/55]) and the surgical resection group (5% [8/168]) (p = 0.30). However overall perioperative morbidity was significantly lower in the cryotherapy group (11% [6/55] than in the resection group (26% [44/168]) (p = 0.01).

2.4.2 A case series of 326 patients reported mortality in 2% (7/326) of patients (follow-up period and details of causes were not reported, but 1 patient died from 'cryoshock' syndrome and 1 from liver failure).

Copyright © NICE 2010. All rights reserved. Last modified December 2010

2.4.3 A case report described death of a patient from hepatic failure related to portal vein thrombosis and intra-hepatic MRSA sepsis, 2 months after a second cryotherapy course via an open approach.

2.4.4 Infections directly related to cryotherapy were reported after 8% (12/158) of procedures in the case series of 150 patients (most occurred within 3 weeks of treatment). Fever over 38°C was reported in 33% (108/326) of patients in the case series of 326 patients (timing of events not stated).

2.4.5 Haemorrhage was reported in 4% (2/55) and 1% (2/168) of patients treated with cryotherapy and surgical resection respectively in the non randomised controlled trial of 223 patients (timing of event not stated).

2.4.6 The Specialist Advisers listed anecdotal adverse events as damage to bile ducts and structures outside the liver. The Specialist Advisers also cited reports of major haemorrhage, the rare but fatal complication of cryoshock syndrome, and a high local recurrence rate; they stated that cryotherapy is therefore no longer widely used.

2.5 Other comments

2.5.1 The Committee noted possible differences in the safety of this procedure when used intraoperatively, compared with the percutaneous approach that uses narrower probes. Evidence on the percutaneous approach is limited in quantity.

3 Further information

3.1 This guidance requires that clinicians undertaking the procedure make special arrangements for audit. NICE has identified relevant audit criteria and has developed an audit tool (which is for use at local discretion).

3.2 For related NICE guidance see our website.

Information for patients

NICE has produced information on this procedure for patients and carers ('Understanding NICE guidance'). It explains the nature of the procedure and the guidance issued by NICE, and has been written with patient consent in mind.

Copyright © NICE 2010. All rights reserved. Last modified December 2010

4 About this guidance

NICE interventional procedure guidance makes recommendations on the safety and efficacy of the procedure. It does not cover whether or not the NHS should fund a procedure. Funding decisions are taken by local NHS bodies after considering the clinical effectiveness of the procedure and whether it represents value for money for the NHS. It is for healthcare professionals and people using the NHS in England, Wales, Scotland and Northern Ireland, and is endorsed by Healthcare Improvement Scotland for implementation by NHSScotland.

This guidance was developed using the NICE interventional procedure guidance process.

It has been incorporated into the NICE pathway on colorectal cancer, along with other related guidance and products.

We have produced a summary of this guidance for patients and carers. Tools to help you put the guidance into practice and information about the evidence it is based on are also available.

Changes since publication

2 January 2012: minor maintenance.

Your responsibility

This guidance represents the views of NICE and was arrived at after careful consideration of the available evidence. Healthcare professionals are expected to take it fully into account when exercising their clinical judgement. This guidance does not, however, override the individual responsibility of healthcare professionals to make appropriate decisions in the circumstances of the individual patient, in consultation with the patient and/or guardian or carer.

Implementation of this guidance is the responsibility of local commissioners and/or providers. Commissioners and providers are reminded that it is their responsibility to implement the guidance, in their local context, in light of their duties to avoid unlawful discrimination and to have regard to promoting equality of opportunity. Nothing in this guidance should be interpreted in a way which would be inconsistent with compliance with those duties.

ABSTRACT

Background

Primary liver tumours and liver metastases from colorectal carcinoma are the two most common malignant tumours to affect the liver. The liver is second only to the lymph nodes as the most common site for metastatic disease. More than half of the patients with metastatic liver disease will die from metastatic complications. In cryoablation, liquid nitrogen or argon gas is delivered to the liver tumour, guided by ultrasound using a specially designed probe. Ice crystal formation during the rapid freezing process causes destruction of cellular structure and kills the tumour cells.

Objectives

To study the beneficial and harmful effects of cryotherapy compared with no intervention, other ablation methods, or systemic treatments in patients with liver metastases.

Search methods

We searched the Cochrane Hepato-Biliary Group Controlled Trials Register, The Cochrane Central Register of Controlled Trials (CENTRAL) in *The Cochrane Library*, MEDLINE, EMBASE, Science Citation Index Expanded, LILACS, and CINAHL up to December 2012.

Selection criteria

We included all randomised clinical trials assessing the beneficial and harmful effects of cryotherapy and its comparators, irrespective of the location of the primary tumour.

Data collection and analysis

We extracted relevant information on participant characteristics, interventions, study outcomes, and data on the outcomes for our review, as well as information on the design and methodology of the trials. Bias risk assessment of and data extraction from the trials fulfilling the inclusion criteria were done by one author and checked by a second author.

ABSTRACT

Background

Hepatocellular carcinoma is the most common primary malignant cancer of the liver. Evidence for the role of cryotherapy in the treatment of hepatocellular carcinoma is controversial.

Objectives

The aim of this review is to evaluate the potential benefits and harms of cryotherapy for the treatment of hepatocellular carcinoma.

Search strategy

We searched *The Cochrane Hepato-Biliary Group Controlled Trials Register,* the *Cochrane Central Register of Controlled Trials (CENTRAL)* in *The Cochrane Library, MEDLINE, EMBASE,* and *LILACS* until June 2009. We identified further studies by searching national and topic-specific databases, bibliographies, conference abstracts, journals, and grey literature. Furthermore, we reviewed the reference lists and contacted the principal authors of the identified studies.

Selection criteria

Randomised clinical trials (irrespective of language or publication status) comparing cryotherapy with or without co-intervention(s) to placebo, no treatment, or other control interventions were considered for the review. Due to the absence of randomised clinical trials, we searched for quasi-randomised studies as well as prospective cohort studies and retrospective cohort studies.

Data collection and analysis

Two authors independently identified and assessed studies for their fulfilment of the inclusion criteria. Dichotomous data were expressed as risk ratio (RR) with 95% confidence intervals (CI). We performed the review following the recommendations of The Cochrane Collaboration.

Main results

We were unable to identify any randomised clinical trials. We were also unable to identify quasi-randomised trials. Instead, we identified two prospective cohort studies and two retrospective cohort studies. However, only one of these studies could be included for the assessment of benefit as the study results were stratified according to both the type of hepatic malignancy (primary or secondary) and the intervention group. This retrospective study compared percutaneous cryotherapy with percutaneous radiofrequency. The remaining

Copyright © 2009 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

studies were excluded for the analyses of benefit but included for the assessment of harm. Both severe and non-severe adverse events were reported, but the true nature and extent of harm was difficult to asses.

Authors' conclusions

At present, there is no evidence to recommend or refute cryotherapy for patients with hepatocellular carcinoma. Randomised clinical trials with low-risk of bias may help in defining the role of cryotherapy in the treatment of hepatocellular carcinoma.

PLAIN LANGUAGE SUMMARY

No evidence to evaluate the potential benefits and harms of cryotherapy in the treatment of hepatocellular carcinoma

Liver cell cancer (hepatocellular carcinoma) is the most common primary cancer of the liver. Liver cancer is regarded as the third most common cause of death from cancer. Only a minority of the patients are candidates for liver surgery or liver transplantation. Cold therapy (cryotherapy), where rapid freezing causes cancerous cells' destruction and death, is one of several 'minimally invasive treatment techniques' that have been recently developed. Currently, no large well-planned clinical investigations have been conducted to establish the potential benefits and harms associated with treating liver cell cancer patients with cryotherapy. Nor have any such investigations been undertaken to establish the superiority or inferiority of cryotherapy compared with other treatments for liver cell cancer. At present, there is no evidence to support or refute the alleged and potential benefits of cryotherapy. Large well-designed randomised clinical trials are feasible and are necessary to define the role of cryotherapy in the treatment of hepatocellular carcinoma.

BACKGROUND

In the year 2002, liver cancer represented the sixth most common cancer world-wide in regard to numbers of patients living with cancer (within 5 years of diagnosis) (626,000 patients or 5.7% of new cancer patients) (Parkin 2005). However, due to the poor prognosis of liver cancer, the number of deaths is almost the same (598,000) (Parkin 2005). Liver cancer is regarded as the third most common cause of death from cancer (Parkin 2005). Hepatocellular carcinoma is the most common primary malignant cancer of the liver, accounting for 80% to 90% of all liver cancers. Furthermore, the incidence of hepatocellular carcinoma has been rising in a number of countries (Taylor-Robinson 1997; Deuffic 1998; Stroffolini 1998; El-Serag 2003; Bosch 2004; Parkin 2005).

Hepatocellular carcinoma is known to be associated with a range of risk factors, mainly cirrhosis of any aetiology (eg, hepatitis C and B virus infection, haemochromatosis, alcohol, and primary biliary cirrhosis) (Regan 1989; Tiribelli 1989; Fattovich 2004; Kumar 2007). Aflatoxin B1 is also regarded as a major factor in the development of hepatocellular carcinoma in Southern China and Sub-Saharan Africa (Yeh 1989; Aguilar 1993).

The diagnosis of hepatocellular carcinoma includes radiology, biopsy, and alpha-fetoprotein serology. According to the American Association for the Study of Liver Diseases (AASLD) and the European Association for the Study of the Liver (EASL), the type and sequence of the tests used to diagnose hepatocellular carcinoma depend on the size and the location of the cancer (Bruix 2001; Bruix 2005).

Surgical resection, liver transplantation, and percutaneous ablation of the liver cancer are considered to be potentially curative treatments. Despite many attempts in the prevention and screening for hepatocellular carcinoma, only 20% to 30% of patients present at an early stage, and therefore, are amenable to potentially curative treatments (Llovet 2003; Schwartz 2007). Although transarterial embolisation and chemoembolisation are recommended as first-line non-curative therapy (Bruix 2005), a recent Cochrane systematic review suggests that the available evidence is insufficient to support such recommendations (Oliveri 2009).

Percutaneous ablation seems to be a promising treatment option for patients with early stage hepatocellular carcinoma who are not suitable for liver resection or transplantation (Bruix 2005). Cancerous cells destruction can be achieved by several techniques; the injection of chemical substances (eg, ethanol injection), by modifying the temperature (eg, cryotherapy), or radiofrequency ablation. However, the indications and results for percutaneous

Transversus Abdominis Plane Block to Ameliorate Postoperative Pain Outcomes After Laparoscopic Surgery: A Meta-Analysis of Randomized Controlled Trials

Gildasio S. De Oliveira Jr, MD, MSCI, Lucas Jorge Castro-Alves, MD, Autoun Nader, MD, Mark C. Kendall, MD, and Robert J. McCarthy, PharmD

BACKGROUND: Transversus abdominis plane (TAP) block has been used as a multimodal strategy to optimize postoperative pain outcomes; however, it remains unclear which type of surgical procedures can benefit from the administration of a TAP block. Several studies have examined the effect of the TAP block on postoperative pain outcomes after laparoscopic surgical procedures and generated conflicting results. Our main objective in the current investigation was to evaluate the effect of TAP block on postoperative analgesia outcomes for laparoscopic surgical procedures.

METHODS: A search was performed to identify randomized controlled trials that evaluated the effects of the TAP block compared with an inactive group (placebo or "no treatment") on postoperative pain outcomes in laparoscopic surgical procedures. Primary outcomes included early (0–4 hours) and late (24 hours) postoperative pain at rest and on movement and postoperative opioid consumption (up to 24 hours). Meta-analysis was performed using a random-effects model. Publication bias was evaluated by examining the presence of asymmetric funnel plots using Egger regression test. Meta-regression analysis was performed to establish an association between the local anesthetic dose and the evaluated outcomes.

RESULTS: Ten randomized clinical trials with 633 subjects were included in the analysis. The weighted mean difference (99% confidence interval) of the combined effects favored TAP block over control for pain at rest (≤4 hours, −2.41 [−3.6 to −1.16]) and (at 24 hours, −1.33 [−2.19 to −0.48]) (0–10 numerical scale). Postoperative opioid consumption was decreased in the TAP block group compared with control, weighted mean difference (99% confidence interval) of −5.74 (−8.48 to −2.99) mg morphine IV equivalents. Publication bias was not present in any of the analysis. Preoperative TAP block administration resulted in greater effects on early pain and opioid consumption compared with postoperative administration. Meta-regression analysis revealed an association between local anesthetic dose and the TAP block effect on late pain at rest and postoperative opioid consumption. None of the studies reported symptoms of local anesthetic toxicity.

CONCLUSIONS: TAP block is an effective strategy to improve early and late pain at rest and to reduce opioid consumption after laparoscopic surgical procedures. In contrast, the TAP block was not superior compared with control to reduce early and late pain during movement. Preoperative administration of a TAP block seems to result in greater effects on postoperative pain outcomes. We also detected a local anesthetic dose response on late pain and postoperative opioid consumption. (Anesth Analg 2014;118:454–63)

The advance in surgical techniques and the development of anesthetics with low side effect profiles have enabled the current rapid growth of outpatient surgical procedures.[1,2] Recently, larger procedures such as prostatectomy and gynecological cancer surgeries have been performed laparoscopically allowing a better and faster postoperative recovery to patients.[3,4] Nevertheless, postoperative pain seems to remain a very important factor that can deteriorate the overall quality of recovery after laparoscopic procedures.[5,6]

Transversus abdominis plane (TAP) block has been used as a multimodal strategy to optimize postoperative pain outcomes. However, in recent reviews evaluating the clinical effectiveness of TAP block, the investigators were not able to identify the surgical procedures, dosing, techniques, and timing that provide optimal analgesia after TAP block.[7,8] Since then, evidence suggested an effective role for TAP block to minimize postoperative pain in certain procedures such as cesarean deliveries that do not include

ABSTRACT

To determine the effectiveness of transversus abdominis plane blocks in gynecological surgery by systematic review and meta-analysis. Embase, MEDLINE and the Cochrane Library (CENTRAL) bibliographic databases were searched using a Cochrane Library search strategy modified for gynecological surgery. We included randomized controlled trials comparing transversus abdominis plane block with no block or placebo block. We retrieved 681 citations from which we included five published studies (225 randomized participants) which fulfilled our inclusion criteria, and identified a further six ongoing studies. Quality was assessed across six risk of bias domains: randomization sequence generation, allocation concealment, blinding, missing outcome data, selective reporting and other biases. Data were meta-analyzed where possible and presented as mean differences with 95% confidence intervals. Study quality was moderate. Compared with no block or saline placebo, transversus abdominis plane block provided significantly less postoperative pain at rest on a 10 cm visual analog scale at 2 h (mean difference −2.14 cm, 95% confidence interval (CI) −3.57 to −0.71) but not at 24 h postoperatively (−0.52 cm, 95% CI −1.49 to 0.45). Pain on movement showed similar results. Transversus abdominis plane block resulted in significantly less postoperative requirement for morphine use at 24 h (−11.76 mg, 95% CI −18.77 to −4.75) but not at 48 h (−16.01 mg, 95% CI −39.40 to 7.39). Evidence exists for the short-term efficacy (within 24 h) of transversus abdominis plane blocks during hysterectomy in terms of reported pain and morphine consumption, which may not be sustained at 48 h. Updates to this review should be undertaken periodically, and until further robust evidence is available, anesthetists should not rush to adopt this procedure into routine practice.

1. Introduction

Pain experienced after abdominal surgery, resulting from both the incision made to the abdominal wall and trauma to the internal viscera, can be considerable and is often inadequately controlled [1]. In addition to the negative emotional and physical suffering of the patient, postoperative complications can include respiratory difficulties, delays in mobilization and prolonged hospital stay

Editor's key points

- The utility of transversus abdominis plane (TAP) block in Caesarean delivery was assessed by analysing results of previous studies.
- TAP block reduced i.v. morphine consumption and pain scores in the first day after surgery.
- TAP block can provide effective analgesia after Caesarean delivery when intrathecal morphine has not been used.

Summary. The transversus abdominis plane (TAP) block is a field block that provides postoperative analgesia for abdominal surgery. Its analgesic utility after Caesarean delivery (CD) remains controversial. This systematic review and meta-analysis examines whether TAP block can reduce i.v. morphine consumption in the first 24 h after CD. The authors retrieved randomized controlled trials comparing TAP block with placebo in CD. Postoperative i.v. morphine consumption during the first 24 h was selected as a primary outcome. Pain scores and both maternal and neonatal opioid-related side-effects were secondary outcomes. Where possible, meta-analytic techniques and random effects modelling were used to combine data. Trials were stratified based on whether or not spinal morphine was used as part of the analgesic regimen. Five trials including 312 patients were identified. TAP block reduced the mean 24 h i.v. morphine consumption by 24 mg [95% confidence interval (CI) −39.65 to −7.78] when spinal morphine was not used. TAP block also reduced visual analogue scale pain scores (10 cm line where 0 cm, no pain, and 10 cm, worst pain) by 0.8 cm (95% CI −1.53 to −0.05, P=0.01), and decreased the incidence of opioid-related side-effects. The differences in primary and secondary outcomes were not significant when spinal morphine was used. TAP block provides superior analgesia compared with placebo and can reduce the first 24 h morphine consumption in the setting of a multimodal analgesic regimen that excludes spinal morphine. TAP block can provide effective analgesia when spinal morphine is contraindicated or not used.

Keywords: acute pain, novel techniques; anaesthesia, obstetric; anaesthetic blocks, regional; analgesia, postoperative; regional blockade

Inadequate postoperative pain relief after Caesarean delivery (CD) can negatively impact ambulation, breastfeeding, and even maternal bonding,[1] while effective analgesia improves the amount of breastfeeding and infant weight gain.[2] Neuraxial anaesthesia has become the anaesthetic technique of choice in CD because of its safety and reduction in maternal mortality.[3]

The transversus abdominis plane (TAP) block, a field block[4] whose analgesic efficacy in several abdominal surgeries has been confirmed,[5–7] has also been proposed for postoperative analgesia in parturients undergoing elective CD under spinal anaesthesia.[8] However, the analgesic utility of TAP block remains controversial; some trials comparing it with placebo reported significant advantages,[8 9] while others found no analgesic benefit.[10 11] Reviews examining the analgesic effects of TAP block in various surgeries have not provided definitive answers regarding the specific role of TAP block in CD. A Cochrane review examining the efficacy of TAP block in abdominal surgeries excluded CD.[12] A recent meta-analysis supporting TAP block for its effective pain relief included only one trial in the setting of CD.[13] A 2012 qualitative systematic review[14] examined the role of TAP block across all abdominal surgeries and raised questions about its role in the setting of multimodal analgesia but stopped short of conducting any further analysis specific to CD. The purpose of this systematic review was to determine whether or not TAP block is effective in providing pain relief after CD. The primary outcome was morphine consumption in the first 24 h, an important issue for the breastfeeding woman.

Methods

The authors followed the PRISMA[15] recommendations in preparing this review.

NCCN Guidelines Version 1.2014 Updates
Breast Cancer Screening and Diagnosis

NCCN Guidelines Index
Table of Contents
Discussion

Updates in Version 1.2014 of the NCCN Guidelines for Breast Cancer Screening from Version 2.2013 include:

BSCR-1
- **4th column, 3rd bullet modified: "Lobular carcinoma in situ (LCIS) or** *ADH/ALH*" **(Also for BSCR-2).**
- **5th bullet modified: "Prior thoracic RT** *for patients younger than* **30 y (eg, mantle)."**
- **"Pedigree suggestive of or known genetic predisposition": prior link to BSCR-3 deleted and replaced with a link to the NCCN Guidelines for Genetic/Familial High-Risk Assessment: Breast and Ovarian.**
- **"Adequate breast exams include the following: upright and supine position during exam, appearance of breast, and palpation of all components of the breast" is a new footnote to the page corresponding to 6th column, 1st bullet, "Clinical breast exam every 1-3 y."**
- **For women with average-risk (≥40 y) screening mammography is now a category 1 recommendation.**
- **"Screening" was added before mammogram for clarification. (Also for BSCR-2).**

BSCR-2
- **Footnote "j": "Randomized trials comparing clinical breast exam versus no screening have not been performed. Rationale for recommending clinical breast exam every 6-12 mo is the concern for interval breast cancers," is new to the page and corresponds to,** *"Annual screening mammogram + clinical breast exam every 6-12 mo."*
- **"Consider beginning at age of first-degree relative's diagnosis of cancer if younger than age 30" is a new footnote to the page and corresponds to the 2nd column, 4th bullet, 1st sub-bullet,** *"beginning at age 30 y."*
- **Footnote "l": High-quality breast MRI limitations include having: a need for a dedicated breast coil, the ability to perform biopsy under MRI guidance, experienced radiologists in breast MRI, and regional availability. "Breast MRI is performed preferably days 7-15 of menstrual cycle for premenopausal women.** *MRI should be integrated with other breast imaging modalities,"* **is new to the page and corresponds to the 7th bullet which has been modified:** *Recommend* ~~**consider**~~ **annual breast MRI.**
- **8th bullet is new to the page: "Referral to genetic counseling if not already done."**

BSCR-3
- **3rd column, 5th bullet,** *Skin ulcers* **is new to the page.**

BSCR-4
- **"***Diagnostic***" was added before mammogram throughout the guidelines for clarity.**
- **2nd column, under Initial Evaluation modified:** *Diagnostic mammogram ± ultrasound as needed.*
- **4th column,** ~~**Ultrasound**~~ **was deleted after BI-RADS® category 1-3.**

BSCR-5
- **5th column, top branch off of "Increase in size," added "***Tissue biopsy* **before (See BSCR-7)"**
- **Modified footnote "u": FNA and core (needle or vacuum-assisted) biopsy are both valuable. FNA requires cytologic expertise. Surgical excision is appropriate if unable to perform core needle biopsy** *or if strongly desired by patient.*
- **The following reference was deleted:** ~~**Stavros A, Thickman D, Rapp C, et al. Solid breast nodules: Use of sonography to distinguish between benign and malignant lesions. Radiology 1995;196:123-124.**~~
- ~~**Routine**~~ **was deleted before Screening (See BSCR-1) throughout the guidelines.**

NCCN Guidelines Version 1.2014 Updates
Breast Cancer Screening and Diagnosis

NCCN Guidelines Index
Table of Contents
Discussion

Updates in Version 1.2014 of the NCCN Guidelines for Breast Cancer Screening from Version 2.2013 include:

BSCR-10

- **2nd column, top branch off Palpable mass age <30 y was modified: Ultrasound (preferred) ± diagnostic mammogram ~~(preferred)~~ "Simple cyst" BI-RADS® category 2 we previously sent the reader to ~~Ultrasound Findings~~, now** *Screening* **(See BSCR-1).**

BSCR-11

- **4th column under Follow-up Evaluation, modified: Observe every 3-6 mo ± imaging for 1-2 y to assess stability** *if low clinical suspicion.*

BSCR-12

- **3rd column, 2nd branch off Age ≥40 y, 1st bullet modified:** *Diagnostic* **mammogram,** *if not done recently.*
- **3rd column, bottom branch modified: Age ≥30 y** *Diagnostic* **mammogram + ultrasound.**

BSCR-14

- **2nd column, bottom branch off Skin changes modified: Clinical suspicion of Paget's disease** *or other manifestations of Breast cancer.*
- **3rd bullet is new to the page:** *Skin ulceration.*

BSCR-A

- **8th bullet modified to include:** *Important outcomes are not yet established for supplemental screening; some states have passed legislation mandating patient notification of breast density.*
- **9th bullet modified: Early studies show promise for tomosynthesis mammography. ~~Currently, there is insufficient evidence to recommend routine use for screening or diagnosis at this time.~~** *Two large trials showing a combined use of digital mammograpy and tomosynthesis resulted in improved cancer detection and decreased call back rates; of note, this is double the dose of radiation and is a factor in recommending this modality. Definitive studies are still pending.*

BSCR-C

- **Global update for BI-RADS® Mammography and Ultrasound to the ACR-BI-RADS®--5th Edition.**

SCREENING OR SYMPTOM CATEGORY	SCREENING FOLLOW-UP
Increased Risk:	
Prior history of breast cancer	→ See NCCN Guidelines for Breast Cancer - Surveillance Section
Women ≥35 y with 5-year risk of invasive breast cancer ≥1.7%[d] OR LCIS (begin screening at diagnosis) OR ADH/ALH	→ • Annual screening mammogram[i] + clinical breast exam every 6-12 mo[j] • Breast awareness[h] • Consider risk reduction strategies (See NCCN Guidelines for Breast Cancer Risk Reduction)
Women who have a lifetime risk >20% as defined by models that are largely dependent on family history[e]	→ • Annual screening mammogram[i] + clinical breast exam every 6-12 mo[j] ▸ beginning at age 30 y[k] • Breast awareness[h] • Consider risk reduction strategies (See NCCN Guidelines for Breast Cancer Risk Reduction) • Recommend annual breast MRI[l] ▸ beginning at age 30 y • Referral to genetic counseling if not already done
Prior thoracic RT between the ages of 10 and 30 y: Age <25 y	→ • Annual clinical breast exam ▸ beginning 8 to 10 y after RT • Breast awareness[h]
Prior thoracic RT between the ages of 10 and 30 y: Age ≥25 y	→ • Annual screening mammogram[i] + clinical breast exam every 6-12 mo[j] ▸ Begin 8-10 y after RT or age 40, whichever comes first • Recommend annual breast MRI[l] • Breast awareness[h]

[d] See Risk Factors Used in the Modified Gail Model (BSCR-B).

[e] Risk models that are largely dependent on family history (eg, Claus, BRCAPRO, BOADICEA, Tyrer-Cuzick). See NCCN Guidelines for Breast Cancer Risk Reduction.

[h] Women should be familiar with their breasts and promptly report changes to their health care provider. Periodic, consistent breast self exam (BSE) may facilitate breast self awareness. Premenopausal women may find BSE most informative when performed at the end of menses.

[i] See Mammographic Evaluation (BSCR-15).

[j] Randomized trials comparing clinical breast exam versus no screening have not been performed. Rationale for recommending clinical breast exam every 6-12 mo is the concern for interval breast cancers.

[k] Consider beginning at age of first-degree relative's diagnosis of cancer if younger than age 30.

[l] High-quality breast MRI limitations include having: a need for a dedicated breast coil, the ability to perform biopsy under MRI guidance, experienced radiologists in breast MRI, and regional availability. Breast MRI is performed preferably days 7-15 of menstrual cycle for premenopausal women. MRI should be integrated with other breast imaging modalities.

Note: All recommendations are category 2A unless otherwise indicated.
Clinical Trials: NCCN believes that the best management of any cancer patient is in a clinical trial. Participation in clinical trials is especially encouraged.

[m]There are some clinical circumstances such as mass with low clinical suspicion or suspected simple cyst, in which ultrasound would be preferred and may suffice for women 30-39 years of age. See Discussion section.
[n]See Assessment Category Definitions (BSCR-C).
[o]Mammography results are mandated to be reported using Final Assessment categories (Quality Mammography Standards: Final Rule. Federal Register. 1997;62:55988).
[p]Assess geographic correlation between clinical and imaging findings. If there is a lack of correlation, return to Category 1-3 for further workup of palpable lesion. If imaging findings correlate with the palpable finding, workup of the imaging problem will answer the palpable problem.
[q]Concordance is needed between clinical exam and ultrasound results. Consider therapeutic aspiration for persistent clinical symptoms.

Note: All recommendations are category 2A unless otherwise indicated.
Clinical Trials: NCCN believes that the best management of any cancer patient is in a clinical trial. Participation in clinical trials is especially encouraged.

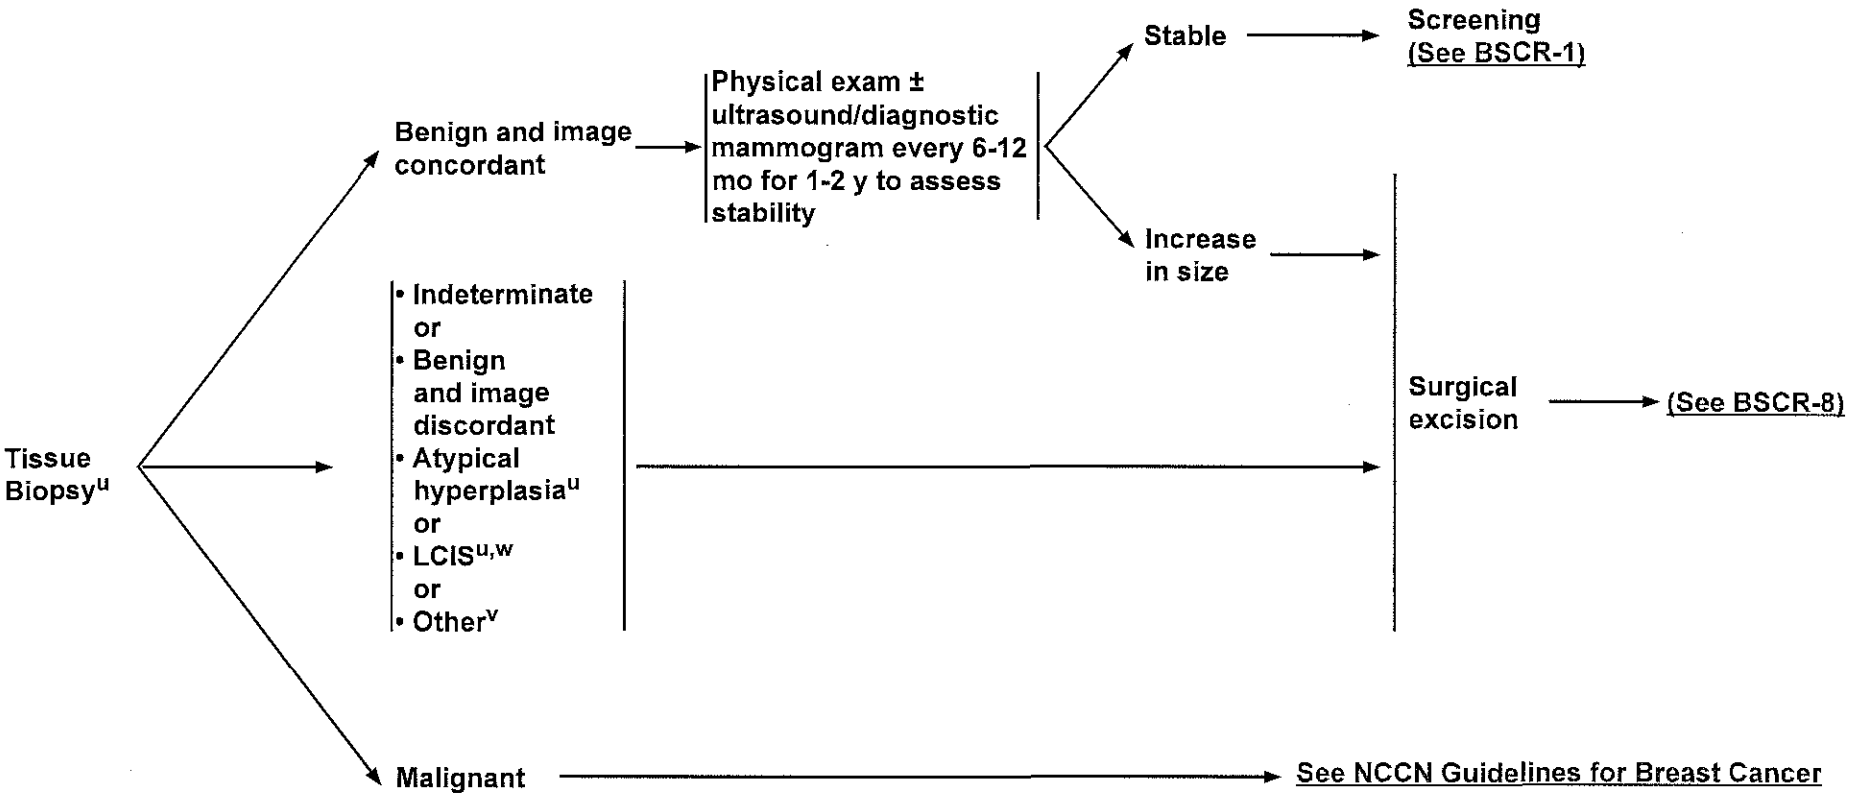
PALPABLE MASS

FOLLOW-UP EVALUATION



[u]FNA and core (needle or vacuum-assisted) biopsy are both valuable. FNA requires cytologic expertise. Surgical excision is appropriate if unable to perform core needle biopsy or if strongly desired by patient.
[w]Select patients may be suitable for monitoring in lieu of surgical excision (eg, ALH, LCIS, papillomas, fibroepithelial lesions, radial scars).
[x]Other histologies that may require additional tissue: mucin-producing lesions, potential phyllodes tumor, papillary lesions, radial scar, or histologies of concern to pathologist.
[y]Multifocal/extensive LCIS involving >4 terminal ductal lobular units on a core biopsy may be associated with increased risk of invasive cancer on surgical excision.

Note: All recommendations are category 2A unless otherwise indicated.
Clinical Trials: NCCN believes that the best management of any cancer patient is in a clinical trial. Participation in clinical trials is especially encouraged.

BREAST SCREENING CONSIDERATIONS

- **Women should be counseled regarding potential benefits, risks, and limitations of breast screening.**
- **Thorough clinical breast exam involves inspection and palpation of all breast tissue, including lymph node basins.**
- **Consider severe comorbid conditions limiting life expectancy and whether therapeutic interventions are planned.**
- **Upper age limit for screening is not yet established.**
- **Current evidence does not support the routine use of breast scintigraphy (eg, sestamibi scan) or ductal lavage as screening procedures.**
- **There are several studies supporting the use of ultrasound for breast cancer screening as an adjunct to screening mammography for high-risk women with dense breast tissue.[1]**
- **Digital mammography appears to benefit young women and women with dense breasts.[2]**
- **Dense breasts limit the sensitivity of mammography. Dense breasts are associated with an increased risk for breast cancer, but there is insufficient evidence to support routine supplemental screening in women with dense breasts and no other risk factors. Important outcomes are not yet established for supplemental screening; some states have passed legislation mandating patient notification of breast density.**
- **Early studies show promise for tomosynthesis mammography. Two large trials showing a combined use of digital mammography and tomosynthesis resulted in improved cancer detection and decreased call back rates; of note, this is double the dose of radiation and is a factor in recommending this modality. Definitive studies are still pending.**

BREAST SCREENING CONSIDERATIONS

RECOMMENDATIONS FOR BREAST MRI SCREENING AS AN ADJUNCT TO MAMMOGRAPHY[3,4]

Recommend Annual MRI Screening (Based on Evidence):[5]
- **BRCA mutation**
- **First-degree relative of BRCA carrier, but untested**
- **Lifetime risk 20% or greater, as defined by BRCAPRO or other models that are largely dependent on family history (See BSCR-2)**

Recommend Annual MRI Screening (Based on Expert Consensus Opinion):[6]
- **Radiation to chest between age 10 and 30 years**
- **Li-Fraumeni syndrome6 and first-degree relatives**
- **Cowden and Bannayan-Riley-Ruvalcaba syndromes[7] and first-degree relatives**

Insufficient Evidence to Recommend for or Against MRI Screening:[8]
- **Lifetime risk 15%–20%, as defined by BRCAPRO or other models that are largely dependent on family history**
- **LCIS or atypical lobular hyperplasia (ALH)**
- **Atypical ductal hyperplasia (ADH)**
- **Heterogeneously or extremely dense breast on mammography**
- **Women with a personal history of breast cancer,[9] including ductal carcinoma in situ (DCIS)**

Recommend Against MRI Screening (Based on Expert Consensus Opinion):
- **Women at <15% lifetime risk**

RISK FACTORS USED IN THE MODIFIED GAIL MODEL[1]

- **Current age**
- **Age at menarche**
- **Age at first live birth or nulliparity**
- **Number of first-degree relatives with breast cancer**
- **Number of previous benign breast biopsies**
- **Atypical hyperplasia in a previous breast biopsy**
- **Race[2]**

For calculation of risk, based on the modified Gail Model, see http://www.cancer.gov/bcrisktool/Default.aspx

[1]For detailed information, see http://www.cancer.gov/bcrisktool/Default.aspx.
[2]The current Gail Model may not accurately assess breast cancer risk in non-Caucasian women.

Note: All recommendations are category 2A unless otherwise indicated.
Clinical Trials: NCCN believes that the best management of any cancer patient is in a clinical trial. Participation in clinical trials is especially encouraged.

MAMMOGRAPHIC ASSESSMENT CATEGORY DEFINITIONS[1,2]

BI-RADS® - MAMMOGRAPHY FINDINGS

A. Assessment Is Incomplete:

Category 0: Incomplete - Need Additional Imaging Evaluation and/or Prior Mammograms For Comparison:

There is a finding for which additional evaluation is needed. This is almost always used in a screening situation. Under certain circumstances this assessment category may be used in a diagnostic mammography report, such as when US equipment or personnel are not immediately available, or when the patient is unable or unwilling to wait for completion of a full diagnostic examination. A recommendation for additional imaging evaluation includes, the use of spot compression (with or without magnification), special mammographic views, and ultrasound. Category 0 should not be used for diagnostic breast imaging findings that warrant further evaluation with MRI. Rather, the interpreting physician should issue a final assessment in a report that is made before the MRI examination is performed. In most circumstances and when feasible, if a mammography examination is not assessed as negative or benign, the current examination should be compared with prior examination(s). The interpreting physician should use judgment on how vigorously to attempt obtaining prior examinations, given the likelihood of success of such an endeavor and the likelihood that comparison will affect the final assessment. In this context, it is important to note that comparison with previous examination(s) may be irrelevant when a finding is inherently suspicious for malignancy.

Category 0 should be used for prior image comparison only when such comparison is required to make a final assessment. When category 0 is used in the context of awaiting prior examinations for comparison, there should be in place a tracking procedure guaranteeing with 100% reliability that a final assessment will be made within 30 days (preferably sooner) even if prior examinations do not become available. Some mammography practices may reasonably choose never to use category 0 in the context of awaiting prior examinations simply because they do not have a 100% reliable tracking procedure. If a mammography examination is assessed as category 0 in the context of awaiting prior examinations and then the prior examinations do become available, an addendum to the initial mammography report should be issued, including a revised assessment. For auditing purposes, the revised assessment should replace the initial assessment.

[1]Mammography results are mandated to be reported using Final Assessment categories (Quality Mammography Standards: Final Rule. Federal Register. 1997;62:55988).

MAMMOGRAPHIC ASSESSMENT CATEGORY DEFINITIONS[1,2]

BI-RADS® - MAMMOGRAPHY FINDINGS

B. Assessment Is Complete - Final Assessment Categories:

Category 1: Negative:
There is nothing to comment on. This is a normal examination.

Category 2: Benign:
Like Category 1, this is a "normal" assessment, but here, the interpreter chooses to describe a benign finding in the mammography report. Involuting, calcified fibroadenomas, skin calcifications, metallic foreign bodies (such as core biopsy and surgical clips),and fat-containing lesions (such as oil cysts, lipomas, galactoceles, and mixed-density hamartomas) all have characteristically benign appearances, and may be described with confidence. The interpreter may also choose to describe intramammary lymph nodes, vascular calcifications, implants, or architectural distortion clearly related to prior surgery while still concluding that there is no mammographic evidence of malignancy. On the other hand, the interpreter may choose not to describe such findings, in which case the examination should be assessed as negative (category 1).

Note that both category 1 and category 2 assessments indicate that there is no mammographic evidence of malignancy. Both should be followed by the management recommendation for routine mammography screening. The difference is that category 2 should be used when describing one or more specific benign mammographic findings in the report, whereas category 1 should be used when no such findings are described (even if such findings are present).

[1]Mammography results are mandated to be reported using Final Assessment categories (Quality Mammography Standards: Final Rule. Federal Register. 1997;62:55988).

MAMMOGRAPHIC ASSESSMENT CATEGORY DEFINITIONS[1,2]

BI-RADS® - MAMMOGRAPHY FINDINGS

Category 3: Probably Benign:

A finding assessed using this category should have a ≤2% likelihood of malignancy, but greater than the essentially 0% likelihood of malignancy of a characteristically benign finding. A probably benign finding is not expected to change over the suggested period of imaging surveillance, but the interpreting physician prefers to establish stability of the finding before recommending management limited to routine mammography screening.

There are several prospective clinical studies demonstrating the safety and efficacy of periodic mammographic surveillance instead of biopsy for specific mammographic findings.

Three specific findings are validated as being probably benign (the noncalcified circumscribed solid mass, the focal asymmetry, and solitary group of punctate calcifications). All the previously cited studies emphasize the need to conduct a complete diagnostic imaging evaluation before making a probably benign (category 3) assessment; hence, it is recommended not to render such an assessment in interpreting a screening mammography examination. The practice of rendering category 3 assessments directly from screening examination also has been shown to result in adverse outcomes: 1) unnecessary follow-up of many lesions that could have been promptly assessed as benign, and 2) delayed diagnosis of a small number of cancers that otherwise may have been smaller in size and less likely to be advanced in stage. Also, all the previously cited studies exclude palpable lesions, so the use of a probably benign assessment for a palpable lesion is not supported by robust scientific data, although there are two single-institution studies that do report successful outcomes for palpable lesions. Finally, because evidence from previously cited studies indicates the need for biopsy rather than continued surveillance when a probably benign finding increases in size or extent, it is not prudent to render a category 3 assessment when a finding that otherwise meets "probably benign" imaging criteria is either new or has increased in size or extent.

While the vast majority of probably benign findings are managed with an initial short-interval follow-up (6 mo) examination followed by additional examinations until long-term (2- or 3-year) stability is demonstrated, there may be occasions in which a biopsy is done instead (patient preference or overriding clinical concern).

[1]Mammography results are mandated to be reported using Final Assessment categories (Quality Mammography Standards: Final Rule. Federal Register. 1997;62:55988).

[2]Terminology in this table is reflective of the American College of Radiology (ACR). ACR-BI-RADS®--5th Edition. ACR Breast Imaging Reporting and Data System, Breast Imaging Atlas; BI-RADS. Reston VA. American College of Radiology, 2014. For more information, see www.acr.org.

MAMMOGRAPHIC ASSESSMENT Category Definitions[1,2]

BI-RADS® - MAMMOGRAPHY FINDINGS

Category 4: Suspicious:
This category is reserved for findings that do not have the classic appearance of malignancy but are sufficiently suspicious to justify a recommendation for biopsy. The ceiling for category 3 assessment is a 2% likelihood of malignanacy and the floor for category 5 assessment is 95%, so category 4 assessments cover the wide range of likelihood of malignancy in between. Thus, almost all recommendations of breast interventional procedures will come from assessments made using this category. By subdividing category 4 into 4A, 4B, and 4C, as recommended in Guidance chapter and using the cut point indicated therein, it is hoped that patients and referring clinicians will more readily make informed decisions on the ultimate course of action.

Category 5: Highly Suggestive of Malignancy:
These assessments carry a very high probability (≥95%) of malignancy. This category initially was established to involve lesions for which 1-stage surgical treatment was considered without preliminary biopsy, in an era when preoperative wire localization was the primary breast interventional procedure. Nowadays, given the widespread acceptance of imaging-guided percutaneous biopsy, 1-stage surgery is rarely, if ever, performed. Rather, current oncologic management almost always involves tissue diagnosis of malignancy via percutaneous tissue sampling to facilitate treatment options, such as when sentinel node biopsy is included in surgical management or when neoadjuvant chemotherapy is administered prior to surgery. Therefore, the current rationale for using a category 5 assessment is to identify lesions for which any non-malignant percutaneous tissue diagnosis is automatically considered discordant, resulting in the recommendation for repeat (usually surgical) biopsy.

Category 6: Known Biopsy - Proven Malignancy:
This category is reserved for examinations performed after biopsy proof of malignancy (imaging performed after percutaneous biopsy but prior to complete surgical excision), in which there are no mammographic abnormalities other than the known cancer that might need additional evaluation.

[1]Mammography results are mandated to be reported using Final Assessment categories (Quality Mammography Standards: Final Rule. Federal Register. 1997;62:55988).

[2]Terminology in this table is reflective of the American College of Radiology (ACR). ACR-BI-RADS®--5th Edition. ACR Breast Imaging Reporting and Data System, Breast Imaging Atlas; BI-RADS. Reston VA. American College of Radiology, 2014. For more information, see www.acr.org.

ULTRASOUND ASSESSMENT CATEGORY DEFINITIONS[1,2]

BI-RADS® - ULTRASOUND FINDINGS

A. Assessment is Incomplete:

Category 0: Incomplete - Need Additional Imaging Evaluation:

There is a finding for which additional imaging evaluation is needed. The is almost always used in a screening situation. In this context, additional imaging evaluation includes the recording of (nonstandard) ultrasound images to supplement the standard images recorded for a screening examination. Note that this does not include repeat real-time scanning by the interpreting physician and/or colleague as long as additional images are not recorded. This respects the unique real-time nature of ultrasound and does not penalize its use.

Under certain circumstances, assessment category 0 may be used in a diagnostic ultrasound report, such as when equipment or personnel are not immediately available to perform a needed concurrent diagnostic mammography examination, or when the patient is unable or unwilling to wait for completion of a full diagnostic examination. Category 0 should not be used for diagnostic breast imaging findings that warrant further evaluation with MRI. Rather, the interpreting physician should issue a final assessment in a report that is made before the MRI examination is performed.

In most circumstances and when feasible, if a screening ultrasound examination is not assessed as negative or benign, the current examination should be compared to prior examination(s), if any exist. The interpreting physician should use judgement on how vigorously to attempt obtaining prior examinations, given the likelihood of success of such an endeavor and the likelihood that comparison will affect the final assessment. In this context, it is important to note that comparison to previous examination(s) may be irrelevant when a finding is inherently suspicious for malignancy.

Category 0 should be used for prior image comparison only when such comparison is required to make a final assessment. When category 0 is used in the context of awaiting prior examinations for comparison, there should be in place a tracking system guaranteeing with 100% reliability that a final assessment will be made within 30 days (preferably sooner), even if prior examinations do not become available. Some breast imaging practices may reasonably choose never to use category 0 in the context of awaiting prior examinations simply because they do not have a 100% reliable tracking system. If an ultrasound examination is assessed as category 0 in the context of awaiting prior examinations and then the prior examinations do become available, an addendum to the initial ultrasound report should be issued, including a revised assessment. For auditing purposes, the revised assessment should replace the initial assessment.

A need for previous studies to determine appropriate management might also temporarily defer a final assessment.

[1]Mammography results are mandated to be reported using Final Assessment categories (Quality Mammography Standards: Final Rule. Federal Register. 1997;62:55988).

[2]Terminology in this table is reflective of the American College of Radiology (ACR). ACR-BI-RADS®--5th Edition. ACR Breast Imaging Reporting and Data System, Breast Imaging Atlas; BI-RADS. Reston VA. American College of Radiology, 2014. For more information, see www.acr.org.

ULTRASOUND ASSESSMENT CATEGORY DEFINITIONS[1,2]

BI-RADS® - ULTRASOUND FINDINGS

B. Assessment is Complete — Final Categories:

Category 1: Negative:

There is nothing to comment on. This is a normal examination.

Category 2: Benign:

As with category 1, this is a "normal" assessment, but here the interpreter chooses to describe a benign finding in the ultrasound report. For example, the interpreter may choose to describe one or more simple cysts, intramammary lymph nodes, postsurgical fluid collections, breast implants, or complicated cysts/probable fibroadenomas that are unchanged for at least 2 or 3 years, while still concluding that there is no sonographic evidence of malignancy. On the other hand, the interpreter may choose not to describe such findings, in which case the examination should be assessed as negative (category 1).

Note that both category 1 and category 2 assessments indicate that there is no sonographic evidence of malignancy. Both should be followed by the management recommendation for routine age-appropriate screening. The difference is that category 2 should be used when describing one or more specific benign sonographic findings in the report, whereas category 1 should be used when no such findings are described (even if such findings are present).

[1]Mammography results are mandated to be reported using Final Assessment categories (Quality Mammography Standards: Final Rule. Federal Register. 1997;62:55988).

ULTRASOUND ASSESSMENT CATEGORY DEFINITIONS[1,2]

BI-RADS® - ULTRASOUND FINDINGS

Category 3: Probably Benign:

Assessment category 3, probably benign, is not an indeterminate category for use simply when the radiologist is unsure whether to render a benign (BI-RADS® category 2) or suspicious (BI-RADS® category 4) assessment, but one that is reserved for specific imaging findings known to have >0% but ≤2% likelihood of malignancy. For ultrasound, there is robust evidence that a solid mass with a circumscribed margin, oval shape, and parallel orientation (most commonly fibroadenoma), and an isolated complicated cyst have a likelihood of malignancy in the defined (≤2%), probably benign range, for which short-interval (6-month) follow-up sonography and then periodic sonographic surveillance may represent appropriate management. Similar data have been reported for clustered microcysts, but these data are less strong because they involve much fewer cases. The use of assessment category 3 for sonographic findings other than these three should be considered only if the radiologist has personal experience to justify a watchful-waiting approach, preferably involving observation of a sufficient number of cases of an additional sonographic finding to suggest a likelihood of malignancy within the defined (≤2%), probably benign range.

This edition of the BI-RADS® Atlas also emphasizes the recommendation that a category 3 assessment should not be made at screening; rather, this should be done only after completion of full diagnostic breast imaging examination. This recommendation is appropriate for screening mammography, for which batch interpretation usually is utilized, because in this setting there is no opportunity to complete the diagnostic workup before interpreting the screening examination. However, screening ultrasound almost always is interpreted online, so a full diagnostic examination also is completed while the patient remains in the breast imaging facility, and a single breast imaging report may be issued that combines the findings of both screening and diagnostic components of the examination. Hence, there is no purpose in recommending against category 3 assessment at screening ultrasound because the diagnostic workup would be completed simultaneously. Note that for auditing purposes, the screening component of a category 3-assessed screening ultrasound examination will be audit-positive, not only because additional nonstandard (diagnostic) images will be recorded but also because a category 3 assessment at screening is defined as being audit-positive.

[1]Mammography results are mandated to be reported using Final Assessment categories (Quality Mammography Standards: Final Rule. Federal Register. 1997;62:55988).

ULTRASOUND ASSESSMENT CATEGORY DEFINITIONS[1,2]

BI-RADS® - ULTRASOUND FINDINGS

For category 3 assessments, the initial short-term follow-up interval is usually 6 months, involving the breast(s) containing the probably benign finding(s). Assuming stability at this 6-month examination, a category 3 assessment again is rendered with a management recommendation for a second short-interval follow-up examination in 6 months. Again assuming stability at this second short-interval follow-up, the examination is once more assessed as category 3, but now the recommended follow-up interval usually is lengthened to 1 year due the already-observed 12-month stability. Note that although the 1-year follow-up coincides with the routine screening interval in the United States, a category 3 assessment is rendered, to indicate that the period of imaging surveillance is still underway. As with surveillance using mammography, after 2 to 3 years of stability, the final assessment category should be changed to benign (BI-RADS® category 2). A benign evaluation may also be rendered before completion of category 3 analysis if, in the opinion of the interpreter, the finding has no chance of malignancy and is thus a category 2.

Category 4: Suspicious:
This category is reserved for findings that do not have the classic appearance of malignancy but are sufficiently suspicious to justify a recommendation for biopsy. The ceiling for category 3 assessment is a 2% likelihood of malignancy, and the floor for category 5 assessment is 95%, so category 4 assessments cover the wide range of likelihood of malignancy in between. Thus, almost all recommendations for breast interventional procedures will come from assessments made using this category. By subdividing category 4 into 4A, 4B, and 4C, it is hoped that patients and referring clinicians will more readily make informed decisions on the ultimate course of action. An example of separating the BI-RADS® assessment category from the management recommendation occurs when a simple cyst, correctly assessed as BI-RADS® 2, undergoes cyst aspiration for pain control.

ULTRASOUND ASSESSMENT CATEGORY DEFINITIONS[1,2]

BI-RADS® - ULTRASOUND FINDINGS

Category 5: Highly Suggestive of Malignancy:
These assessments carry a very high probability (≥95%) of malignancy. This category initially was established to involve lesions for which 1-stage surgical treatment could be considered without preliminary biopsy in an era when preoperative wire localization was the primary breast interventional procedure. Nowadays, given the widespread acceptance of imaging-guided percutaneous biopsy, 1-stage surgery rarely, if ever, is performed. Rather, current oncologic management almost always involves tissue diagnosis of malignancy via percutaneous tissue sampling to facilitate treatment options, such as when sentinel node imaging is included in surgical management or when neoadjuvant chemotherapy is administered prior to surgery. Therefore, the current rationale for using a category 5 assessment is to identify lesions for which any nonmalignant percutaneous tissue diagnosis is considered discordant, resulting in the recommendation for repeat (usually vacuum-assisted or surgical) biopsy. Also note that whereas the fourth edition simply indicated that "appropriate action should be taken" as management for category 5 assessments, the fifth edition provides the more directed management recommendation that "biopsy should be performed in the absence of clinical contraindication." This new text unequivocally specifies tissue diagnosis as the interpreting physician's management recommendation for category 5 assessments, appropriately and effectively transferring the burden of establishing a contraindication to this recommendation to the referring clinician.

Category 6: Known Biopsy-Proven Malignancy:
This category is reserved for examinations performed after biopsy proof of malignancy (imaging performed after percutaneous biopsy but prior to surgical excision), in which there are no abnormalities other than the known cancer that might need additional evaluation.

[1]Mammography results are mandated to be reported using Final Assessment categories (Quality Mammography Standards: Final Rule. Federal Register. 1997;62:55988).

Overview

The average lifetime risk of breast cancer for a woman in the United States has been estimated at 12.3% (ie, 1 in 8 women).[1] In 2013, the American Cancer Society (ACS) estimates, 64,640 cases of female carcinoma in situ of the breast and 234,580 cases of invasive breast cancer (232,340 women and 2240 men) will be diagnosed in the United States.[2] About 40,030 deaths are estimated in 2013.[2] The good news is that mortality from breast cancer has dropped slightly. This decrease has, in part, been attributed to mammographic screening.[3]

The National Comprehensive Cancer Network (NCCN) Clinical Practice Guidelines in Oncology® (NCCN Guidelines®) for Breast Cancer Screening and Diagnosis are for facilitating clinical decision-making. The general public and health care providers need to be aware that mammography or any other imaging modality is not a stand-alone procedure. Neither the current technology of mammography or other imaging tests nor the subsequent interpretation of such tests is foolproof. Clinical judgment is needed to ensure appropriate management. The patient's concerns and physical findings must be taken into account along with imaging results and histologic assessment.

Breast Screening

Breast screening is performed in women without any signs or symptoms of breast cancer so that disease can be detected as early as possible. The components of a breast screening evaluation are dependent on patient age and other factors such as medical and family history, and can include breast awareness (ie, patient familiarity with her breasts), physical examination, risk assessment, screening mammography, and in selected cases, screening breast magnetic resonance imaging (MRI).

A diagnostic breast evaluation differs from breast screening in that it is used to evaluate an existing problem (eg, palpable mass, discharge from the nipple). Although there is preliminary evidence that breast ultrasonography can be a useful screening adjunct to mammography in the evaluation of high-risk women with dense breasts,[4] its use as a screening test is not recommended at this time. These guidelines include ultrasonography in the diagnostic work-up of selected women only based on specific positive findings (see section on "Breast Ultrasonography" on MS-12). Current evidence does not support the routine use of breast scintigraphy (eg, sestamibi scan) or ductal lavage as screening procedures.

History and physical examination

The starting point of these guidelines for screening and evaluating breast abnormalities is a complete medical history followed by the clinical breast examination (CBE). Inspection of the breasts should be performed with the patient in upright and supine positions. Positioning may be done so as to elicit any subtle shape or contour changes in the breast.[5]

Women should be familiar with their breasts and promptly report any change to their health care provider.[6,7] This does not need to be in any specific formalized education program. Data from a large randomized trial of breast self-examination (BSE) screening has shown that instruction in BSE has no effect on reducing breast cancer mortality. In this study, 266,064 women were randomly assigned to either receive instruction in BSE or not.[8] Compliance was encouraged through feedback and reinforcement sessions. After 10 to 11 years of follow-up, 135 breast cancer deaths in the instruction group and 131 in the control group were observed and the cumulative breast cancer mortality rates were not significantly different between the two arms (RR, 1.04; 95% CI,

Discussion Final Progress

0.82–1.33; $P = .72$). The number of benign breast lesions detected in the BSE instruction group was higher than that detected in the control group. Nevertheless, women should be encouraged to be aware of their breasts since this may facilitate detection of interval cancers between routine screenings. The NCCN Panel recommends that the women should be familiar with their breasts and promptly report changes to their health care provider and that periodic, consistent BSE may facilitate breast self-awareness.

Risk Assessment

If the physical examination is negative in an asymptomatic woman, the next decision point is based on risk stratification. Women can be stratified into two basic categories for the purpose of screening recommendations: those at average risk and those at increased risk. Risk assessment is outlined in the NCCN Guidelines for Breast Cancer Risk Reduction. The increased risk category consists of six groups: (1) women with a prior history of breast cancer; (2) women 35 years or older with a 5-year risk of invasive breast carcinoma ≥1.7% by per Gail model; (3) women with a lifetime risk of breast cancer > 20% based on models largely dependent on family history; (4) women who have previously received therapeutic thoracic irradiation (eg, mantle irradiation) between the ages of 10-30 years; (5) women with lobular carcinoma in situ (LCIS) and (6) women with a pedigree suggestive of or with a known genetic predisposition.

Screening Women at Average Risk

For women between ages 25 and under 40 years, the NCCN Panel recommends CBE every 1 to 3 years and breast awareness encouraged.

For women aged 40 years and older, the NCCN Panel recommends annual CBE and screening mammography, and encourages breast awareness. Although controversies persist regarding the benefits and risks of mammographic screening in certain age groups (notably women age 40-49),[9-16] most medical experts reaffirmed current recommendations supporting screening mammography (see section on "Mammographic Evaluation" on MS-8). The recommendation that women at normal risk begin annual mammographic screening at age 40 years is based on a consensus statement from the American Cancer Society (ACS) and National Cancer Institute in 1997 and is supported by the ACS guidelines for breast cancer screening published in 2003,[15] as well as the results and meta-analyses of randomized clinical trials. Women also should be informed about the evidence demonstrating the value of detecting breast cancer early, before symptoms develop. The benefits of early detection include less aggressive treatment and a wide range of treatment options. The evaluation of benefits versus risk strongly supports the value of screening and the importance of adhering to a schedule of regular mammograms.

A second consideration is the time interval of screening in women aged 50-74 years. Whether breast screening should be performed annually or every other year remains controversial.[16] The NCCN Panel believes that the benefits of yearly mammography outweigh the risks of the procedure as breast cancer mortality is lower with annual compared to biennial screening mammograms.[17] Additionally, mammograms can often detect a lesion 2 years before the lesion is discovered by CBE. To reduce mortality from breast cancer, yearly screening is thought to be more beneficial.

There are limited data regarding screening of elderly women because most clinical trials for breast screening have used a cutoff age of 65 or 70 years.[18-20] With the high incidence of breast cancer in the elderly

Printed by Ariel Smits on 10/2/2014 11:42:36 AM. For personal use only. Not approved for distribution. Copyright © 2014 National Comprehensive Cancer Network, Inc., All Rights Reserved.

population, the same screening guidelines used for women who are age 40 or older are recommended. Clinicians should always use judgment when applying screening guidelines. Mammography screening should be individualized weighing its potential benefits/risks in the context of the patients overall health and estimated longevity.[21] If a patient has severe comorbid conditions limiting her life expectancy and no intervention would occur based on the screening findings, then the patient should not undergo screening.[15,21]

Recently Bleyer and Welch published a study on screening mammography and the risk of over-diagnosis of breast cancer.[22] The NCCN panel believes that this study analysis is misleading. The authors used the period 1976 through 1978 to estimate an annual increase of 0.25% in breast-cancer incidence. In fact, 40 years of recorded data shows that the actual increase is 1% per year.[23] In addition, the study analysis did not differentiate between DCIS and invasive cancers. If their analysis had included invasive cancers alone with a valid baseline of an annual increase of 1% and then compared the results with SEER data, they would have found fewer invasive cancers than predicted.

Screening Women at Increased Risk

Women with Prior History of Breast Cancer: These women should be treated according to the surveillance and follow-up recommendations outlined in NCCN Guidelines for Breast Cancer.

Women Aged 35 Years or Older with a 5-Year Risk of Invasive Breast Carcinoma Greater Than or Equal to 1.7%: For women age 35 and older, a risk assessment tool is available to identify those who are at increased risk. The National Cancer Institute (NCI) and the National Surgical Adjuvant Breast and Bowel Project (NSABP) Biostatistics Center has developed a computerized interactive risk-assessment tool based on the modified Gail model[24-28] that can be accessed at: http://www.cancer.gov/bcrisktool/Default.aspx which provides risk projections on the basis of several risk factors for breast cancer. The modified Gail model assesses the risk of invasive breast cancer as a function of age, menarche, age at first live birth or nulliparity, number of first-degree relatives with breast cancer, number of previous benign breast biopsies, atypical hyperplasia in a previous breast biopsy, and race. The model calculates and prints 5-year and lifetime projected probabilities of developing invasive breast cancer and can be used to identify women who are at increased risk. The Gail model should not be used for women with a predisposing gene mutation, a strong family history of breast or ovarian cancer suggestive of a genetic predisposition, women with a prior history of thoracic radiation, or for those with LCIS.

The Gail model was updated using combined data from the Women's Contraceptive and Reproductive Experiences (CARE) study and the Surveillance Epidemiology and End Results (SEER) database, as well as causes of death from the National Center of Health Statistics, to provide a more accurate determination of risk for African-American women.[29] It has also been updated using the data from the Asian American Breast Cancer Study (AABCS) and the SEER database to provide a more accurate risk assessment for Asian and Pacific Islander women in the United States.[30]

Increased risk of developing breast cancer is defined by the modified Gail model for women ≥35 years of age as a 5-year risk of 1.7% or greater. This is the average risk of a 60-year-old woman, which is the median age of diagnosis of breast cancer in the U.S. The 5-year predicted risk of breast cancer required to enter the NSABP Breast Cancer Prevention Trial of tamoxifen versus placebo, as well as the Study of Tamoxifen and Raloxifene (STAR) trial, was 1.7% or greater. As previously mentioned, the modified Gail model risk assessment tool

Printed by Ariel Smits on 10/2/2014 11:42:36 AM. For personal use only. Not approved for distribution. Copyright © 2014 National Comprehensive Cancer Network, Inc., All Rights Reserved.

also provides an estimate of a woman's lifetime risk of breast cancer. However, this estimate is based on the Gail model risk criteria which differ from criteria used in risk assessment models predominantly based on family history (see below); lifetime breast cancer risk as determined by the Gail model is not used in these guidelines to determine whether a woman is eligible for screening breast MRI.

For a woman aged 35 years or older with a 5-year risk ≥1.7%, the NCCN Panel encourages breast awareness and recommends CBE every 6 to 12 months and annual mammography. In addition, according to the NCCN Panel, women in these groups should be asked to consider risk reduction strategies in accordance with the NCCN Guidelines for Breast Cancer Risk Reduction.

Women with LCIS: A diagnosis of LCIS is associated with estimated risks of 10%-20% for the subsequent development of cancer in either breast over the next 15 years, although it is not in itself considered to be a site of origin for cancer.[31,32]

For women with LCIS, the NCCN Panel encourages breast awareness and recommends CBE every 6 to 12 months and annual mammography beginning at diagnosis. In addition, according to the NCCN Panel, women in these groups should be asked to consider risk reduction strategies in accordance with the NCCN Guidelines for Breast Cancer Risk Reduction.

Women with a Lifetime Risk of Breast Cancer >20% based on models largely dependent on family history: A lifetime risk of breast cancer of >20% as assessed by models based largely on family history is another risk threshold used in the guidelines to identify a woman as a potential candidate for risk reduction strategies, as well as to direct screening strategies. According to the ACS guidelines for breast screening, MRI may be performed as an adjunct to mammography[33] in a high risk woman if her lifetime risk of breast cancer is approximately 20% or greater based on models that rely mainly on family history. A cancer genetic professional should be involved in determining the lifetime risk of the individual based on models dependent on family history. These include Claus,[34] Tyrer-Cuzick,[35] and other models[36-38]. BRCAPRO[39] and Breast and Ovarian Analysis of Disease Incidence and Carrier Estimation Algorithm (BOADICEA)[40] are more commonly used to estimate the risk based of *BRCA* mutations. Strong genetic association between breast and ovarian cancer has been demonstrated in some families by linkage analyses.

For a woman with a >20% lifetime risk of breast cancer based on models largely dependent on family history, the NCCN Panel encourages breast awareness and beginning at age 30, the NCCN Panel recommends CBE every 6 to 12 months and annual mammography. In addition, in accordance with the ACS guidelines,[33] the NCCN Panel recommends considering annual breast MRI for women who have a lifetime risk of breast cancer >20% based on models that rely mainly on family history. According to the NCCN Panel, women in this group should be asked to consider risk reduction strategies in accordance with the NCCN Guidelines for Breast Cancer Risk Reduction.

Women Who Have Received Prior Thoracic Irradiation Between the Ages of 10 to 30 Years: Results from several studies have demonstrated that women who received thoracic irradiation in their second or third decade of life have a substantially increased risk of developing breast cancer by age 40 years.[41-46] For example, in the Late Effects Study Group trial, the overall risk of breast cancer associated with prior thoracic irradiation at a young age was found to be 56.7–fold (55.5-fold for female patients) greater than the risk of breast cancer in

Printed by Ariel Smits on 10/2/2014 11:42:36 AM. For personal use only. Not approved for distribution. Copyright © 2014 National Comprehensive Cancer Network, Inc., All Rights Reserved.

the general population.[42,45] In that study, the relative risk of female breast cancer according to follow-up interval was: 0 at 5-9 years; 71.3 at 10-14 years; 90.8 at 15-19 years; 50.9 at 20-24 years; 41.2 at 25-29 years; and 24.5 at > 29 years.[45] Results from a case-control study of women treated with thoracic radiation at a young age for Hodgkin lymphoma indicated that the estimated cumulative absolute risk of breast cancer at 55 years of age was 29.0% (95% CI, 20.2%-40.1%) for a woman treated at 25 years of age with at least 40 Gy of radiation and no alkylating agents.[47] Although there is a concern that the cumulative radiation exposure from mammography in a young woman may itself pose a risk for cancer, it is felt that the benefit of early detection of breast cancer in this high-risk group would outweigh the potential side effect. Findings from a survey of breast screening practices in this population of patients suggest that a sizable segment of this group is not undergoing regular mammographic screening.[48]

For women aged 25 years and older who have received prior thoracic irradiation, the NCCN Panel recommends encouraging breast awareness, annual mammograms, annual MRI as an adjunct to mammograms[49] and CBE every 6 to 12 months be initiated 8 to 10 years after radiation exposure or 40, whichever comes first.[50]

For women younger than 25 years who have received prior thoracic irradiation, the NCCN Panel recommends encouraging breast awareness, counseling on risk, and an annual CBE starting 8-10 years after the radiation therapy.

Women with a Pedigree Suggestive Of or With a Known Genetic Predisposition: Accurate family history information is needed to adequately assess a woman's breast cancer risk. Familial cancers share some but not all features of hereditary cancers. For example, although familial breast cancers occur in a given family more frequently than expected on the basis of statistics, they generally do not exhibit inheritance patterns or onset age consistent with hereditary cancers. Familial breast cancers may be associated with chance clustering, genetic variations in lower-penetrance genes, a shared environment, small family size, and/or other factors.

The NCCN Guidelines for Genetic/Familial High-Risk Assessment include a recommendation for referral to a cancer genetics professional for further evaluation for an individual who has either a personal history or a close family history meeting any of the following criteria (see NCCN Guidelines for Genetic/Familial High-Risk Assessment).

In the statement on Genetic Testing for Cancer Susceptibility from the American Society of Clinical Oncology (ASCO) updated in 2003, genetic counseling/testing is recommended when there is: (i) a personal or family history suggesting genetic cancer susceptibility (ii) the test can be adequately interpreted and (iii) the results will aid in the diagnosis or influence the medical or surgical management of the patient or family members at hereditary risk of cancer.[51] Additional genetic testing criteria are included in the NCCN Guidelines for Genetic/Familial High-Risk Assessment. Genetic testing should be done only in the setting of pre-and post-test genetic counseling.

The manifestations of hereditary syndromes are often variable in individuals (e.g., age of onset, tumor site, and number of primary tumors). The risk of developing breast cancer in individuals with one of these hereditary syndromes depends upon numerous variables including the gender and age of the individual. Therefore there is variation in screening recommendations for different genetic syndromes. The NCCN Guidelines for Genetic/Familial High-Risk Assessment lists screening recommendations for common hereditary

Printed by Ariel Smits on 10/2/2014 11:42:36 AM. For personal use only. Not approved for distribution. Copyright © 2014 National Comprehensive Cancer Network, Inc., All Rights Reserved.

syndromes that put the individuals at increased risk for breast and ovarian cancer.

Hereditary breast and ovarian cancer syndrome (HBOC): It has been estimated that over 90% of early onset cancers in families with both breast and ovarian cancers are caused by mutation(s) in the *BRCA1* or *BRCA2* genes.[52] Hence, the degree of clinical suspicion for breast cancer in an individual with *BRCA* mutation or someone with a family history of both breast and ovarian cancer should be very high. The emphasis on initiating screening considerably earlier than standard recommendations is a reflection of the early age of onset seen in hereditary breast/ovarian cancer.[38,53-55] The overall sensitivity of screening mammography was reported to be only 33% in a study of women with suspected or known *BRCA1/2* mutations who were more likely to be younger and to have dense breasts.[56] Other reasons for the low sensitivity of mammography in women with *BRCA1/2* mutations include an increased likelihood of developing tumors with more benign mammographic characteristics (e.g., less likely to appear as a spiculated mass).[57] The ACS recommends annual MRI as an adjunct to screening mammogram.[33]

The risk from radiation exposure due to mammography in young women with an inherited cancer predisposition is unknown, and there is some concern about whether this genetic factor may increase sensitivity to irradiation. A recent study of *BRCA1/BRCA2* mutation carriers showed that lifetime mammogram exposure was not associated with an increased risk in breast cancer when the overall group was considered; however, a small increase in risk was seen when only those women with *BRCA1* mutations were evaluated.[58] Because the lifetime risk of breast cancer in BRCA1 or BRCA2 mutation carriers is estimated to be 3-6 fold greater (40% to 80% range)[59] than in the general population, the benefit of screening may justify the radiation exposure.

For a woman with a pedigree suggestive of a genetic predisposition or who is a carrier of a *BRCA1/2* mutation, the NCCN Panel recommends encouraging breast awareness and CBE every 6-12 months starting at age 25 years. The NCCN Panel also recommends screening women with annual mammograms and breast MRI as an adjunct to mammogram (MRI performed preferably on day 7-15 of menstrual cycle for premenopausal women) starting at age 25 years or on an individualized timetable based on the earliest age of cancer onset in family members. According to the NCCN Panel, women in this group should be offered risk reduction counseling and the opportunity to consider risk reduction strategies following multidisciplinary consultation in accordance with the NCCN Guidelines for Breast Cancer Risk Reduction.

Male carriers of a *BRCA* gene mutation also have a greater risk for cancer susceptibility.[60] In one study of 26 high-risk families with at least one case of male breast cancer, 77% demonstrated a *BRCA2* mutation.[52] However, among males with breast cancer who were not selected on the basis of family history, only 4%-14% tested positive for a germline *BRCA2* mutation.[61,62] For males with a *BRCA2* mutation, the risk of breast cancer by age 80 years has been estimated at 6.9%.[63] A mutation in the *BRCA2* gene, accounts for about 1 in10 breast cancers in men. *BRCA1* mutations can also cause breast cancer in men, but the risk is not as high as it is for mutations in the *BRCA2* gene. In contrast, for men without such a mutation, the lifetime risk of breast cancer has been estimated at about 1/10th of 1% (1 in 1,000).[64]

The NCCN Panel recommendations for men positive for a *BRCA1/2* mutation include breast awareness and a CBE every 6-12 months starting at age 35. Baseline mammography should be considered at age 40 years, followed by annual mammography for those men with

gynecomastia or parenchymal/glandular breast density on baseline study.

Mammographic Screening

A screening mammogram typically involves 2 x-ray images of each breast (ie, one taken from the top [craniocaudal] of the breast and the other from the side [mediolateral oblique]). Randomized clinical trials have demonstrated that screening mammography lowers the rate of death from breast cancer,[5,65] with a reported overall sensitivity of about 75%.[66] Nevertheless, the overall sensitivity of screening mammography was reported to be only 50% in a study of women with at least heterogeneous dense tissue,[67] and 33% in a study of women with suspected or known BRCA mutations who were more likely to be younger and to have dense breasts.[56]

Technical aspects of mammography can affect the quality of screening results. Digital mammography differs from conventional film mammography in that the former generates an electronic image of the breast and allows for computer storage and manipulation. Four large scale trials have compared these two procedures although the designs and findings of these trials differ.[68-73] In a study of 49,528 women who underwent both film and digital mammography, no difference was seen in the overall accuracy of the two procedures.[68,69] However, digital mammography was significantly more accurate in younger women with dense breasts, and there was a nonsignificant trend toward improved accuracy of film mammography in women aged 65 years and older. In another trial of women aged 45 to 69 years randomly assigned to film or digital screening mammography, the latter procedure was shown to result in a higher rate of cancer detection.[70] Other outstanding issues related to these two procedures include possible differences in recall rates, and cost and availability issues.

Dense breast tissue as measured by mammography is increasingly recognized as an important risk factor for breast cancer.[74,75] Although there are some studies supporting the use of ultrasound for breast cancer screening as an adjunct to mammography for high risk women with dense breast tissue,[67] the NCCN Panel however cautions that there is insufficient evidence to support routine supplemental screening in women with dense breasts and no other risk factors.

Mammographic Assessment Category Definitions:
Mammographic results are mandated to be reported using Final Assessment Categories [Breast Imaging Reporting and Data System (BI-RADS®)] categories developed by the American College of Radiology [Mammography Quality Standards Act, 1997][76] The purpose of the Final Assessment Category definitions is to create a uniform system of reporting mammography results with a recommendation associated with each category. The fourth edition of BI-RADS® is adopted in these guidelines. In this edition, substantive changes have been incorporated and category 6 has been added.[77]
BI-RADS® assessment categories apply to an individual imaging method if only one type of imaging is done (eg, mammography), but if multiple imaging modalities are used (e.g. additional ultrasonography and MRI), the BI-RADS® categories represent the cumulative findings of the examinations that were performed. Therefore, the overall BI-RADS® assessment category can change depending on subsequent imaging findings (ie, the BI-RADS® assessment category given following a mammographic study may increase, decrease, or remain the same upon diagnostic ultrasonography or MRI). In the event that multiple abnormalities are identified on imaging, the overall final BI-RADS® assessment category is based on the most worrisome findings present. After the mammographic evaluation is completed, the results are classified according to one of the following BI-RADS® categories[76]:

Printed by Ariel Smits on 10/2/2014 11:42:36 AM. For personal use only. Not approved for distribution. Copyright © 2014 National Comprehensive Cancer Network, Inc., All Rights Reserved.

- ***Category 1 - Negative:*** This is a negative mammogram. The breasts are symmetric, and there are no masses, architectural distortion or suspicious calcification.
- ***Category 2 - Benign Finding(s):*** This is also a negative mammogram, but there may be an actual finding that is benign. The typical case scenarios include benign-appearing calcifications, such as a calcifying fibroadenoma, an oil cyst, or a lipoma. The interpreter may also choose to describe intramammary lymph nodes, vascular calcification, implants or architectural distortion clearly related to prior surgery while still concluding that there is no mammographic evidence of malignancy.
- ***Category 3 - Probably Benign Finding(s) – Short-Interval Follow-up Suggested:*** This is a mammogram that is usually benign. Close monitoring of the finding is recommended to ensure its stability. The risk of malignancy is estimated to be less than 2%.
- ***Category 4 - Suspicious Abnormality –Biopsy Should Be Considered:*** These lesions fall into the category of having a wide range of probability of being malignant but are not obviously malignant mammographically. The risk of malignancy is widely variable and is greater than that for category 3 but less than that for category 5.
- ***Category 5 - Highly Suggestive of Malignancy-Appropriate Action Should Be Taken***: These lesions have a high probability (≥ 95%) of being a cancer. They include spiculated mass or malignant-appearing pleomorphic calcifications, etc.
- ***Category 6 - Known Biopsy - Proven Malignancy-Appropriate Action Should Be Taken:*** This category is reserved for breast lesions identified on the imaging study with biopsy proof of malignancy but prior to definitive therapies.

There is also another BI-RADS® category - Category 0 – which represents an incomplete assessment.

Category 0: Needs Additional Imaging Evaluation and/or Prior Mammograms For Comparison. This category is almost always used in the context of a screening situation, if a finding requiring additional evaluation has been identified. A recommendation for additional imaging evaluation may include, but is not limited to spot compression, magnification, special mammographic views and ultrasound. Under certain circumstances, this category may be used after a full mammographic workup. Whenever possible, if the study is not negative and does not contain a typical benign finding, the current examination should be compared to previous studies. The radiologist should use judgment on how vigorously to attempt obtaining previous studies. The practice guideline for the performance of screening and diagnostic mammography from the American College of Radiology can be accessed at: http://www.acr.org/SecondaryMainMenuCategories/quality_safety/guidelines/breast/Screening_Diagnostic.aspx.

NCCN Recommendations after Mammographic Evaluation

For patients with mammograms classified as BI-RADS® categories 1 and 2, in which the mammogram is completely normal or the finding is benign mammographically, the NCCN Panel recommends routine screening, based on age and risk of breast cancer. When screening mammography reveals an abnormal finding, the radiologist should attempt to obtain any prior mammograms. This is most important for lesions that are of low suspicion mammographically. If, after a comparison of films, there is still a questionable area that is not clearly benign, then a diagnostic mammogram (see section on "Diagnostic

Printed by Ariel Smits on 10/2/2014 11:42:36 AM. For personal use only. Not approved for distribution. Copyright © 2014 National Comprehensive Cancer Network, Inc., All Rights Reserved.

Mammography" on MS-11), with or without ultrasonography (see section on "Breast Ultrasonography" on MS-12) should be performed.

For NCCN recommendations and follow-up of patients with mammograms categorized as BI-RADS® 0 and 3 or higher, see section on "Diagnostic Evaluation for Positive Findings" on MS-11.

Breast Magnetic Resonance Imaging Screening

The sensitivity of breast MRI at detecting breast cancer is higher than the sensitivity of mammography, although the specificity of the former procedure is lower, resulting in a higher rate of false-positive findings.[78] In addition, microcalcifications are not detectable with MRI,[79,80] and the issue of whether breast MRI screening impacts survival has not been addressed in randomized clinical trials. Therefore, careful patient selection for additional screening with MRI is needed. Although current evidence does not support the use of breast MRI to screen women at average risk of breast cancer, benefits of screening MRI for women with prior thoracic radiation, and those with a genetic predisposition for breast cancer have been demonstrated in several studies,[49,56,81-87] and the ACS has published guidelines recommending use of breast MRI as an adjunct to screening mammography in certain populations of women at high risk of breast cancer.[33] Nevertheless, a high false-positive rate for screening MRI was identified in several these studies. For example, in one study of high-risk women, many of whom were young and had very dense breast tissue, screening MRI led to 3 times as many benign biopsies as mammography.[54]

A single retrospective study of asymptomatic women with atypical hyperplasia or LCIS enrolled in a high-risk screening program has evaluated use of MRI in this population.[88] Approximately half of the women underwent screening with mammography and MRI whereas the other half was screened with mammography alone. For those undergoing both types of screening, breast cancer was detected by MRI in 4% of patients with LCIS who had negative mammogram results. MRI screening did not impact the rate of cancer detection in women with atypical hyperplasia. Women who underwent screening with MRI were more likely to be younger and premenopausal, and to have a stronger family history of breast cancer than those who were evaluated by mammography alone. However, only one woman with cancer detected by MRI following a negative mammography finding had reported a family history of breast cancer, and no difference was seen in the percentages of patients who ultimately developed cancer in the 2 groups.

The NCCN Panel recommends an annual MRI as an adjunct to screening mammogram and CBE for the following groups with increased risk of breast cancer: 1) Women with a pedigree suggestive of or known genetic predisposition for breast cancer, starting at age 25 for HBOC, or individualized based on earliest age of onset in the family and 2) Women who received with thoracic radiation therapy between ages 10 to 30 years (MS-6). MRI may be considered as an adjunct to screening mammogram for women with a >20% lifetime risk of breast cancer as defined by models largely based on family history as described in the ACS guidelines.[40]

Criteria for the performance/interpretation of high quality breast MRI include: a dedicated breast coil, radiologists experienced in breast MRI; and the ability to perform MRI-guided needle sampling and/or wire localization of MRI-detected findings. Breast MRI Guidelines from the European Society of Breast Imaging include detailed descriptions of the technical aspects of the use of breast MRI.[78] The American College of Radiology has also published guidelines for the performance of contrast-enhanced MRI of the breast.[89]

Diagnostic Evaluation for Positive Findings

Additional evaluations in selected patients with positive findings can include diagnostic mammography, ultrasonography, diagnostic breast MRI, and tissue sampling.

Diagnostic Mammography

Screening mammography which consists of 2 standard X-ray images of each breast differs from diagnostic mammography in that the latter is used to evaluate a patient with a positive clinical finding—such as a breast lump or an abnormal screening mammogram. A diagnostic mammogram includes additional views, such as spot compression views or magnifications views, to investigate the finding in question.

NCCN Recommendations for Mammogram BI-RADS® Assessment Categories 0, 3, 4, 5 and 6

For BI-RADS® category 0 (need additional imaging evaluation), the diagnostic work-up includes comparison to prior films and/or diagnostic mammogram with or without ultrasound scan.

For BI-RADS® category 3 (probably benign), diagnostic mammograms at 6 months, then every 6 to 12 months for 2 to 3 years are appropriate. At the first 6-month follow-up, a unilateral mammogram of the index breast is performed. The 12-month study would be bilateral in women aged 40 years and older so that the contralateral breast is imaged at the appropriate yearly interval. Depending on the level of concern, the patient is then followed, either annually with bilateral mammograms or every 6 months for the breast in question, for a total of 2 to 3 years.

If the lesion remains stable or resolves mammographically, the patient resumes routine screening intervals for mammography. If, in any of the interval mammograms, the lesion increases in size or changes its benign characteristics, a biopsy is then performed. The exception to this approach of short-term follow-up is when a return visit is uncertain or the patient is highly anxious or has a strong family history of breast cancer. In those cases, initial biopsy with histologic sampling may be a reasonable option.

For BI-RADS® categories 4 and 5, tissue diagnosis using core needle biopsy (preferred) or needle localization excisional biopsy with specimen radiograph is necessary. When a needle biopsy (aspiration or core needle biopsy) is performed, concordance between the pathology report and the imaging finding must be obtained.[77,90] For example, a negative needle biopsy associated with a spiculated category 5 mass is discordant and clearly would not be an acceptable diagnosis. When the pathology and the imaging are discordant, the breast imaging should be repeated and/or additional tissue sampled or excised; surgical excision is recommended when pathology/image remain discordant. Women with a benign result exhibiting pathology/image concordance should be followed with mammography every 6-12 months for 1-2 years before returning to routine screening.

For BI-RADS® category 6 (proven malignancy), the patient should be managed according to the NCCN Guidelines for Breast Cancer.

Breast Ultrasonography

Mammography and ultrasound are complementary imaging methods for diagnosing breast cancer. However, breast ultrasonography does not detect most microcalcifications.[56,67,91-93]

Initial diagnostic imaging with breast ultrasonography is recommended as the preferred option for women aged < 30 years presenting with a palpable mass or asymmetric thickening/nodularity. Breast

Printed by Ariel Smits on 10/2/2014 11:42:36 AM. For personal use only. Not approved for distribution. Copyright © 2014 National Comprehensive Cancer Network, Inc., All Rights Reserved.

ultrasonography is recommended for women ≥ 30 years of age with a palpable mass and a diagnostic mammogram assessed as BI-RADS® 1-3, and as an adjunct to diagnostic mammography for women in this age group with a finding of asymmetric thickening/nodularity. In addition, breast ultrasonography should be considered as an adjunct to mammography for those of all ages with skin changes consistent with serious breast disease or with spontaneous nipple discharge in the absence of a palpable mass, and as a possible option for women with a BI-RADS® category 0 screening mammographic assessment. Consideration of follow-up ultrasound testing is also recommended when initial ultrasound findings of a solid mass are classified as a probably benign finding, or when biopsy results are found to be benign and image concordant. Ultrasound-guided biopsy is included in the guidelines for women with a complex cyst or a persistent mass following cyst aspiration.

Ultrasonographic Assessment Category Definitions

After the ultrasonographic evaluation is completed, the results are classified according to one of the following BI-RADS® categories:[94]

- ***Category 0 – Needs Additional Imaging Evaluation:*** This represents an incomplete assessment. A finding for which additional evaluation is needed. If ultrasound is the initial study, mammography might be indicated, or if mammography and ultrasound findings are nonspecific, MRI might be appropriate.
- ***Category 1 - Negative:*** This is a negative ultrasound. No abnormalities are detected.
- ***Category 2 - Benign Finding(s):*** This is also a negative ultrasound, but there may be an actual finding that is benign. Included in this category are simple cysts (see section below on "Breast cysts") and breast implants.
- ***Category 3 - Probably Benign Finding(s) - Short-Interval Follow-up Suggested:*** This is a ultrasound that is usually benign. Close monitoring of the finding is recommended to ensure its stability. The risk of malignancy is estimated to be less than 2%. Fibroadenomas and nonpalpable complicated cysts and clustered microcysts might be placed in this category for short-interval follow-up (see section below on "Breast cysts")
- ***Category 4 - Suspicious Abnormality –Biopsy Should Be Considered:*** These lesions fall into the category of having a wide range of probability of being malignant but are not obviously malignant ultrasonographically. The risk of malignancy is widely variable and is greater than that for category 3 but less than that for category 5. A complex cyst would be included in this group (see section below on "Breast cysts").
- ***Category 5 - Highly Suggestive of Malignancy-Appropriate Action Should Be Taken:*** These lesions have a high probability (≥ 95%) of being a cancer.
- ***Category 6 - Known Biopsy - Proven Malignancy-Appropriate Action Should Be Taken:*** This category is for breast lesions identified on the imaging study with biopsy proof of malignancy but prior to definitive therapies.

Breast Cysts

Breast cysts are either classified as simple or non-simple cysts, with the latter class being subdivided into complicated cysts and complex cysts (see Table 1 for definitions).

Simple cyst

A cyst meeting all criteria of a simple cyst is considered to be benign,[67,95] if the clinical findings and ultrasonographic results are concordant. Therapeutic fluid aspiration can be considered if clinical

Version 1.2014, 05/30/14 © National Comprehensive Cancer Network, Inc. 2014, All rights reserved. The NCCN Guidelines® and this illustration may not be reproduced in any form without the express written permission of NCCN®.

symptoms persist, and these patients can be followed with routine screening. Cytologic examination is recommended if bloody fluid is obtained.

Non-simple Cysts

A complicated non-simple cyst is associated with a low risk of malignancy (<2%).[67,96-98] Options for managing complicated cysts are either aspiration or short-term follow-up with physical examination and ultrasonography with or without mammography every 6-12 months for 2-3 years to assess stability. There may be variability on the follow-up interval based on the level of suspicion. The option of aspiration may be more strongly considered in a patient likely to be lost to follow-up. Complicated cysts which increase in size should be biopsied. As with simple cysts, cytologic analysis of fluid aspirated from a complicated cyst is required only if bloody fluid is obtained. In the event of a persistent mass, a biopsy is needed.

For cysts which resolve following aspiration but are characterized by bloody fluid, the NCCN Panel recommends placement of a tissue marker followed by cytologic evaluation of fluid. Follow-up of a positive finding includes percutaneous vacuum-assisted biopsy or excision. If findings are negative, physical examination with or without ultrasound/mammogram every 6-12 months for 1-2 years is recommended to assess stability. Repeat imaging (ultrasound with or without mammogram) is recommended for a recurrent mass whereas routine screening is the recommended strategy when follow-up examinations are negative.

Complex cysts have a relatively high risk of malignancy (eg, 14% and 23% in 2 studies).[67,97-100] Hence, these cysts should be evaluated by tissue biopsy.

Diagnostic Breast MRI

MRI can also play a role in the diagnostic setting. For patients with skin changes consistent with serious breast disease, consideration of breast MRI is included in the guidelines for those with benign biopsy of skin or nipple following BI-RADS® category 1-3 assessment. Since a benign skin punch biopsy in a patient with a clinical suspicion of inflammatory breast cancer (IBC) does not rule out malignancy, further evaluation is recommended. There is evidence that certain MRI features may facilitate diagnosis of IBC.[101]

Breast Tissue Biopsy

Breast biopsy is recommended if diagnostic mammogram and/or ultrasound findings are suspicious or highly suggestive of malignancy.

Fine Needle Aspiration (FNA) Biopsy

An FNA biopsy involves use of a smaller-bore needle to obtain cytologic samples from a breast mass. Advantages of FNA biopsy include its minimally invasive methodology and low cost,[102,103] whereas the need for pathologists with specific expertise in the interpretation of test results and the necessity of performing a follow-up tissue biopsy when atypia or malignancy is identified are disadvantages of the procedure. FNA of nonpalpable lesions can be performed under imaging guidance (eg, ultrasound), although there is evidence to indicate that both core-needle biopsy and excisional biopsy are more accurate than FNA in the evaluation of nonpalpable breast lesions.[104,105]

Core Needle Biopsy

A core needle biopsy, also called percutaneous core breast biopsy, is an automated procedure that typically involves obtaining multiple cores of solid tissue using standard techniques.[106,107] It can be performed under imaging guidance (eg, stereotactic [mammographic] or ultrasound). Advantages of breast core needle biopsy include increased

Printed by Ariel Smits on 10/2/2014 11:42:36 AM. For personal use only. Not approved for distribution. Copyright © 2014 National Comprehensive Cancer Network, Inc., All Rights Reserved.

accuracy over FNA when the procedure is performed in situations where no mass is palpable and an ability to obtain tissue samples of sufficient size so as to eliminate the need for a follow-up biopsy to confirm malignancy.[108] In some situations, the core needle biopsy is performed under vacuum assistance which can facilitate collection of adequate tissue from a breast lesion without the need for multiple needle insertions.[109,110] Clip placement is done at the time of core needle biopsy so that the radiologist can identify the location of the lesion in the event that it is entirely removed or disappears during neoadjuvant treatment of a breast cancer.[111] With a few exceptions, core needle biopsy is preferred in the NCCN Guidelines over surgical excision when tissue biopsy is required. According to the NCCN panel, surgical excision is appropriate if unable to perform core needle biopsy.

Excisional Biopsy

An excisional biopsy involves removal of the entire breast mass or suspicious area of the breast by a surgeon in an operating room setting. Needle or wire localization is done by the radiologist immediately prior to an excisional biopsy of a nonpalpable mammographic or sonographic finding to direct surgical excision. The wire localization may bracket a lesion that had a clip placed in it at the time of the core needle biopsy.[111]

Excisional biopsy is included in the NCCN Guidelines as an option when tissue biopsy is required. Although excisional biopsy is a more invasive method than core needle biopsy and requires needle localization when lesions are not palpable, there are situations where larger tissue samples may be needed. In most cases, excisional biopsy is recommended following diagnosis by core biopsy of an indeterminate lesion, atypical hyperplasia, LCIS, or a benign and image discordant lesion. Other histologies that may require additional tissue include mucin-producing lesions, potential phyllodes tumor, papillary lesions, radial scars or other histologies of concern to the pathologist.[100,103,108,112]

Support for this recommendation includes results of studies demonstrating an underestimation of cancer when atypical hyperplasia and LCIS are diagnosed by CNB.[113-118] However, there are situations (eg, select cases of LCIS, ALH, papillomas, fibroepithelial lesions, radial scars) where close observation may be substituted for excisional biopsy in select patients.[103,112,119-125]

Physical Examination

Symptomatic or positive findings on physical examination include: palpable mass in the breast, nipple discharge without a palpable mass, asymmetric thickening or nodularity, and skin changes

NCCN Recommendations for Positive Findings on Physical Exam

Palpable Mass in the Breast

A palpable mass is a discrete lesion that can be readily identified during a physical exam. The guidelines separate the evaluation of women with the palpable mass into two age groups: women aged 30 years or older and women under 30 years of age.

Women with palpable mass aged 30 years or older:

The main difference in the guidelines for evaluating a palpable mass in women age 30 or older compared with younger women is the increased degree of suspicion of breast cancer. The initial evaluation begins with a bilateral diagnostic mammogram. Observation without further evaluation is not an option in these women. There are some clinical circumstances such as mass with low clinical suspicion or suspected simple cyst, in which ultrasound would be preferred and may suffice for women 30-39 years of age.[126] After the mammographic assessment, the abnormality is placed in one of the six BI-RADS® categories.

Printed by Ariel Smits on 10/2/2014 11:42:36 AM. For personal use only. Not approved for distribution. Copyright © 2014 National Comprehensive Cancer Network, Inc., All Rights Reserved.

For women with BI-RADS® categories 4 and 5, assessment of the geographic correlation between clinical and imaging findings is indicated. If the imaging findings correlate with the palpable findings, the NCCN Panel recommends tissue evaluation through core needle biopsy. The NCCN Panel notes that fine needle aspiration (FNA) and core needle biopsy are both valuable. However, FNA requires cytologic expertise. When a core needle biopsy is utilized, concordance between the pathology report and imaging finding must be obtained. If there is a lack of geographic correlation between clinical and imaging findings, further evaluation is as recommended for BI-RADS® categories 1, 2, or 3.

For BI-RADS® categories 1, 2, and 3, the next step is to obtain an ultrasound and the findings are discussed below under "Ultrasound findings".

Ultrasound findings:

If the solid lesion found on the ultrasound is suspected to be probably benign (ie, BI-RADS® 3), the options are: observation, or core needle biopsy. Observation may be elected only if there is low clinical suspicion, in which case a physical examination with or without ultrasound or mammogram is recommended every 6 months for 2-3 years to assess stability. If the option of core needle biopsy is elected, and the result is benign and is concordant with the imaging results, the NCCN Panel recommends a physical examination every 6 to 12 months, with or without ultrasound or mammogram, for 1 to 2 years to ensure that the lesion is stable. Routine breast screening is recommended if the lesion is stable. If the solid lesion increases in size, the NCCN Panel recommends surgical excision. If the diagnosis by core biopsy is an indeterminate lesion, atypical hyperplasia, LCIS, or a benign and image discordant lesion, the NCCN Panel recommends surgical excision. Mucin-producing lesions, potential phyllodes tumor, papillary lesions, radial scars or other histologies of concern to the pathologist may also require excisional biopsy. Select patients (ie, some patients with atypical hyperplasia, LCIS, fibroepithelial lesions, radial scars etc) may be suitable for monitoring in lieu of surgical excision.

If the ultrasound evaluation reveals the mass to be consistent with an asymptomatic simple cyst (ie, BI-RADS® 2), the NCCN Panel recommends routine screening. However, it is important that there is concordance between the CBE and the ultrasound results before recommending routine screening. Therapeutic aspiration of such a simple cyst can be performed if persistent clinical symptoms are present.

If the cyst on the ultrasound is classified as a complicated non-simple cyst, options include aspiration or short-term follow-up (BI-RADS® 3). For short term follow-up, the NCCN Panel recommends physical examination and ultrasound with or without mammography every 6-12 months for 2-3 years to assess stability. A tissue biopsy should be performed for a complicated cyst which increases in size during follow-up.

Alternatively, aspiration may be performed. If blood-free fluid is obtained on aspiration, the mass resolves, and cytology results are negative, the NCCN Panel recommends that the patient should return to routine screening. If the mass first resolves after aspiration and then recurs, then repeat assessment with ultrasound or surgical excision if warranted. If the mass persists after aspiration, the NCCN Panel recommends ultrasound with image-guided biopsy. Surgical excision is appropriate if unable to perform core needle biopsy.

For cysts that resolve following aspiration but are characterized by bloody fluid, the NCCN Panel recommends placement of a tissue

Discussion updated 10/1/2013

Printed by Ariel Smits on 10/2/2014 11:42:36 AM. For personal use only. Not approved for distribution. Copyright © 2014 National Comprehensive Cancer Network, Inc., All Rights Reserved.

marker followed by cytologic evaluation of fluid. Follow-up of a positive finding includes percutaneous vacuum-assisted biopsy or excision. If findings are negative, physical examination with or without ultrasound/mammogram every 6-12 months for 1-2 years is recommended to assess stability. Repeat imaging is recommended for a recurrent mass whereas routine screening is the recommended strategy when follow-up examinations are negative. The NCCN Panel recommends a tissue biopsy for cysts classified as complex (BI-RADS® 4).

If the ultrasound with image-guided biopsy findings are benign and image concordant (BI-RADS® 1), physical exam with or without ultrasound or mammogram every 6-12 months for 1-2 years is recommended. If the mass increases in size, surgical excision should be repeated, with a routine breast screening recommended if the mass remains stable. If the ultrasound and image guided biopsy findings are interpreted as benign and image discordant or indeterminate or atypical hyperplasia or LCIS or other (ie, mucin-producing lesions, potential phyllodes tumor, papillary lesions, radial scar or other histologies of concern to the pathologist), surgical excision is recommended, although select patients (ie, some patients with atypical hyperplasia, LCIS, fibroepithelial lesions, radial scars, etc.) may be suitable for monitoring in lieu of surgical excision (see section on "Excisional Biopsy" on MS-14). Multifocal/extensive LCIS involving 4 terminal ductal lobular units on a core biopsy may be associated with increased risk of invasive cancer on surgical excision.

If the mass has been surgically excised and proven to be benign, the patient undergoes routine screening. If the mass is classified as atypical hyperplasia or LCIS, routine breast screening along with risk reduction therapy according to the NCCN Guidelines for Breast Cancer Risk Reduction is recommended.

If no ultrasonographic abnormality is detected (BI-RADS® 1), tissue biopsy (core needle biopsy or excision) or observation at 3-6 months intervals for 1-2 years should be considered to assess stability. If the lesion increases in size, tissue sampling should be repeated, whereas routine breast screening is recommended if the lesion remains stable.

Malignant findings either on ultrasound with image guided biopsy or surgical excision should be treated according to the NCCN Guidelines for Breast Cancer.

Women with palpable mass under 30 years of age:
The preferred option for initial evaluation of a palpable mass is to proceed directly to ultrasound with or without mammogram.[126] From this point, the decision tree for women under 30 years of age is almost identical to the pathway for older women. The main difference is consideration of a diagnostic mammogram in only some situations for the younger women. Because the degree of suspicion in women who are under the age of 30 is low, observation of the mass for one or two menstrual cycles is also an option in cases with low clinical suspicion. If observation is elected and the mass resolves after one or two menstrual cycles, the patient may return to routine screening. If the mass persists, ultrasound should be performed. Needle sampling prior to imaging is not recommended.

If no ultrasonographic abnormality is found (BI-RADS® 1), a mammogram is recommended in cases where there is high clinical suspicion or those at higher risk due to known genetic mutation or family history. Based on the mammogram results, from this point, the management is identical to the pathway for older women. Whereas if the clinical suspicion is low, observation every 3-6 months for 1-2 years is recommended. If the mass increases in size during the observation period, mammogram may be considered followed by

Printed by Ariel Smits on 10/2/2014 11:42:36 AM. For personal use only. Not approved for distribution. Copyright © 2014 National Comprehensive Cancer Network, Inc., All Rights Reserved.

tissue biopsy. If the mass remains stable, routine breast screening is recommended.

Nipple Discharge without a Palpable Mass

Nipple discharge is common, and, in many cases, unrelated to breast pathology.[127-133] For example, non-spontaneous discharge from multiple breast ducts in a non-lactating woman can occur during pregnancy, following breast stimulation, in women with certain thyroid conditions, and in those taking certain medications, such as estrogen, oral contraceptives, opiates, and particular antihypertensive agents.[127] Suspicion of underlying pathology (eg, papilloma, ductal ectasia) is raised when nipple discharge is persistent and reproducible on examination, spontaneous, unilateral, from a single duct with fluid characterized as clear and colorless, serous, sanguineous, or serosanguineous.[134]

In patients with a nipple discharge but no palpable mass, an evaluation of the characteristics of the nipple discharge is the first step. The appropriate follow-up of a non-spontaneous, multiple-duct discharge in women under age 40 is observation, coupled with education of the patient to stop compression of the breast and to report the development of any spontaneous discharge. In women aged 40 years or older, screening mammography and a further workup based upon the BI-RADS® category along with education similar to that for younger women is recommended.. Evaluation of this type of nipple discharge is based on the overall BI-RADS® category of the diagnostic mammogram with or without adjunctive ultrasound.

Mammary ductoscopy is useful in evaluating patients who have nipple discharge, for accurate visualization, analysis, and excision of intraductal abnormalities.[135-137] Magnetic resonance imaging (MRI) may play an adjunctive role, aiding in the differentiation of benign ductal abnormalities from malignant ones. Preliminary studies have shown that breast MRI aids in the diagnosis of suspected ductal disease and is an alternative to ductoscopy when the latter cannot be used.[138,139]

According to the NCCN Panel, for an overall BI-RADS® assessment category 1, 2, or 3, either a ductogram or MRI (optional) is recommended to guide the duct excision. Ductal excision is indicated for diagnosis of an abnormal nipple discharge, even if the ductogram is negative.[140] However, the ductogram is useful to exclude multiple lesions and to localize the lesions prior to surgery.

For an overall BI-RADS® assessment category 4 or 5, the NCCN Panel recommends a tissue biopsy. If the findings are benign or indeterminate, a ductogram is optional, but surgical duct excision would still be necessary. If findings are indicative of malignancy, the patient should be treated according to the NCCN Guidelines for Breast Cancer.

Asymmetric Thickening or Nodularity

Thickening, nodularity, or asymmetry is distinct from a palpable mass in that the finding is ill defined and often vague on physical breast examination. Factors to consider include whether the thickening is a new or previous finding, and whether or not it appears to be representative of normal asymmetry. If the patient is under the age of 30 years and has no high risk factors, ultrasound evaluation is appropriate followed by consideration of diagnostic mammography. Diagnostic mammograms for this age group are fairly low in yield because of the density of the breast and low risk of breast cancer. In a woman aged 30 years or older, a bilateral diagnostic mammogram, and an ultrasound evaluation should be obtained.

If a clinically suspicious change is noted or the overall imaging findings are classified as BI-RADS® assessment category 4-5 a tissue biopsy is recommended.

If the overall imaging findings are classified as BI-RADS® category 1-3 *and* the clinical assessment is benign, the patient should be reexamined in 3 to 6 months to assess stability. For BI-RADS® category 3, the physical exam is followed by ultrasound and/or mammogram every 6-12 months for 2-3 years. If the findings on physical and/or imaging is stable, routine screening can be resumed. If the finding shows clinical progression, it should be investigated as previously described for palpable mass.

Skin Changes

Any type of unusual skin changes around the breast may represent serious disease and needs evaluation. Inflammatory breast cancer (IBC) should be considered when dermal edema (peau d'orange) and breast erythema are present, and nipple excoriation, scaling, and eczema should increase clinical suspicion of Paget's disease. IBC is a rare, aggressive form of breast cancer estimated to account for 1%-6% of breast cancer cases in the U.S. IBC is a clinical diagnosis that requires erythema and dermal edema of a third or more of the skin of the breast with a palpable border to the erythema.[141,142] Paget's disease of the breast is a rare manifestation of breast cancer characterized by neoplastic cells in the epidermis of the nipple areolar complex. It most commonly presents with eczema of the areola, bleeding, ulceration, and itching of the nipple. The diagnosis is often delayed because of the rare nature of the condition and confusion with other dermatologic conditions.[143,144]

The management of patients with IBC or Paget's disease is outlined in NCCN Guidelines for Breast Cancer.

The initial evaluation of a patient with breast skin changes begins with a bilateral diagnostic mammogram with or without ultrasound imaging. If the imaging results are abnormal, the evaluation proceeds on the basis of the imaging findings. If the breast imaging results are normal, further workup is still needed.

Punch biopsy of skin or nipple biopsy should be performed following imaging findings consistent with an overall BI-RADS® assessment category 1-3. Antibiotics may or may not be given, depending on the clinical scenario, but should not delay diagnostic evaluation. If biopsy results are benign, clinical and pathological correlation should be reassessed. In addition, a breast MRI, a repeat biopsy, and consultation with a breast specialist should be considered. If the skin biopsy is malignant, the patient should be treated according to the NCCN Guidelines for Breast Cancer.

A tissue biopsy should be performed if imaging findings are consistent of an overall BI-RADS® assessment category 4-5. According to the NCCN Panel, core needle biopsy is the preferred option with or without punch biopsy although surgical excision is also an option. A benign biopsy result should be followed by a punch biopsy of skin if not previously performed or nipple biopsy, with reassessment as described above for BI-RADS® category 1-3. A biopsy showing a malignant finding should be managed according to the NCCN Guidelines for Breast Cancer.

Summary

The intent of these guidelines is to give health care providers a practical, consistent framework for screening and evaluating a spectrum of breast lesions. Clinical judgment should always be an important component of the optimal management of the patient.

Discussion

If the physical breast examination, radiologic imaging, and pathologic findings are not concordant, the clinician should carefully reconsider the assessment of the patient's problem. Incorporating the patient into the health care team's decision-making empowers the patient to determine the level of breast cancer risk that is personally acceptable in the screening/follow-up settings.

Table 1: Breast Cysts - Types and Definitions

Simple cyst	Anechoic (cystic), well circumscribed, round or oval with well-defined imperceptible wall and posterior enhancement.
Non-simple cyst	Has one or more characteristics not found in a simple cyst.
• complicated	Has most but not all elements of a simple cyst. Complicated cysts do not contain solid elements, intracystic masses, thick walls, or thick septa. This type of cyst may contain low-level echoes or intracystic debris, and can be described as a round, circumscribed mass containing low level echoes without vascular flow, fulfilling most but not all criteria of a simple cyst.
• complex	Has some discrete solid component which may include thick walls, thick septa, and/or intracystic mass. Complex cysts have both anechoic (cystic) and echogenic (solid) components.

Update in Progress

Use of Digital Breast Tomosynthesis with Mammography for Breast Cancer Screening or Diagnosis

Assessment Program
Volume 28, No. 6
January 2014

Executive Summary

Background

Digital breast tomosynthesis was developed to improve the accuracy of mammography by capturing three-dimensional (3D) images of the breast to clarify areas of overlapping tissue. Digital breast tomosynthesis produces a 3D image by taking multiple low-dose images per view along an arc over the breast. During breast tomosynthesis, the compressed breast remains stationary while the x-ray tube moves approximately 1 degree for each image in a 15- to 50-degree arc, acquiring 11–49 images. These images are projected as cross-sectional "slices" of the breast, with each slice typically 1 mm thick. By reducing problems caused by overlapping tissue, the amount of compression needed for digital breast tomosynthesis can be reduced by up to 50% compared with mammography, thereby improving patient satisfaction.

Objective

To compare the sensitivity and specificity, as well as the recall rate, of mammography and digital breast tomosynthesis for screening or diagnosis.

Search Strategy

A search was conducted in June 2013 of the MEDLINE® (via PubMed) and EMBASE databases, limited to studies in humans, published in English, and using the following terms: ((breast OR mammary) AND tomosynthesis) OR ("Mammography"[MeSH] AND (3D OR "3-D" OR "3-dimensional" OR "three-dimensional")). The Cochrane database was also searched for applicable studies. In addition, relevant journals and newsletters were monitored subsequent to the search to identify new publications.

Selection Criteria

- The population of women represented at least part of the spectrum of findings encountered in clinical practice; for example, studies that only include women with cancer would be excluded.
- The study used digital breast tomosynthesis in addition to mammography for screening. For diagnosis, breast tomosynthesis was compared with mammographic spot views, with or without results from other tests such as ultrasound.
- Two views of mammography (craniocaudal [CC] and mediolateral-oblique [MLO]) were compared with mammography plus the same two views of breast tomosynthesis.
- The reference standard was histopathology or long-term (minimum of 6 months) follow-up for women with negative findings, i.e., no indication of possible cancer.
- The equipment used was similar to the U.S. Food and Drug Administration (FDA) -approved Hologic system.

Sensitivity and specificity

ABSTRACT

Digital breast tomosynthesis (DBT, or 3D-mammography), a three-dimensional derivative of digital mammography (DM), reduces the effect of tissue superimposition and may improve mammographic interpretation. In this review, we examined the evidence on the accuracy of DBT in clinical studies. Published studies of DBT were relatively small studies, mostly test-set observer (reader) studies or clinical series that included symptomatic and screen-recalled cases, and were generally enriched with cancers. With these limitations in mind, the evidence showed some consistent findings, summarized as follows: two-view DBT has at least equal or better accuracy than standard two-view DM, whereas one-view DBT does not have better accuracy than standard DM; the *addition* of DBT to standard mammography (for mammographic interpretation or for assessment or triage of screen-recalled abnormalities) increases accuracy; improved accuracy from using DBT (relative to, or added to, DM) may be due to increased cancer detection or due to reduced false positive recalls, or both; and subjective interpretation of cancer conspicuity consistently found that cancers were equally or more conspicuous on DBT relative to DM.

Preliminary data from population screening trials suggest that the integration of DBT with conventional DM (screen-reading using combined 2D + 3D mammography) may substantially improve breast cancer detection, although final results are not yet available, and many logistical issues need further evaluation to determine the potential implications and cost of combined 2D + 3D mammographic screening. At present, there is insufficient evidence to justify a change from standard DM to DBT however the available data strongly support investment in new large-scale population screening trials. These trials need to avoid the 'double' acquisitions required for 2D + 3D mammograms, and should therefore focus on evaluating integrated 2Dsynthetic + 3D mammography (where 2D-images are reconstructed from the DBT acquisition), and should consider using a randomized design.

Introduction

The evolution of conventional two-view mammography from film-screen to full-field digital mammography (FFDM or DM), has paved the way for digital breast tomosynthesis (DBT), a 3-dimensional transformation of FFDM. A proposed advantage of this derivative digital mammographic technology is its potential to improve breast imaging by providing a series of images (thin slices) through the breast which reduces the effect of tissue superimposition. Consequently, this may allow better visualization of malignancy (by reducing tissue overlap and the masking effect of tissue density), and may also facilitate discrimination between normal tissue structures and lesions. Thus, in theory, DBT could lead to improvement in sensitivity and/or specificity relative to standard mammography. At present, DBT is undergoing further technological refinement and is also the focus of much interest through clinical research, with several large-scale screening studies in progress or nearing completion; these trials will potentially provide evidence to guide the future application of DBT. In the context of breast imaging, DBT is in essence 'at a translational crossroads' as aptly said by Dobbins.[1]

DBT technology

The technologic derivation of DBT from FFDM platforms, and description of both prototype and state-of-the art DBT systems and

Assessing Radiologist Performance Using Combined Digital Mammography and Breast Tomosynthesis Compared with Digital Mammography Alone: Results of a Multicenter, Multireader Trial[1]

Elizabeth A. Rafferty, MD
Jeong Mi Park, MD
Liane E. Philpotts, MD
Steven P. Poplack, MD
Jules H. Sumkin, MD
Elkan F. Halpern, PhD
Loren T. Niklason, PhD

Purpose: To compare radiologists' diagnostic accuracy and recall rates for breast tomosynthesis combined with digital mammography versus digital mammography alone.

Materials and Methods: Institutional review board approval was obtained at each accruing institution. Participating women gave written informed consent. Mediolateral oblique and craniocaudal digital mammographic and tomosynthesis images of both breasts were obtained from 1192 subjects. Two enriched reader studies were performed to compare digital mammography with tomosynthesis against digital mammography alone. Study 1 comprised 312 cases (48 cancer cases) with images read by 12 radiologists; study 2, 312 cases (51 cancer cases) with 15 radiologists. Study 1 readers recorded only that an abnormality requiring recall was present; study 2 readers had additional training and recorded both lesion type and location. Diagnostic accuracy was compared with receiver operating characteristic analysis. Recall rates of noncancer cases, sensitivity, specificity, and positive and negative predictive values determined by analyzing Breast Imaging Reporting and Data System scores were compared for the two methods.

Results: Diagnostic accuracy for combined tomosynthesis and digital mammography was superior to that of digital mammography alone. Average difference in area under the curve in study 1 was 7.2% (95% confidence interval [CI]: 3.7%, 10.8%; $P < .001$) and in study 2 was 6.8% (95% CI: 4.1%, 9.5%; $P < .001$). All 27 radiologists increased diagnostic accuracy with addition of tomosynthesis. Recall rates for noncancer cases for all readers significantly decreased with addition of tomosynthesis (range, 6%–67%; $P < .001$ for 25 readers, $P < .03$ for all readers). Increased sensitivity was largest for invasive cancers: 15% and 22% in studies 1 and 2 versus 3% for in situ cancers in both studies.

Conclusion: Addition of tomosynthesis to digital mammography offers the dual benefit of significantly increased diagnostic accuracy and significantly reduced recall rates for noncancer cases.

Purpose: To assess cancer detection rates, false-positive rates before arbitration, positive predictive values for women recalled after arbitration, and the type of cancers detected with use of digital mammography alone and combined with tomosynthesis in a large prospective screening trial.

Materials and Methods: A prospective, reader- and modality-balanced screening study of participants undergoing combined mammography plus tomosynthesis, the results of which were read independently by four different radiologists, is under way. The study was approved by a regional ethics committee, and all participants provided written informed consent. The authors performed a preplanned interim analysis of results from 12631 examinations interpreted by using mammography alone and mammography plus tomosynthesis from November 22, 2010, to December 31, 2011. Analyses were based on marginal log-linear models for binary data, accounting for correlated interpretations and adjusting for reader-specific performance levels by using a two-sided significance level of .0294.

Results: Detection rates, including those for invasive and in situ cancers, were 6.1 per 1000 examinations for mammography alone and 8.0 per 1000 examinations for mammography plus tomosynthesis (27% increase, adjusted for reader; $P = .001$). False-positive rates before arbitration were 61.1 per 1000 examinations with mammography alone and 53.1 per 1000 examinations with mammography plus tomosynthesis (15% decrease, adjusted for reader; $P < .001$). After arbitration, positive predictive values for recalled patients with cancers verified later were comparable (29.1% and 28.5%, respectively, with mammography alone and mammography plus tomosynthesis; $P = .72$). Twenty-five additional invasive cancers were detected with mammography plus tomosynthesis (40% increase, adjusted for reader; $P < .001$). The mean interpretation time was 45 seconds for mammography alone and 91 seconds for mammography plus tomosynthesis ($P < .001$).

Conclusion: The use of mammography plus tomosynthesis in a screening environment resulted in a significantly higher cancer detection rate and enabled the detection of more invasive cancers.

Medical Policy

Subject: Digital Breast Tomosynthesis
Policy #: RAD.00060 **Current Effective Date:** 01/14/2014
Status: Reviewed **Last Review Date:** 11/14/2013

Description/Scope

Digital breast tomosynthesis (three-dimensional [3-D] mammography) (DBT) is being investigated as an adjunct and alternative to x-ray mammography for the screening and diagnosis of breast cancer. DBT combines the use of tomography and 3-D reconstruction with breast imaging to improve the visibility of breast lesions.

DBT utilizes an x-ray tube which sweeps along an arc around the breast to acquire multiple two-dimensional (2-D) projections from slightly different angles in about 10 to 20 seconds. The resulting 2-D images are digitally maneuvered to create tomograms (i.e., slices) in any plane, thus allowing for 3-D reconstruction that reflects depth. The number of slices that can be created depends on the number of 2-D projections captured during image sweeping. The tomograms can be displayed individually (similar to enhanced conventional mammograms) or in a dynamic "movie" mode. It has been theorized that providing a 3-D reconstruction of the breast will eliminate the problem of overlying tissue that might be mistaken for lesions or that might obscure small cancers.

For information related to the use of diagnostic tests for breast cancer, please see the following documents:

- RAD.00002 Positron Emission Tomography (PET) and PET/CT Fusion
- RAD.00036 MRI of the Breast

Position Statement

Investigational and Not Medically Necessary:

Digital breast tomosynthesis is considered **investigational and not medically necessary** for all indications.

Rationale

In February 2011, the Center for Devices and Radiological Health of the Food and Drug Administration (FDA) granted premarket approval for the Selenia Dimensions 3D system. According to the premarket approval letter (P080003), "the device is indicated to generate digital mammographic images that can be used for screening and diagnosis of breast cancer." The Selenia Dimensions 3-D system is an improvement on the existing 2-D system. The FDA approval letter also states that the Selenia Dimensions (2D or 3D) system is intended for use in the same clinical applications as 2D mammography systems for screening mammograms and may be used for additional diagnostic workup of the breast.

As part of the premarket approval process, the FDA reviewed results from two studies where board-certified radiologists were asked to review 2-D and 3-D images from more than 300 mammography exams. In both studies, radiologists viewing the 2-D images in conjunction with the 3-D images obtained a seven percent improvement in their ability to distinguish between cancerous and non-cancerous cases versus viewing the 2-D images alone. While the combination of the Selenia's 2-D and 3-D images approximately doubled the amount of radiation the individual was exposed to, it improved the accuracy with which radiologists detected cancers, decreasing the number of women recalled for a diagnostic workup. The Selenia Dimensions System is marketed by Hologic Inc., located in Bedford, Massachusetts.

In May 2013, the FDA expanded the scope of the premarket approval for Hologic Inc. Selenia Dimensions System to include the C-View software, which generates a synthetic 2D image using information obtained from the multiple 3D views of the breast. With the expanded application,

"each screening examination may consist of: a 2D FFDM image set; or a 2D and 3D image set, where the 2D image can be either a FFDM or a 2D image generated from the 3D image set."

Chen and colleagues (2007) carried out a small pilot study of 13 women recruited between April 2005 and November 2005 to assess the clinical feasibility of contrast enhanced (CE) DBT as an adjunct to digital mammography, and to correlate lesion enhancement characteristics and morphology obtained with CE-DBT to digital mammography, magnetic resonance (MR) and ultrasound (US). After undergoing breast imaging evaluation (including digital mammography, US, and MR) as part of the parent multimodality breast imaging study (NCI-funded grant [PO1-CA85484]) the participants were evaluated with CEDBT. Eleven of the 13 participants had pathology proven malignancies, (6 invasive ductal carcinoma, 4 ductal carcinoma in situ, and 1 invasive lobular carcinoma). Suspicious lesions were demonstrated with CE-DBT in 10 of 11 cases of proven breast malignancy. The researchers concluded that when used in conjunction with diagnostic mammography, CE-DBT may be a potential alternative tool for breast lesion morphologic and vascular characterization.

A 2007 comparative study by Poplack and colleagues assessed the image quality of DBT with that of conventional mammography and estimated the recall rate of screening when tomosynthesis is used in addition to mammography. A total of 100 consecutive women with an abnormal digital screening mammogram were included in the study. During the initial evaluation each woman underwent a DBT examination using a research prototype tomosynthesis unit (Genesis, Hologic) and screening mammography using full-field digital technology. The image quality of DBT was subjectively rated as equivalent in 52% (51/99) or superior 37% (37/99) to diagnostic mammography in 89% (88/99) of cases. In the identification of masses, DBT image quality was rated as equivalent in 26% (5/19) or superior to diagnostic mammography in 68% (13/19) of cases. Masses constituted 19% (19/99) of screening-detected findings but were 35% (13/37) of findings in which DBT had superior image quality. Calcifications usually showed better image quality on diagnostic mammography than on DBT. The authors concluded that "tomosynthesis has comparable or superior image quality to that of film-screen mammography in the diagnostic setting, and it has the potential to decrease the recall rate when used adjunctively with digital screening mammography." However, limitations of the study included, but are not limited to, the small sample size and the fact that the study was unblinded, non-randomized and uncontrolled. It also remains to be seen how these data will generalize to other populations and in the clinical setting. DBT may perform differently in a general screening population than in the study group of women who were recruited because of a breast screening abnormality. In this study group, only 5% (5/98) of women had fatty breast composition; the remainder, 95% (93/98), had higher density compositions. In a population with a greater proportion of fatty breast composition, DBT may prove to be less effective.

Good and colleagues (2008) assessed issues associated with the interpretation of images produced by DBT. The study included the breast images of 30 women who underwent digital mammography and DBT. Nine board-certified radiologists were asked to detect and rate masses and microcalcification clusters using full-field digital mammography (FFDM) images, the 11 frames mode, and the reconstructed DBT images. When compared to digital mammography, the reconstructed DBT examination took much longer to review and interpret (1.58 ± 1.07 versus 2.72 ± 1.44 minutes). Three of the nine radiologists (33%) rated the tomosynthesis frame mode to be better than digital mammography, and 6 of the 9 radiologists (66%) rated the reconstructed DBT examination to be better than digital mammography. The detection rate of malignancies was somewhat better for the reconstructed DBT examination than for digital mammography (93.9% versus 90%), and the recall rate for nonmalignancies was somewhat lower (62.6% versus 64.3%). The researchers concluded that DBT may have great potential in screening and diagnostic breast imaging practices; however, additional studies are needed before this imaging approach finds its optimal role in the clinical environment.

Gur and colleagues (2009) carried out a retrospective observer study evaluating the diagnostic performance of FFDM with that of DBT. Eight experienced radiologists interpreted images from 125 selected examinations, 35 with verified findings of cancer and 90 with negative findings. The four display conditions incorporated FFDM alone, 11 low-dose projections, reconstructed DBT images, and a combined display mode of FFDM and DBT images. The longest mean time (2.39 ± 1.65 minutes) to view and rate an examination was for the combined mode in which readers first viewed and rated the FFDM images and then viewed the corresponding DBT images together with the FFDM images and rerated the images if deemed necessary. The radiologists had the shortest mean time (1.22 ± 1.15 minutes) for viewing and rating examinations when using the FFDM image displays (FFDM alone and FFDM before viewing of the DBT images). Researchers found

that digital mammography in combination with DBT were associated with a 30% reduction in recalls for the cancer-free examinations compared with the use of digital mammography alone. DBT alone reduced recall rates by approximately 10%. DBT did not substantially improve sensitivity. The authors acknowledged that while initial results are encouraging, further work is needed before DBT finds its optimal role in the clinical environment.

Gennaro and colleagues (2010) reported the results of a study which included 200 women who had at least one breast lesion discovered by mammography and/or ultrasound classified as doubtful or suspicious or probably malignant. The study participants underwent DBT with one view (mediolateral oblique [MLO]) of both breasts at a radiation dose noted to be comparable to that of standard screen-film mammography in two views (craniocaudal [CC] and MLO). Images were rated by six radiologists using the breast imaging reporting and data system (BIRADS) score. The overall clinical performance with DBT and FFDM for malignant versus all other cases was not significantly different (AUCs 0.851 vs. 0.836, p=0.645). The authors concluded that the clinical performance of DBT in one view at the same total dose as standard screen-film mammography is not inferior to digital mammography in two views.

In another 2010 study (Teertstra, 2010), researchers assessed mammography and DBT in 513 women with an abnormal screening mammogram or with clinical symptoms. The ACR BI-RADS criteria were used to classify the cases. In 112 newly detected cancers, DBT and mammography were each false-negative in 8 cases (7%). In three cases, both mammography and DBT failed to detect the carcinoma. The sensitivity of both techniques for the detection of breast cancer was 92.9%, and the specificity of mammography was 86.1% and 84.4% for DBT. The authors concluded that DBT can be used as an additional technique to mammography in individuals referred with an abnormal screening mammogram or with clinical symptoms. They also acknowledged that the additional lesions detected by DBT are also likely to be detected by other techniques used in the clinical work-up of these individuals.

A 2012 study by Michell and colleagues examined the impact of the addition of FFDM and DBT on the diagnostic accuracy of mammography in a population of women recalled following film-screen mammography alone. Women eligible for recruitment were those recalled for further evaluation of a mammographic abnormality found on routine filmscreen mammographic screening. A total of 738 women participated in the study (93.2% recruitment rate). Participants underwent bilateral, two-view FFDM and two-view DBT. Readers rated each lesion separately for probability of malignancy on screen-film mammography, FFDM, and then DBT. The scores were compared with the presence or absence of malignancy based on the final histology report. Following assessment 204 (26.8%) were diagnosed as malignant (147 invasive and 57 in-situ tumors), 286 (37.68%) as benign, and 269 (35.4%) as normal. The diagnostic accuracy was evaluated by using receiving operating characteristic (ROC) and measurement of area under the curve (AUC). The AUC values demonstrated a significant ($p = 0.0001$) improvement in the diagnostic accuracy with the addition of DBT combined with FFDM and film-screen mammography (AUC = 0.9671) when compared to FFDM plus film-screen mammography (AUC = 0.8949) and film-screen mammography alone (AUC = 0.7882). The authors acknowledged that the equipment from a single manufacturer was used in this study but the technique and features of DBT machines vary considerably between different manufacturers and clinical performance results are, therefore, not necessarily generalizable. The authors also state that "the conclusions that can be reached from this prospective preliminary study are limited by the method; the readers were not blinded, they read and scored the DBT images with knowledge of the film-screen mammography and FFDM findings."

Skaane and colleagues (2013) reported a preplanned interim analysis of two arms of a four-arm study comparing DM and DBT in a side-by-side feature analysis for cancer detection. This single institution, prospective screening trial, was sponsored by the manufacturer of the DBT equipment (Hologic, Inc.). Cancer detection rates, false-positive rates before arbitration, positive predictive values for women recalled after arbitration, and the type of cancers detected with use of digital mammography alone and combined with tomosynthesis were reported. Of the 29,652 women invited to participate in the study, 17,960 (60.6%) attended the screening program, with 12,631 consenting to participate in the study. Independent double reading was the standard of practice and any mammogram considered suspicious for malignancy by at least one reader were discussed at a consensus-based arbitration meeting. The diagnostic work-up, including additional views, ultrasonography, magnetic resonance imaging, and needle biopsy (if indicated), was performed by the same group of radiologists. Analyses were based on marginal log-linear models for binary data, accounting for correlated interpretations and adjusting for reader-specific performance levels by using a two-sided significance level of .0294. The cancer detection rate for mammography

alone was 6.1/1000 examinations (77 of 12,631 cases) and 8.0/1000 examinations (101 of 12,621 cases) with mammography plus tomosynthesis (an increase of 31%). The false positive rate was 61.1/1000 examinations (771 of 12,621 cases) with mammography alone and 53.1/1000 examinations (670 of 12,621 cases) with mammography plus tomosynthesis (a decrease of 13%). After arbitration, positive predictive values for recalled participants with cancers verified later were comparable with 29.1% for mammography alone and 28.5%, for mammography plus tomosynthesis. Twenty-five additional invasive cancers were identified with mammography plus tomosynthesis (40% increase, adjusted for reader; $P < 0.001$). The mean interpretation time was 45 seconds for mammography alone and 91 seconds for mammography plus tomosynthesis ($P < 0.001$).

The Society of Breast Imaging (SBI) and the American College of Radiology (ACR) statement on the on Skaane et al – Tomosynthesis Breast Cancer Screening Study states the following:

> While the study results are promising, they do not provide adequate information to define the role of tomosynthesis in clinical practice… Although the cancer detection rate was higher when tomosynthesis was added to mammography alone, it is not known if an equal incremental benefit will be realized in a second screening round. This small study does not supply statistical information regarding subgroups of women that might benefit, or might not benefit from adding tomosynthesis. How the technology will affect screening accuracy among women of different ages, risk profiles and parenchymal density is uncertain. In addition, how this technology would affect reader performance among U.S. radiologists with varying practice patterns and expertise is also uncertain. Other questions include whether computer aided detection will provide any further benefit, and if reconstructed images can be used, in lieu of standard full field digital images, to reduce radiation dose (ACR, 2013).

Rafferty and colleagues (2013) compared the diagnostic accuracy and recall rates for radiologists using breast tomosynthesis combined with digital mammography versus digital mammography alone. One thousand one hundred and ninety-two (1192) participants provided mediolateral oblique and craniocaudal digital mammographic and tomosynthesis images of both breasts. At each accruing site, a breast imager read the digital mammographic images and a second breast imager trained in tomosynthesis interpretation read the tomosynthesis images for each participant presenting for screening. The breast imager was blinded to the results of the other modality and the investigational examination images of the participants presenting for biopsy were not interpreted prospectively. Study 1 consisted of 312 cases (48 cancer cases) with images read by 12 radiologists while study 2 included 312 cases (51 cancer cases) with 15 radiologists. The readers in Study 1 recorded only that an abnormality requiring recall was present; the readers in study 2 received additional training and recorded both lesion type and location. Diagnostic accuracy was compared with receiver operating characteristic analysis. Recall rates of noncancerous cases, sensitivity, specificity, and positive and negative predictive values determined by analyzing Breast Imaging Reporting and Data System scores were compared for the two methods. The authors reported the diagnostic accuracy for combined tomosynthesis and digital mammography was better than that of digital mammography alone. The average difference in area under the curve in study 1 was 7.2% (95% confidence interval [CI]: 3.7%, 10.8%; $P = 0.001$). The average difference in area under the curve in study 2 was 6.8% (95% CI: 4.1%, 9.5%; $P = 0.001$). All 27 radiologists experienced an increase in diagnostic accuracy with addition of tomosynthesis. Recall rates for noncancerous cases for all readers decreased with the addition of tomosynthesis (range, 6%–67%; $P = 0.001$ for 25 readers, $P = 0.03$ for all readers). The increase in the rate of sensitivity was greatest for invasive cancers: 15% and 22% in studies 1 and 2 versus 3% for in situ cancers in both studies. The authors concluded that the addition of tomosynthesis to digital mammography provides the dual benefit of significantly increased diagnostic accuracy and significantly reduced recall rates for noncancerous cases. Some of the limitations of the study which were acknowledged by the authors include the fact that the reader studies were enriched, and the results in true screening populations may differ. The authors also acknowledge that there was an inherent inclusion bias against tomosynthesis with regards to cancer detection in a screening population. Almost all of the cancers were acquired in participants who were scheduled for biopsy and had been detected on conventional mammograms as part of standard screening evaluation. Therefore, it is likely that the study results underestimate the potential gains in sensitivity that might occur in clinical practice. Additional studies done in the clinical environment are needed to confirm the performance of tomosynthesis combined with digital mammography versus digital mammography alone.

The American College of Obstetricians and Gynecologists guidelines on breast cancer screening

considered color Doppler ultrasonography, computer-aided detection, positron emission tomography, scintimammography, and digital breast tomosynthesis but did not include them in the recommended screening methods. ACOG acknowledged that these technologies have shown promise in selected clinical situations or as adjuncts to mammography for breast cancer diagnosis but concluded that they are not considered alternatives to routine mammography (ACOG, 2011).

According to the National Comprehensive Cancer Network's (NCCN®) clinical practice guideline for breast cancer screening and diagnosis (NCCN, 2013), though studies show promise for digital breast tomosynthesis, there is currently insufficient evidence to recommend this technology for routine screening or diagnosis at this time.

Comparative data demonstrating that DBT is equal to or better than other breast imaging technologies with regards to accuracy, sensitivity, specificity, and recall rates are lacking. The published feasibility and experimental studies also have not made it clear if DBT should be utilized for diagnostic, screening or surveillance purposes or if it should be used in lieu of or in conjunction with other imaging technologies. In addition to these issues, there remains some concern regarding radiation exposure and the learning curve for radiologist to accurately interpret the DBT results.

Background/Overview

DBT is being investigated as an adjunct and alternative to x-ray mammography for the screening and diagnosis of breast cancer. DBT utilizes a three-dimensional (3-D) breast imaging technique based on full-field digital mammography. During DBT, a woman is typically positioned for the conventional mammography. A machine takes multiple images (slices) approximately one milliliter or less as it rotates around the breast. The images are then digitally manipulated by a computer and displayed as a 3-D, high-resolution image on a workstation. Developers of this technology propose that a 3-D reconstruction of the breast will eliminate the problem of overlying tissue that might be mistaken for lesions or that might mask small cancers.

Definitions

Ductal carcinoma in situ: The presence of abnormal cells in a milk duct in the breast; considered the earliest form of breast cancer.

Full-field digital mammography (FFDM): A technology which combines the x-ray generators and tubes used in analog screen-film mammography with a detector plate that then converts the x-rays into a digital signal.

Microcalcification: A tiny deposit of calcium in the breast that cannot be felt but can be detected on a mammogram; a cluster of these very small specks of calcium may indicate that cancer is present.

Coding

The following codes for treatments and procedures applicable to this document are included below for informational purposes. Inclusion or exclusion of a procedure, diagnosis or device code(s) does not constitute or imply member coverage or provider reimbursement policy. Please refer to the member's contract benefits in effect at the time of service to determine coverage or non-coverage of these services as it applies to an individual member.

When services are Investigational and Not Medically Necessary:|
When the code describes a procedure indicated in the Position Statement section as investigational and not medically necessary.

CPT

76499	Unlisted diagnostic radiographic procedure [when specified as digital breast tomosynthesis]

ICD-9 Diagnosis ***[For dates of service prior to 10/01/2014]***

Clinical Policy Bulletin Notes

Policy

1. Aetna considers annual mammography screening a medically necessary preventive service for women aged 40 and older. Annual screening is also considered medically necessary for younger women who are judged to be at high-risk by their primary care physician. Screening mammography for other women is considered experimental and investigational because its benefits in these other women are unproven.

2. Aetna considers screening mammography for men experimental and investigational, as the clinical benefits of such screening in men are unproven. Current guidelines from the U.S. Preventive Services Task Force and the American College of Radiology recommend such screening only for women. Aetna considers mammography medically necessary for surveillance of men with a prior history of breast cancer.

3. Aetna considers diagnostic mammography medically necessary for members with signs or symptoms of breast disease or history of breast cancer.

   Note: Diagnostic mammography is covered regardless of whether the member has preventive services benefits

4. Aetna considers digital mammography an acceptable alternative to film mammography.

5. Aetna considers computer-aided detection (CAD) a medically necessary adjunct to mammography.

6. Aetna considers xeroradiography for breast imaging experimental and investigational because this method of radiography is obsolete.

7. Aetna considers breast tomosynthesis imaging experimental and investigational because of insufficient evidence of its effectiveness.

8. Aetna considers contrast-enhanced spectral mammography experimental and investigational because of insufficient evidence of its effectiveness.

Background

This policy is based on the recommendations of the American Cancer Society, American College of Radiology, and the American College of Obstetricians and Gynecologists.

A mammogram is an x-ray of the breast. A screening mammography is one of several tools that are used for early detection of breast cancer in asymptomatic women. Other screening tools include the clinical breast examination and breast self-examination. Diagnostic mammography is used to diagnose breast cancer in women who have signs or symptoms of breast disease.

Screening mammography aims to reduce morbidity and mortality from breast cancer by early detection and treatment of occult malignancies. There is extensive evidence from a variety of well-conducted, randomized controlled studies that annual or biennial mammography is effective in reducing breast cancer mortality by 30 % in women aged 50 to 69 years. Data on women under age 50 are less clear. Results from the Canadian National Breast Screening Study

(CNBSS) suggest that the contribution of mammography over good physical examinations to breast cancer mortality reduction may be less than has been assumed. This observation re-emphasizes a truism of screening -- that it is not necessary to detect cancers as early as possible to obtain a benefit -- it is only necessary to detect them early enough. What is early enough in any individual case is uncertain because there are insufficient outcomes data. This has made it difficult for professional societies to develop specific mammography screening recommendations for high-risk women.

The U.S. Preventive Services Task Force (USPSTF) revised their recommendations for mammography screening in 2009. Whereas they had formerly recommended routine screening every 1 to 2 years starting at age 40, they now recommend against routine screening for women aged 40 to 49 and biennial rather than annual screening for women aged 50 to 74. In their 2009 recommendations, the USPSTF recommend that women aged 40 to 49 consider their personal risk for developing breast cancer before deciding to participate in regular, biennial screening. The USPSTF concluded that the current evidence is insufficient to assess the additional benefits and harms of (i) screening mammography in women aged 75 years or older, (ii) clinical breast examination (CBE) beyond screening mammography in women aged 40 years or older, and (iii) either digital mammography or magnetic resonance imaging instead of film mammography as screening modalities for breast cancer. In addition, the USPSTF recommended against clinicians teaching women how to perform breast self-examination.

The American Medical Association (AMA), the Society of Breast Imaging (SBI), the American College of Radiology (ACR), and the American Cancer Society (ACS), all support screening with mammography and CBE beginning at age 40. Recent recommendations from the SBI and the ACR (2010) released after the 2009 USPSTF recommendations, which recommended that average-risk women wait until age 50 to undergo screening mammography, continue to support yearly screening mammography beginning at age 40 for women at average-risk for breast cancer. The American College of Obstetricians and Gynecologists (ACOG, 2000) supports screening with mammography beginning at age 40 and CBE beginning at age 19. The Canadian Task Force on Preventive Health Care (CTFPHC), the American Academy of Family Physicians (AAFP), and the American College of Preventive Medicine (ACPM) recommend beginning mammography for average-risk women at age 50. The AAFP and ACPM recommend that mammography in high-risk women begin at age 40, and AAFP recommends that all women aged 40 to 49 be counseled about the risks and benefits of mammography before making decisions about screening.

A 1997 Consensus Development Panel convened by the National Institutes of Health concluded that the evidence was insufficient to determine the benefits of mammography among women aged 40 to 49. This panel recommended that women aged 40 to 49 should be counseled about potential benefits and harms before making decisions about mammography. In 2001, the CTFPHC concluded there was insufficient evidence to recommend for or against mammography in women aged 40 to 49.

Organizations differ on their recommendations for the appropriate interval for mammography. Annual mammography is recommended by AMA, ACR, and ACS. Mammography every 1 to 2 years is recommended by AAFP, ACPM, and the CTFPHC. ACOG recommends mammography every 1 to 2 years for women aged 40 to 49 and annually for women aged 50 and older.

Berg et al (2008) compared the diagnostic yield, defined as the proportion of women with positive screen test results and positive reference standard, and performance of screening with ultrasound plus mammography versus mammography alone in women at elevated risk of breast cancer. A total of 2,809 women, with at least heterogeneously dense breast tissue in at least 1 quadrant, were recruited from 21 sites to undergo mammographic and physician-performed ultrasonographic examinations in randomized order by a radiologist masked to the other examination results. Reference standard was defined as a combination of pathology and 12-month follow-up and was available for 2,637 (96.8 %) of the 2,725 eligible participants. Main outcome measures included diagnostic yield, sensitivity, specificity, and diagnostic accuracy (assessed by the area under the receiver operating characteristic curve) of combined mammography plus ultrasound versus mammography alone and the positive predictive value of biopsy recommendations for mammography plus ultrasound versus mammography alone. A total of 40 participants (41 breasts) were diagnosed with cancer: 8 suspicious on both ultrasound and mammography, 12 on ultrasound alone, 12 on mammography alone, and 8 participants (9 breasts) on neither. The diagnostic yield for mammography was 7.6 per 1,000 women screened (20 of 2,637) and increased to 11.8 per 1,000 (31 of 2,637) for combined mammography plus ultrasound; the supplemental yield was 4.2 per 1,000 women screened (95 % confidence interval [CI]: 1.1 to 7.2 per 1,000; p = 0.003 that supplemental yield is 0). The diagnostic accuracy for mammography was 0.78 (95 % CI: 0.67 to 0.87) and increased to 0.91 (95 % CI: 0.84 to 0.96) for mammography plus ultrasound (p = 0.003 that difference is 0). Of 12 supplemental cancers detected by ultrasound alone, 11 (92 %) were invasive with a median size of 10 mm (range of 5 to 40 mm; mean [SE], 12.6 [3.0] mm) and 8 of the 9 lesions (89 %) reported had negative nodes. The positive predictive value of biopsy recommendation after full diagnostic workup was 19 of 84 for mammography (22.6 %; 95 % CI: 14.2 % to 33 %), 21 of 235 for ultrasound (8.9 %, 95 % CI: 5.6 % to 13.3 %), and 31 of 276 for combined mammography plus ultrasound (11.2 %; 95 % CI: 7.8 % to 15.6 %). The authors concluded that adding a single screening ultrasound to mammography will yield an additional 1.1 to 7.2 cancers per 1,000 high-risk women, but it will also substantially increase the number of false positives.

Although digital mammography has not shown greater accuracy than film mammography, it has become standard of

care. The Food and Drug Administration (FDA)'s initial market approval of digital mammography technology was based, in part, on studies that demonstrated its effectiveness in patients referred for further testing after an initial suspicious mammogram (FDA, 2004). In that setting, the FDA found the accuracy of digital technology was similar to that of screen film. Studies are currently underway to evaluate the effectiveness of digital mammography in screening of the general population.

Hendrick and colleagues (2008) retrospectively compared the accuracy for cancer diagnosis of digital mammography with soft-copy interpretation with that of screen-film mammography for each digital equipment manufacturer, by using results of biopsy and follow-up as the reference standard. The American College of Radiology Imaging Network Digital Mammographic Imaging Screening Trial (DMIST) collected screening mammography studies performed by using both digital and screen-film mammography in 49,528 women (mean age of 54.6 years; range of 19 to 92 years). Digital mammography systems from 4 manufacturers (Fischer, Fuji, GE, and Hologic) were used. For each digital manufacturer, a cancer-enriched reader set of women screened with both digital and screen-film mammography in DMIST was constructed. Each reader set contained all cancer-containing studies known for each digital manufacturer at the time of reader set selection, together with a subset of negative and benign studies. For each reader set, 6 or 12 experienced radiologists attended 2 randomly ordered reading sessions 6 weeks apart. Each radiologist identified suspicious findings and rated suspicion of breast cancer in identified lesions by using a 7-point scale. Results were analyzed according to digital manufacturer by using areas under the receiver operating characteristic curve (AUCs), sensitivity, and specificity for soft-copy digital and screen-film mammography. Results for Hologic digital are not presented owing to the fact that few cancer cases were available. The implemented design provided 80 % power to detect average AUC differences of 0.09, 0.08, and 0.06 for Fischer, Fuji, and GE, respectively. No significant difference in AUC, sensitivity, or specificity was found between Fischer, Fuji, and GE soft-copy digital and screen-film mammography. Large reader variations occurred with each modality. The authors concluded that no statistically significant differences were found between soft-copy digital and screen-film mammography for Fischer, Fuji, and GE digital mammography equipment.

Pisano and associates (2008) retrospectively compared the accuracy of digital versus film mammography in population subgroups of the DMIST defined by combinations of age, menopausal status, and breast density, by using either biopsy results or follow-up information as the reference standard. For analysis, AUCs for each modality were compared within each subgroup evaluated (age less than 50 versus 50 to 64 versus greater than or equal to 65 years; dense versus non-dense breasts at mammography; and pre- or peri-menopausal versus post-menopausal status for the 2 younger age cohorts) while controlling for multiple comparisons ($p < 0.002$ indicated a significant difference). All DMIST cancers were evaluated with respect to mammographic detection method (digital versus film versus both versus neither), mammographic lesion type (mass, calcifications, or other), digital machine type, mammographic and pathologic size and diagnosis, existence of prior mammographic study at time of interpretation, months since prior mammographic study, and compressed breast thickness. A total of 33 centers enrolled 49,528 women. Breast cancer status was determined for 42,760 women, the group included in this study. Pre- or peri-menopausal women younger than 50 years who had dense breasts at film mammography comprised the only subgroup for which digital mammography was significantly better than film (AUCs, 0.79 versus 0.54; $p = 0.0015$). Breast Imaging Reporting and Data System-based sensitivity in this subgroup was 0.59 for digital and 0.27 for film mammography. AUCs were not significantly different in any of the other subgroups. For women aged 65 years or older with fatty breasts, the AUC showed a non-significant tendency toward film being better than digital mammography (AUCs, 0.88 versus 0.70; $p = 0.0025$). The authors concluded that digital mammography performed significantly better than film for pre- and peri-menopausal women younger than 50 years with dense breasts, but film tended non-significantly to perform better for women aged 65 years or older with fatty breasts.

Computer-aided detection and diagnosis (CAD) systems consist of computer programs that are designed to recognize patterns in images. CAD may be applied to digital mammograms or to plain film mammograms that have been digitized. CAD has been used for 2 different purposes: (i) to improve radiologists' ability to identify suspicious areas that may otherwise be overlooked on screening mammograms (detection), and (ii) to distinguish between benign and malignant lesions (diagnosis). The radiologist remains the reader and interpreter of the mammogram. CAD assists the radiologist by identifying areas warranting further review.

The American Cancer Society breast cancer screening guidelines (Smith et al, 2003) indicate that for digital mammography and CAD there is “some clinical evidence for effectiveness or equivalence to screen-film mammography for screening” (Evidence Level B).

Bennett et al (2006) assessed current evidence to ascertain if the accuracy of single reading with CAD compares with that of double reading. These researchers performed a literature review to identify studies where both protocols had been investigated and compared. They identified 8 studies that compared single reading with CAD against double reading, of which 6 reported on comparisons of both sensitivity and specificity. Of the 6 studies identified, 3 showed no differences in either sensitivity or specificity; 1 showed single reading with CAD had a higher sensitivity at the same specificity; 1 showed that single reading with CAD had a higher specificity at the same sensitivity. However, 1 study, in a real-life setting, showed that single reading with CAD had a higher sensitivity but a lower specificity. The authors concluded that as the majority of the studies were not in a real-life setting, used test sets, lacked sufficient training in the use of CAD and simulated double reading (using a protocol of recall if one suggests), current evidence

is therefore limited as to the accuracy, in terms of sensitivity and specificity, of single reading with CAD in comparison with the most common practice in the United Kingdom of double reading using a protocol of consensus or arbitration.

Fenton and colleagues (2007) stated that CAD identifies suspicious findings on mammograms to assist radiologists. Since the FDA approved the technology in 1998, it has been disseminated into practice, but its effect on the accuracy of interpretation is unclear. These investigators determined the association between the use of CAD at mammography facilities and the performance of screening mammography from 1998 through 2002 at 43 facilities in 3 states. They had complete data for 222,135 women (a total of 429,345 mammograms), including 2,351 women who received a diagnosis of breast cancer within 1 year after screening. They calculated the specificity, sensitivity, and positive predictive value of screening mammography with and without CAD, as well as the rates of biopsy and breast-cancer detection and the overall accuracy, measured as the area under the receiver-operating-characteristic (ROC) curve. A total of 7 facilities (16 %) implemented CAD during the study period. Specificity decreased from 90.2 % before implementation to 87.2 % following implementation ($p < 0.001$), the positive predictive value decreased from 4.1 % to 3.2 % ($p = 0.01$), and the rate of biopsy increased by 19.7 % ($p < 0.001$). The increase in sensitivity from 80.4 % before implementation of CAD to 84.0 % after implementation was insignificant ($p = 0.32$). The change in the cancer-detection rate (including invasive breast cancers and ductal carcinomas in situ) was insignificant (4.15 cases per 1,000 screening mammograms before implementation and 4.20 cases after implementation, $p = 0.90$). Analyses of data from all 43 facilities showed that the use of CAD was associated with significantly lower overall accuracy than was non-use (area under the ROC curve, 0.871 versus 0.919; $p = 0.005$). The authors concluded that the use of CAD is associated with reduced accuracy of interpretation of screening mammograms. The increased rate of biopsy with the use of CAD is not clearly associated with improved detection of invasive breast cancer. This is in agreement with Bazzocchi et al (2007) who noted that there is still considerable variation among different studies in the level of benefit deriving from CAD. Thus, the role of these systems in clinical practice is still debated, and their real contribution to the overall management of the diagnostic process is still unclear.

An assessment of CAD in mammography screening by the Swedish Council on Health Technology Assessment (SBU, 2011) concluded that the scientific evidence is insufficient to determine whether CAD plus single reading by one breast radiologist would yield results that are at least equivalent to those obtained in standard practice, i.e. double reading where two breast radiologists independently read the x-ray images.

Screening film mammography has been shown to reduce the mortality rate from breast cancer; however, conventional mammography does not detect all breast cancers. A significant factor contributing to the limitations of mammography is the structure overlap that results on a 2-dimensional mammogram. Structure overlap not only obscures lesions, but can mimic abnormalities, thus contributing to reductions in both the sensitivity and specificity of mammography. A number of new imaging techniques and enhancements for digital mammography have recently become available or are likely to become available in the near future.

Breast tomosynthesis is a 3-dimensional imaging technique that involves acquiring images of a stationary compressed breast at multiple angles during a short scan. The individual images are then reconstructed into a series of thin, high-resolution slices that can be displayed individually or in a dynamic cine mode. While holding the breast stationary, images are acquired at a number of different x-ray source angles. Objects at different heights in the breast project differently for each angle. The data are then reconstructed to generate images that enhance objects from a given height by appropriate shifting of the projections relative to one another. Three important areas in tomosynthesis system requirements are: (i) detector efficiency and dose, (ii) field of view, and (iii) equipment geometry. While holding the breast stationary, an x-ray tube is rotated over a limited angular range and a series of low-dose exposures are made every few degrees, creating a series of digital images. The x-ray tube is rotated about +/-15 degrees, and 11 exposures are made every 3 degrees during a total scan of a few seconds. These individual images are then reconstructed into slices. There are 2 basic tomosynthesis system designs that differ in the motion of the detector during acquisition. One method moves the detector in concert with the x-ray tube so as to maintain the shadow of the breast on the detector. An altenate method is to keep the detector stationary relative to the breast platform. The tomosynthesis reconstruction process consists of computing high-resolution images whose planes are parallel to the breast support plates. These images are reconstructed with slice separation of 1 mm; thus, a 5-cm compressed breast tomosynthesis study will have 50 reconstructed slices. The reconstructed tomosynthesis slices can be displayed similarly to computed tomography reconstructed slices. Proponents of breast tomosynthesis hope it will resolve many of the tissue overlap reading problems that are a major source of recalls and additional imaging in 2-D mammography examinations (Smith, 2005). Tomosynthesis is currently in clinical trials to evaluate its effectiveness. Initial pilot studies suggested that breast tomosynthesis has comparable or superior image quality to that of film-screen mammography and has the potential to decrease the recall rate when used adjunctively with digital screening mammography (Good et al, 2008; Chen et al, 2007; Poplack et al, 2007); however, further studies are needed to evaluate its effectiveness in clinical practice.

Helvie (2010) discussed recent developments in advanced derivative technologies associated with digital mammography. Digital breast tomosynthesis, its principles, development, and early clinical trials, were reviewed. Contrast-enhanced digital mammography and combined imaging systems with digital mammography and ultrasound

were also discussed. Although all these methods are currently research programs, they hold promise for improving cancer detection and characterization if early results are confirmed by clinical trials.

Spangler and colleagues (2011) compared the ability of digital breast tomosynthesis and full field digital mammography (FFDM) to detect and characterize calcifications. A total of 100 paired examinations were performed utilizing FFDM and digital breast tomosynthesis: 20 biopsy-proven cancers, 40 biopsy-proven benign calcifications, and 40 randomly selected negative screening studies were retrospectively reviewed by 5 radiologists in a crossed multi-reader multi-modal observer performance study. Data collected included the presence of calcifications and forced Breast Imaging, Reporting and Data System (BI-RADS) scores. Receiver operator curve analysis using BI-RADS was performed. Overall calcification detection sensitivity was higher for FFDM (84 % [95 % CI: 79 % to 88 %]) than for digital breast tomosynthesis (75 % [95 % CI: 70 % to 80 %]). In the cancer cohort, 75 (76 %) of 99 interpretations identified calcification in both modes. Of those, a BI-RADS score less than or equal to 2 was rendered in 3 (4 %) and 9 (12 %) cases with FFDM and digital breast tomosynthesis, respectively. In the benign cohort, 123 (62 %) of 200 interpretations identified calcifications in both modes. Of those, a BI-RADS score greater than or equal to 3 was assigned in 105 (85 %) and 93 (76 %) cases with FFDM and digital breast tomosynthesis, respectively. There was no significant difference in the non-parametric computed AUC using the BI-RADS scores (FFDM, AUC = 0.76 and SD = 0.03; digital breast tomosynthesis, AUC = 0.72 and SD = 0.04 [p = 0.1277]). The authors concluded that in this small data set, FFDM appears to be slightly more sensitive than digital breast tomosynthesis for the detection of calcification. However, diagnostic performance as measured by AUC using BI-RADS was not significantly different. With improvements in processing algorithms and display, digital breast tomosynthesis could potentially be improved for this purpose.

On February 2011, the FDA approved the Selenia Dimensions 3D System (Digital Breast Tomosynthesis), a mammography device that provides digital 2D and 3D images for the screening and diagnosis of breast cancer.

Guidelines on breast cancer screening from the American College of Obstetricians and Gynecologists (ACOG, 2011) considered, but did not recommend, breast tomosynthesis. The guidelines concluded that "[c]olor Doppler ultrasonography, computer-aided detection, positron emission tomography, scintimammography, and digital breast tomosynthesis have shown promise in selected clinical situations or as adjuncts to mammography for breast cancer diagnosis. However, these technologies are not considered alternatives to routine mammography."

The ongoing TOMMY trial: (A comparison of TOMosynthesis with digital MammographY in the UK NHS Breast Screening Programme) will compare the accuracy of digital breast tomosynthesis (DBT) with standard digital full field mammography(FFDM) in the diagnosis of breast cancer. The aim of the trial is to assess whether DBT could improve upon digital mammography as a screening tool, particularly in certain groups of women, e.g. those with a family history of breast cancer, or women with dense breasts. The diagnostic accuracy of DBT, FFDM and DBT+FFDM will be evaluated in an independent retrospective reading study and compared to the final clinical outcome for each case.

Sahiner et al (2012) designed a computer-aided detection (CADe) system for clustered micro-calcifications in reconstructed DBT volumes and performed a preliminary evaluation of the CADe system. Institutional review board approval and informed consent were obtained in this study. A data set of 2-view DBT of 72 breasts containing micro-calcification clusters was collected from 72 subjects who were scheduled to undergo breast biopsy. Based on tissue sampling results, 17 cases had breast cancer and 55 were benign. A separate data set of 2-view DBT of 38 breasts free of clustered micro-calcifications from 38 subjects was collected to independently estimate the number of false-positives (FPs) generated by the CADe system. A radiologist experienced in breast imaging marked the biopsied cluster of micro-calcifications with a 3D bounding box using all available clinical and imaging information. A CADe system was designed to detect micro-calcification clusters in the reconstructed volume. The system consisted of pre-screening, clustering, and FP reduction stages. In the pre-screening stage, the conspicuity of micro-calcification-like objects was increased by an enhancement-modulated 3D calcification response function. An iterative thresholding and 3D object growing method was used to detect cluster seed objects, which were used as potential centers of micro-calcification clusters. In the cluster detection stage, micro-calcification candidates were identified using a 2nd iterative thresholding procedure, which was applied to the signal-to-noise ratio (SNR) enhanced image voxels with a positive calcification response. Starting with each cluster seed object as the initial cluster center, a dynamic clustering algorithm formed a cluster candidate by including micro-calcification candidates within a 3D neighborhood of the cluster seed object that satisfied the clustering criteria. The number, size, and SNR of the micro-calcifications in a cluster candidate and the cluster shape were used to reduce the number of FPs. The pre-screening stage detected a cluster seed object in 94 % of the biopsied micro-calcification clusters at a threshold of 100 cluster seed objects per DBT volume. After clustering, the detection sensitivity was 90 % at 15 marks per DBT volume. After FP reduction, at 85 % sensitivity, the average number of FPs estimated using the data set containing micro-calcification clusters was 3.8 per DBT volume, and that estimated using the data set free of micro-calcification clusters was 3.4. The detection performance for malignant micro-calcification clusters was superior to that for benign clusters. The authors concluded that these findings indicated the feasibility of the 3D approach to the detection of clustered micro-calcifications in DBT and that the newly designed enhancement-modulated 3D calcification response function is promising for pre-screening. They stated that further work is needed to assess the generalizability of this approach and to improve its performance.

Skaane and colleagues (2012) noted that DBT is a promising new technology. Some experimental clinical studies have shown positive results, but the future role and indications of this new technique, whether in a screening or clinical setting, need to be evaluated. These investigators compared DM and DBT in a side-by-side feature analysis for cancer conspicuity, and examined if there is a potential additional value of DBT to standard state-of-the-art conventional imaging work-up with respect to detection of additional malignancies. The study had ethics committee approval. A total of 129 women underwent 2D DM including supplementary cone-down and magnification views and breast ultrasonography if indicated, as well as DBT. The indication for conventional imaging in the clinical setting included a palpable lump in 30 (23 %), abnormal mammographic screening findings in 54 (42 %), and surveillance in 45 (35 %) of the women. The women were examined according to present guidelines, including spot-magnification views, ultrasonography, and needle biopsies, if indicated. The DBT examinations were interpreted several weeks after the conventional imaging without knowledge of the conventional imaging findings. In a later session, 3 radiologists performed a side-by-side feature analysis for cancer conspicuity in a sample of 50 cases. State-of-the-art conventional imaging resulted in needle biopsy of 45 breasts, of which 20 lesions were benign and a total of 25 cancers were diagnosed. The remaining 84 women were dismissed with a normal/definitely benign finding and without indication for needle biopsy. The subsequent DBT interpretation found suspicious findings in 4 of these 84 women, and these 4 women had to be called back for repeated work-up with knowledge of the tomosynthesis findings. These delayed work-ups resulted in 2 cancers (increasing the cancer detection by 8 %) and 2 FP findings. The side-by-side feature analysis showed higher conspicuity scores for tomosynthesis compared to conventional 2D for cancers presenting as spiculated masses and distortions. The authors concluded that DBT is a promising new technique. The authors' preliminary clinical experience showed that there is a potential for increasing the sensitivity using this new technique, especially for cancers manifesting as spiculated masses and distortions.

Also, an UpToDate review on "Breast imaging: Mammography and ultrasonography" (Venkataraman, 2012) states that "Tomosynthesis is a modification of digital mammography and uses a moving x-ray source and digital detector. A three dimensional volume of data is acquired and reconstructed using computer algorithms to generate thin sections of images …. The examination has a slightly longer exposure time of 10 seconds per acquisition compared to standard digital mammography, which could increase the radiation dose per acquisition and increase the risk of motion artifacts. This technique shows promise in screening women with dense breast tissue and with high risk for breast cancer".

Bernardi et al (2012a) stated that there is limited evidence on the role of 3D mammography with tomosynthesis in breast screening, although early studies suggested that it may improve specificity. These researchers prospectively evaluated the effect of integrating 3D mammography as a triage to assessment in 158 consecutive recalls to assessment (recalled in standard 2D-mammographic screening) in asymptomatic subjects. Radiologists provided 3D mammography-based opinion as to whether recall/assessment was warranted or unnecessary, and all subjects proceeded to assessment. 3D triage was positive (confirmed the need for assessment) in all 21 subjects with breast cancer (there were no false-negatives), and would have avoided recall in 102 of 137 (74.4 %) subjects with a negative/benign final outcome in whom 3D triage did not recommend recall. Proportion of true negative 3D triage (as a proxy for potential reduction in recalls) was slightly higher in dense than non-dense breasts, did not differ across age-groups, but was significantly associated with the type of lesion seen on imaging (being highest for distortions, asymmetric densities, and lesions with ill-defined margins). While the simulation design may have over-estimated the potential for 3D mammography triage to reduce recalls, this study clearly demonstrates its capability to improve breast screening specificity and to reduce recall rates. The authors stated that future studies of 3D mammography should further assess its role as a recall-reducing strategy in screening practice and should include formal cost-analysis.

Bernardi et al (2012b) supplemented the paucity of information available on logistical aspects of the application of 3D mammography in breast screening. These investigators prospectively examined the effect on radiographers' and radiologists' workload of implementing 3D mammography in screening by comparing image acquisition time and screen-reading time for 2D mammography with that of combined 2D+3D mammography. Radiologists' accuracy was also calculated. Average acquisition time (measured from start of first-view breast positioning to compression release at completion of last view) for 7 radiographers, based on 20 screening examinations, was longer for 2D+3D (4 min 3 s; range of 3 min 53 s to 4 min 18 s) than 2D mammography (3 min 13 s; range of 3 min 0 s to 3 min 26 s; $p < 0.01$). Average radiologists' reading time per screening examination (3 radiologists reading case-mix of 100 screens: 10 cancers, 90 controls) was longer for 2D+3D (77 s; range of 60 to 90 s) than for 2D mammography (33 s; range of 25 to 46 s; $p < 0.01$). 2D+3D screen-reading was associated with detection of more cancers and with substantially fewer recalls than 2D mammography alone. The authors concluded that relative to standard 2D mammography, combined 2D+3D mammography prolongs image acquisition time and screen-reading time (at initial implementation), and appears to be associated with improved screening accuracy. They stated that these findings provided relevant information to guide larger trials of integrated 3D mammography (2D+3D) and its potential implementation into screening practice.

Zhao et al (2012) noted that mammography is the primary imaging tool for screening and diagnosis of human breast cancers, but approximately 10 to 20 % of palpable tumors are not detectable on mammograms and only about 40 % of biopsied lesions are malignant. These researchers reported a high-resolution, low-dose phase contrast X-ray

tomographic method for 3D diagnosis of human breast cancers. By combining phase contrast X-ray imaging with an image reconstruction method known as equally sloped tomography, these investigators imaged a human breast in 3D and identified a malignant cancer with a pixel size of 92 μm and a radiation dose less than that of dual-view mammography. According to a blind evaluation by 5 independent radiologists, this method can reduce the radiation dose and acquisition time by approximately 74 % relative to conventional phase contrast X-ray tomography, while maintaining high image resolution and image contrast. The authors concluded that these results demonstrated that high-resolution 3D diagnostic imaging of human breast cancers can, in principle, be performed at clinical compatible doses.

Houssami and Skaane (2013) stated that DBT, a 3D derivative of DM, reduces the effect of tissue superimposition and may improve mammographic interpretation. These investigators examined the evidence on the accuracy of DBT in clinical studies. Published studies of DBT were relatively small studies, mostly test-set observer (reader) studies or clinical series that included symptomatic and screen-recalled cases, and were generally enriched with cancers. With these limitations in mind, the evidence showed some consistent findings, summarized as follows: 2-view DBT has at least equal or better accuracy than standard 2-view DM, whereas 1-view DBT does not have better accuracy than standard DM; the addition of DBT to standard mammography (for mammographic interpretation or for assessment or triage of screen-recalled abnormalities) increases accuracy; improved accuracy from using DBT (relative to, or added to, DM) may be due to increased cancer detection or due to reduced false positive recalls, or both; and subjective interpretation of cancer conspicuity consistently found that cancers were equally or more conspicuous on DBT relative to DM. Preliminary data from population screening trials suggested that the integration of DBT with conventional DM (screen-reading using combined 2D + 3D mammography) may substantially improve breast cancer detection, although final results are not yet available, and many logistical issues need further evaluation to determine the potential implications and cost of combined 2D + 3D mammographic screening. At present, there is insufficient evidence to justify a change from standard DM to DBT however the available data strongly support investment in new large-scale population screening trials. These trials need to avoid the 'double' acquisitions required for 2D + 3D mammograms, and should therefore focus on evaluating integrated 2Dsynthetic + 3D mammography (where 2D-images are reconstructed from the DBT acquisition), and should consider using a randomized design.

Alakhras et al (2013) reviewed the major limitations in current mammography and described how these may be addressed by DBT. Digital breast tomosynthesis is a novel imaging technology in which an x-ray fan beam sweeps in an arc across the breast, producing tomographic images and enabling the production of volumetric, 3D data. It can reduce tissue overlap encountered in conventional 2D mammography, and thus has the potential to improve detection of breast cancer, reduce the suspicious presentations of normal tissues, and facilitate accurate differentiation of lesion types.

Also, an ACOG technology assessment on “Digital breast tomosynthesis” (2013) stated that this strategy of 2D plus 3D mammography would need to be compared to other potential strategies for comparative cost-effectiveness, such as the use of computer aided detection. Additional studies will be needed to confirm whether digital mammography with tomosynthesis is a cost-effective approach capable of replacing digital mammography alone as the first-line screening modality of choice for breast cancer screening. Furthermore, the ACOG technology assessment also noted the concern with the high-dose of radiation with breast tomosynthesis.

Poller et al (2012) stated that annual ultrasound screening may detect small, node-negative breast cancers that are not seen on mammography; and magnetic resonance imaging (MRI) may reveal additional breast cancers missed by both mammography and ultrasound screening. These researchers examined supplemental cancer detection yield of ultrasound and MRI in women at elevated risk for breast cancer. From April 2004 to February 2006, a total of 2,809 women at 21 sites with elevated cancer risk and dense breasts consented to 3 annual independent screens with mammography and ultrasound in randomized order. After 3 rounds of both screenings, 612 of 703 women who chose to undergo an MRI had complete data. The reference standard was defined as a combination of pathology (biopsy results that showed in-situ or infiltrating ductal carcinoma or infiltrating lobular carcinoma in the breast or axillary lymph nodes) and 12-month follow-up. Main outcome measures included cancer detection rate (yield), sensitivity, specificity, positive-predictive value (PPV3) of biopsies performed and interval cancer rate. A total of 2,662 women underwent 7,473 mammogram and ultrasound screenings, 110 of whom had 111 breast cancer events: 33 detected by mammography only, 32 by ultrasound only, 26 by both, and 9 by MRI after mammography plus ultrasound; 11 were not detected by any imaging screen. Among 4,814 incidence screens in the 2nd and 3rd years combined, 75 women were diagnosed with cancer. Supplemental incidence-screening ultrasound identified 3.7 cancers per 1,000 screens (95 % CI: 2.1 to 5.8; $p < 0.001$). Sensitivity for mammography plus ultrasound was 0.76 (95 % CI: 0.65 to 0.85); specificity, 0.84 (95 % CI: 0.83 to 0.85); and PPV3, 0.16 (95 % CI: 0.12 to 0.21). For mammography alone, sensitivity was 0.52 (95 % CI: 0.40 to 0.64); specificity, 0.91 (95 % CI: 0.90 to 0.92); and PPV3, 0.38 (95 % CI: 0.28 to 0.49; $p < 0.001$ all comparisons). Of the MRI participants, 16 women (2.6 %) had breast cancer diagnosed. The supplemental yield of MRI was 14.7 per 1,000 (95 % CI: 3.5 to 25.9; $p = 0.004$). Sensitivity for MRI and mammography plus ultrasound was 1.00 (95 % CI: 0.79 to 1.00); specificity, 0.65 (95 % CI: 0.61 to 0.69); and PPV3, 0.19 (95 % CI: 0.11 to 0.29). For mammography and ultrasound, sensitivity was 0.44 (95 % CI: 0.20 to 0.70, $p = 0.004$); specificity 0.84 (95 % CI: 0.81 to 0.87; $p < 0.001$); and PPV3, 0.18 (95 % CI: 0.08 to 0.34; $p = 0.98$). The number of screens needed to detect 1 cancer was 127 (95 % CI: 99 to 167) for mammography;

234 (95 % CI: 173 to 345) for supplemental ultrasound; and 68 (95 % CI: 39 to 286) for MRI after negative mammography and ultrasound results. The authors concluded that the addition of screening ultrasound or MRI to mammography in women at increased risk of breast cancer resulted in not only a higher cancer detection yield but also an increase in false-positive findings.

Currently, there are no recommendations to screen men at risk for hereditary breast cancer with mammography. Robson (2002) explained "There are no established guidelines for screening of men at risk for hereditary breast cancer. It is reasonable to suggest periodic self-examination and evaluation by a provider experienced in clinical breast examination. The utility of screening mammography in men is unknown, although it is technically possible in at least some individuals." However, diagnostic mammography may be indicated in men with a breast mass on clinical examination (American Cancer Society, 2003).

Xeroradiography (Xerox Corporation, Stamford, CT) is an outmoded X-ray imaging method that had been used especially in mammographic screening for breast cancer. With Xeroradiography, X-rays pass through the body to an X-ray-sensitive metal plate. The plate is then processed through a unique photocopying-type machine, and the X-ray image transferred to paper rather than X-ray film. Unlike photographically recorded X-ray images, Xeroradiographs produce a "positive" image in which the denser elements appear darker. Unlike X-ray films, the Xeroradiographic image is a mirror image of the object. The primary advantage of Xeroradiography over conventional plain film mammography is that the former produces instant radiographs. However, Xeroradiography has become outmoded because the radiation exposure required is much higher than with conventional radiographs, and the Xeroradiographic image has a number of defects, such as excessive contrast and edge enhancement.

Fredenberg and colleagues (2010) noted that spectral imaging is a method in medical x-ray imaging to extract information about the object constituents by the material-specific energy dependence of x-ray attenuation. The authors have investigated a photon-counting spectral imaging system with 2 energy bins for contrast-enhanced mammography. System optimization and the potential benefit compared to conventional non-energy-resolved absorption imaging were studied. A framework for system characterization was set up that included quantum and anatomical noise and a theoretical model of the system was benchmarked to phantom measurements. Optimal combination of the energy-resolved images corresponded approximately to minimization of the anatomical noise, which is commonly referred to as energy subtraction. In that case, an ideal-observer detectability index could be improved close to 50% compared to absorption imaging in the phantom study. Optimization with respect to the signal-to-quantum-noise ratio, commonly referred to as energy weighting, yielded only a minute improvement. In a simulation of a clinically more realistic case, spectral imaging was predicted to perform approximately 30 % better than absorption imaging for an average glandularity breast with an average level of anatomical noise. For dense breast tissue and a high level of anatomical noise, however, a rise in detectability by a factor of 6 was predicted. Another approximately 70 to 90 % improvement was found to be within reach for an optimized system. The authors concluded that contrast-enhanced spectral mammography is feasible and beneficial with the current system, and there is room for additional improvements. Inclusion of anatomical noise is essential for optimizing spectral imaging systems.

Schmitzberger et al (2011) demonstrated the feasibility of low-dose photon-counting tomosynthesis in combination with a contrast agent (contrast material-enhanced tomographic mammography) for the differentiation of breast cancer. All studies were approved by the institutional review board, and all patients provided written informed consent. A phantom model with wells of iodinated contrast material (3 mg of iodine per milliliter) 1, 2, 5, 10, and 15 mm in diameter was assessed. A total of 9 patients with malignant lesions and 1 with a high-risk lesion (atypical papilloma) were included (all women; mean age of 60.7 years). A multi-slit photon-counting tomosynthesis system was utilized (spectral imaging) to produce both low- and high-energy tomographic data (below and above the k edge of iodine, respectively) in a single scan, which allowed for dual-energy visualization of iodine. Images were obtained prior to contrast material administration and 120 and 480 seconds after contrast material administration. Four readers independently assessed the images along with conventional mammograms, ultrasonographic images, and magnetic resonance images. Glandular dose was estimated. Contrast agent was visible in the phantom model with simulated spherical tumor diameters as small as 5 mm. The average glandular dose was measured as 0.42 mGy per complete spectral imaging tomosynthesis scan of one breast. Because there were 3 time-points (prior to contrast medium administration and 120 and 480 seconds after contrast medium administration), this resulted in a total dose of 1.26 mGy for the whole procedure in the breast with the abnormality. Seven of 10 cases were categorized as Breast Imaging Reporting and Data System score of 4 or higher by all four readers when reviewing spectral images in combination with mammograms. One lesion near the chest wall was not captured on the spectral image because of a positioning problem. The authors concluded that the use of contrast-enhanced tomographic mammography has been demonstrated successfully in patients with promising diagnostic benefit. They stated that further studies are necessary to fully assess diagnostic sensitivity and specificity.

An American College of Obstetrician and Gynecologist technology assessment on "Digital breast tomosynthesis" (ACOG, 2013) noted that "Clinical data suggest that digital mammography with tomosynthesis produces a better image, improved accuracy, and lower recall rates compared with digital mammography alone. Further study will be necessary to confirm whether digital mammography with tomosynthesis is a cost-effective approach, capable of replacing digital mammography alone as the first-line screening modality of choice for breast cancer screening".

An UpToDate review on “Breast imaging: Mammography and ultrasonography” (Venkataraman and Slanetz, 2014) states that “At present, tomosynthesis is approved only to be performed in conjunction with a conventional mammogram. Hence, when performed in the screening setting, the patient is exposed to approximately twice the usual radiation dose, which sometimes is greater if the patient had dense or thick breasts. This technique shows promise in screening women with dense breast tissue and with high risk for breast cancer, although there are no prospective large studies to justify its routine use at the present time”.

A BlueCross BlueShield Association TEC Assessment, “Use of digital breast tomosynthesis with mammography for breast cancer screening or diagnosis” (BCNSA, 2014), concluded that “Improved health outcomes following the addition of breast tomosynthesis to screening or diagnostic mammography [has] not been demonstrated in the investigational setting. Based on the above, the addition of digital breast tomosynthesis to screening or diagnostic mammography does not meet the TEC criteria”.

National Cancer Institute’s Factsheet on “Mammograms” (NCI, 2014) states that “Three-dimensional (3D) mammography, also known as breast tomosynthesis, is a type of digital mammography in which x-ray machines are used to take pictures of thin slices of the breast from different angles and computer software is used to reconstruct an image. This process is similar to how a computed tomography (CT) scanner produces images of structures inside of the body. 3D mammography uses very low dose x-rays, but, because it is generally performed at the same time as standard two-dimensional (2D) digital mammography, the radiation dose is slightly higher than that of standard mammography. The accuracy of 3D mammography has not been compared with that of 2D mammography in randomized studies. Therefore, researchers do not know whether 3D mammography is better or worse than standard mammography at avoiding false-positive results and identifying early cancers”.

NCCN guidelines on breast cancer screening (NCCN, 2014) conclude: "Early studies show promise for tomosynthesis mammography. Two large trials showing a combined use of digital mammography and tomosynthesis showed improved cancer detection and decreased call back rates; of note, this is double the dose of radiation and is a factor in recommending this modality. Definitive studies are still pending."

An assessment by the Standing Committee on Screening of the Screening Section of the Australian Department of Health and Ageing (2013) stated that: "Whilst there is some evidence that DBT is at least as sensitive and specific as DM, it is not clear whether the use of DBT in large populations outside of a research setting would deliver the same results or whether the additional cost is justified. The issue of radiation dose also needs to be considered in terms of safety for women being screened.'

Allec et al (2011) noted that the accumulation of injected contrast agents allows the image enhancement of lesions through the use of contrast-enhanced mammography. In this technique, the combination of 2 acquired images is used to create an enhanced image. There exist several methods to acquire the images to be combined, which include dual energy subtraction using a single detection layer that suffers from motion artifacts due to patient motion between image acquisition. To mitigate motion artifacts, a detector composed of 2 layers may be used to simultaneously acquire the low and high energy images. In this work, these researchers evaluated both of these methods using amorphous selenium as the detection material to find the system parameters (tube voltage, filtration, photoconductor thickness and relative intensity ratio) leading to the optimal performance. They then compared the performance of the 2 detectors under the variation of contrast agent concentration, tumor size and dose. The detectability was found to be most comparable at the lower end of the evaluated factors. The single-layer detector not only led to better contrast, due to its greater spectral separation capabilities, but also had lower quantum noise. The single-layer detector was found to have a greater detectability by a factor of 2.4 for a 2.5 mm radius tumor having a contrast agent concentration of 1.5 mg ml(-1) in a 4.5 cm thick 50 % glandular breast. The authors stated that the inclusion of motion artifacts in the comparison is part of ongoing research efforts.

Furthermore, an UpToDate review on "MRI of the breast and emerging technologies" (Slanetz, 2013) states that "Emerging Imaging Technology for Breasr Cancer Detection -- Recognition of the limitations of mammography, ultrasound, and breast MRI has led to investigation of other breast imaging techniques including contrast-enhanced dual energy digital mammography, high-field strength MRI, magnetic resonance spectroscopy, diffusion weighted imaging, breast specific gamma imaging, and positron emission mammography". Contrast enhanced spectral mammography is not mentioned in this review.

CPT Codes / HCPCS Codes / ICD-9 Codes

CPT codes covered if selection criteria are met:

+ 77051

+ 77052

77055

77056

77057

HCPCS codes covered if selection criteria are met:

G0202	Screening mammography, producing direct digital image, bilateral, all views
G0204	Diagnostic mammography, producing direct digital image, bilateral, all views
G0206	Diagnostic mammography, producing direct digital image, unilateral, all views

ICD-9 codes covered if selection criteria are met:

174.0 - 174.9	Malignant neoplasm of female breast
198.81	Secondary malignant neoplasm of breast
217	Benign neoplasm of breast
233.0	Carcinoma in situ of breast
238.3	Neoplasm of uncertain behavior of breast
610.0 - 611.9	Disorders of breast
V10.3	Personal history of malignant neoplasm of breast
V16.3	Family history of malignant neoplasm of breast
V76.11	Screening mammogram for high-risk patient
V76.12	Other screening mammogram
