

Samples #1 (lost piece) from 62

43338500

The limestone has veins in numerous large boulders in a matrix of soil. Broken in thin a clean cut exposure of undecomposed well developed fine looking white granite and by all that's holy, the pieces that made that granite have permeated this matrix of detrital material - including lake bed soil, and formed the granite a la Goodspeed's general hypothesis. Actual pebbles of lake gravel + angular pieces of limestone to be seen surrounded by granite. - a soft decomposed loosely crystalline sort of granite - and the texture grades from granite to clay + back again imperceptibly. If this sort a la Goodspeed, I'd eat my shirt + buy a size 44 special for the occasion.

Travertine around 83 all dips back towards the rim above, but dips so at acute angles which vary from 20° to 65°, averaging possibly 45°. This together with the fact that the veins in broken into large pieces suggests it has slid from the veins in the rim above, + that the occurrence of travertine at both this + lower elevation on this particular slope should not be construed to indicate ~~the~~ possible thickness of the deposit back under the rim of the main hill top - (area 77-79, etc)
