

# Oregon Forest Ecosystem Carbon Inventory: 2001-2016

Glenn A. Christensen<sup>1</sup>, Andrew N. Gray<sup>1</sup>, Olaf Kuegler<sup>1</sup>, & Andrew C. Yost<sup>2</sup>

Report completed through an agreement between the U.S. Forest Service, Pacific Northwest Research Station, and the Oregon Department of Forestry  
(PNW Agreement No. 18-C-CO-11261979-019)

<sup>1</sup>U.S. Department of Agriculture, Forest Service, Pacific Northwest Research Station

<sup>2</sup> Oregon Department of Forestry

October 29, 2019

## Acronyms

AB – Assembly Bill

BLM – Bureau of Land Management

C – carbon

CF – cubic feet

CH<sub>4</sub> - methane

CI – confidence interval

CO - carbon monoxide

CO<sub>2</sub>e – carbon dioxide equivalent

DBH – diameter at breast height

EPA – Environmental Protection Agency

FF – Forest Land Remaining Forest (IPCC terminology)

FIA – Forest Inventory and Analysis

FIADB – FIA database

FMRL – Forest Management Reference Level

GHG – greenhouse gas

GRM – Growth, Removals and Mortality

HA – hectares

HWP – harvested wood product

ICE – Image-based Change Estimation

IPCC – Intergovernmental Panel on Climate Change

LF – Forest Land Conversions (IPCC terminology)

mm – millimeter

MMT – million metric tons

MT – metric tons

NFS – National Forest System

NGHGI – National Greenhouse Gas Inventory

NMVOC – non-methane volatile organic compounds

N<sub>2</sub>O – nitrous oxide

NO<sub>x</sub> - nitrogen oxides

NRCS – Natural Resources Conservation Service

NRI – Natural Resources Inventory

ODF – Oregon Department of Forestry

PNW – Pacific Northwest Research Station

RPA – Resources Planning Act

SOC – soil organic carbon

µm – micrometer i.e., one millionth of a meter

UNFCCC – United Nations Framework Convention on Climate Change

USDA – United States Department of Agriculture

USFS – United States Forest Service

USGS – United States Geological Survey

<b>Aboveground and belowground live understory vegetation pools, 10-year averages:</b> All of Oregon by 10-year averages (Tables C27.1)
<b>Belowground live understory vegetation pool:</b> All of Oregon (Table C28) and by ecoregion (Tables C29-C35), 2007-2016
<b>Belowground live tree pool:</b> All of Oregon (Table C36) and by ecoregion (Tables C37-C43), 2007-2016
<b>Belowground live and dead tree pools, 10-year averages:</b> All of Oregon by 10-year averages (Tables C44.1)
<b>Belowground dead tree pool:</b> All of Oregon (Table C45) and by ecoregion (Tables C46-C52), 2007-2016
<b>Soil-organic carbon pool:</b> All of Oregon (Table C53) and by ecoregion (Tables C54-C60), 2007-2016
All of Oregon by 10-year averages (Tables C61.1)
<b>Aboveground down dead wood pool:</b>

All of Oregon (Table C62) and by ecoregion (Tables C63-C69), 2007-2016
All of Oregon by 10-year averages (Tables C70.1)
<b>Aboveground forest floor pool:</b>
All of Oregon (Table C71) and by region (Tables C72-C78), 2007-2016
All of Oregon by 10-year averages (Tables C79.1)
<b><i>Forest land conversions (LF)</i></b>
Annual change in forest land area to/from other IPCC landuse classes in Oregon, 2001-6 to 2011-16 (Table E1)
<b>Net forest carbon flux from forest land-use conversions:</b>
Annual change in carbon pools due to change in land use between forest and nonforest in Oregon, 2001-6 to 2011-16 (Table E2)
<b><i>Net flux from other GHG emissions:</i></b>
Annual net emissions of non-CO <sub>2</sub> greenhouse gasses from fire by owner group and class for all of Oregon, 2001-2006 to 2011-2016 (Table F1)

## Chapter 1. Executive summary and key findings

The pursuit of carbon mitigation with forest management policy in Oregon has consistently resulted in the recognition that a reliable forest carbon accounting framework is fundamental to the policy development and monitoring process. This report, based on an extensive field plot monitoring system, supplies the quantitative dimension of that forest carbon accounting framework by providing estimates for the status and trends of carbon in Oregon's forest ecosystems and ownerships since 2001. The information in this report is based on measurements conducted on 9,483 forested plots in Oregon by the Forest Inventory and Analysis Program (FIA) within the USDA Forest Service. This report includes a brief introduction to the pursuit of forest carbon accounting in Oregon and an overview of the forest carbon cycle (Chapter 2) followed by a description of the methods used to inventory Oregon's forests and estimate forest carbon (Chapter 3). The results of the analysis are presented in Chapter 4 and are based on a subset of the abundant tabular data this analysis provides. Estimates of forest carbon across five forest ownerships and seven ecoregions are first reported in terms of flux, which is the difference between the amount of carbon that enters, and the amount that leaves, one of seven different pools of carbon. Estimates are then reported in terms of the amount of carbon stored in each pool. The results are compared with estimates from other reports and research in Chapter 5 and strategies for improving the inventory and analytical methods are discussed in Chapter 6. In this analysis results of carbon physically present in the forest are given in metric tons (MT) of carbon (C). Results of carbon flux, the amount and rate of gaseous carbon being emitted or sequestered by the forest, are given in metric tons (MT) of carbon dioxide equivalent (CO<sub>2</sub>e).

### Forest Carbon Flux

One of the most important features of this report is that as of the 2016 reporting period, Oregon's forests have been functioning as a net sink of carbon. According to the estimates made from remeasured FIA plots, Oregon's recent statewide rate of carbon flux from all forest pools across all ownerships and ecoregions is approximately  $30.9 \pm 7.4$  MMT CO<sub>2</sub>e per year (Table 4.1). This estimate excludes net CO<sub>2</sub>e contributions from other sources such as harvested wood products which will appear in a separate analysis for this reporting period. After accounting for forest land use conversions and non-CO<sub>2</sub> greenhouse gas emissions from wildfire, the 2016 statewide rate of carbon flux on all forest land is approximately  $31.84 \pm 7.2$  MMT CO<sub>2</sub>e per year (Table 4.2). The pools of live vegetation (trees, foliage, live roots, and understory vegetation) are accumulating carbon at a net rate of about  $37.9 \pm 5.8$  MMT CO<sub>2</sub>e per year (Table 4.3). However, the pools of dead vegetation (standing dead trees, dead roots, and down wood) have been losing CO<sub>2</sub>e to the atmosphere and other forest ecosystem pools at a rate of about  $7.3 \pm 2.1$  MMT CO<sub>2</sub>e per year.

National forests alone account for approximately  $19.1 \pm 2.0$  MMT CO<sub>2</sub>e per year of the total carbon flux (Table 4.3) mostly from growth of live trees. The contribution of those pools on other federal forests is about  $9.5 \pm 1.4$  MMT CO<sub>2</sub>e per year. Tree mortality, especially from fire,

is highest on productive forests owned by the USDA Forest Service that are withdrawn from harvest at a rate of  $0.8 \pm 0.4$  metric tons of CO<sub>2</sub>e annually per acre. Net tree growth on forests owned by private individuals contributes about  $3.6 \pm 2.3$  MMT CO<sub>2</sub>e per year. The variation in live tree growth and carbon flux in other pools on forests owned by local and state governments and corporations is too large in this reporting period to determine if the average annual rate of carbon sequestration is statistically different than zero. Nonetheless, on a per acre basis gross tree growth is highest for these two ownerships that contribute the most to the wood products pool (Table 4.4 and Table 4.5).

This report also provides estimates of forest flux from growth, harvest, and mortality of live trees for each ecoregion in Table 4.6. Two ecoregions account for about 58% of the annual net CO<sub>2</sub>e sequestration in live trees, the forests of the Western Cascades ( $9.4 \pm 3.0$  MMT CO<sub>2</sub>e/year) and the Oregon Coast Range ( $8.1 \pm 4.3$  MMT CO<sub>2</sub>e/year) (Table 4.6). Although there is a large amount of uncertainty the importance of Coast Range forests to annual carbon flux is reflected in the estimate for gross growth of trees at  $30.3 \pm 2.4$  MMT CO<sub>2</sub>/year while the amount harvested from that growth each year is about  $17.5 \pm 3.8$  MMT CO<sub>2</sub>. Growth of trees in the Western Cascades ecoregion is also high at about  $26.9 \pm 1.7$  MMT CO<sub>2</sub>/year with much less transfer to harvest ( $8.0 \pm 2.5$  MMT CO<sub>2</sub>e/year) than the Coast Range but experiencing a higher rate of mortality ( $9.5 \pm 1.1$  MMT CO<sub>2</sub>e/year). The annual net change in live trees is less than 5 MMT CO<sub>2</sub>e for the other ecoregions and less than 0.5 MMT CO<sub>2</sub>e/year in forests of East Oregon outside of the Blue Mtns.

The carbon accumulation from growth of live trees has been approximately  $90.2 \pm 2.4$  MMT CO<sub>2</sub>e/year from all forests in Oregon (Table 4.7a). After accounting for the amount of carbon removed by harvest ( $-34.8 \pm 4.7$  MMT CO<sub>2</sub>e/year) and mortality from all causes ( $-25.3 \pm 1.7$  MMT CO<sub>2</sub>e/year) the net accumulation of carbon in live trees is approximately  $30.1 \pm 5.7$  MMT CO<sub>2</sub>e per year reflecting the state's high annual tree growth rate across all forest ownerships.

Estimates of carbon flux in live trees for each county from growth, harvest, and mortality can be found in Table 4.7b. Washington county is estimated to have a net loss of carbon ( $-2.3 \pm 2.1$  MMT CO<sub>2</sub>e/ year) and Douglas County shows a high rate of live tree mortality ( $-3.5 \pm 0.8$  MMT CO<sub>2</sub>e/year) mostly due to fire and natural causes, but is partially compensated for with a high rate of annual tree growth ( $12.1 \pm 1.4$  MMT CO<sub>2</sub>e/year). The forests of Lane County lead the state in net carbon flux by sequestering approximately  $7.6 \pm 2.3$  MMT of CO<sub>2</sub>e/year.

For carbon flux on National Forests (Table 4.7c) the Deschutes National Forest is currently estimated to have a net loss of carbon based on all pools ( $-0.2 \pm 0.6$  MMT CO<sub>2</sub>e/year) but this estimate is not statistically different than zero. Other National Forests where net carbon flux is not statistically different from zero include the Fremont, Ochoco, Columbia River Gorge National Scenic Area, and the Crooked River National Grassland. All other National Forests are accumulating carbon with the highest rate of net flux for all pools on the Willamette with approximately  $4.1 \pm 0.9$  MMT CO<sub>2</sub>e/year. The Rogue River-Siskiyou National Forest is experiencing the highest rate of live tree mortality among national forests ( $-2.8 \pm 0.6$  MMT CO<sub>2</sub>e/year). The causes of tree mortality on National Forests in terms of percent of carbon

were fire (23%), disease (20%), insect (18%), and wind (13%). The rate of mortality in terms of percentages of live tree carbon was 0.7% per year for the state and ranged from 1.0 percent in the East Cascades to 0.4% in the Willamette Valley ecoregions.

Fire was estimated to affect  $103 \pm 16$  thousand acres/year (95% CI), with an additional  $16 \pm 7$  thousand acres/year affected by both fire and tree cutting. The total estimate of emissions from fire is approximately  $-3.6 \pm 1.2$  MMT CO<sub>2</sub>e/year as CO<sub>2</sub> and  $-0.2 \pm 0.05$  MMT CO<sub>2</sub>e/year for methane (CH<sub>4</sub>) and nitrous oxide (N<sub>2</sub>O) (Table 4.8).

Approximately  $20 \pm 7$  thousand acres of forest land were converted to non-forest every year in Oregon while about  $24 \pm 7$  thousand acres of non-forest land were converted to forest every year (Table 4.9). About 53% of the forest loss was conversion to grassland, 88% of which consisted of mechanical removal of juniper and 12% from lack of forest regeneration more than 30 years after a disturbance, primarily fire. Another 34% of the conversion was for powerlines and logging roads. Conversion of non-forest lands to forest is accounted for by regrowth on abandoned logging roads and tree encroachment on grasslands. However, the net change of  $4.5 \pm 9.3$  thousand acres/year is not statistically significant. Consequently, the net gain of  $0.9 \pm 1.1$  MMT CO<sub>2</sub>e/year from forest land conversions was also not significant with most of the gains and losses occurring in the live tree pool (Table 4.10).

### Forest Carbon Storage

In Section 4.2 of this report you will find estimates for the amount of forest area in each ecoregion, such as Table 4.11, and each forest type across productivity levels of each ownership, such as table 4.12. The heart of the forest carbon numbers for each pool across ownerships is in Table 4.13a where according to estimates made from the FIA plot measurements over the most recent 10-year reporting cycle (2007-2016) there are  $3.2 \pm 0.03$  billion metric tons of carbon stocks (C) on forest land including forest floor and forest soils across all ownerships in Oregon. Approximately 70% of this C is found on public forest land with the National Forests containing over half of all C (52%). Just under half of all stored C is found belowground in forest soils (49%), and about a third is found aboveground in the live tree pool (32%). The remaining stored C is distributed among dead trees (2%), roots (7%), down wood (5%), forest floor (4%) and the understory vegetation pool (1%). Table 4.13a also reports the amount of forest area estimated for each ownership.

For each county Table 4.13b provides estimates of forest C storage for each forest pool and estimates for the amount of forest area. Douglas and Lane County have the largest amount of forest C storage with  $380.1 \pm 25.9$  MMT C and  $377.6 \pm 25.3$  MMT C, respectively. Counties east of the Cascade Mountains tend to have the largest amount of C stored in standing dead and down wood pools relative to other forest pools such as Jefferson County with 32% and Wheeler County with 26%. Similar estimates for each National Forest are found in Table 4.13c.

Forest land carbon stocks by specific pool on both public and private ownerships are reported in Tables 4.14 through Table 4.21 for all of Oregon and each ecoregion of the state. These

tables show that two Westside regions account for over half of Oregon's forest C stocks (52%), the Western Cascades with 969.1 MMT C and the Oregon Coast Range with 717.7 MMT C. In the Oregon Coast Range public forests have on average 168.4 MT C/acre while privately managed forests have 111.8 MT of C/acre. The Willamette Valley has the lowest total forest carbon storage with about 106.3 MMT C.

Carbon stock estimates in each pool for the major forest types (Table 4.22 and Table 4.23) show that the Douglas-fir forest type contains about 47% of Oregon's C stocks ( $1,511.1 \pm 42.0$  MMT C) (Table 4.22). The fir/spruce/mountain hemlock type stores over three times less at approximately  $435.3 \pm 24.8$  MMT and the ponderosa pine forest type stores about  $419.5 \pm 17.9$  MMT C. Of the hardwood forest types, the alder/maple forests are currently storing the most total forest carbon at  $122.7 \pm 15.5$  MMT C.

Estimates of forest carbon stocks and flux for each ownership are reported in four pairs of tables for live trees and understory vegetation (Table 4.24 and 4.25), Roots (Table 4.26 and 4.27), standing dead trees and down woody material (Table 4.28 and 4.29), and forest floor and soil carbon (Table 4.30 and 4.31). Carbon storage for each forest pool based on 10 year averages are provided in Table 4.32 and for ownership and land status in Table 4.33 and 4.34.

Chapter 5 provides a comparison of the results in this report are with estimates of forest carbon reported in the National Greenhouse Gas Inventory (USDA OCE Climate Change Program Office 2016), the 2018 forest carbon report from the Oregon Global Warming Commission, and other research that contains comparable forest carbon information (Gray and Whittier 2014, Gray et al. 2014, Law et al. 2018, Campbell et al. 2007). Strategies to improve the inventory are described in Chapter 6 and include increasing the number of plots that are measured each year, improved estimation of non-sampled plots, increased use of remote sensing, better equations for calculating tree biomass, and ideas for improving forest carbon reporting.

## Chapter 2. Introduction

### 2.1 Oregon's Forest Carbon Accounting Background

The need for a reliable forest carbon accounting system in Oregon expanded in 2001 when the Oregon State Legislature passed a bill that allowed *the State Forester to enter into agreements with nonfederal forest landowners as a means to market, register, transfer, or sell forestry carbon offsets on behalf of the landowners to provide a stewardship incentive for nonfederal forestlands* (ORS 526.780). This legislation required the State Forester to develop a forestry carbon offset accounting system for measuring and monitoring carbon benefits of mitigation projects and accounting for emission debits and credits for carbon storage and sequestration.

In its 2003 strategic planning document, The Forestry Program for Oregon, the Oregon Board of Forestry recognized the threat of climate change from rising levels of carbon dioxide and other greenhouse gases in the atmosphere and the contribution of forest ecosystems to Earth's carbon cycle. The Board agreed on enhancing carbon storage in Oregon's forests and forest products as one of seven key strategies toward sustainable forest management. The Board identified several priorities for implementing the strategy including increasing the forest land base, developing analytical tools for calculating the effects of forest management and wildfires on forest pools of carbon, increasing public understanding of the potential for storing carbon in forests, promote forestry carbon-offset markets, and improving consumer awareness of the carbon benefits associated with forest management and wood products.

In the 2011 update to the Forestry Program for Oregon the Board of Forestry established the goals of improving forest carbon sequestration and storage and reducing carbon emissions in Oregon's forests and forest products. The Board acknowledged that sustainable forest management included stable or increasing rates of carbon sequestration and storage in Oregon forests and forest products as well as promoting the use of biomass to offset emissions from fossil fuels. The Board also recognized that a primary challenge lies in monitoring forests on a statewide scale with respect to pools of above- and below-ground carbon, live and dead forest carbon, and carbon in harvested wood products, to learn where and under what conditions forests are acting as net carbon sinks

In 2007 Oregon established goals to reduce future greenhouse gas emissions. The legislation passed that year requires the State to arrest the growth of greenhouse gas emissions and reduce them to 10% below 1990 levels by 2020 and 75% below 1990 levels by 2050 (ORS 468A.205). That legislation also established the Oregon Global Warming Commission (OGWC) and required the Commission to *"track and evaluate...The carbon sequestration potential of Oregon's forests, alternative methods of forest management that can increase carbon sequestration and reduce the loss of carbon sequestration to wildfire, changes in the mortality and distribution of tree and other plant species and the extent to which carbon is stored in tree-based building materials."*

In 2010 the OGWC created the Roadmap to 2020 that was designed to offer recommendations for how Oregon can meet its GHG reduction goals and support a clean energy-based economy. The final report included recommendations from six technical committees from economic sectors that included energy and utilities, transportation and land use, industry, forestry, agriculture, and materials and waste management. The purpose of the forestry committee was to develop and prioritize a set of strategies and actions for primarily increasing carbon storage in forest ecosystems and long-lived forest products to meet Oregon's 2020 goal. Establishing a carbon inventory for Oregon's forests was the first of four key actions the committee recommended. The other three key actions included investing in research to understand the impacts of climate change on carbon storage in forests, pursue reforestation/afforestation, advance energy and forest policies supporting biomass facilities.

Following on the recommendations from the Roadmap to 2020 the OGWC started a forest carbon accounting project in 2016 to advance our understanding of the carbon potential of Oregon's forests. A Forest Carbon Task Force subcommittee to the OGWC was formed to review potential sources of forest carbon accounting data and provide recommendations to the Commission and Board of Forestry. The Task Force recognized the value of the USFS Forest Inventory and Analysis Program for providing Oregon with a standardized and statistically sufficient system of monitoring and accounting for forest carbon.

The Board of Forestry supervises all matters of forest policy within Oregon and adopts rules regulating forest practices. The Board of Forestry and Oregon Department of Forestry have been integral partners with the OGWC since inception and provided contributing support in developing the Roadmap to 2020 and the 2016 Forest Carbon Taskforce. The Board of Forestry agrees with the first Key Action of the Roadmap to 2020 and is committed to establishing a long-term, statistically reliable, forest carbon accounting system that can be used to monitor the status and trends of carbon in Oregon's forests, provide a baseline for evaluating alternative forest carbon management policies, and for measuring the effect of carbon enrichment and climate change on forest productivity. The Governor's Office of Carbon Policy, established in the 2018 Legislative session, is also fully committed and has provided support for this report. The analysis that follows in this report does not provide a complex policy analysis but it does provide a quantitative forest monitoring framework that is fundamental to the development of forest carbon policy.

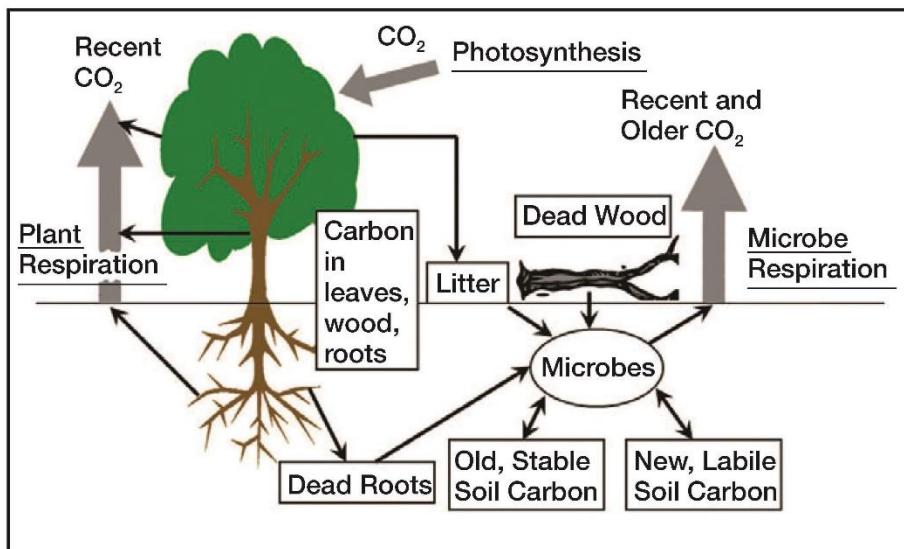

## 2.2 U.S. National Greenhouse Gas Inventory

The U.S. Environmental Protection Agency (US EPA) coordinates and compiles summaries and analyses by multiple agencies to produce the National Greenhouse Gas Inventory (NGHGI). The most recent published report provides national estimates of stocks and flux of greenhouse gases for 1990-2017 (US EPA 2019). The last NGHGI that included state-level estimates was released in 2016. The core dataset for forest carbon used in the NGHGI is the USDA Forest Service's Forest Inventory and Analysis (FIA) inventory. The inventory is based on empirical field measurements of carbon pools and on models that complement the field measurements for pools and/or time periods with few data. The NGHGI follows IPCC guidance as closely as possible with available datasets.

This report differs from the NGHGI analysis in that some of the fluxes can be estimated from measurements available in Oregon, rather than models designed for national estimation, and in not attempting to model results back to 1990 for all lands. Instead, we summarize available empirical data for that time-period and identify alternatives for improving estimates. We refer to the methods of the NGHGI extensively, however, for estimating flux in pools and processes for which empirical data are limited (e.g., soils). This report also includes the use of regional biomass equations instead of national models, and adjustments for decay and fragmentation of snags that differ from the NGHGI.

### 2.3 Forest carbon cycle overview

The global carbon cycle includes movement of carbon (C) among vegetation, soil, ocean, rock, and atmosphere (Ryan et al. 2010). Although the amount of C in vegetation and soils (i.e., **stores**) is much smaller than that in the ocean, the movement of C to and from the atmosphere (i.e., **flux**) is comparable. Vegetation absorbs C from the atmosphere through photosynthesis and fixation of C in living material, and vegetation and soils emit C to the atmosphere through respiration and microbial decay of dead plant matter (Figure 2.1). Forests are particularly important to the carbon cycle because they can store large amounts of C and can be dynamic over relatively short time periods (e.g., decades). It is thought that forests in the Northern Hemisphere in particular are absorbing more C from the atmosphere than they are emitting (Pacala et al. 2001). C removed from the atmosphere by forest growth or stored in harvested wood products for the U.S. in 2017 were estimated to offset 11.3% of U.S. emissions from industry and agriculture (US EPAa 2019).

**Figure 2.1:** Flows of carbon in a forest from the atmosphere to the forest and back. Carbon is stored mostly in live and dead wood as forests grow (extracted from Ryan et al. 2010 Figure 2). This figure does not include C removed from harvest, or soil C removed in groundwater or erosion.

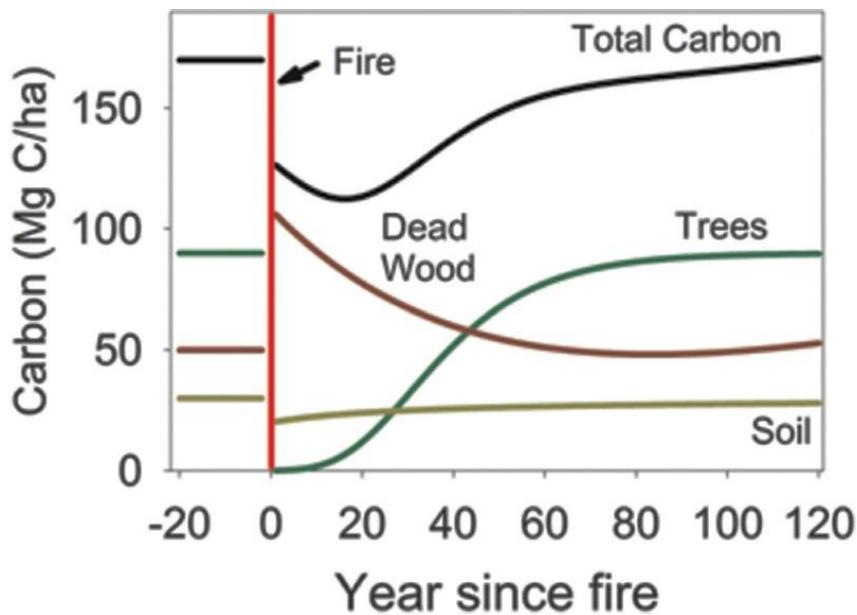

Live forest vegetation builds plant tissues with carbon dioxide ( $\text{CO}_2$ ) from the atmosphere through the process of photosynthesis. A large proportion of the photosynthetic carbon is respired by living plant cells, but a portion of it goes into the production of tissues like leaves; twigs; fine roots; flowers and fruits; and wood and bark in boles, branches, and coarse roots. Depending on their longevity (a matter of weeks for fine roots, or centuries for tree boles), these tissues die and begin to decompose due to microbial action, whereby C is emitted to the atmosphere, primarily as  $\text{CO}_2$ . The increase in volume or biomass of live trees over a specific time period is called **gross growth**, and is similar to estimates of net primary production (NPP) of wood. The volume or biomass of live trees that die during a specific time period is called **mortality**. The difference between gross growth and mortality is the net change in live tree volume or biomass, referred to as **net growth**, which can be positive or negative. Some of the partially-decomposed tissue stays in the soil mineral and organic layers, where C may accumulate over time. When the net effect of the many C fluxes in a forest results in increased storage of C it is referred to as **sequestration**.

In addition to carbon dioxide ( $\text{CO}_2$ ), other greenhouse gases emitted by forests and/or forest products include methane ( $\text{CH}_4$ ), and nitrous oxide ( $\text{N}_2\text{O}$ ). In this report carbon stocks are reported in metric tons of carbon. Changes in carbon stocks that involve transfers between different components of the forest ecosystem or to/from the atmosphere are reported in units of metric tons of carbon dioxide equivalent ( $\text{CO}_2\text{e}$ ), which puts the various greenhouse gases on the same footing in terms of their absorption of infrared radiation. One metric ton of carbon mass in live and dead biomass or soil is equal to 3.667 metric tons  $\text{CO}_2\text{e}$  (also the fraction 44/12<sup>1</sup>).

While tree mortality occurs naturally in all forests, natural disturbance events such as wildfire, pest outbreaks, wind throw, and drought can result in high mortality rates, potentially killing all aboveground live vegetation over large areas. In the case of wildfire, some C (as well as other greenhouse gases such as  $\text{N}_2\text{O}$ ) can be emitted directly to the atmosphere through combustion, or lost from the area as soot. Fine particulate matter in soot ( $\leq 2.5 \mu\text{m}$  in diameter) is referred to as "black carbon" and although it only remains in the atmosphere for a few weeks, it contributes to the greenhouse effect by absorbing solar radiation and heating the atmosphere. In some cases, black carbon can take on the form of charcoal, which can be a stable, long-lived form of C in the forest. Dead tissue left after the disturbance then decays, emitting C to the atmosphere over weeks in the case of scorched needles or over decades to centuries in the case of large dead trees. In severely disturbed forests, C emissions to the atmosphere will initially exceed absorption, and total C will decrease (Figure 2.2). As vegetation becomes established and the amount of growing tissue increases, at some point absorption will exceed emissions, and total C stocks will increase. This net flux from the atmosphere (accumulation) tends to decrease as forests age and appears to come close to zero, or equilibrium, in older forests (Gray et al. 2016). At this point when annual emissions equal annual uptake, forests have reached the **carbon sink saturation point**.

---

<sup>1</sup> Throughout the forest ecosystem portion of the inventory, results are converted from C to  $\text{CO}_2\text{e}$  by multiplying by 3.667

**Figure 2.2:** Idealized cartoon of carbon trajectories in live trees, dead wood, and soil in a forest where all trees are killed by severe wildfire and vegetation subsequently regenerates (extracted from Ryan et al. 2010 Figure 3). With sufficient time, the forest will recover the carbon lost in the fire and the decomposition of trees killed by the fire as long as there were no conversion to lower carbon vegetation types such as shrub lands or grasslands.

In addition to growth and mortality, the C stored in forests can change through increases in forest area (**afforestation**) or decreases in forest land (**deforestation**). While vegetation on afforested sites may accumulate at rates comparable to regenerating forest, levels of soil C tend to take longer (e.g., several decades) to accumulate to levels typically found in forests. Consequently, recently deforested areas may not reflect a significant loss in soil C for many years. Similarly, deforested lands lose soil C over decades until they reach levels typical of non-forest land-uses. While trees are often found in non-forest land-uses (e.g., urban areas, windbreaks or stream buffers in agricultural lands), their C stores are typically included in the carbon assessments of those other land-uses identified as sectors of national assessments.

Tree harvest removes C from forests in the form of logs. However, the C in those logs is emitted to the atmosphere at different rates depending on how the wood and bark are used, so the tracking of the fate of forest C in various harvested wood products (HWP) becomes an important part of forest C accounting. Some portions of harvested trees remain in the forest, moving between forest ecosystem carbon pools and decay slowly along with other dead tissue (e.g., branches and foliage) or are disposed of through in-forest burning with immediate carbon and other greenhouse gas emissions. Other parts become stored in short-lived or long-lived products (e.g., paper and house frames, respectively), converted into other bioproducts, or burned to supply industrial or residential energy and/or heat. At the mill, sawlogs, pulpwood, fuelwood (termed **timber product classes**) are converted to primary timber products (i.e.,

lumber, plywood, veneer, residues, etc.). Each of these products are then allocated to various end-uses such as residential construction, manufacturing, packaging and shipping, or biomass energy, to name a few. Wood products within these various end-uses have different lifetimes. A product's **half-life** is the number of years it takes for half of the initial amount of wood to be discarded and can be used to determine how much of the original product remains in use versus disposed (Skog 2008). Once disposed, discarded wood products decay over time releasing carbon back to the atmosphere. The process by which this happens is dependent on the manner of disposal. In anaerobic environments such as in landfills, wood decay releases carbon (mostly in the form of methane ( $\text{CH}_4$ ), a more potent greenhouse gas than  $\text{CO}_2$ ) and ceases after several decades, leaving a carbon fraction that persists in solid form indefinitely. Newer landfill technologies are being implemented in parts of the country to allow for methane capture and combustion (oxidation), thus reducing overall methane emissions to the atmosphere with formation of  $\text{CO}_2$ , a less powerful greenhouse gas. In some cases, at the end of product use-life, products can remain in use through recycling, burned for energy, or burned as waste (Stockmann et al. 2012). When the product is kept out of the landfill methane emissions from landfill decay are substantially decreased.

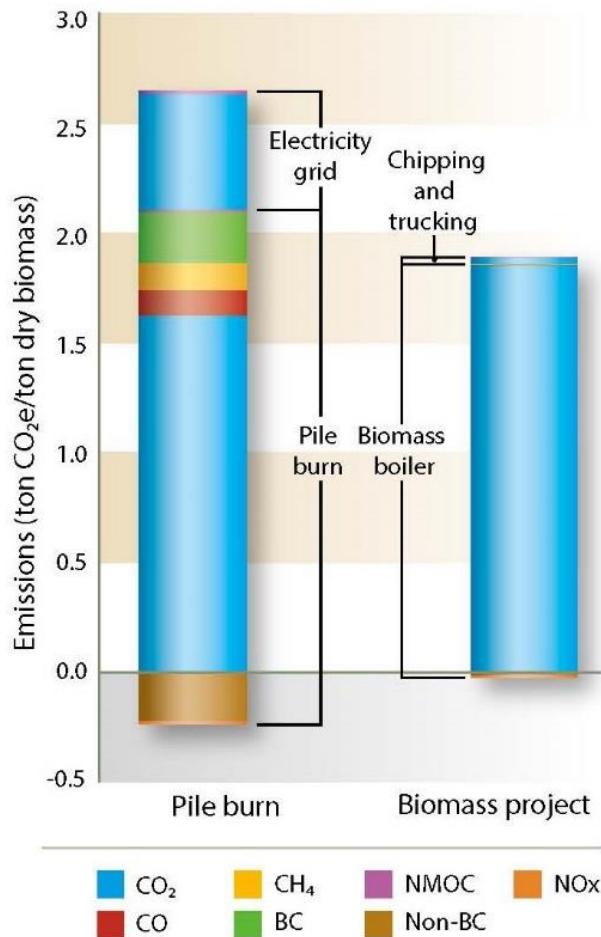

Fossil fuel and other emissions not derived directly from forest ecosystems that are generated in the forest management and manufacturing process are typically not included in forest sector C analyses but are included in the industrial sector (e.g., US EPA 2019).

Accumulating C in standing forests is one way to increase absorption from the atmosphere. Accumulating C in forests could be accomplished by reducing the amount of C removed during harvest. However, to the extent that the demand for wood products remains, one result could be **leakage** where storing more carbon in forests in one region (or country) is offset by reduced storage of carbon in other regions, with no net gain in global carbon storage (McKinley et al. 2011). Conversely, intensive commercial timber production may decrease demand for wood from other lands, thereby increasing the in-forest carbon stocks on those other lands (Heath et al. 2010).

Another concern with increasing carbon stores in forests is the notion of **permanence**; areas that are fire-prone are at higher risk that live trees will be killed and C lost to fire and decay, especially in forest types where denser (higher C) forests are likely to burn at higher severity. The use of harvested wood and wood products may reduce overall C emissions through their use as **biomass energy** in situations where the use of wood as biomass for fuel results in fewer C emissions from the use of fossil fuels. Another effect of using wood products could be through **substitution** of wood instead of steel or concrete, which result in more C and other greenhouse gas emissions to produce.

While tracking the changes in C stocks (and therefore C flux) can be relatively straight-forward, quantifying leakage, permanence, and substitution can be more difficult. One example of an analysis that incorporated biomass energy as a reduction in fossil fuel emissions compared overall emissions from open pile burning of logging residues to processing and burning in a

biomass energy plant, and found a net reduction in emissions of 0.54 tons CO<sub>2</sub>e per dry ton of biomass (Figure 2.3; Springsteen et al. 2015).

**Figure 2.3:** Comparison of greenhouse gas emissions between a pile burn of logging residue versus chipping, hauling, and burning it in a biomass energy plant. Analysis estimates CO<sub>2</sub>-equivalent effects of different gases and particulates, as well as the additional emissions needed in the case of the pile burn to generate the same amount of electricity from natural gas. (Extracted from Springsteen et al. 2015).

## 2.4 Overview of Oregon forests

Oregon hosts a wide variety of tree species, including many species of conifers as well as oaks and other hardwoods. Assemblages of tree species are often grouped into forest types to support inventory and reporting. The Forest Inventory and Analysis (FIA) program defines a variety of coniferous forest types in Oregon including Douglas-fir, Ponderosa pine, fir/spruce/mountain hemlock, western juniper, western hemlock/Sitka spruce, lodgepole pine, and others. Hardwood forest types include alder/maple, tanoak/laurel, western oak, and elm/ash/cottonwood among others.

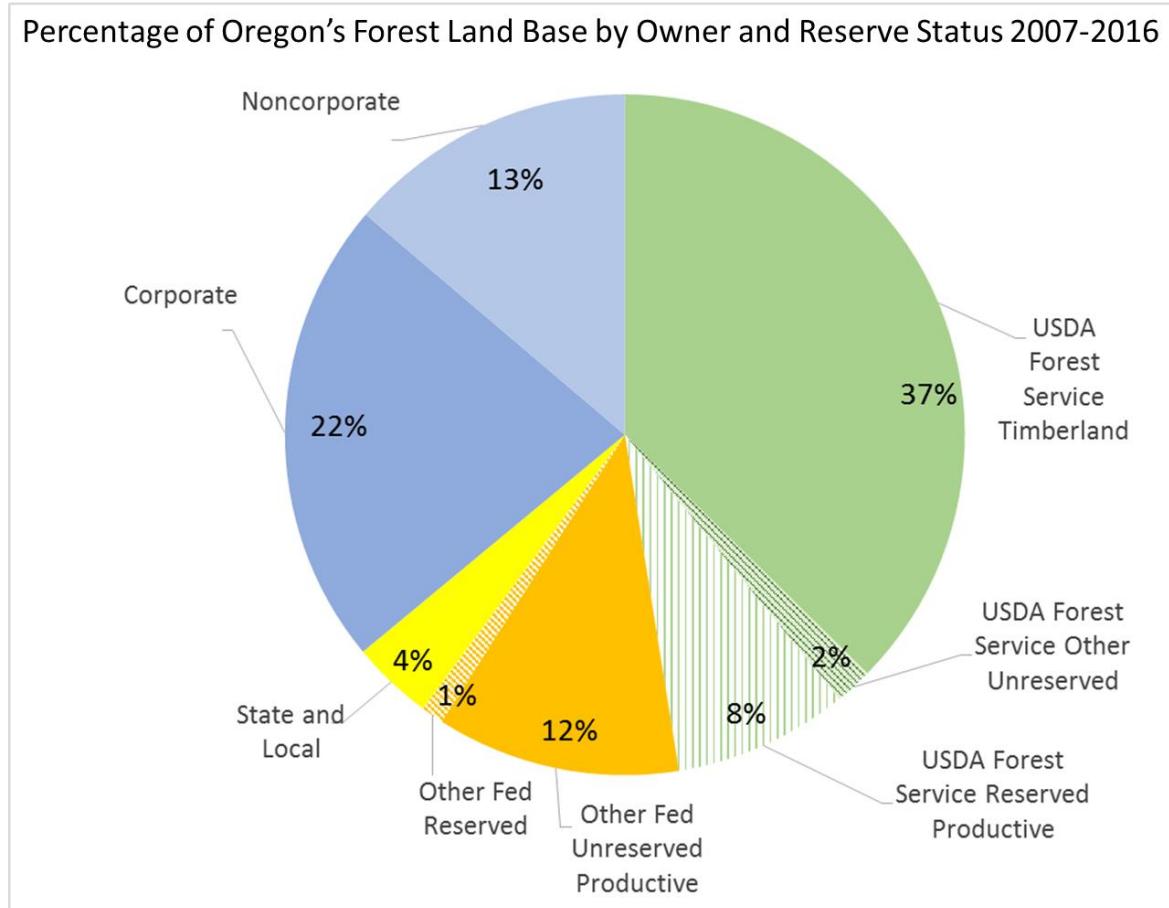

**FIA land status** distinguishes **forest land** from non-forest (i.e., crops, improved pasture, residential areas, city parks, etc.) and other area (i.e., water), and also distinguishes differences in **forest land status**. For example, forest land in Oregon is also categorized into timberland and other forest land based on its ability to grow commercial tree species (**productive capacity**) and its availability for timber extraction. Lands that can produce 20 cubic feet of wood volume per acre per year of commercial tree species are termed **Productive Forest land**. Productive forest land that is available for management for timber production (i.e., not in a **reserve status**) is called **Timberland**. Forest land that is not capable of producing 20 cubic feet of wood volume per acre per year of commercial tree species is called **Other forest land**. Forests in reserve status (i.e., wilderness designation, National Monuments, National Parks, etc.) can include both productive and other forest land. Although management for production of wood products in reserved forests is precluded, in some cases timber harvest can still occur for various objectives (i.e., restoration, salvage, etc.). Approximately 80% (23.7 million acres) of the 29.7 million acres of forest land in Oregon are classified as timberland, with an estimated 2.5 million acres of productive forest land in reserves (Palmer et al. 2018). There are approximately 3.2 million acres of non-reserved other forest land and 270 thousand acres of reserved other forest land. Management and use of forest land is often a function of ownership and land status in Oregon. Oregon's forest land is divided between private and public ownership (see Figures 2.4 and 2.5). The federal government manages 60% of these lands, with the remaining areas under state and local government (3.8%) or private management (36%). Approximately 13.3 million of the 23.7 million acres of timberland are managed by the federal government, 9.4 million are in private ownership, with the remainder in other public ownership. Approximately 1.3 million of the 3.2 million acres of other forest land in non-reserved status is privately owned, 1.8 million acres in federal management, with the remainder in other public ownership. Of the 2.8 million acres of forest land in Oregon in reserved status (National Wilderness designations, etc.), 98% are managed by the federal government, with the remainder in other public ownership.

To better understand the carbon dynamics in Oregon's forests, information in this report and appendices is provided for different forest types, ownerships, forest reserve classes, and on a regional basis (see figure 4.6a,b).

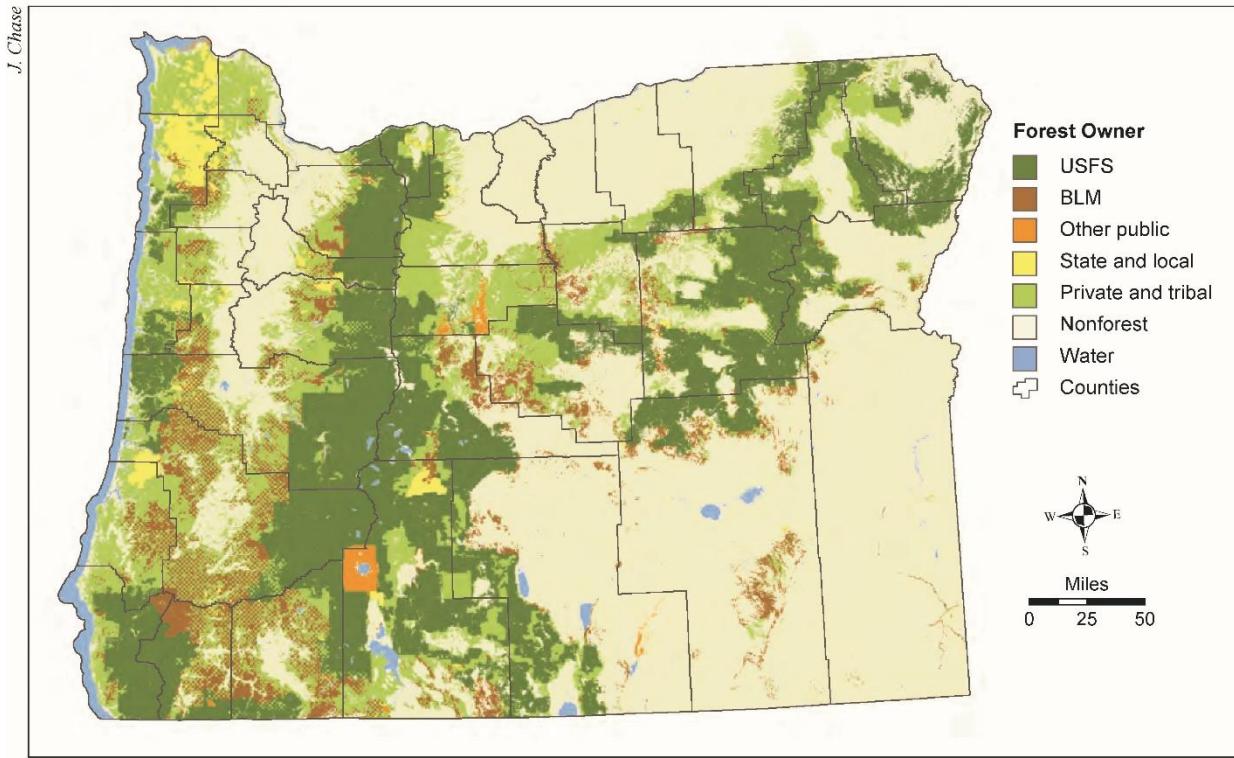

The way in which forests are used and managed impact both forest health and resilience as well as carbon storage and sequestration. Oregon's forested landscape consists of a mosaic of land-uses including working forests, conservation reserves, and those associated with human-dominated uses. Forests in which trees are harvested regularly are often referred to as **working forests**. Whether a forest is considered a working forest or not, forested landscapes provide many important ecosystem services, including carbon sequestration as well as wildlife habitat, clean water, recreational opportunities and other cultural values. A variety of recent studies exhibit concern that current forest conditions resulting from management activities focused on commodity production or on fire suppression have negatively impacted the resiliency of forest ecosystems and carbon stocks. For example, 20 years after sweeping changes in management of federal lands under the Northwest Forest Plan have protected and promoted older forests (Spies et al. 2018), models suggest that abundance of birds dependent on older as well as younger forest has declined (Phalan et al. 2019). Other studies suggest that forests in drier

conditions, such as Ponderosa pine forests in eastern Oregon, have changed when compared to historic conditions, with more of the biomass in higher densities of small, fire-prone trees (Merschel et al. 2014, Stine et al. 2014). These forests are thought to be vulnerable to fire, pest outbreaks, and other disturbance, especially as changes in climate continue to affect the timing, frequency, intensity and extent of disturbances such as wildfire and pest outbreaks. In the short-term, management strategies to improve forest health and resiliency and reduce hazardous fuels may decrease in-forest carbon stocks and result in other greenhouse gas emissions through tree removal or prescribed fire. In the long-term forest carbon stocks might benefit from these treatments through continued growth and decreased mortality from wildfire, pests and drought (North and Hurteau 2011), although there is disagreement on whether total carbon stocks reach the same levels as untreated stands (Mitchell et al. 2009) or whether treated areas will burn in the period when treatments are effective (Restaino and Peterson 2013).

The focus of this report is not to present or debate policy options and the desirability of different approaches to forest management. However, we expect that a comprehensive assessment of carbon stocks and fluxes, broken down by pool, ownership, and disturbance impacts, will help ground and guide those policy discussions going forward.

## Chapter 3. Forest ecosystem carbon inventory methods

### 3.1 Use of IPCC inventory approach/methods

The Intergovernmental Panel on Climate Change (**IPCC**) was created in 1988 to prepare assessments on all aspects of climate change and its impacts based on available scientific information and is the key international body studying global warming. The IPCC issues guidance on reporting carbon stock inventories and emissions designed to implement the international United Nations Framework Convention on Climate Change (UNFCCC) 1992 Kyoto Protocol agreement. Although the U.S. is not a signatory to the Kyoto Protocol, the U.S. NGHGI follows IPCC guidance for international reporting for subsequent agreements and negotiations. Similarly, although Oregon is not a reporting party to the Kyoto Protocol, this inventory will comply with IPCC-defined “good practices” as much as possible. The 2006 IPCC “Guidelines for National Greenhouse Gas Inventories” (IPCC 2006) provides a conceptual framework, sectoral scope definition, description of tiered inventory methods, calculation steps and uncertainty assessment steps. An important element specified in the 2006 Guidelines is a **key category analysis** in which key emissions categories are identified and prioritized. The focus of this report is on determining whether the forest sector in Oregon is sequestering or emitting carbon from the atmosphere, and by how much.

The key categories described in IPCC (2006) for forest-related fluxes include:

- CO<sub>2</sub> emissions and removals resulting from C stock changes in biomass, dead organic matter and mineral soils; and
- CO<sub>2</sub> and non-CO<sub>2</sub> emissions from fire on all managed land, including methane (CH<sub>4</sub>), nitrous oxide (N<sub>2</sub>O), non-methane volatile organic compounds (NMVOC), nitrogen oxides (NO<sub>x</sub>), and carbon monoxide (CO).

Minor elements that may be relevant to forested wetlands and fertilized forest plantations include:

- N<sub>2</sub>O emissions from managed soils, and
- CO<sub>2</sub> emissions associated with liming and urea application to managed soils.

The U.S. NGHGI calculates N<sub>2</sub>O emissions from southeastern pine forests and commercial Douglas-fir stands in western Oregon and Washington that are fertilized (US EPA 2019). The U.S. NGHGI only calculates CO<sub>2</sub> emissions associated with liming and urea for agricultural soils, so these emissions are assumed to be negligible for Oregon forests and are not included in this report.

The IPCC guidelines only require reporting for **managed lands** under the assumption that nations cannot affect, or be held responsible, for changes happening on lands that are not directly influenced by humans. According to IPCC 2006, “managed land is land where human interventions and practices have been applied to perform production, ecological or social

functions” (Paustian et al. 2006). Because even most Wilderness areas and National Parks in the U.S. are impacted by human management in some form, e.g., from fire suppression, in practice all lands in the lower 48 states are considered “managed” (e.g., US EPA 2019, Ogle et al. 2018).

In 2014, the IPCC published the “Revised Supplementary Methods and Good Practice Guidance Arising from the Kyoto Protocol” (IPCC 2014) which provides additional guidance on estimating flux from land-use, land-use change and forestry (LULUCF) activities. For forest land, the primary changes from IPCC 2006 are guidelines for reporting on forest management and on harvested wood products (HWP). Procedures for estimating HWP stocks and flux will be addressed in a separate report.

### 3.1.1 Rationale for use of Tier 3 approach

The IPCC guidance on greenhouse gas accounting describes three “tiers” or approaches to reporting that accommodate the range of data and institutional support in different countries. Gain-loss methods estimate the net balance of additions to and removals from each carbon stock. Stock-difference methods are a more rigorous approach that track the amounts in each carbon stock and their change over time.

Tier 1 methods are the simplest, and apply IPCC equations and default parameter values for emission and stock change factors (e.g., deforestation/afforestation, disturbance, harvest, grazing) to available information on land-use and activity (e.g., from land cover maps derived from satellite mapping). Tier 2 can use the same approach as Tier 1 but applies region- or country-specific emission and stock change factors. Tier 3 methods apply models and inventory measurements tailored to national conditions, are repeated over time, are driven by high-resolution activity data and disaggregated at sub-national level. Models are expected to undergo quality checks, audits, and validations and be thoroughly documented. Tier 3 methods are often referred to as “stock-difference,” because C flux is derived from the difference in estimates of individual C pools at different points in time.

Most nations with more detailed economic and natural resource information are expected to follow the Tier 3 approach. This is the approach used by the U.S. NGHGI, built on a wide range of economic, environmental, and natural resource data already being collected for a variety of objectives. This is the approach used in this report as well, with a focus on forested lands as sampled by the FIA program.

Six land-use classes are recognized in IPCC assessments. While the IPCC does not prescribe specific definitions for each class, it does require that countries explicitly and consistently define and track them. These land-uses are further defined for the U.S. in the NGHGI (US EPA 2019) and are described in section 3.2.2. The IPCC land-use classes are:

1. Forest land: includes all land with woody vegetation, using consistent and well-defined criteria for minimum area, minimum cover, and minimum height at maturity to define “forest land” (specifying minimum width too is “good practice”). Assessment of this land-use class is

split between land remaining forest land, and land converted to forest land from other uses. In the U.S., the FIA definition for forest land is used for reporting this category.

2. Cropland: cropped land and agro-forestry where structure falls below forest land.
3. Grassland: includes rangelands and pasture not considered cropland. Also includes systems with woody vegetation or herbs that fall below thresholds for forest land. For example, chaparral falls in this category in the U.S. NGHGI.
4. Wetlands: areas of peat extraction and covered by water for all or part of the year that doesn't fall in the vegetated or settlement categories.
5. Settlements: developed land, including transportation infrastructure and settlements of any size, unless placed in other categories by national definitions.
6. Other land: bare soil, rock, ice, and all other land areas, including unmanaged lands. In addition to identifying these six land-use categories and subcategories, IPCC requires distinguishing natural from planted forest, identifying areas subject to different natural disturbances and their effects on flux, identifying areas subject to management, and identifying areas of mineral and organic soils, with the latter split into drained, wet, or rewetting.

### 3.1.2 Determining the Forest Management Reference Level

The concept of a Forest Management Reference Level (FMRL) was established in the 1992 Kyoto Protocols and guidelines for implementing it are described in IPCC (2014, section 2.7.5). The FMRL is a baseline value of average annual net emissions and removals from “forest management” (i.e., all lands that remain forested or that change land-use to/from forest). All pools and gases and the area under forest management that are included in the calculation of the FMRL are to be identified. The FMRL facilitates consistent comparison of forest carbon stocks and losses through time by comparing one or more time periods to a reference baseline that is calculated in the same way, including all the same pools and assumptions. The UNFCCC refers to emissions in 1990 as the baseline that targets are tied to for future emissions levels.

For Oregon, the availability of forest inventory data is more limited for the period including 1990 than for more recent years (2001 and on). Specifically, field measurements that span 1990 and that can be used to estimate change only consist of live trees on timberland outside of National Forests (Azuma et al. 2004a, 2004b). Estimation of flux in 1990 for other lands and carbon pools requires substantial modeling and/or extrapolation from more recent datasets. An extrapolation approach was adopted for U.S. forests in the most recent U.S. NGHGI but the resolution of the estimates currently does not support analysis at less than the state level (US EPA 2019, Woodall et al. 2015). Some national and international assessments and negotiations have used other dates as baselines (e.g., 2005) to align better with available data.

In this report, we establish an FMRL for in-forest carbon based on data from the complete 10-year inventory in Oregon conducted during the time-period 2001-2010 (the first comprehensive, standardized FIA inventory of Oregon's forest lands since 1955).

In this report, the FMRL provides a complete estimate of all pools of forest carbon in Oregon and the trends over time as 10-year moving averages. Although there are large overlaps between periods, re-measurement data makes it possible to review trends from complete samples (i.e., all plots) in Oregon for 2001-2010, 2002-2011, 2003-2012, 2004-2013, 2005-2014, 2006-2015, and 2007-2016. However, estimates of change between 10-year stock averages (i.e., Stock-Change approach) are a less accurate and less precise way to infer flux than the Growth, Removals and Mortality (GRM) method described below. The FMRL identifies six key pools including Aboveground Live (trees and shrubs), Aboveground Dead (standing snags and down wood), Belowground Live (roots), Belowground Dead, Forest Floor Litter and Soil Organic Carbon (organic soil layers). The Harvested Wood Product (HWP) carbon pools will be determined for the FMRL in a separate report.

Although we present data for the FMRL and 10-year moving stock averages to compare to it, in this report we determine annual flux through the Growth, Removals and Mortality (GRM) approach. Comprehensive forest inventories that are based on re-measured, permanent sample plots have the potential to provide the most accurate estimates of forest volume and carbon. This direct measurement of growth, removals and mortality would be considered an IPCC Tier 3 approach to carbon accounting as it is based on more advanced country-specific data and methods. It is also still considered a stock-difference approach, but by measuring changes in the same trees over time the components of change can be detailed (i.e., growth, removals, mortality).

The Forest Inventory and Analysis Program (FIA) began a new inventory of forest land in Oregon in 2001 by installing a complete sample of the state each year using 10% of the full set of plots (15,082 on land, excluding census water). This equates to a complete sample of all inventory plots in Oregon every 10 years. FIA completed their first full annualized inventory of Oregon forests in 2010 (previous inventories were conducted periodically on a nominal 10-year interval). In 2011, FIA began re-measuring the same plot locations as established in 2001 and as of 2016, they had re-measured 60% of the plots in the state. As FIA re-measures more forest inventory plots in Oregon (through 2020 and beyond) the ability to derive more precise estimates of change for smaller domains of interest will improve (e.g., regions and ownerships), and will be incorporated into future annual reports. The USDA Forest Service Pacific Northwest Research Station (PNW) manages the FIA program for the state of Oregon.

### 3.2 Forest inventory compilation methods

This section is designed to document the basic estimation and compilation methods used for this report, and identify options for improving estimates in future reports. As mentioned above, this assessment relies primarily on empirical data from FIA inventories of the forests of Oregon

and to a large extent applies methods and models used in the NGHGI in accordance with IPCC guidance.

### 3.2.1 Inventory design

The population, or scope, of the inventory of Oregon is the boundaries of the state, including offshore islands and approximately 3 nautical miles of ocean out from the coastline. Beginning in the 2001 nationally-standardized “annual inventory”, the sampling frame for this area was determined by a national layer of hexagons approximately 6,000 acres in size. Plot sample locations were identified within each hexagon in a manner sometimes referred to as “randomized systematic”. For hexagons that contained plot locations that were part of the previous FIA or National Forest System (NFS) inventories, the previous plot was selected for the annual inventory (or one was randomly selected if more than one was present). For hexagons without a previous plot, a new location was randomly generated within the hexagon. In addition, in 2001 NFS began installing the annualized FIA inventory using the same procedures on their earlier Current Vegetation Survey (CVS) inventory plot locations, based on a square grid of plots every 1,875 acres outside of Wilderness (Max et al. 1996). FIA has included this sample and the data collected in their databases, estimates, and reports since 2001. The total number of plots (forested, non-forested, and census water) in Oregon is 15,320. Starting in 2017, the Bureau of Land Management (BLM) in western Oregon began implementing the annualized FIA inventory on the CVS grid on their lands in cooperation with NFS; that data will be added to the existing FIA grid on BLM lands and incorporated in future FIA reports.

The hexagons in Oregon are assigned to ten evenly-dispersed panels. Each panel is measured in a specific year, providing a balanced annual sample of the state each year. All panels are measured after ten years, at which point the cycle starts over and plots are re-measured on a ten-year interval. The first cycle of annual inventory in Oregon occurred in 2001-2010, and six years of re-measurement data are available for this report, covering 2011-2016.

All inventory estimates are based upon the grid of plots and the classifications and measurements taken on them. The precision of the estimates is improved, however, by incorporating information from independent, ancillary datasets in a process referred to as “post-stratification” (MacLean 1972, Bechtold and Patterson 2005). Satellite imagery, historic maps, and ownership layers are combined and pixels with similar attributes related to forest/non-forest delineation and forest characteristics, and land areas sampled with the same plot density, are grouped into strata. The number of pixels in each strata and the number of plots that intersect them are used to define weights for each plot in the inventory. Potentially-forested plots that were unable to be sampled (e.g., access was denied or plots were too hazardous to measure safely) are assumed to be missing at random. The methods represent nonsampled plots by increasing the weights of sampled plots found in the same strata as the nonsampled plots.

The plot sample and stratification are used in the calculation of sampling errors, which are provided with the results of this report. These errors describe the uncertainty associated with sampling the forest (i.e., with plots) instead of measuring the entire population. Additional

details on inventory design and estimation methods are provided in Bechtold and Patterson (2005) and Palmer et al. (2018).

### 3.2.2 Forest land-use and land-use change

As provided for in IPCC guidelines, the NGHGI uses the FIA definition of forest land to define the specific lands covered, including the change in land-use between forest land and other land-uses. The current FIA definition of forest land (Woudenberg et al. 2010) is land with at least 10% cover by live forest trees of any size, or that formerly had such cover and that will be artificially or naturally regenerated (i.e., is not being managed for non-forest uses). The area must be at least 1 acre in size and at least 120 feet wide. Tree-covered areas where management precludes natural vegetation development (e.g., through mowing, disking, regular herbicide application, or intensive grazing) are not considered forest land. FIA maintains a national list of species that are considered forest trees; these generally are species that form dominant central stems and attain heights greater than 16 feet over the majority of their range. However, some international definitions refer to trees being able to attain 16 feet in height “*in situ*”, and recent NGHGI and Resources Planning Act (RPA) reports (Oswalt et al. 2014) have reclassified some forest land as “woodland”. The *in-situ* criterion implemented for NGHGI/RPA classifies plots based on a combination of current tree height, forest type, site class, and ecoregion. The criteria relevant to Oregon that would result in changes of FIA data from forest land to woodland (a component of forest land) are:

- mean height of trees  $\geq$  5 inches diameter is  $< 16.4$  feet; and
- FIA forest type code =184 (juniper woodland)
- site class = 7 (unproductive forest of  $< 20 \text{ ft}^3/\text{ac}/\text{yr}$  maximum growth; i.e., culmination of mean annual increment); and
- in ecoregions 342 (Northwestern Basin and Range).

The NGHGI also states that “land is not classified as Forest Land if completely surrounded by urban or developed lands, even if the criteria are consistent with the tree area and cover requirements for Forest Land. These areas are classified as Settlements” (US EPA 2019). Forested FIA plots in urban areas were not specifically excluded from the NGHGI calculations; instead, forest estimates were adjusted by the land-use categories derived from the USDA Natural Resources Conservation Service (NRCS) Natural Resources Inventory (NRI) to implement these criteria (e.g., USDA NRCS 2015).

In this analysis, we did not separate out FIA-classified forested lands that fell in the NGHGI-classes of woodland and urban from total forest land. We estimate that 3 thousand acres of forest land meet the woodland definition, or 0.01% of the total forested area. Using currently-measured heights in the criteria ends up misclassifying some recently disturbed (seral) stands where trees have not reached their height potential. However, a ***potential change*** to match NGHGI reporting as closely as possible would be to incorporate woodland and urban criteria in the next iteration of the report.

Inventory crews delineate the area covered by different land-uses that fall in the FIA plot footprint. These proportions, in combination with the plot weights from the stratification, enable FIA to estimate the area of all land-use classes in the state (i.e., forest, non-forest, water). In sparsely-covered stands, crews take additional measurements and estimates (e.g., of dead or harvested trees) to determine whether the 10% tree canopy cover threshold is met. Non-forest land-uses are identified either on the ground (for field-visited plots) or using recent imagery (for non-field-visited plots), which makes it possible to classify non-forest lands into most of the other IPCC classes (i.e., cropland, grassland, settlements, other). When plots were re-measured, changes in land-use within the plot footprint were delineated, enabling the estimation of change in forest land area and the land-uses that forest lands are coming from or changing into. Wetlands are apparently delineated in the USDA NRCS NRI used in the NGHGI, but their locations are not yet clear; we assumed there was no land-use change between wetlands and forest.

The NGHGI definitions for non-forest land-uses are:

- Cropland: Areas used to produce adapted crops for harvest, including both cultivated and non-cultivated (e.g., hay, orchards), and agroforestry and windbreaks.
- Grassland: Areas where plant cover is composed principally of grasses, grass-like plants (i.e., sedges and rushes), forbs, or shrubs, including pastures and native rangelands. Savannas, deserts, and tundra, and drained wetlands with the appropriate plant cover are included. Systems with woody vegetation or herbs that fall below the thresholds for forest land are also included in grasslands (i.e., chaparral).
- Wetlands: Areas covered or saturated by water for all or part of the year, in addition to the areas of lakes, reservoirs, and rivers. Does not include areas of drained wetland that meet other categories, or un-drained forested wetlands.
- Settlements: Areas of at least 0.25 acres that includes residential, industrial, commercial, and institutional land; construction sites; public administrative sites; railroad yards; cemeteries; airports; golf courses; sanitary landfills; sewage treatment plants; water control structures and spillways; parks within urban and built-up areas; and highways, railroads, and other transportation facilities. Also included are tracts of less than 10 acres that may meet the definitions for Forest Land, Cropland, Grassland, or Other Land but are completely surrounded by urban or built-up land.
- Other Land: Areas of bare soil, rock, ice, and all land areas that do not fall into any of the other five land-use categories. Following IPCC (2006), C stock changes and non-CO<sub>2</sub> emissions are not estimated for Other Lands. However, C stock changes and non-CO<sub>2</sub> emissions are estimated for Land Converted to Other Land during the first 20 years following conversion to account for legacy effects.

Prior to the implementation of the national FIA field guide 6.0 in 2012, the definition of forest land used on the west coast was slightly different and was based on a 10% stocking threshold rather than cover. This was changed to cover to improve national and international consistency and the ability to relate ground classifications to imagery. The change in definition has little impact on the majority of forest land in Oregon which easily exceeds both thresholds, but can lead to some differences in sparse forest conditions that may be found in oak and juniper woodlands (Azuma and Gray 2014). Nevertheless, the change raises the possibility that areas may change designation due to procedural change and not real change on the ground. PNW-FIA field crews have been distinguishing procedural from real changes and taking additional measurements of cover and stocking in sparse stands to be able to better quantify the relationship between cover and stocking in different forest conditions. This will make it easier to compare estimates between older and newer inventories.

This report incorporates regional assessments of land-use change, after accounting for definition changes, procedural changes, and previous errors. This analysis of land-use change is NOT reflected in the publicly-available online FIA databases. The PNW-FIA program is in the process of evaluating how to implement databases that reflect correct analyses of change using current definitions while maintaining previous data used to generate earlier assessments.

### 3.2.3 Carbon pool calculations

**Aboveground live tree**—Estimates of aboveground live-tree woody C were based on regional FIA equations of the sum of bole, bark, and branch biomass in metric tons for each tree measurement multiplied by 0.5, the C fraction of biomass. Bole biomass (ground to tip) was calculated from regional species-specific volume equations documented in Zhou and Hemstrom (2010) and species-specific wood density values documented in Woudenberg et al. (2010). Bark and branch biomass were calculated from regional species-specific equations selected from Means et al. (1994) and documented in Zhou and Hemstrom (2010), except red alder branch equation (Eqn. 16) used Snell and Little (1983) and Douglas-fir and red alder bark equations (Eqn. 8 and 20) used Means et al. (1994) equations 5 and 275, respectively. Most equations use both diameter at breast height (dbh) and height data, whereas a few bark and branch equations use diameter only. Foliage biomass was calculated using the Jenkins et al. (2003) ratios to total tree biomass as implemented in Woodall et al. (2011) and added to aboveground wood biomass before calculating aboveground live tree C. In contrast, the NGHGI estimates of live tree biomass are based on the “component ratio method” equations in Woodall et al. (2011). An expansion factor derived from the fixed-area plot size was used to convert individual tree C to an area basis (e.g., metric tons per acre).

**Aboveground standing dead tree**—Estimates of aboveground standing dead tree carbon followed the same procedures as for aboveground live trees, but with the following modifications. Gross volume from ground to tip was adjusted for broken tops by calculating the gross volume (to an intact “total” height estimated in the field or modeled using Barrett (2006)) and the net volume to the broken “actual” height with a Flewelling (1994) taper equation for Douglas-fir. The proportion of net to gross volume from the Flewelling equation was applied to reduce the gross volume calculated for each tree. In addition, the biomass of all components

(bole, bark, and branch) were reduced for decay using the hardwood/softwood parameters in Harmon et al. (2011), Table 6. Standing dead biomass was further reduced to account for the tendency of bark and branches to be dropped from snags sooner than bole biomass; component reductions described in Harmon et al. (2011) were applied to further reduce bark and branch biomass. Biomass calculations in metric tons were multiplied by 0.5 to calculate C. In contrast, the NGHGI estimates of standing dead tree biomass are based on the equations in Woodall et al. (2011) and the species-specific decay-reduction factors in the table REF\_SPECIES in Woudenberg et al. (2010). The species-level decay factors appear to be based on small datasets and highly variable among similar species; the hardwood/softwood parameters seemed more reliable. Stumps are not included and it is unlikely that they will be included in future inventories without substantial additional effort.

***Belowground live and standing dead tree (i.e., roots)***—Estimates of belowground biomass (i.e., coarse roots > 2 mm diameter) were based on the ratios for species-groups developed in Jenkins et al. (2003) as implemented in Woodall et al. (2011); i.e., adjusting the estimate by the ratio of the FIA volume-based estimate of bole biomass to the Jenkins equation-based estimate. Decay class of standing dead trees was used to reduce belowground calculations using the species- and decay class-specific parameters in the REF\_SPECIES table (Woudenberg et al. 2010); biomass calculations in metric tons were multiplied by 0.5 to calculate C.

***Aboveground down woody debris***—Estimates of carbon in down wood were based on the transect-intercept measurements of coarse wood ( $\geq 3$  inches intersect diameter) and counts of fine wood ( $\geq 0.25$  to  $< 3$  inches diameter). Piles were not included, as the field estimates of pile density in the initial years of the inventory were unreliable. Biomass of coarse wood was calculated using the equations in Woodall and Monleon (2008) with wood density and decay-class reduction factors from the REF\_SPECIES table (Woudenberg et al. 2010). A ***potential improvement*** for a future report would involve using the hardwood/softwood decay-reduction parameters from Harmon et al. (2011) instead (as described above for snags), as they seem less variable among similar species than the species-specific variables in REF\_SPECIES, which were also derived from Harmon et al. (2011). Log inclinations were measured in PNW inventories starting in 2013 with the implementation of core FIA manual 6.0. Where available, inclinations were factored into the calculation of coarse wood biomass and carbon (inclined logs have a lower probability of being intercepted by a transect, so the calculated C per acre is greater than if the same log were lying flat). For the smaller size classes of down wood (“fine wood”) we followed the procedures in Woodall and Monleon (2008) where the fine wood piece counts in each size class are multiplied by a quadratic mean diameter (QMD) to calculate volume, and a wood density factor to calculate biomass, which is multiplied by 0.5 to calculate C. Parameters are specific to forest type group and available in REF\_FOREST\_TYPE\_GROUP in the FIA database (FIADB) (Woudenberg et al. 2010). Although measurements of piles were taken, estimates of wood density in piles tended to be unrealistically high, particularly in the initial inventory years. As a result, we currently do not include pile data in the down wood calculations, but may be able to develop replacements for current values with reasonable assumptions with greater scrutiny.

**Aboveground and belowground understory vegetation**—Estimates of above- and belowground biomass and C of understory vegetation (which includes live trees < 1 inch in diameter) are based on the calculations from the U.S. Forest Carbon Budget Model (FORCARB2) (Smith et al. 2006), as populated in the FIADB. Calculations are based on FORCARB estimates of live-tree biomass, (calculated from forest type and stand age), and are highest at low levels of live tree biomass and decline slightly at higher levels. Dead understory vegetation is not included and there are no plans to include it at this time. It was previously identified that a potential improvement for a future report would use the cover and layer height data collected on FIA plots to calculate understory biomass directly, provided suitable equations can be found. However, after further research it was determined that potential equations were very general and from different vegetation types/areas that are likely not relevant for Oregon.

**Forest floor**—Estimates for carbon in the forest floor (i.e., duff and litter) use the same model used in the NGHGI which was based on FIA Phase 3 data and predictor variables of location, elevation, forest type group, live tree C, and some climate variables (Domke et al. 2016). Although PNW-FIA crews have measured forest floor depth on the down wood transects since the beginning of annual inventory, there were methodological problems in the initial years and the estimates are quite sensitive to seemingly small measurement errors of depth (e.g., a tenth of an inch). **A potential improvement** for a future report is to continue evaluating flux estimates using more recently-remasured forest floor depths and adopt them if/when they appear to be reliable.

**Soil**—We estimate soil organic C stocks to a 1 meter depth using the modeled estimates from Domke et al. (2017) as implemented in the latest NGHGI report. This model incorporated data from soil cores on FIA plots with other national datasets and values compare favorably with those calculated from FIA cores in Oregon. The new values are 3.4 times greater than those estimated from the earlier NGHGI model by Smith et al. (2006) and appear to correspond much better with other expert estimates of forest soil C.

### 3.2.4 Flux calculations

The Growth, Removals, and Mortality (i.e., GRM) approach was used to calculate change in forest C pools and the magnitude of flux by comparing measurements taken on the same set of plots and trees 10 years apart.

All flux calculations were summarized based on the condition classification at the initial measurement (e.g., owner, forest type, etc.). It was fairly common for the condition classification on a plot to change over time: usually it was a result of disturbance or management changing the forest type and/or stand size class, but sometimes there was a change in land-use on the plot. The change in C was calculated for individual trees between measurements. For live trees that died or were cut between measurements, growth equations were used to estimate tree diameter and height at the midpoint of the measurement interval and calculate C at the time of death (Bechtold and Patterson 2005); using the dimensions at the first measurement would result in a biased under-estimate for mortality and harvest. New trees that grew into the sapling size class ( $\geq 1$  inch diameter) between estimates were considered

ingrowth (a component of growth). Live tree C was allocated into the components of change based on initial and re-measurement tree status, namely: growth, removals, and mortality. Change in C for standing dead trees was based on the difference in calculated C at each time period and would include live tree C entering this pool through mortality, and dead tree C leaving this pool through decay, transition to other pools, or combustion; trees that fell over or were cut were assigned zero for the second measurement. Changes in down wood C were estimated at the plot level, based on calculations that did not incorporate log inclination from the most recent measurements. Changes in this pool include tree C entering this pool from live or standing dead pools and C leaving this pool through decay, transition to other pools, or combustion. Changes in understory vegetation were based on modeled estimates (from live tree biomass) from each measurement. Flux was also calculated for forest floor and mineral soil C based on the difference in modeled estimates for each plot at each measurement, using the models described in sections 3.2.3. While there is some confidence in the estimates of C stocks using these models, their accuracy at estimating C flux in Oregon is unknown.

For land-use change (i.e., forest to non-forest or non-forest to forest), all non-soil pools were assumed to be zero for non-forest conditions. Although in some cases this is unrealistic (e.g., not all trees are cut when houses are built on forest land), there are currently no data to estimate those pools on non-forest lands. For soil organic carbon (SOC), the IPCC Tier 2 approach is to use country-specific data to assign carbon concentrations by land-use, climate zone, and soil type, and assume a 20-year lag for SOC to reach a new equilibrium. However, most of the recent IPCC values and research on SOC appear to focus on agricultural soils and effects of different types of management (Ogle et al. 2003, IPCC 2006). The approach in Ogle et al. (2003), which is used in the NGHGI, assumes that forest, rangeland, and urban land-uses have the same SOC as uncultivated land (primarily due to lack of information for urban). Because the agricultural land-uses involved in land-use changes in Oregon were either pasture or orchard (i.e., did not involve any plowing or intensive row cropping), we assumed that SOC changes due to land-use were zero.

### 3.2.5 Disturbance classification and assessment

FIA crews identify the types of treatments and disturbances that have occurred on the plot since the previous measurement. Up to three management treatments, and up to three natural disturbances can be coded. Disturbances must meet a minimum threshold that cause mortality or damage to at least 25% of all trees in a stand or 50% of an individual species' count. We classified disturbance codes hierarchically for analysis, with both fire and harvest taking precedence over other disturbances. Harvest treatments of Trees removed (generic), Clearcut, Partial heavy, Partial light, Precommercial, and Improvement were classified as "Cut". Any record of fire (Fire [generic], Ground fire, and Crown fire) were classified as "Fire". If either of these types were recorded, they were identified with the condition; if both were recorded, the condition was classified as "Cut and Fire". (Note: Cut and Fire includes stands that were thinned and prescribe burned, as well as stands that were burned by wildfire and salvage-logged.) If neither of those were coded, then any insect or disease disturbances were used to classify the condition disturbance as "Insect and Disease". If nothing had been classified yet, then any weather disturbances (including landslide and avalanche) were coded as "Weather". Finally, if

none of the previous had been recorded but treatment codes for Firewood cutting, Incidental cutting, Stand conversion, Clean and release, or Chaining were present, then the disturbance was classified as “Other cut”. Although estimated trends in area burned are similar between FIA and other methods, other approaches don’t distinguish forest from non-forest burned area (Christensen et al. 2016).

Because change analyses are based on the conditions as designated at the first measurement, and disturbance is coded at the second measurement, when condition mapping may change, a mechanism to associate the disturbance code with the condition as classified at the first measurement is needed. For changes in tree carbon, the individual trees were assigned to both the current and previous condition IDs. For the other pools (e.g., down wood and understory veg) biomass estimates for each subplot were proportioned by the condition-change proportions on the subplot to link up the first and second measurements and calculate change. **Potential additions:** there is substantial interest in using remote sensing of disturbances to provide modeled up-to-date estimates of change; however, this would also require modeling growth, mortality, and decay on the undisturbed plots which could require substantial effort.

### 3.2.6 Estimation of additional greenhouse gases

The primary non-CO<sub>2</sub> greenhouse gas emissions for forest land are for methane (CH<sub>4</sub>) and nitrous oxide (N<sub>2</sub>O) from combustion in prescribed fire and wildfire. The default IPCC (2006) method is to estimate pre-fire fuel mass (live vegetation, litter, and dead wood), and apply combustion factors for the amount of woody material consumed (defaults in IPCC 2006 Table 2.6). Because we have measurements of change in C pools on plots that burned, we used the change in C on each burned plot instead. We then multiplied the amount combusted by emissions factors listed in IPCC 2006 Table 2.5 (CH<sub>4</sub>=4.7, N<sub>2</sub>O=0.26 g/kg of dry matter burnt for non-tropical forests). The CO<sub>2</sub> equivalents for the greenhouse gas effect of these gases (i.e., 100-year global warming potentials) are listed in IPCC (2007b) as CH<sub>4</sub>=25 and N<sub>2</sub>O=298. Greenhouse gas equivalents were not found for CO and NO<sub>x</sub>, so analyses of emissions of these gases were not included, which is consistent with the NGHGI.

For N<sub>2</sub>O emissions due to fertilization of commercial Douglas-fir stands in western Oregon, we followed the NGHGI approach (EPA 2019, page 6-38) where the area estimates (3.22 million acres in this case) are multiplied by the typical rate used in this region (200 pounds N per acre applied to 20 of every 1,000 acres of private industrial Douglas-fir timberland per year) to estimate total N applied (Briggs 2007). The total N applied to forests was multiplied by the IPCC (2006) default emission factor of one percent to estimate direct N<sub>2</sub>O emissions. For indirect emissions, the volatilization and leaching/runoff N fractions for forest land were calculated using the IPCC default factors of 10% and 30%, respectively. The amount of N volatilized was multiplied by the IPCC default factor of one percent for the portion of volatilized N that was converted to N<sub>2</sub>O off-site. The amount of N leached/runoff was multiplied by the IPCC default factor of 0.075% for the portion of leached/runoff N that was converted to N<sub>2</sub>O off-site. The resulting estimates are summed to obtain total indirect emissions. We calculate the size of this emission at 0.20 ± 0.1 MMT CO<sub>2</sub>e per year. While we report the state total, we did not incorporate this flux as a standard component of all the reported estimates.

## 4. Forest ecosystem results: Carbon flux, stocks, and trends

In this analysis results of carbon physically present in the forest are given in metric tons (MT) of carbon (C). Results of carbon flux, the amount and rate of gaseous carbon being emitted or sequestered by the forest, are given in metric tons (MT) of carbon dioxide equivalent (CO<sub>2</sub>e). Net changes in individual carbon pools are also shown in units of CO<sub>2</sub>e and referred to as flux to provide insight into the components of change, even if they aren't a direct flux with the atmosphere (e.g., tree mortality, which is a conversion from live to dead wood that initially stays in the ecosystem). Carbon can be converted to CO<sub>2</sub>e by multiplying by 3.667<sup>2</sup>. Negative values indicate a loss from the pool. Ranges in the text (i.e., ±) represent a 95% confidence interval (CI), while estimates in the tables report the sampling error (SE; CI = 1.96\*SE). Estimates of carbon storage and net flux provided in this report based on modeled attributes (e.g., belowground roots, soils), or estimates based on measured values but summarized for a small area or filtered set of specific criteria (e.g., C in storage for a forest type, single ownership, and a small forested region) must be interpreted with caution. An estimate of error (SE and 95% CI) is provided as an aid in interpretation and as a measure of confidence in each summarized result. The sampling error for modeled attributes does not account for potentially much larger amount of error associated with the model itself. Additionally, modeled attributes are developed by estimating total carbon storage and not carbon change. Any small bias for carbon model totals can lead to very large biases for carbon change.

### 4.1 Average annual net carbon flux

#### 4.1.1 Statewide net carbon flux 2001-2006 & 2011-2016—overview

Estimated average annual net carbon sequestration is based on a 10-year average from plots and trees initially measured between 2001 and 2006 then re-measured 10 years later between 2011 and 2016. Results from this remeasurement period are referred to as 2016 results, or results from the 2016 reporting period throughout the report. Remeasuring permanently located inventory plots gives the FIA forest inventory program the unique ability to fully evaluate and monitor changes on each plot in all carbon pools especially changes in tree growth, removals, and mortality across all ownerships and forested areas of the state. Most of the results focus on net change in forest ecosystem carbon for forestland remaining forested at both measurement intervals, and incorporates effects on CO<sub>2</sub> flux from growth, harvest, and mortality from any disturbances such as wildfire. In addition, we account for the carbon impacts of land changing to or from forestland, and for gasses in addition to CO<sub>2</sub> that are emitted from combustion in wildfire.

As of the 2016 reporting period, according to the FIA plot measurements, Oregon's statewide rate of carbon sequestration from all forest ecosystem pools across all ownerships is 30.9 ± 7.3 MMT CO<sub>2</sub>e per year, excluding net CO<sub>2</sub>e contributions from other sources such as harvested wood products, land moving to and from a forested condition, and non-CO<sub>2</sub> greenhouse gas

---

<sup>2</sup> Throughout the forest ecosystem portion of the inventory, results are converted from C to CO<sub>2</sub>e by multiplying by 3.667.

emissions from wildfire (Table 4.1, 4.3). After accounting for forest land use conversions and non-CO<sub>2</sub> greenhouse gas emissions from wildfire, the 2016 statewide rate of carbon sequestration on all forest land is 31.~~48~~ ± 7.2 MMT CO<sub>2</sub>e per year (Table 4.2). Changes in land-use between forest and non-forest land condition is estimated to have a net effect of sequestering 0.9 ± 1.2 MMT CO<sub>2</sub>e per year (Table 4.2, 4.10). Combined annual net emissions of non-CO<sub>2</sub> greenhouse gases (methane and nitrous oxide) from wildfire is also accounted for and is estimated to be 0.2 ± 0.0 MMT CO<sub>2</sub>e per year (Table 4.2, 4.8).

**Table 4.1.** Statewide average annual net CO<sub>2</sub>e flux from forest pools in forest land remaining forest land based on plots initially measured between 2001-2006 and re-measured between 2011-2016.

#### 4.1.2 Net carbon flux for forest land remaining forest (FF)

##### 4.1.2.1 *Net carbon flux by pool and ownership*

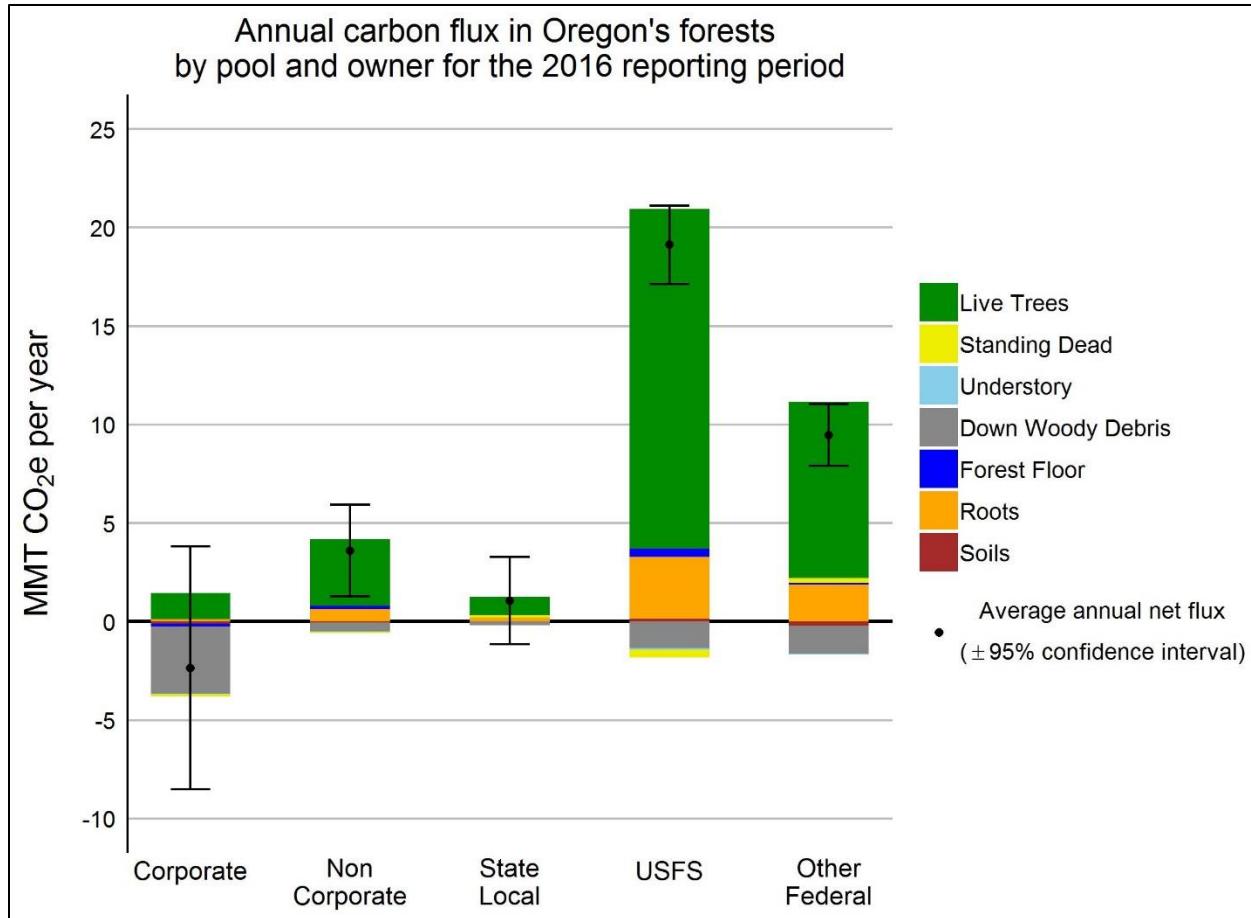

Annual growth in all live vegetation carbon pools is exceeding annual losses from these pools by 124%. Live vegetation including trees, foliage, live roots, and understory growth contribute to Oregon's forest carbon stock at a net rate of about  $37.9 \pm 5.8$  MMT CO<sub>2</sub>e per year (Table 4.1, 4.3). Dead vegetation including standing dead trees, dead roots, and down wood as fallen logs and other decaying woody material is losing CO<sub>2</sub>e to the atmosphere and other forest ecosystem pools at a rate of  $7.3 \pm 2.1$  MMT CO<sub>2</sub>e per year. Net loss of CO<sub>2</sub>e from down wood pool is partially due to the overall rate of wood decay combined with losses from disturbance events such as wildfire exceeding the rate of recruitment of new material through fallen trees and branches. Potential down woody material is also being partially off-set from harvested trees that would have become part of the down wood carbon pool. Carbon in wood products manufactured from a portion of the wood volume in these harvested trees is not immediately emitted as CO<sub>2</sub>, but is stored as sequestered C. An analysis of harvested wood products and the role they play in Oregon's forest carbon cycle are not included as part of this carbon reporting effort, however, the final results will be published in a separate report.

**Table 4.3.** Statewide estimate of average annual net carbon flux (CO<sub>2</sub>e) by pools and owner, 2001-2006 to 2011-2016. Changes in CO<sub>2</sub>e due to land-use and non-CO<sub>2</sub> greenhouse gas emissions are not included. See also Appendix 2, Table B1.

As a single ownership, federally managed forests contribute to the majority of overall net annual CO<sub>2</sub>e sequestration in Oregon. National forests alone account for 54% of the annual net change in live trees (Table 4.3). Adding forest land managed by other federal agencies brings the statewide contribution to 82% of the net change coming from federal forests. Tree growth on private ownerships, corporate and private individual owners, has a net contribution of 15% to the overall rate of sequestration in live trees after accounting for removals due to harvest and mortality. State and local government managed forests contribute about 3%.

Evaluating the contribution of each ownership by carbon pool reveals the significant amount the National Forests and private ownerships provide to overall annual carbon sequestration. It is the combined effect of annual growth on live trees from all ownerships that overcome annual carbon losses due to any single source of emission (Figure 4.1). Of the  $30.9 \pm 7.3$  MMT CO<sub>2</sub>e per year being sequestered in Oregon's forests,  $19.1 \pm 2.0$  MMT CO<sub>2</sub>e per year is taken up by forest land on the National Forests. Of the forest land managed by private owners, those managed by private individuals are sequestering carbon at rate of  $3.6 \pm 2.3$  MMT CO<sub>2</sub>e per year. Although the estimate for net annual change on private corporate forest lands is negative ( $-2.4 \pm 6.2$  MMT CO<sub>2</sub>e per year), the variation in the estimate of current annual growth when accounting for trees removed through management activities is too large to determine if the average net annual rate of carbon sequestration is statistically different from zero. For the 80% of Oregon's forests classified as timberland the rate of carbon flux among owners differs only slightly from the amounts estimated for all forestland (Figure 4.2).

**Figure 4.1.** Oregon statewide estimate of average annual carbon flux (MMT CO<sub>2</sub>e/yr) by pool and ownership, 2001-2006 to 2011-2016. Estimates exclude emissions from land-use changes and non-CO<sub>2</sub> greenhouse gases. Roots includes belowground live and dead tree roots. Understory includes aboveground and belowground pools. Error bars represent 95% confidence intervals around point estimates for net flux. Figure derived from Appendix 2, Table B1.

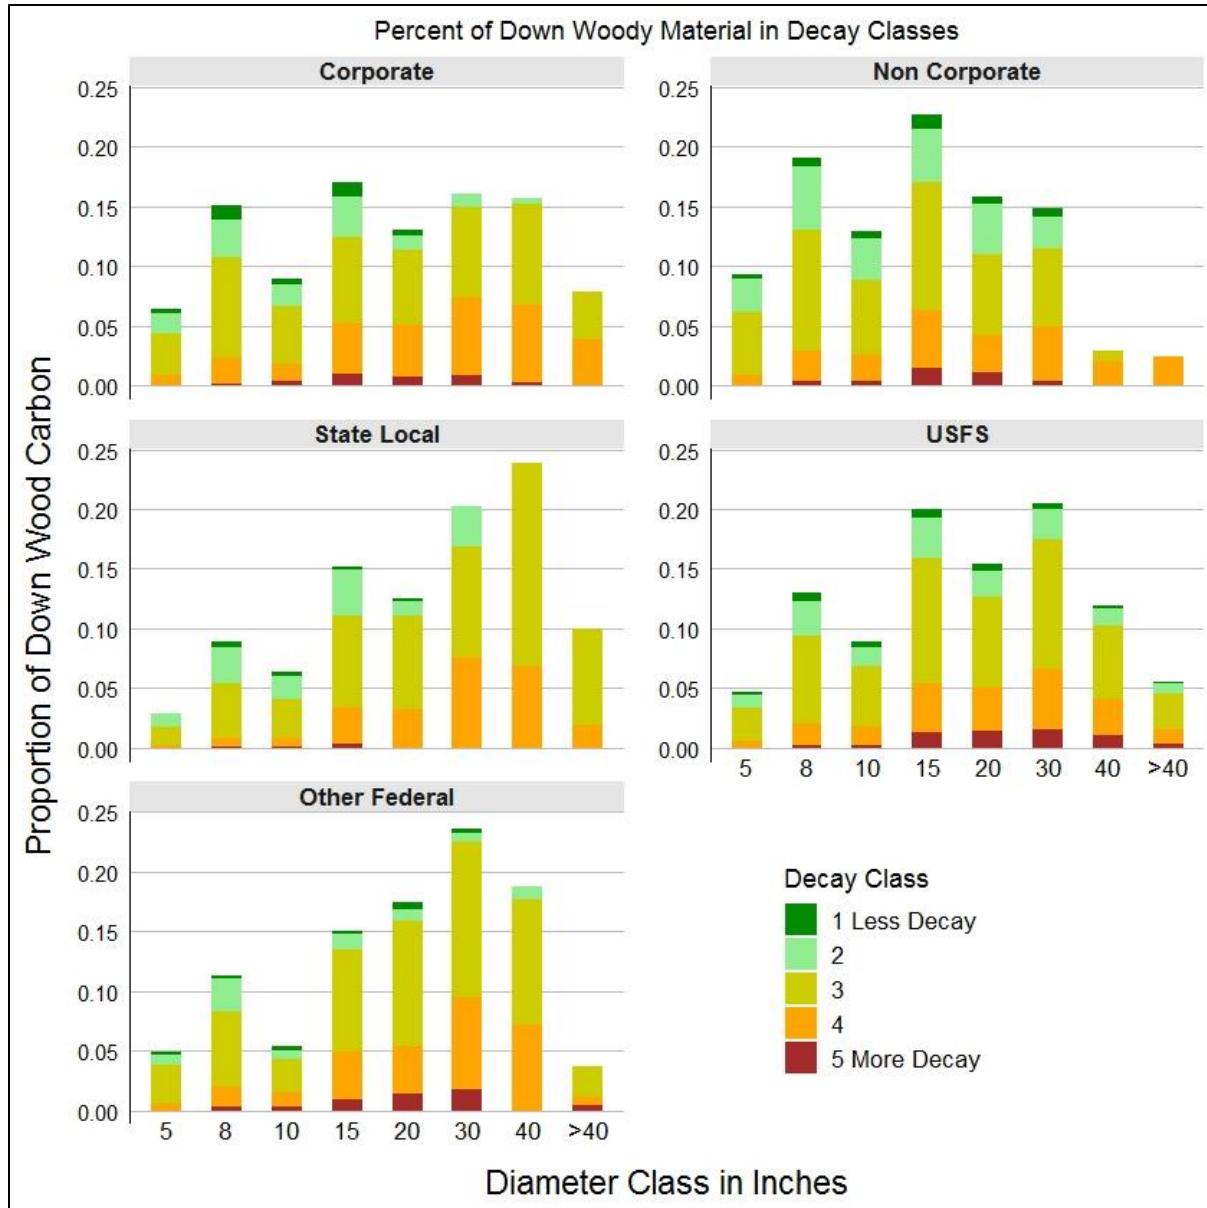

**Figure 4.2.** Oregon timberland statewide estimate of average annual carbon flux (MMT CO<sub>2</sub>e/yr) by pool and ownership, 2001-2006 to 2011-2016. Estimates exclude emissions from land-use changes and non-CO<sub>2</sub> greenhouse gases. Roots includes belowground live and dead tree roots. Understory includes aboveground and belowground understory vegetation. Error bars represent the 95% confidence interval of net change. Figure derived in part from aboveground totals in Appendix 2, Table B11.

#### 4.1.2.2 Investigation of patterns of flux in down wood in Oregon's forests, 2001-6 to 2011-16

Unlike most other pools down woody material declined significantly in Oregon ( $6.8 \pm 1.6$  MMT CO<sub>2</sub>e per year, 95% confidence interval). Converting to units of C and comparing to down wood stocks, this indicates a decline of 1.2% per year (%/yr) over this period, or a loss of 12% over 10 years. The estimates range from a decline 0.4%/yr on National Forests to a decline of 2.7%/yr on private corporate lands. We do not have decades of measuring down wood to know how these changes over the last 16 years compare with other time periods, but we analyzed the data a few different ways to try to understand the changes better (Figure 4.3). The percent of down woody material by log diameter class indicates a greater proportion of material in the larger classes (> 20 inches) for State/Local, Other Federal, and to some extent USFS. Larger logs tend to decay more slowly than smaller logs. These ownerships also tended to have more of

their larger logs in the lower decay classes (1-3), indicating more recent input of large material from mortality than the private ownerships. The largest decreases (75%) occurred in undisturbed stands, which occupied 67% of the landscape, for a loss of 0.26 MT CO<sub>2</sub>e /ac/yr. Across all owners, this rate was highest on private corporate lands, with a loss of 0.72 MT CO<sub>2</sub>e /ac/yr on undisturbed forest. The decrease on undisturbed stands indicates that the input of mortality and standing dead trees to down wood is less than the output of decaying down wood. Indeed, the carbon in mortality trees was higher across all owners than on private corporate lands (0.86 vs. 0.47 MT CO<sub>2</sub>e/ac/yr). The standing dead tree pool was essentially unchanged on all ownerships, which would indicate less input to the down wood pool from mortality. While the amount of cut trees was much higher on private lands than on public lands, logging slash that isn't yarded or burned tends to be small and decays relatively quickly. Estimates from down wood piles were not included in this report because field estimates are highly variable and problematic (pile density was often over-estimated in the field in the 2000s). Nevertheless, the data are compiled and available and even with an over-estimate, suggest that piles make up 0.49% of down wood mass in Oregon.

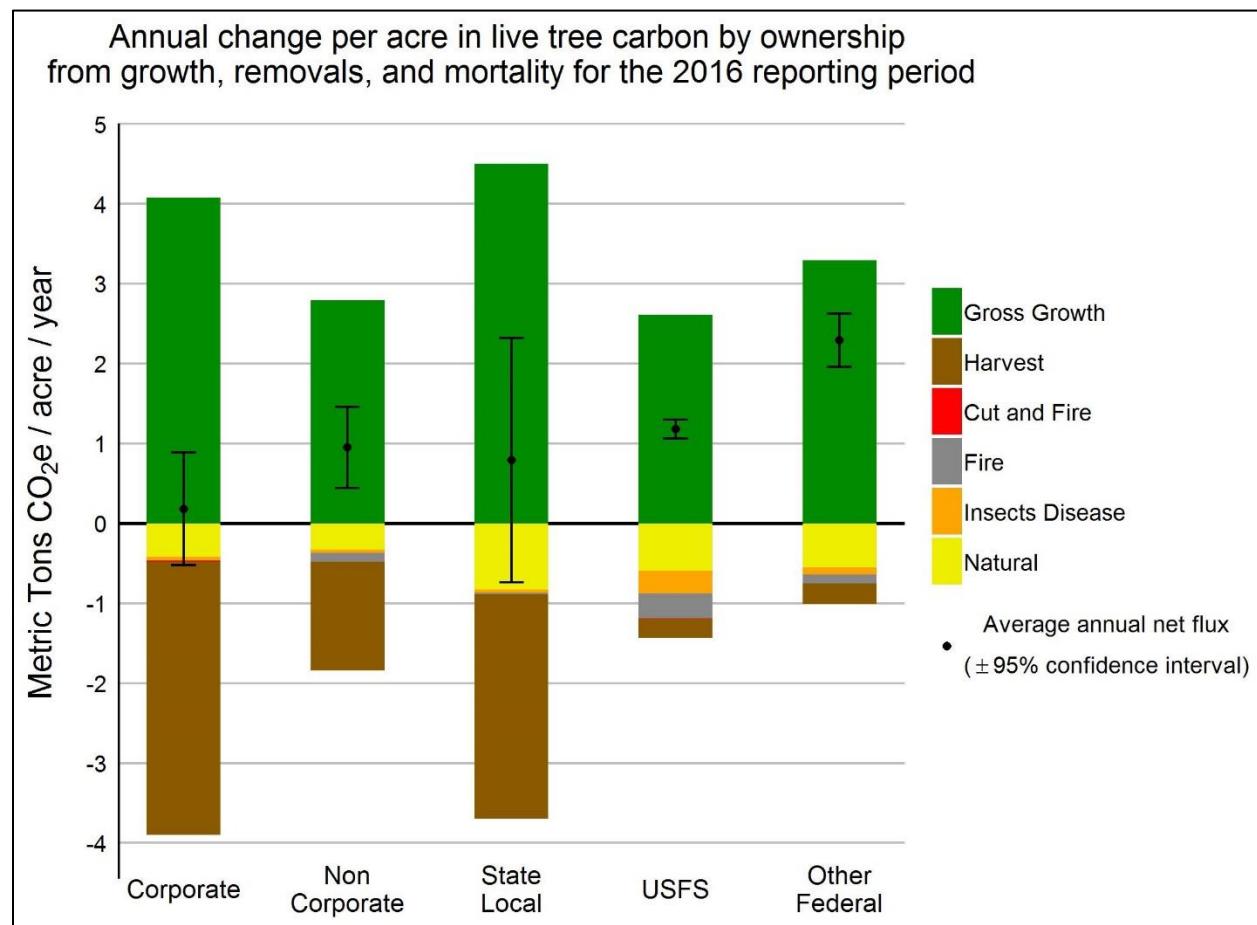

**Figure 4.3.** Proportion of carbon in down woody material by ownership and log diameter class and decay class in Oregon, 2011-2016.

#### 4.1.2.3 Net carbon flux aboveground live tree pool, by owner and land status

Annually on a per acre basis, carbon sequestration as gross tree growth is highest on forest lands managed by state and local governments ( $4.5 \pm 0.5$  MT CO<sub>2</sub>e/ac/yr), and private corporate owners ( $4.1 \pm 0.2$  MT CO<sub>2</sub>e/ac/yr) (Figure 4.4, Table 4.4). These ownerships also have the highest rate of annual timber harvest and are expected to contribute more to the harvested wood products carbon pool as compared to contributions from the other ownerships including forests managed by private noncorporate individuals, national forests managed by the USDA Forest Service, or other federal forest lands. An analysis of carbon stored in harvested wood

products is being prepared and will be released in a subsequent report. Combined with a relatively high annual rate of gross tree growth and less harvest per acre, forest land managed by other federal owners such as the BLM currently have the highest average annual rate of net carbon flux where  $2.3 \pm 0.3$  MT of CO<sub>2</sub>e per acre has been added each year (from a gross growth rate of  $3.3 \pm 0.3$ ).

Transfers of sequestered carbon from the live tree pool into dead wood pools from mortality are represented as a negative flux as shown by the portion of the bars below the horizontal zero line in figure 4.4. These carbon transfers are driven primarily by timber harvest, but also by wildfire and other mortality events. In Oregon's forests, naturally occurring mortality is consistently occurring at a rate greater than any other cause of mortality (except harvest) across all ownerships.

**Figure 4.4.** Average annual net change per acre in aboveground live tree carbon (MT/CO<sub>2</sub>e/acre) by ownership in Oregon's forests, 2001-2006 to 2011-2016. The error bars represent the 95% confidence interval of net change. Figure derived from Appendix 2, Table B10.

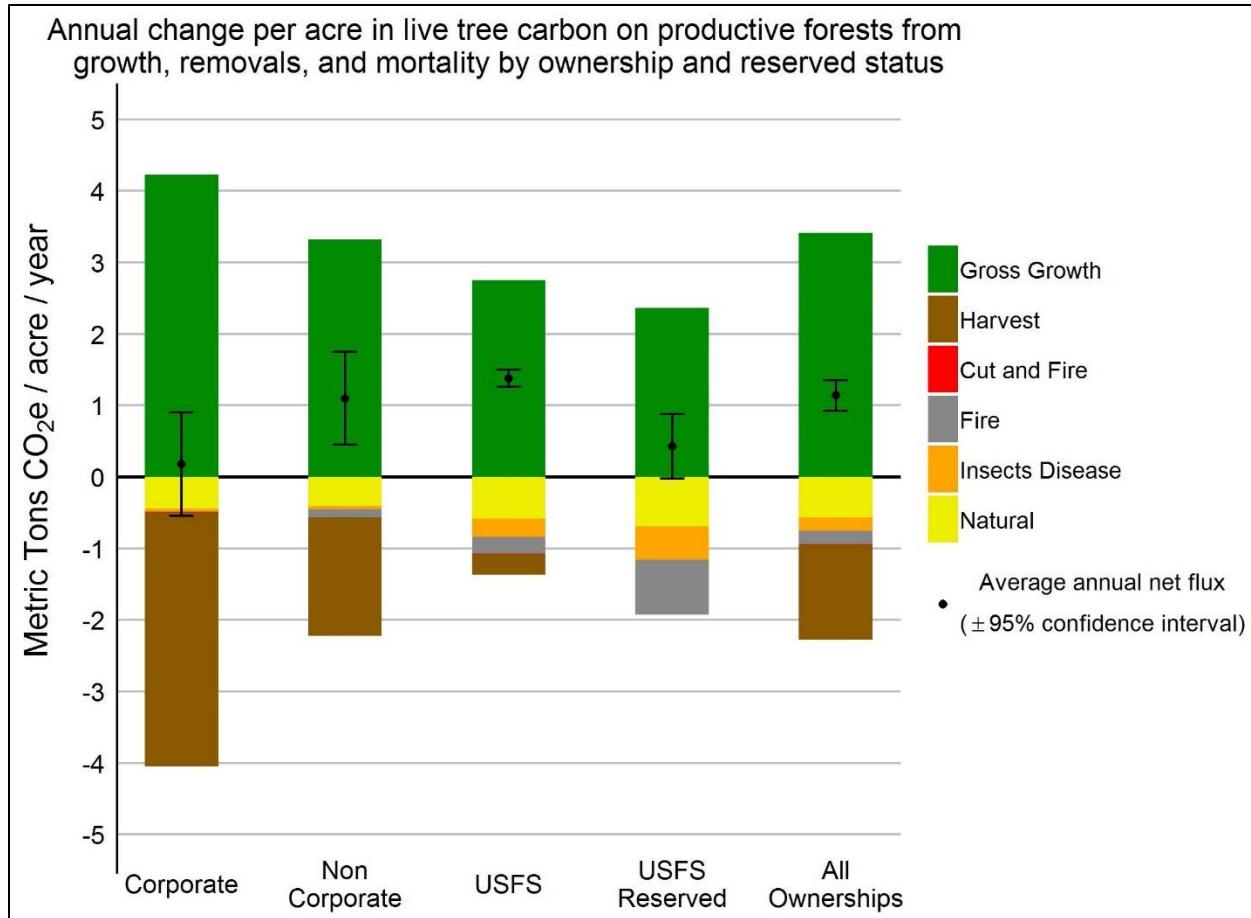

**Table 4.4.** Forest land average annual growth, mortality, harvest, and net change per acre in aboveground live tree carbon (CO<sub>2</sub>e) pool by ownership of Oregon's forests, 2001-2006 to 2011-2016. See also Appendix 2, Table B10.

<sup>1</sup>Mortality - Cut and fire: plots where tree mortality has occurred due to both harvest and fire.

Figure 4.5 illustrates carbon sequestered annually on a per acre basis from productive forest lands such as managed timberlands and other productive forest land not actively managed for timber production, such as congressionally withdrawn wilderness areas. When comparing the two largest ownership groups, carbon sequestration from gross tree growth is highest on ownerships managed by private corporations. On average, gross tree growth accounts for an increase of  $4.2 \pm 0.2$  metric tons of CO<sub>2</sub>e annually per acre on these timberlands compared to  $2.8 \pm 0.1$  metric tons per acre per year for National Forests timberlands (Table 4.5). Note: State and local government and other federal owners have higher gross tree growth at  $4.9 \pm 0.5$  and  $4.9 \pm 0.4$  metric tons per acre per year, respectively (See Appendix 2, Table B12).

Regardless of the cause, tree mortality transfers carbon from tree growth into carbon pools that eventually emit carbon through decomposition. Productive forests being managed by the USDA Forest Service are currently experiencing the greatest impact of tree mortality, in part due to wildfire on productive forests withdrawn from management for the production of timber. Fire caused tree mortality on these reserved forests is currently reducing the live tree carbon pool by  $0.8 \pm 0.4$  metric tons of CO<sub>2</sub>e annually per acre (Table 4.5).

**Figure 4.5.** Average annual net change per acre in aboveground live tree carbon (CO<sub>2</sub>e) for Oregon's productive forests by largest ownerships and land status of Oregon's forests, 2001-2006 to 2011-2016. Productive forests are capable of producing 20 ft<sup>3</sup> of tree volume per acre every year. The "All Ownerships" category includes all other state and federal agencies managing forest land in Oregon. The error bars represent the 95% confidence interval of net change. Figure derived from Appendix 2, Table B10, B12.

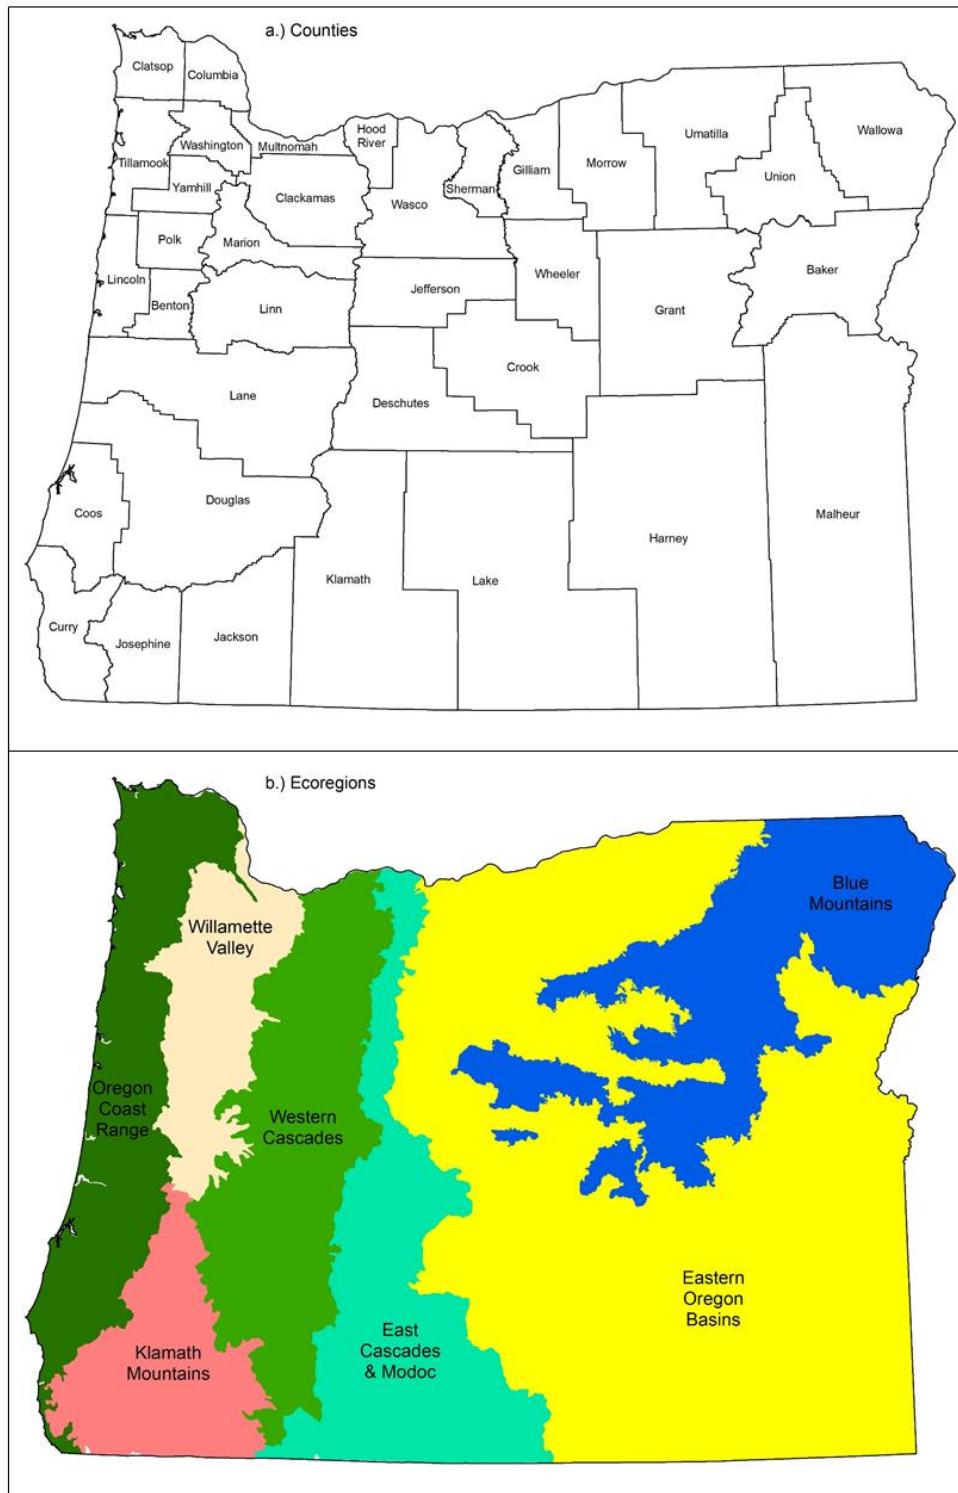

**Table 4.5.** Timberland (productive forest land) average annual growth, mortality, harvest, and net change per acre in aboveground live tree carbon (CO<sub>2</sub>e) pool by ownership and land status of Oregon's productive forests, 2001-2006 to 2011-2016. The all ownerships category includes all other state and federal agencies managing forest land in Oregon. See also Appendix 2, Table B10, B12.

#### 4.1.2.4 Net carbon flux aboveground live tree pool, by region

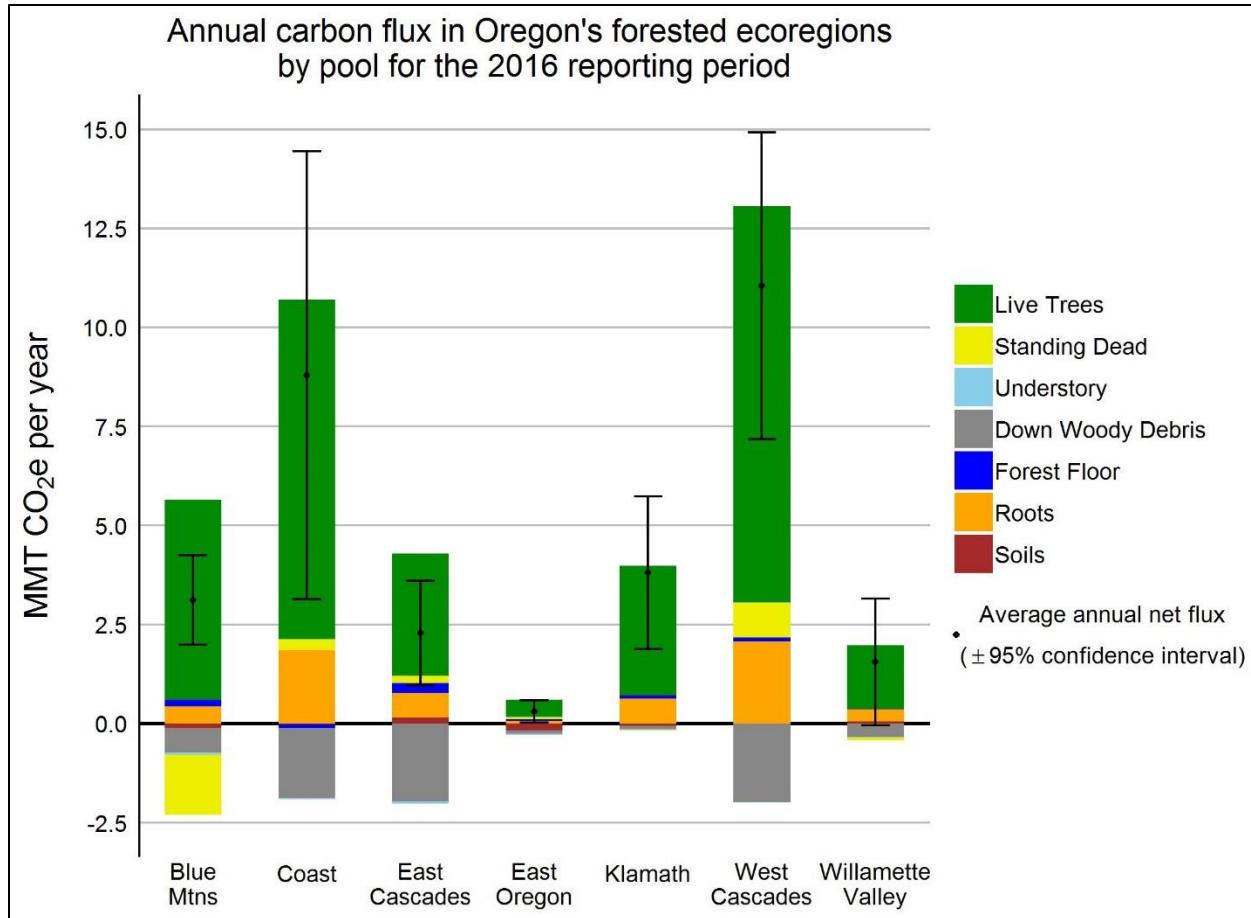

In Oregon, over half of the annual CO<sub>2</sub>e sequestration in live tree gross growth is occurring in two regions, the forests of the Western Cascades and the Oregon Coast Range (Figures 4.6a, 4.7, and 4.8). Due to the high rate of annual tree growth these regions account for 58% of the net CO<sub>2</sub>e sequestered annually from tree growth in Oregon's forests. The Western Cascades region accounts for 31% of the state's total annual net CO<sub>2</sub>e flux in live trees at 9.4 ± 3.0 MMT per year, slightly more than the live tree net flux of 8.1 ± 4.3 MMT CO<sub>2</sub>e sequestered annually from the Oregon Coast Range (Table 4.6). However, this does not account for carbon removed through timber harvest where a portion is sequestered as harvested wood products. Combined with a high rate of annual tree growth, annual output of high value wood products, and relatively less area impacted by tree mortality make forests of the Oregon Coast Range the most important region to the state for annual carbon flux. The highest annual rate of conversion to mortality occurs in the Western Cascades region where on average there is 9.4 ± 1.1 MMT of CO<sub>2</sub>e per year in tree mortality, or 37% of the statewide total mortality. After accounting for tree mortality from all causes and carbon removed through timber harvest, no single region is currently losing more CO<sub>2</sub>e annually than is being sequestered through live tree growth (Table 4.6).

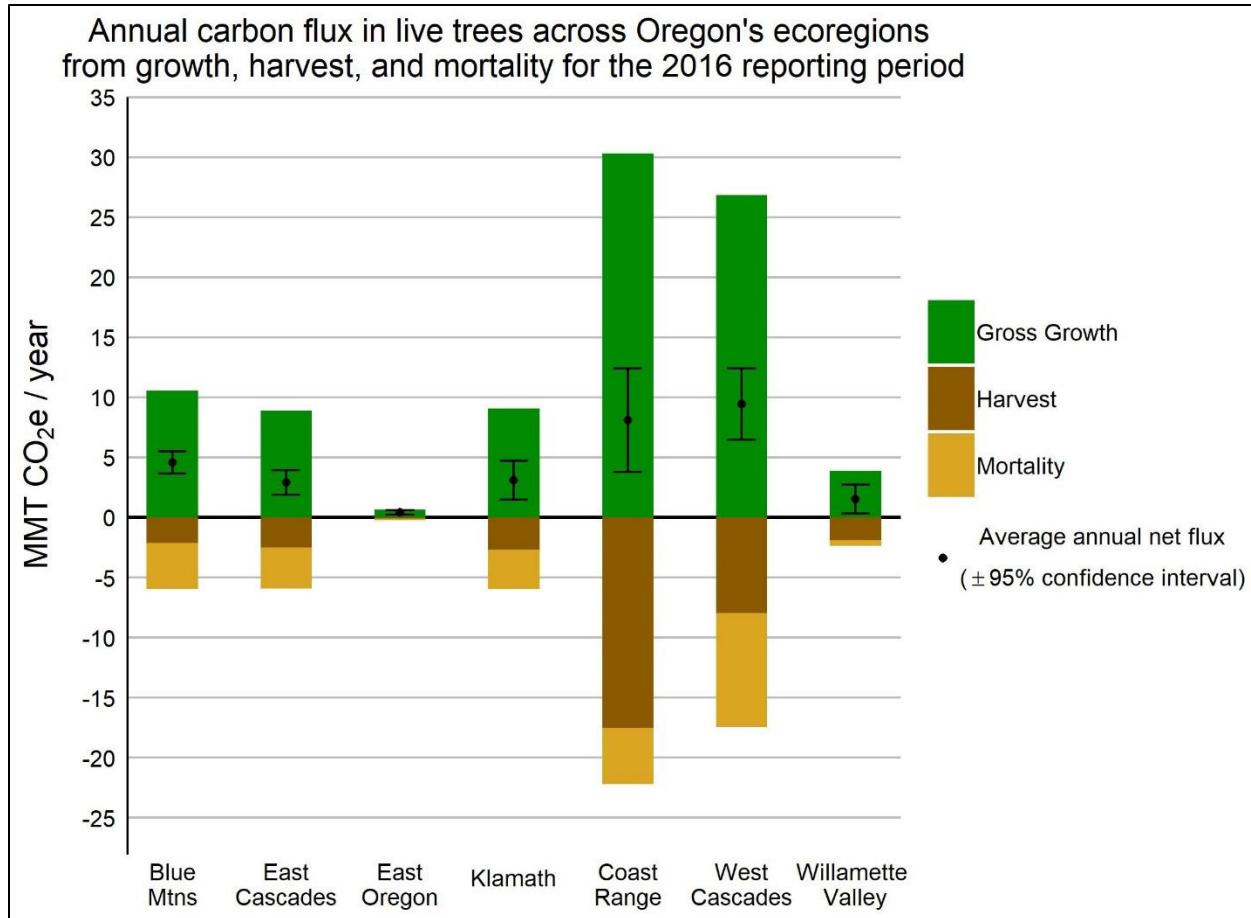

**Figure 4.6a.** Oregon a.) Counties; b.) Ecoregions used in this analysis, based on ecological sections as described by Cleland et al. (2007).

**Figure 4.6b.** Oregon a.) National Forest System boundaries; b) Ownership of forest land.

**Figure 4.7.** Average annual carbon flux in Oregon forested ecological regions by pool (MMT/CO<sub>2</sub>e/acre), 2001-2006 to 2011-2016. The error bars represent the 95% confidence interval of net change.

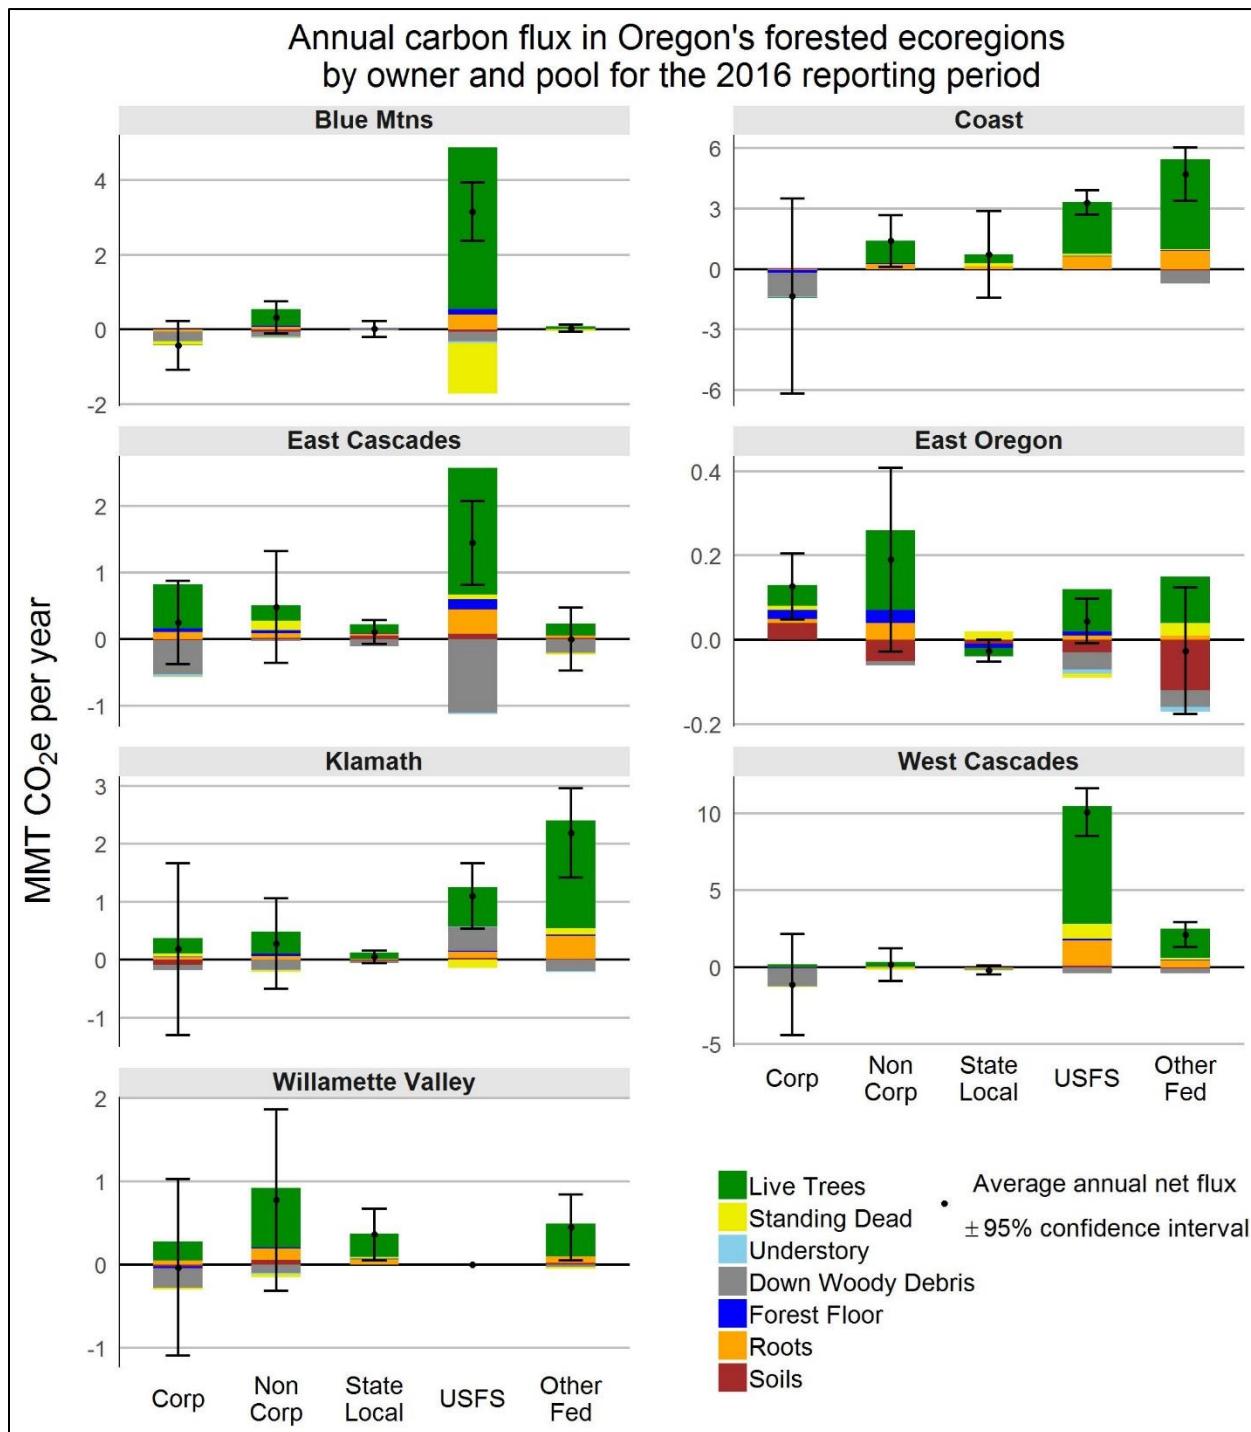

**Figure 4.8.** Average annual net CO<sub>2</sub>e flux in live trees from growth, harvest and mortality by ecological region, 2001-2006 to 2011-2016 (MMT CO<sub>2</sub>e /yr). Error bars represent the 95% confidence interval of estimated net flux. Figure derived from Table 4.5/Appendix 2, Tables B2-B8.

**Table 4.6.** Average annual net CO<sub>2</sub>e flux in live trees from growth, harvest, mortality by ecological region, 2001-2006 to 2011-2016. Compare to Appendix 2, Tables B2-B8.

Annual CO<sub>2</sub>e flux by pool and ownership from each region shows increased statistical uncertainty as wider confidence intervals for many of the estimates (Figure 4.9). The increased uncertainty illustrates the current useful limit of the FIA collected measurement data and compiled estimates. As the sample size of measured plots decreases through additional estimation classifications covering smaller geographic scales the statistical uncertainty with each estimate quickly increases. Despite the increased uncertainty there is useful information that can be obtained from this detailed look at annual CO<sub>2</sub>e flux. Of the estimates not statistically different from zero, annual CO<sub>2</sub>e flux in live tree growth is exceeding CO<sub>2</sub>e loss into other carbon pools for most regions especially for USDA Forest Service managed forests. Despite the relatively high rate of live tree growth, the Blue Mountains region has a notable transfer of live trees into the standing dead tree pool on USDA Forest Service forests where 1.4 ± 0.5 MMT of CO<sub>2</sub>e is added to this pool each year (Table B2).

**Figure 4.9.** Oregon average annual net CO<sub>2</sub>e flux by ecoregion, pool and ownership, 2001-2006 to 2011-2016. Roots includes belowground live and dead tree roots. Understory includes aboveground understory vegetation. Error bars represent the 95% confidence interval of net change. Figure derived from Appendix 2, Tables B2-B8. Note the different y-axis scales on individual graphs.

#### *4.1.2.5 Disturbance effects on carbon flux*

The net change in C by pool varied with management, disturbance, and ownership. In stands that experienced harvesting, the loss of live trees on National Forest lands was slightly more than growth when also accounting for natural mortality ( $-0.87 \pm 0.5$  MMT CO<sub>2</sub>e per year), since on average growth was roughly proportional to harvest in those stands (Table 4.7a). In contrast, on private corporate lands, the net change in live trees on cut stands was  $-16.1 \pm 3.7$  MMT CO<sub>2</sub>e per year, reflecting greater proportional removals of live trees in stands that were cut on that ownership compared to others. Accounting for additional losses of dead wood resulted in a net removal of  $-29.0 \pm 5.3$  MMT CO<sub>2</sub>e per year in stands where harvesting occurred across all ownerships in Oregon. Of the estimated  $34.8 \pm 4.6$  MMT CO<sub>2</sub>e per year of live trees cut within the forest (Table 4.7a), live tree growth annually exceeded harvest and mortality.

The total net change in C in stands that experienced fire in Oregon was  $-2.3 \pm 0.8$  MMT CO<sub>2</sub>e per year. Most of that loss occurred on National Forest lands. Although live tree mortality was nearly twice that amount on National Forests ( $-4.3 \pm 1.2$  MMT CO<sub>2</sub>e per year), live tree growth and the increase in standing dead was significant.

In contrast to stands experiencing fire and/or cutting, stands affected by weather disturbances or insect and disease accumulated C in the live and dead tree pools. Overall, in spite of annual statewide losses due to fire and/or cutting across Oregon, accumulations on stands experiencing other disturbances, and undisturbed stands, resulted in a net overall accumulation of nearly  $30.1 \pm 5.7$  MMT CO<sub>2</sub>e per year reflecting the state's high annual tree growth rate across all forest ownerships.

Washington county is estimated to have a net loss of carbon based on all pools ( $-2.3 \pm 2.1$  MMT CO<sub>2</sub>e per year), due to an estimated high rate of harvest (Table 4.7b). Douglas County is also notable with a high rate of live tree mortality ( $-3.5 \pm 0.8$  MMT CO<sub>2</sub>e per year) mostly due to fire and natural causes, but is partially compensated for this loss by also having a high rate of annual tree growth ( $12.1 \pm 1.4$  MMT CO<sub>2</sub>e per year) second only to Lane County. The forests of Lane County lead the state in net carbon flux by sequestering approximately  $7.6 \pm 2.3$  MMT of CO<sub>2</sub>e annually, making it responsible for nearly a quarter of all the CO<sub>2</sub>e sequestered each year by Oregon's forests. Douglas and Lane are the two largest counties in terms of forest area in western Oregon. See figure 4.6a for a map of Oregon counties.

Of the National Forests or other forested areas managed by the USDA Forest Service in Oregon, only the Deschutes National Forest is currently estimated to have a net loss of carbon based on all pools ( $-0.2 \pm 0.6$  MMT CO<sub>2</sub>e per year) but this estimate is not statistically different than zero (Table 4.7c). Other forests managed by the USDA Forest Service where net flux is not statistically different from zero include Fremont National Forest, Ochoco National Forest, Columbia River Gorge National Scenic Area, and the Crooked River National Grassland. As of 2016, due to recent fires the Rogue River-Siskiyou National Forest is experiencing the highest

rate of mortality on a National Forest at  $-2.8 \pm 0.6$  MMT CO<sub>2</sub>e per year. See figure 4.6b for a map of National Forests within Oregon.

**Table 4.7a.** Average annual net carbon (CO<sub>2</sub>e) flux by pool on forest land by disturbance type and ownership, 2001-2006 to 2011-2016. See also Appendix 2, Table B9.1.

#### *4.1.2.6 Implications of recent tree mortality events on carbon flux*

Recent large fires, insect outbreaks, and drought conditions in Oregon's forests have caused tree mortality to fluctuate. Concerns are sometimes raised that high levels of mortality, particularly on National Forest lands that are not managed as intensively as other ownerships, have caused the forests in Oregon to become net emitters of carbon due to dead tree decay. Here we summarize recent trends in mortality in relation to other carbon fluxes.

On average, between 2001-2016, there were approximately 9.7 billion live trees in Oregon, of which about 137 million died each year, for an annual mortality rate of  $1.42\% \pm 0.097\%$  (95% CI). For National Forests, there were 5.1 billion live trees, of which 73 million died each year, for an annual mortality rate of  $1.44\% \pm 0.15\%$ . As shown in report table 4.3, storage of carbon in live trees increased on most ownerships over this time-period, while storage in dead wood remained stable or declined. Mortality rates in terms of carbon were highest on National Forest system lands ( $1.0 \pm 0.08\%$ ), with 47% of the mortality occurring on plots with no significant disturbance, and 21% occurring on plots disturbed by fire (Table B9 Disturbance). Despite the mortality on National Forest, the increase in the aboveground live tree wood pool was large ( $16.3 \pm 1.7$  MMT CO<sub>2</sub>e per year) with a modest decrease in the snag plus down wood pool (- $1.8 \pm 1.0$  MMT CO<sub>2</sub>e per year).

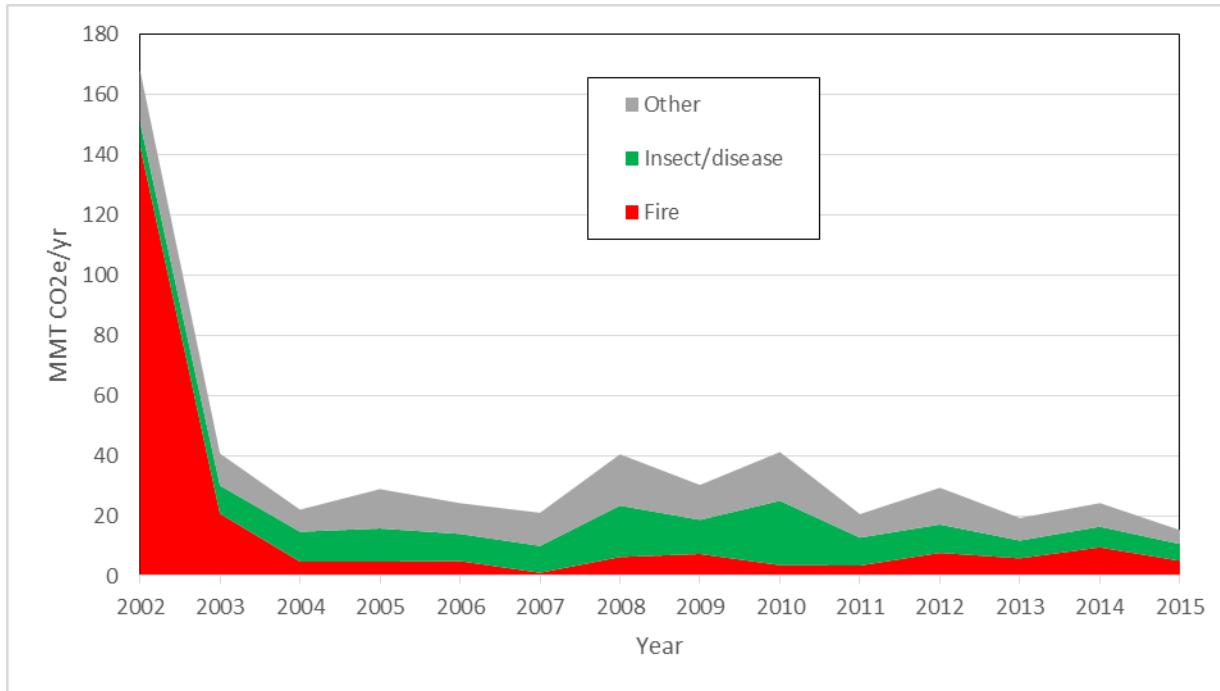

The amount of carbon in mortality trees ranged between 20-40 MMT CO<sub>2</sub>e over the assessment period, with the exception of 2002 (Figure 4.10). The large fires in 2002, including the 500 thousand acre Biscuit Fire in southwest Oregon, caused the spike in tree mortality in 2002. Overall, the most prominent mortality causes in terms of C were fire (23%), disease (20%), insect (18%), and wind (13%). Mortality rates in terms of live tree C was 0.7% per year for the state and ranged from 1.0% in the East Cascades to 0.4% in the Willamette Valley ecoregions.

The immediate effect of a pulse of tree mortality is to reduce storage in the live tree pool and the transfer of live tree carbon to dead tree carbon. The decreasing dead wood pool in recent years (Table 4.3) indicates that wood was being added at a slower rate than it was decaying, possibly in response to prior pulses of mortality (e.g., in high fire years). Live tree growth is the engine that drives forest carbon sequestration. For the balance to result in a net emission, mortality would have to exceed growth for an extended period such that the live tree pool declines and decay of the larger dead wood pool results in greater emissions.

Given a total aboveground dead pool of  $145 \pm 3.5$  MMT C on National Forests (not including litter or duff), annual decay could range from a low of 1.5 MMT CO<sub>2</sub>e per year (1%) to 7.2 MMT CO<sub>2</sub>e per year (5%)(decay rates are highly variable—Kahl et al. 2017 found the former rate for conifers and the latter for hardwoods). In order for forests on National Forests to be net emitters, the sum of additions to dead wood (mortality) and live wood (net live), or gross

growth minus harvest, currently  $33.0 \pm 1.0$  MMT CO<sub>2</sub>e per year) would need to fall below the actual flux from decomposition.

The available data on mean carbon storage in recent years in Oregon, and on National Forests in particular, indicates that the forests are still a net sink of carbon from the atmosphere. It is possible that during specific years of severe drought, growth rates can become so low and mortality so high that decay exceeds new storage. A physiological model based on annual climate would likely be required to assess that question (e.g., Turner et al. 2016).

**Figure 4.10.** Estimated amount of carbon in mortality trees in Oregon by year and cause of death, 2002-2015.

#### 4.1.2.7 Net flux from non-CO<sub>2</sub> GHG emissions from wildfire

Fire was estimated to affect  $103 \pm 16$  thousand acres per year (95% CI), with an additional  $16 \pm 7$  thousand acres per year affected by both fire and cutting. Emissions of methane and nitrous oxides due to fires on forest land are estimated to add  $192 \pm 47$  thousand metric tons of CO<sub>2</sub>e per year (95% CI) to Oregon's statewide emissions (Table 4.8, Figure 4.11). (Note that CO<sub>2</sub> emissions are already included in the previous net flux tables and are included here only for context.) The greatest source of these emissions was from fire on National Forest lands. A substantial amount was also estimated for the “cut and fire” category on private corporate lands. There are a few uncertainties with this estimate that may result in compensating effects. Our approach underestimates non- CO<sub>2</sub> gas emissions because we currently do not have an estimate of combustion of forest floor; and because, in the use of net change in C, some of the

C that was combusted would be masked by subsequent forest growth. Alternatively, our approach may overestimate non- CO<sub>2</sub> gas emissions because some of the cut and fire category were cut before they were burned, so the amount combusted was less than the net change; and because some of the change in C of dead wood came from decay after the fire, and not entirely from combustion. We will examine options to refine this estimate. Nevertheless, we believe the calculation based on field measurements will be more accurate than a default emission factor applied to an estimate of area burned as in the default approach for IPCC 2006.

**Table 4.8.** Annual Net Emissions of CO<sub>2</sub> and Non- CO<sub>2</sub> Greenhouse Gases from Fire, 2001-2006 to 2011-2016: All Oregon. CO<sub>2</sub> values are from table 4.4 and were used to calculate the other gases. See also Appendix 2, Table F1.

#### 4.1.3 Net carbon flux associated with forest land conversions (LF)

##### *4.1.3.1 Changes in forest land area from forest land conversions*

Approximately  $20 \pm 7$  thousand acres (95% CI) of forest land were converted to non-forest (i.e., deforested) every year in Oregon between 2001-2006 and 2011-2016 (Table 4.9). Most of the deforestation (53%) was conversion to grassland, 88% of which consisted of mechanical removal (e.g., chaining of juniper), and the remaining 12% due to lack of forest regeneration more than 30 years after a disturbance, primarily fire. Another 34% of the deforestation was conversion to developed, 90% of which was to rights-of-way (i.e., powerlines and roads, including logging roads). Approximately  $24 \pm 7$  thousand acres of non-forest land were converted to forest every year (i.e., afforestation). Most of the afforestation (43%) occurred on developed uses (primarily rights of way—e.g., abandoned logging roads), with another 37% from grassland (natural tree encroachment). Overall, the estimate for the net loss of forest land

is not statistically significant at the rate of  $4.5 \pm 9.3$  thousand acres per year. The confidence interval is high compared to the estimate because it is a relatively rare event at the scale of the inventory. Net forest land losses appeared to occur (not significant) on non-productive “other forest”, with gains seen on timberland, and some apparent gains on reserved lands as well.

**Table 4.9.** Annual change in forest land area to/from other IPCC land-use classes in Oregon, 2001-2006 to 2011-2016. See also Appendix 2, Table E1.

#### 4.1.3.2 Net carbon flux from forest land conversions

Deforestation resulted in a loss of  $2.4 \pm 0.8$  (95% CI) MMT CO<sub>2</sub>e from forest carbon pools per year (Table 4.10). This was compensated for by the addition of  $3.4 \pm 0.8$  MMT CO<sub>2</sub>e per year due to afforestation, resulting in an insignificant net gain of  $0.9 \pm 1.1$  MMT CO<sub>2</sub>e per year. Most of the gains and losses were due to the live tree pool. Uncertainties in land classification are low, because FIA plots are visited on the ground in the case where there is any potential for forest land to be present on the plot (based on past history, the vegetation of the local area,

and examination of aerial photography). Non-forest plots which are not field visited are classified from aerial photography of at least one-meter resolution. Where definitions have changed over time, field crew measurements and detailed written descriptions are used to correctly assess change between forested lands and other land-uses.

**Table 4.10.** Annual change in carbon pools due to change in land-use between forest and non-forest in Oregon, 2001-2006 to 2011-2016. See also Appendix 2, Table E2.

## 4.2 Carbon stocks for forest land remaining forest land (FF)

### 4.2.1 FF land area

For the 2007-2016 reporting period, FIA estimates there are approximately 30 million acres of forest land across all ownerships in Oregon. Approximately 64% (19.0 million acres) of these forests are managed by federal agencies and state/local governments (Table 4.11). Private ownerships are divided between corporate forest lands, approximately 6.6 million acres, and private individuals owning 4.1 million acres. By region, over half (54%) of the forested acres are found within the Westside regions comprised of the Oregon Coast Range, Willamette Valley, Western Cascades, and Klamath Mountains (Figure 4.6a, Table 4.11). The region with the greatest share of forested area is the Western Cascades having 22% of all forested acres in the state. The Willamette Valley region is the only region that has a disproportionately larger share of privately owned forests (87%) compared to those managed by public agencies (13%). Douglas-fir has the greatest area of all forest types at approximately 37%, or  $11.0 \pm 0.3$  million acres, followed by ponderosa pine at approximately 17%, or  $5.2 \pm 0.2$  million acres (Table 4.12).

Forest land that is capable of producing in excess of 20 cubic feet per acre per year of wood at culmination of mean annual increment.

Forest land that is not capable of producing in excess of 20 cubic feet per acre per year of wood at culmination of mean annual increment.

#### 4.2.2 FF carbon stock by ownership and land status, all Oregon

FIA plot measurements indicate that for the most recent 10-year reporting cycle (2007-2016) there are  $3.2 \pm 0.03$  billion metric tons of carbon stocks stored on forest land including forest floor and forest soils across all ownerships in Oregon (Table 4.13a, Figure 4.12). Approximately 70% of these carbon stocks are found on public forest land with the National Forests containing over half of all carbon stocks (52%) (Table 4.13a, Figures 4.12 and 4.13). Just under half of all stored carbon is found belowground in forest soils (49%), and about a third is found aboveground in the live tree pool (32%) (Figure 4.12). The remaining stored carbon is distributed among the dead trees (2%), roots (7%), down wood (5%), forest floor (4%) and understory vegetation pools (1%). By land status, approximately 82% of the forest carbon stores are found on unreserved timberland, with about 12% found within areas reserved from timber harvest (Figure 4.14). Less productive unreserved forest land accounts for the remaining 6% of carbon stores. Table 4.13a below provides detailed estimates of forest carbon stocks for each pool by ownership and land status for the ten-year measurement period between 2007 and 2016.

In general, there is a close relationship between the proportion of forest land area by ownership and total stored carbon. Differences in this relationship between ownerships is a reflection of current management priorities, forest policy, recent disturbances, and the inherent productive ability of the land base. For example the national forests are storing over half of the carbon stocks (52%) and manage just under half of the forest land base (47%) (Figure 4.13). While private ownerships store 30% of the carbon stocks and managed 36% of forest land. This difference in the proportion of carbon stores per area of land base illustrates the generally older over-story stands, denser tree stocking, and additional dead and down wood carbon stores found on national forests as compared to more intensively managed private ownerships. On private ownerships more live tree carbon is transferred out of forest carbon through timber harvest and stored as harvested wood products (Section 4.2.2.1 below provides additional information on forest carbon density with stand age). State and local government store 4.5% of the carbon stocks and manage 3.9% of forest land.

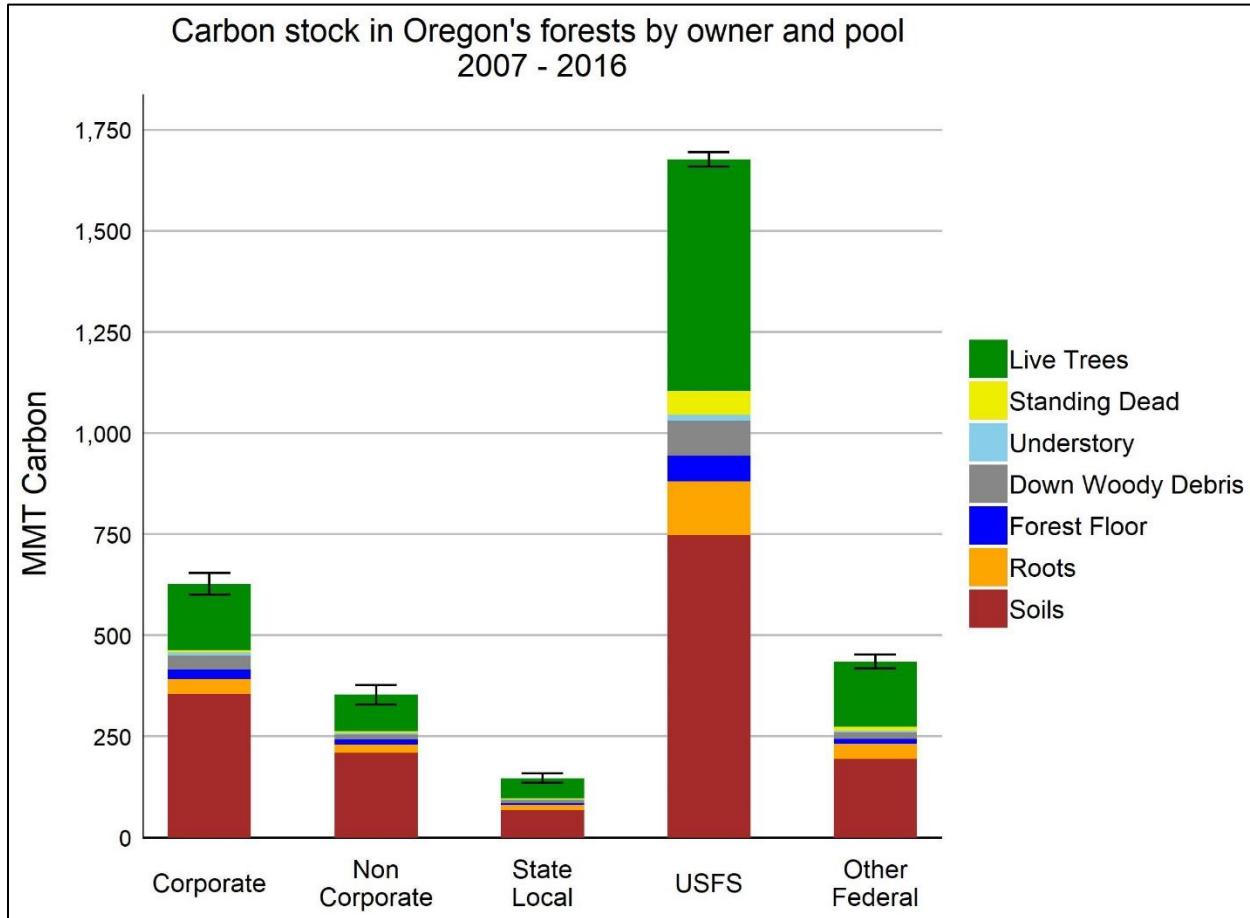

The counties with the highest carbon stocks are Douglas County with  $380.1 \pm 25.9$  MMT C, and Lane County with  $377.6 \pm 25.3$  MMT C (Table 4.13b). These counties have the largest area of forest land in western Oregon. Counties east of the Cascade Mountains tend to have the largest amount of carbon stored in standing dead and down wood pools relative to carbon stored in all other forest vegetation pools. Jefferson County has greatest amount with 32% of forest vegetation carbon stored in standing dead or down wood followed by Wheeler County with 26%.

The Willamette National Forest has the highest total carbon stocks at  $273.5 \pm 9.9$  MMT C and is also one of the largest National Forests in the state (Table 4.13c). However, in terms of carbon stocks per acre, the Siuslaw National Forest has the greatest density of forest carbon per acre with 185.8 thousand MT C per acre on average.

<sup>1</sup>Multiply carbon (C) by 3.667 to calculate equivalent carbon dioxide (CO<sub>2</sub>e)

**Figure 4.12.** Oregon statewide average forest carbon stock by pool and ownership, 2007-2016 (MMT C). Error bars represent 95% interval of estimated total stock for each ownership. Figure derived from table 4.12.

**Figure 4.13.** Oregon statewide percent of forest land base and carbon stocks by owner, 2007-2016 (MMT C). Figure derived from Table 4.12.

**Figure 4.14.** Oregon statewide average forest carbon stock by land status and ownership, 2007-2016 (MMT C). Error bars represent 95% confidence interval of estimated total stock for each ownership. Figure derived from table 4.12.

**Table 4.13b.** Forest land carbon stock by county, 2007-2016: COUNTY

#### *4.2.2.1 Patterns of forest carbon density with stand age*

After a stand-replacing disturbance (e.g., severe fire or clearcutting) carbon stocks tend to decline initially and then accumulate over time as trees regenerate and grow to store more carbon than what is being released by decaying dead wood and soils. Because there is very little data that has measured individual trees and stands over multiple decades or centuries, a common approach to approximate this pattern is to examine how carbon density (MMT per acre) differs with stand age, termed a chronosequence. However there are many reasons why chronosequences may provide inaccurate results:

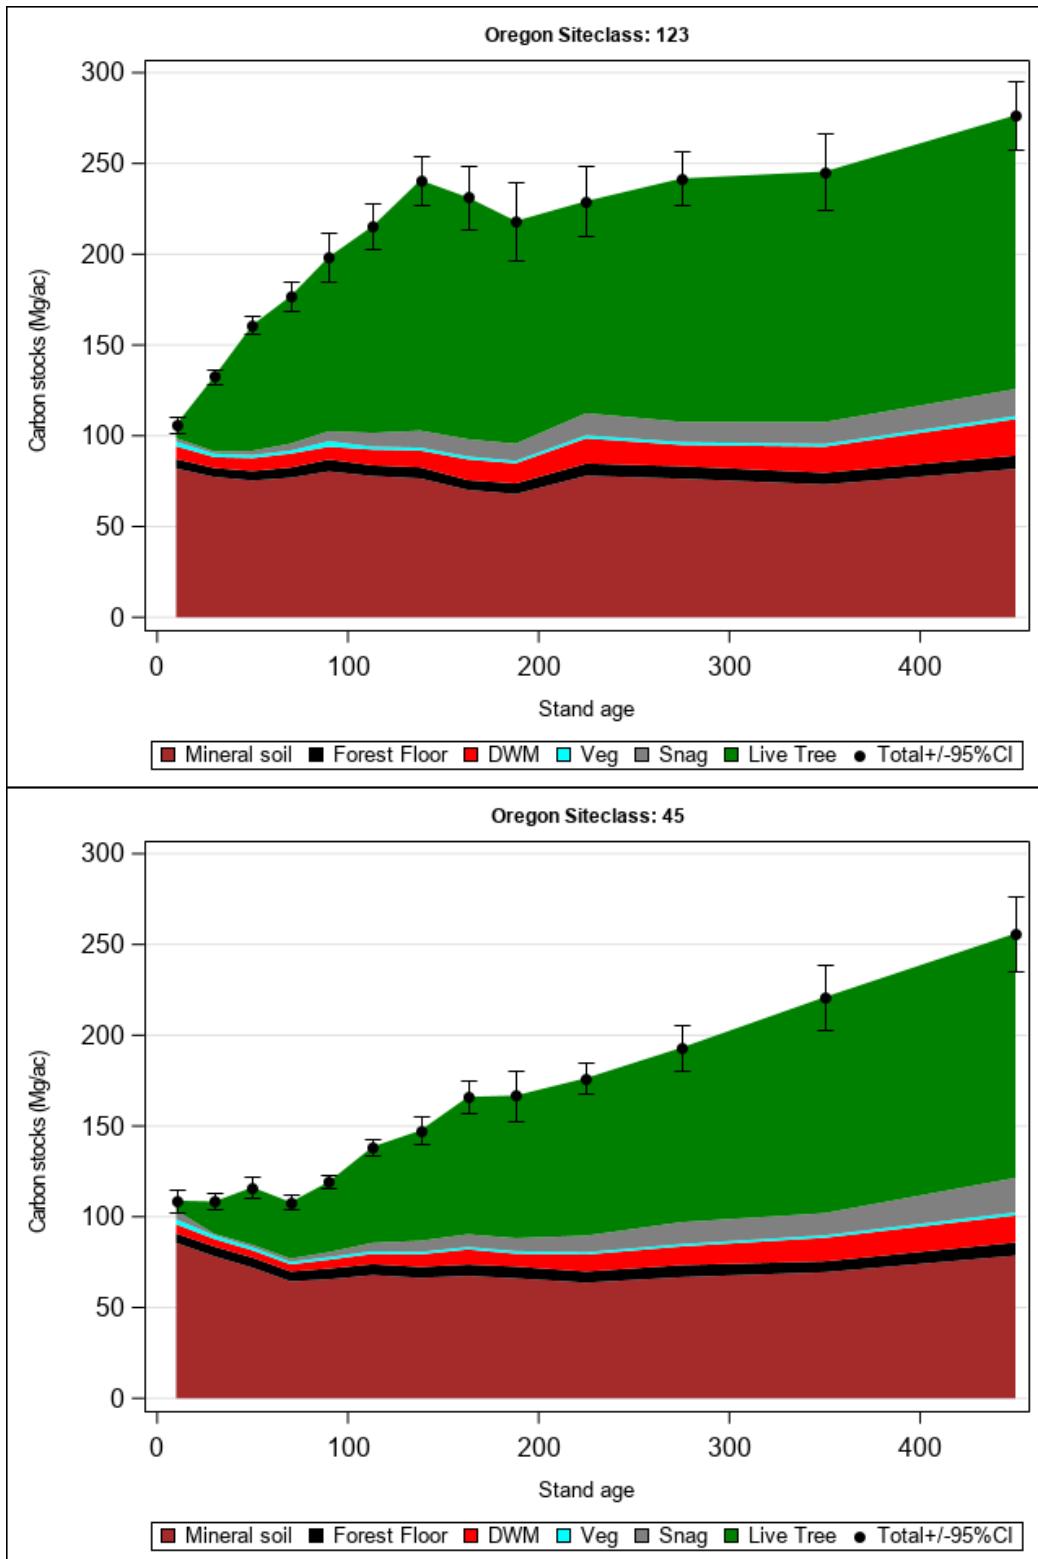

1. Stand age is not the same as time since severe disturbance (Stevens et al. 2016). Many forests experience multiple disturbances during their development and may have trees that span a wide range of ages. Because FIA stand age is a mean of the ages of the dominant size class of trees, it will not reflect the last severe disturbance in stands that receive uneven-age management or experience multiple moderate disturbances. Stands that have developed for a century or more since the last severe disturbance are likely to have experienced mortality events such that the mean age of the dominant size class will usually be less than the time since stand origin.
2. Intensively-managed forests in Oregon, which rarely attain advanced age, tend to occur on more productive sites than federally-managed forests where most old stands are found (Bansal et al. 2017). In addition, many are planted with genetically-improved seedlings, which can result in a 25% gain in volume over stands with standard local seed sources (St. Clair et al. 2004, Ye et al. 2010).
3. Even controlling for productivity (e.g., using site index), many older forests are generally old because they might be difficult to access (e.g., remote locations or steep and rough terrain) and/or had low amounts of merchantable timber (e.g., less desirable species, poor tree form). In addition, estimates of productivity using site index assume “normal” stands that are “fully stocked”, yet many site factors can affect stocking, including rock outcrops, cliffs, coarse or shallow soils, competing vegetation, or pockets of root disease (e.g., MacLean and Bolsinger 1974, Cochran et al. 1994).

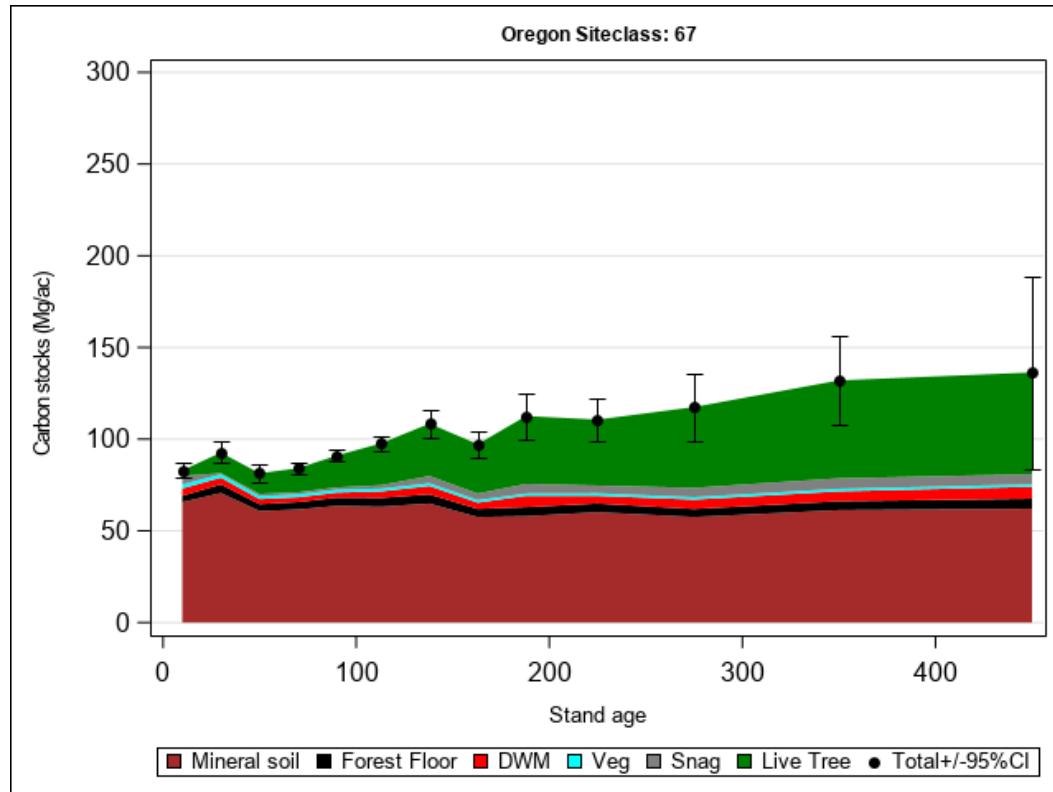

For this analysis, we grouped stands based on their estimated productivity at culmination of mean annual increment (MAI) where FIA site classes 1, 2, and 3 have estimated MAI of >120 ft<sup>3</sup>/ac/yr, site classes 4 and 5 have estimated MAI of 50 - 120 ft<sup>3</sup>/ac/yr, and site classes 6 and 7 have estimated MAI of <50 ft<sup>3</sup>/ac/yr (Hanson et al. 2002). In spite of the grouping by site class, there was still a distinct pattern of decreasing MAI with age (Figure 4.15), indicating that the estimates from different age classes were not strictly comparable.

**Figure 4.15.** Mean productivity in terms of estimated mean annual increment at culmination (MAI) with stand age for grouped site classes (classes 123, 45, and 67 have estimated MAI of >120, 50 – 120, and <50 ft<sup>3</sup>/ac/yr, respectively).

Stands on more productive sites had higher carbon densities (1 Mg/ac = 1 MT/ac) than stands on less productive sites (e.g., classes 1, 2, and 3 vs. 6 and 7). Older stands had greater carbon density than younger stands across all classes, primarily due to differences in live tree carbon, although snag and down wood carbon contributed to that pattern as well (Figure 4.16). Given the caveats described above, it is difficult to attach too much meaning to the different shapes of the figures, other than to say that the difference in carbon density among younger stands tends to be greater than the difference in carbon density among older stands.

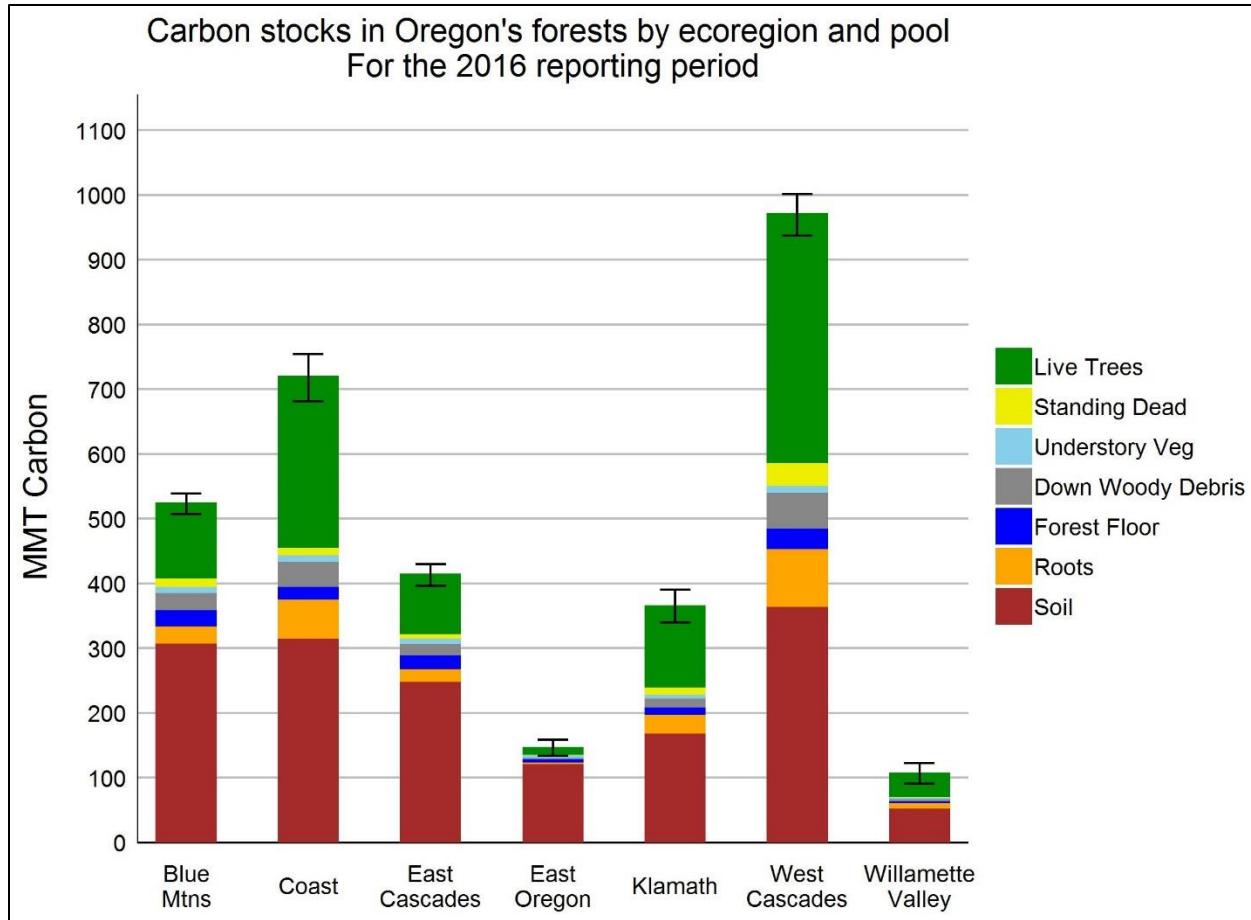

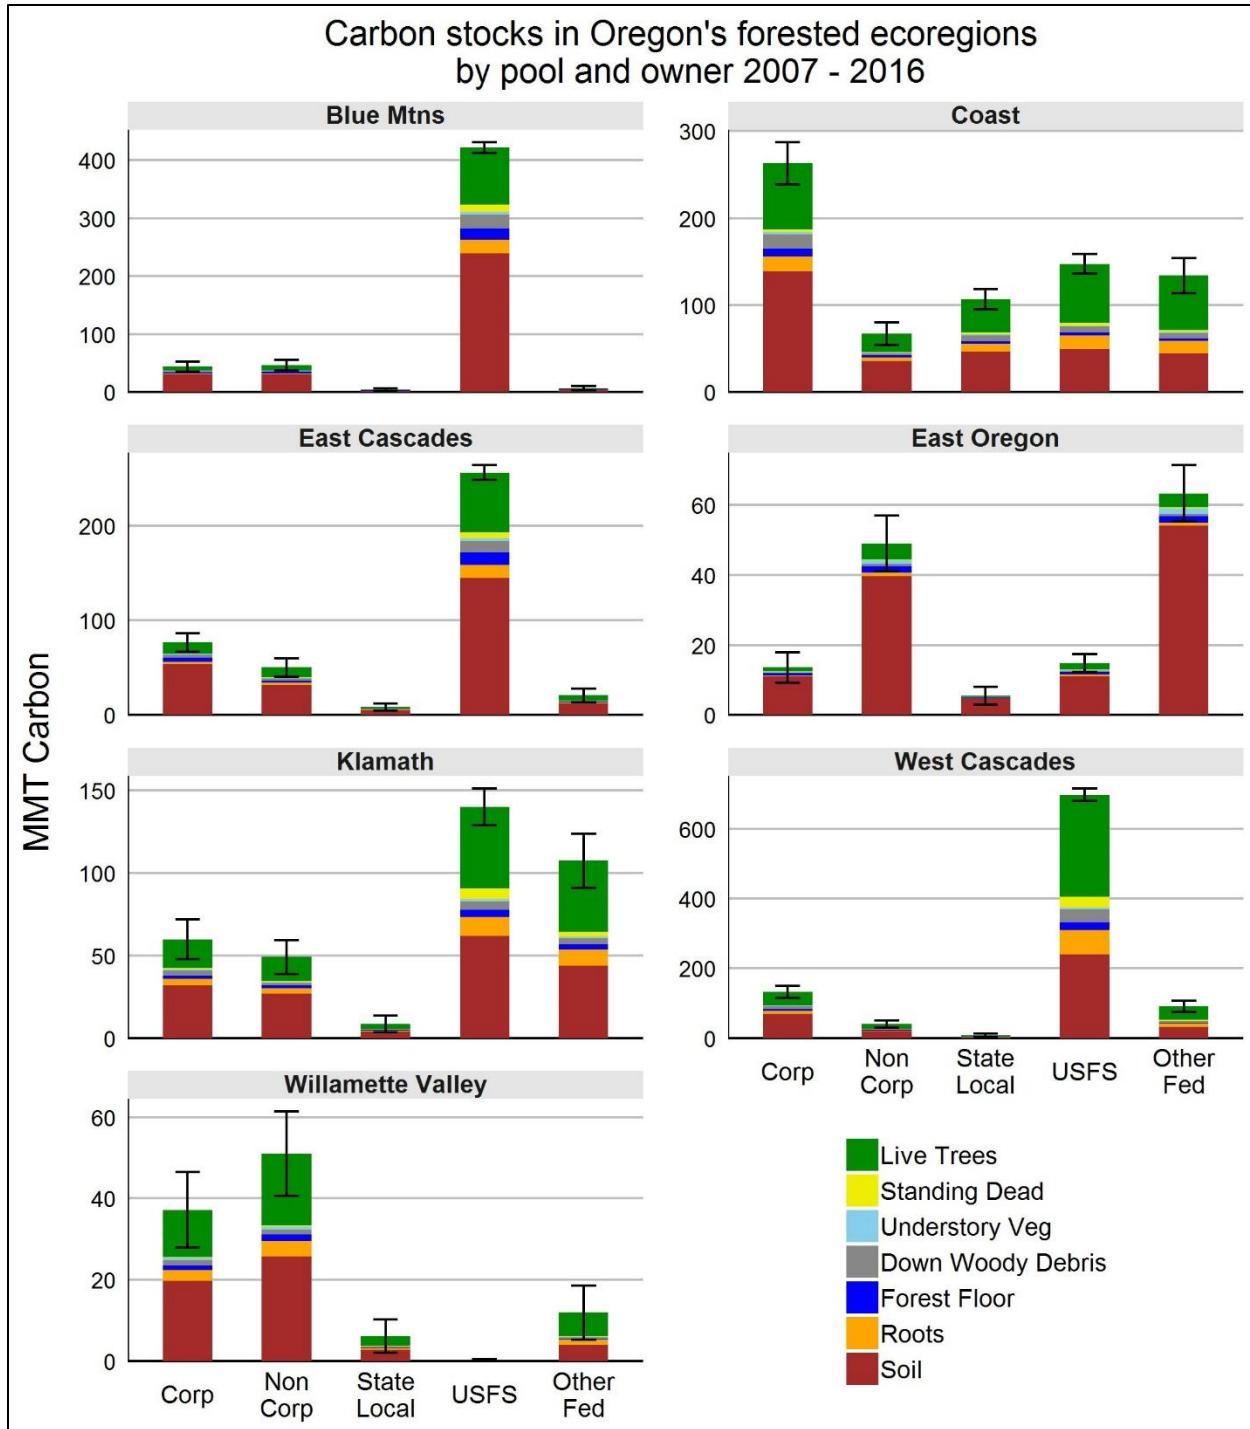

**Figure 4.16.** Patterns of carbon density by pool and total by stand age and site productivity class. Values for different ages within a site class group are not strictly comparable due to a wide range of differences in site conditions and stand management and disturbance history.

#### 4.2.3 FF carbon stocks by pool and region

Figures 4.17, 4.18 and Tables 4.14 to 4.21 below summarize forest land carbon stocks by specific pool as found on both public and private ownerships for each region of the state. Similar to forested acres, the greatest proportion of Oregon's forest carbon stocks are found in the forests of the Westside. Two Westside regions account for over half of Oregon's forest carbon stocks (52%), the Western Cascades (30%) and the Oregon Coast Range (22%) (Tables 4.19 and 4.20, Figure 4.17). Of these two regions, the Oregon Coast Range has the greatest proportion of total carbon stocks managed by private ownerships (46%). However, within these two regions, publically managed carbon stocks in all pools tend to carry a greater density of carbon per acre compared to privately managed ownerships. For example, in the Oregon Coast Range public forests have on average 168.4 MT of carbon stocks per acre within this same region. While the privately managed forests have 111.8 MT of carbon stocks per acre within this same region. This does not account for carbon removed from the live tree pool because some of the harvested timber is now stored in wood products.

**Figure 4.17.** Average carbon stock (MMT C) by pool and ecological region, 2007-2016. Error bars represent 95% confidence interval of estimated total stock for each region.

**Figure 4.18.** Oregon statewide average forest carbon stock by pool, ownership, and ecoregion, 2007-2016 (MMT C). Error bars represent 95% interval of estimated total stock for each ownership. Figure derived from Appendix 2, C tables. Note the different y-axis scales on individual graphs.

<sup>1</sup>Multiply carbon (C) by 3.667 to calculate equivalent carbon dioxide (CO<sub>2</sub>e)

#### 4.2.4 FF carbon stocks by forest type

The Douglas-fir forest type by far contains the largest total carbon stocks compared to all other major forest types, storing approximately  $1,511.1 \pm 42.0$  MMT C (Table 4.22, Figure 4.19). This is 47% of Oregon's forest carbon stocks. Douglas-fir forests store more than 3 times the carbon stocks of the next most abundant forest types which are split between fir/spruce/mountain hemlock and ponderosa pine forest types. Of the hardwood forest types, the alder/maple forests are currently storing the most total forest carbon at  $122.7 \pm 15.5$  MMT C. Across all forest types live trees account for roughly 32% of the total forest carbon and forest soils make up about 49% of all carbon pools. As of 2016, dead trees comprise only about 2% of all carbon stocks across the major forest types. Down wood accounts for 5% of total forest carbon. Of the major forest types western white pine has the greatest proportion of carbon in dead trees (26%) compared to Douglas-fir with 6%.

Most softwood carbon stocks are found on unreserved timberland (73%) (Table 4.23, Figure 4.20). However, of the distinct forest types, the fir/spruce/mountain hemlocks forests have the greatest proportion of carbon in reserved forests with 31% of this type mostly in reserved-productive forests. Approximately 78% of the carbon stocks associated with hardwood forest types are found in unreserved timberland (Table 4.23, figure 4.20). Although Douglas-fir forests have the largest carbon stocks and covers a substantial area, the western hemlock/Sitka spruce forest type has the highest carbon density per acre (figure 4.21), probably due to a combination of the high inherent productivity of these types and the management and disturbance history where they are found. For information on forest types by region refer to appendix 1.

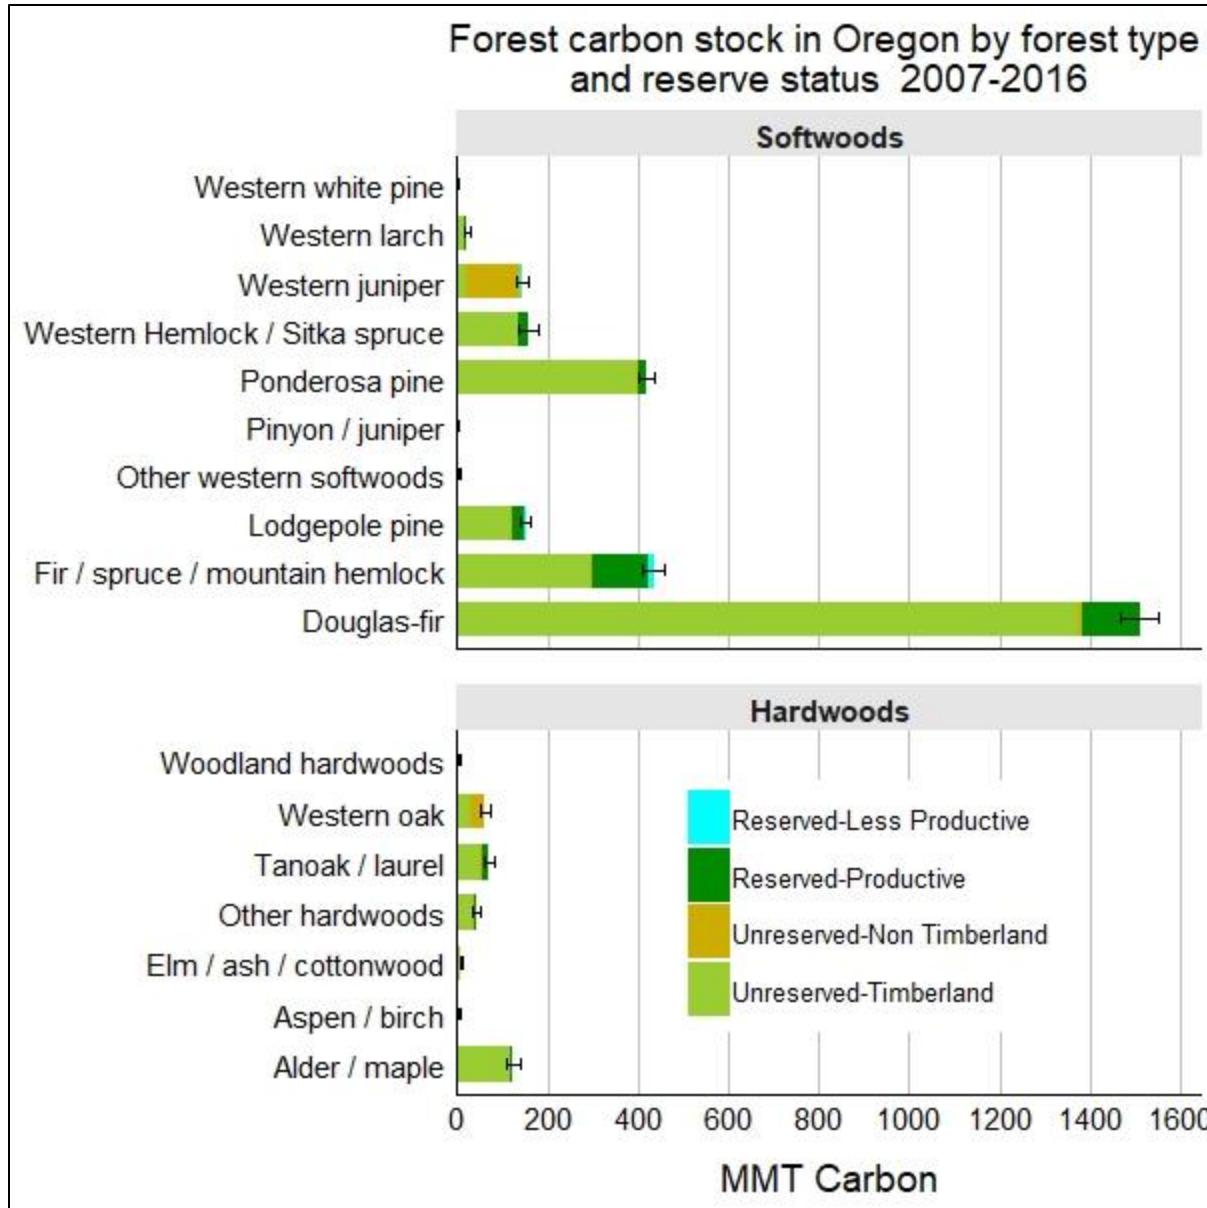

**Figure 4.19.** Oregon statewide average carbon stock by pool and forest type, 2007-2016 (thousand metric tons C). Error bars represent the 95% confidence interval of total stock for each forest type. Figure derived from Table 4.21; compare to Appendix 2, D tables.

**Table 4.22:** Forest land carbon stocks by forest type and pool, 2007-2016: All Oregon. Compare to Appendix 2, D tables.

**Figure 4.21.** Oregon statewide carbon density by pool and forest type, 2007-2016 (metric tons C/acre).

#### 4.2.5 FF carbon pools stock and flux

The following tables provide carbon stock and flux data for each pool by ownership group. These carbon stock results are also compiled in table 4.13a as the totals for each pool for each ownership group. Carbon flux results are also compiled in table 4.3 as the totals for each pool for each ownership group.

#### 4.2.5.1 Aboveground live carbon

The aboveground carbon pool includes all live trees 1-inch dbh and larger and includes estimates of the live understory vegetation component (Tables 4.24, 4.25). Carbon in live tree foliage is included in estimates of live tree stocks and flux.

**Table 4.24:** Aboveground live carbon (C) stocks on forest land by ownership, 2007-2016. Compare to Table 4.13; Appendix 2, Tables C1 and C19.

#### 4.3 Forest management reference levels (FMRL) and C stock-change

As described in the 1992 Kyoto Protocols and Guidelines, the concept of a forest management reference level (FMRL) is used to establish baseline forest carbon stock values so that average annual net change from managed forests can be calculated (IPCC 2014, section 2.7.5) and for comparing long term projections to reference conditions in a consistent fashion. For this report, we have established FIA's initial 10-year forest inventory in Oregon as the FMRL baseline, which was installed from 2001 through 2010. Calculating a current stock in a consistent way with the FMRL is an IPCC-recommended approach to carbon accounting and allows evaluation of relative changes in Oregon forest carbon stocks by pool and ownership between measurement periods. In this way progress toward specific statewide climate objectives can be estimated. However, estimates of change between 10-year stock averages (i.e., Stock-Change approach) are not as accurate or precise as those made using the Growth, Removals and Mortality (GRM) approach.

Each successive 10-year period includes 9 years of the previous period's measurements. For example, the periods 2005-2014 and 2006-2015 share data for years 2006-2014. Although these 10-year moving stock averages can be used for estimating the relative direction of change between periods, especially between two full 10-year inventories, it is problematic to use for evaluating flux until then. A more accurate and meaningful way to calculate change and the magnitude of flux is by using the Growth, Removals and Mortality (GRM) approach. This GRM approach is considered an IPCC Tier 3 approach to carbon accounting, which refers to using more advanced country-specific data and methods. The GRM method compares measurements taken on the same set of plots and trees at different times. This method measures trees 10 years apart to allow enough growth between each measurement to reliably distinguish measurement of actual change from possible measurement error. In addition, it makes it possible to identify causes of changes to individual plots instead of simply comparing total stocks. The GRM approach to calculate change is the approach used nationally by the FIA Program and is also used for this report (see section 4.1).

Our estimate of C flux and current trends is determined by comparing measurements taken in 2001-2006 to those taken on the same plots and trees in 2011-2016. This provides 6 years of re-measured tree data to calculate actual growth, removals, and mortality on the same set of trees. However, because the current estimates of change use only 6 years of re-measured plot data, only 60% of all the plots initially installed from 2001 to 2010 are included. One would expect estimates of flux to change slightly as more data are collected, with improvements in sampling error as plots approach 100% re-measurement in 2020 and beyond. See section 3.1.2 for more information about FMRL and methods used.

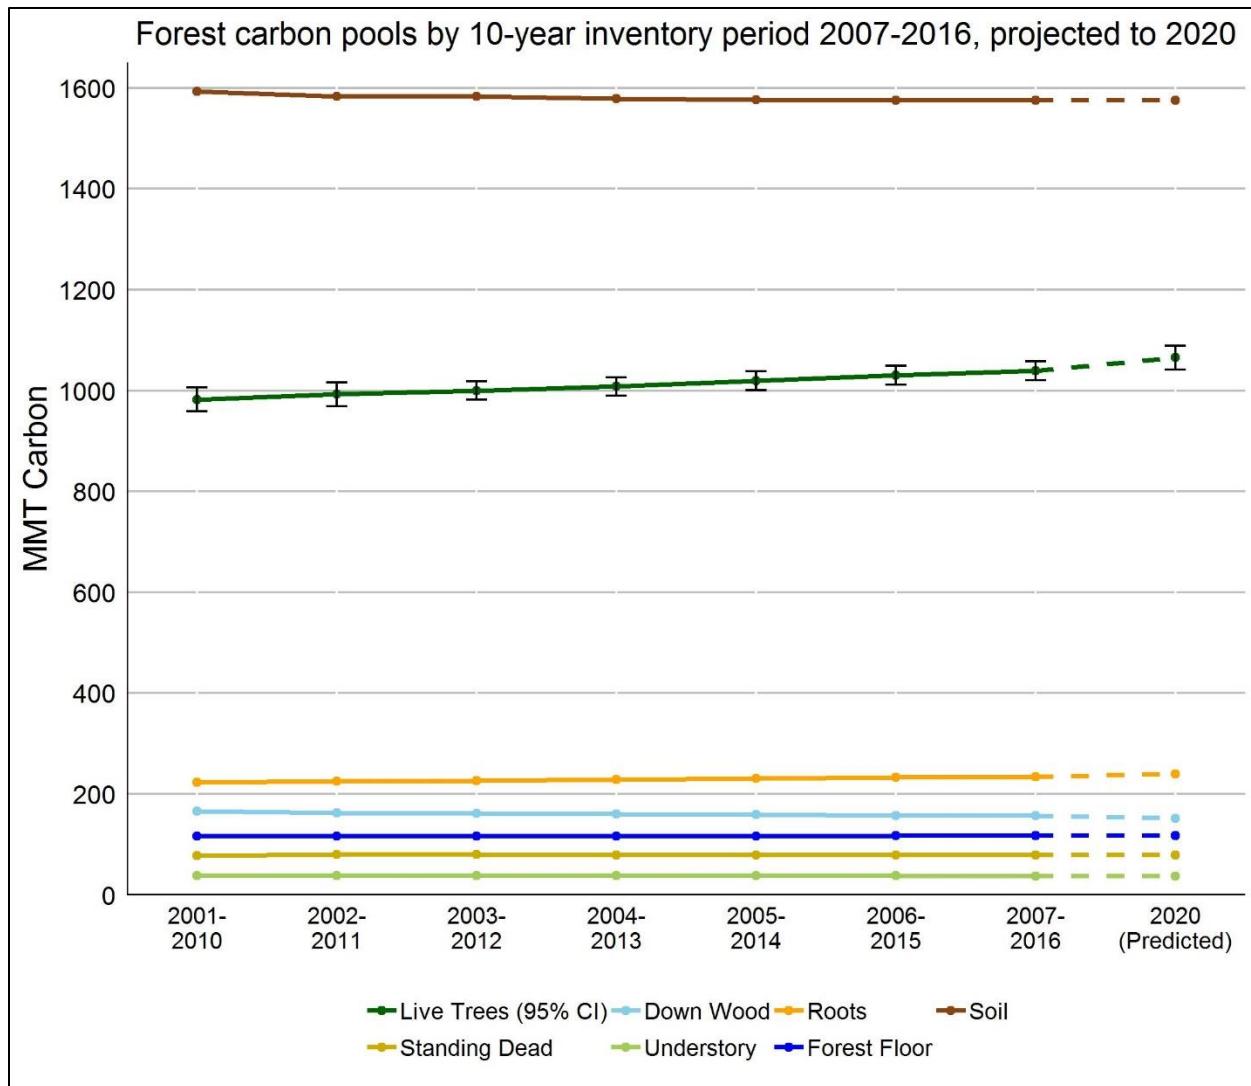

Table 4.32 provides FMRL estimates from 2001-2010 by forest carbon pools including the total estimated carbon for this initial 10-year period. The 2001-2010 FMRL for total carbon from all pools including estimates for soil organic carbon and carbon found on the forest floor is  $3,198.25 \pm 39$  MMT C. The live tree pool accounts for approximately 31% of the entire forest carbon pool, while organic carbon in forest soils account for 50% of the total carbon. Standing dead trees, down wood, understory vegetation, forest floor and roots account for the remaining carbon. The current stock values for each of these pools are estimated as stock totals for each 10-year period (i.e., complete plot set) through the current period of 2007-2016. During this time, there is no meaningful change in most carbon pools from the established FMRL except in growth from live trees (Figure 4.22), demonstrating the limitation in using this approach as it does not take full advantage of re-measurement information. The 2016 statewide rate of carbon sequestration with the GRM approach on all forest land including flux from forest land conversions but excluding other greenhouse gas emissions from fire, is estimated at  $30.3 \pm 7.2$  MMT CO<sub>2</sub>e per year. The 2001-2010 FMRL baseline for live tree carbon is  $982.34 \pm 23.2$  MMT C and in 2007-2016 total carbon in live trees increased to  $1,039 \pm 18.9$  MMT C. Using the stock-change approach to compare the 2007-2016 time-period to the FMRL, which is equivalent to a difference of 6 years, puts the net change in carbon stocks on all forest land at approximately 57 MMT C. When this value is converted to CO<sub>2</sub>e and annualized over a 6-year period, it is equivalent to approximately 34.7 MMT CO<sub>2</sub>e per year. This value is greater than the net live tree sequestration rate determined by the direct-measurement GRM approach

and again highlights some of the challenges with using the stock-change approach until full re-measurement is complete. Future forest carbon pools are projected out to the year 2020 by applying current flux estimates based on re-measured trees to each 2007-2016 C pool estimate (Figure 4.22) assuming a constant flux rate.

**Table 4.32:** Forest carbon pools by 10-year inventory period, 2001-2010 through 2007-2016. Compare to Appendix 2, C tables. Please review section 4.3 for an understanding of how stock changes calculated from this table differ from flux determined by directly measuring growth, removals and mortality on the same plots over time.

**Figure 4.22.** Oregon carbon stocks by source pool, 2001-2010 through 2007-2016 with projection to 2020. Error bars represent the 95% confidence interval of live tree carbon stocks to 2020.

We also evaluate current C stocks by ownership from the 2001-2010 FMRL in 10-year periods to 2007-2016. The aboveground live tree C pool by ownership and land status is highlighted in Table 4.33. The live tree pool is evaluated on its own since re-measurement has so far suggested an elevated rate of annual flux relative to all other C pools. Most ownerships and land status (timberland and reserved forest land) indicate increasing or flat C stocks throughout this time-period based on the 2001-2010 FMRL and the standard error of each estimate. This same trend appears to persist when evaluating the sum of all C pools by the same ownership and land status groups (Table 4.34).

**Table 4.33:** Live tree carbon stocks by ownership and land status, 2001-2010 through 2007-2016. Compare to Appendix 2, C tables. Please review section 4.3 for an understanding of how stock changes calculated from this table differ from flux determined by directly measuring growth, removals and mortality on the same plots over time. The all ownerships category includes all other state and federal agencies managing forest land in Oregon.

<sup>1</sup>Multiply carbon (C) by 3.667 to calculate equivalent carbon dioxide (CO<sub>2</sub>e)

## Chapter 5. Comparison with other reports

### 5.1 National Greenhouse Gas Inventory

The U.S. National Greenhouse Gas Inventory (NGHGI) is aggregated at the national level, so state-level estimates are not available to compare to those produced here. However, a report that uses the same data and methods is produced periodically that provides disaggregated results at regional and state levels. The most recent version of this report provides forest carbon stock and flux estimates for 2013 (USDA OCE Climate Change Program Office 2016). The USDA report estimates live tree net stock change at 51.7 MMT CO<sub>2</sub>e per year for Oregon, while in this report we estimate the change at 38.1 MMT CO<sub>2</sub>e per year (Table 5.1). The primary cause for this difference is in the use of regional equations used to calculate biomass from the tree measurements; the difference in time periods is also a factor. While both methods are based on the same merchantable tree volume calculations as described in section 3, we use a set of regionally-derived biomass equations while the NGHGI uses national component ratio equations. Both approaches use equations with built-in assumptions and are based on small datasets resulting in estimates of unknown accuracy (Weiskittel et al. 2015). This issue is further discussed in chapter 6 of this report. In addition, the USDA flux estimates use a stock-change approach as opposed to a GRM approach, but given the similarity of the estimates from both approaches in this report the effect is likely minor.

**Table 5.1.** Differences between net carbon sequestration rates for Oregon in the U.S. NGHGI and this report (MMT CO<sub>2</sub>e/yr).

Inventory	Live Tree <sup>1</sup>	Non-live tree, non-soil	Method/year
<i>Net Sequestration, MMT CO<sub>2</sub>e/yr</i>			
U.S. NGHGI (USDA OCE Climate Change Program Office 2016)	51.7	1.0	Stock-change, FIA direct-measurement 2013
OR Forest Ecosystem (i.e., this report)	38.1	-7.6	GRM, FIA direct-measurement 2016

<sup>1</sup> Live tree includes aboveground wood, foliage, and roots

The USDA (2016) report estimates total non-soil stock change at 52.7 MMT CO<sub>2</sub>e; after subtracting the live tree change this results in a non-live tree, non-soil stock change of 1.0 MMT CO<sub>2</sub>e per year. In comparison, we estimate losses in those pools of 7.6 MMT CO<sub>2</sub>e per year, with most of the change attributed to down wood. While the difference in tree-level biomass equations may have played a role, the use of models based on forest type and stand age to estimate down wood, the use of older soil models, and the lack of inclusion of land-use change in the NGHGI report may have been a factor as well.

### 5.2 Other comprehensive carbon research in Oregon

The Oregon Global Warming Commission (OGWC) produced a carbon accounting report based primarily on an earlier, less complete FIA dataset than that used in this report and compilation

by Dr. Mark Harmon, Oregon State University (Oregon Global Warming Commission 2018). Despite having to make some assumptions about down wood and snag decay, the mid-point estimate reported by OGWC for non-soil forest carbon stocks were very similar to the value in this report (1,621 vs. 1,664 MMT C, respectively). The mineral soil values differed because the OGWC analysis relied on older FIA modeled values while this report uses values from an improved model (1,078 vs. 1,575 MMT C, respectively). The OGWC reported a midpoint estimate of flux that was higher than our estimate at 39.6 vs. 30.9 MMT CO<sub>2</sub>e/yr. While the live tree net change was similar (35.2 vs. 38.1 MMT CO<sub>2</sub>e/yr), the OGWC analysis did not have data on change in standing and down dead wood, and assumed a small increase, while we found from our analysis a decrease in those pools for this time period.

A study of aboveground live-tree carbon on non-federal lands in Oregon used FIA data to estimate change between 1985-9 to 1995-9 (Gray and Whittier 2014). That study estimated forestland increase in the state to be 27 thousand acres per year, primarily due to establishment of western juniper on rangelands, while our current study suggests the increase from 2001-6 to 2011-16 was only 5 thousand acres per year. Though not definitive, the conversion of juniper stands back to range with chaining and cutting seen in recent plot records suggest there has been more effort to limit juniper expansion. The previous study estimated net land use change resulted in a loss of 1.2 MMT CO<sub>2</sub>e/yr, while this report estimated a gain of 0.7 MMT CO<sub>2</sub>e/yr. The difference appears to be that most of the afforestation in the previous study was low C-density juniper, while in the current analysis it was primarily higher C-density timberland. Aboveground live tree net change on non-federal lands was estimated at 1.8 MMT CO<sub>2</sub>e/yr in Gray and Whittier (2014), and 5.3 MMT CO<sub>2</sub>e/yr in this report, primarily due to higher mortality rates in the older data, which included a period of severe spruce budworm activity in eastern Oregon. Gray and Whittier estimated less aboveground live tree C on non-federal lands than this report, 290.7 vs. 304.6 MMT C in 1995-9 vs. 2007-16, respectively. The modest increases in live tree C on non-federal lands in the intervening years could explain the difference.

A more comprehensive study of live and dead carbon pools was done for National Forests in Oregon and Washington using their CVS inventory and assessing change from 1993-7 to 1997-2007 (Gray et al. 2014). The field measurements and data compilation methods were quite similar to those of FIA, with the primary difference to this report being that Gray et al. (2014) used a modified CRM method (Woodall et al. 2011) rather than regional biomass equations. From Table 4 in Gray et al. (2014) and area of NFS forestland in each region, the sum of non-soil C pools was 811 MMT C, compared to 867 MMT C in this report. Although the live tree C accounted for most of the difference in estimates, the effect of using different biomass equations is not clear, given that the CRM method appears to under-estimate or over-estimate some species in our region, but is quite accurate for Douglas-fir, the most abundant species in Oregon (Poudel et al. 2018). Instead, the ~10-year time difference and the estimated increase of 4.4 MMT C/yr for live trees on NFS lands from this report could account for most of the difference in stock estimates. Flux estimates could not be readily compared because they were not reported at the state or sub-state level in Gray et al. (2014).

A recent study of forest carbon balance in Oregon combined information from FIA plots, satellite-based land cover and change detection, intensive ecosystem plots, and a wood decomposition database (Law et al. 2018). They report forest stocks for 2011-15 of 3,036 MMT C, compared to 3,240 MMT C for 2007-2016 in this report. The greatest differences are in live trees (this report is lower by 277 MMT) and in soils (this report is higher by 610 MMT). Given the overlap in source data, the difference in live tree C is likely due to the use of different allometric equations for volume and biomass components, though these are not specified sufficiently in Hudiburg et al. (2009) to evaluate. It is not clear how Law et al. (2018) estimated soil carbon stocks. Law et al. (2018) estimated net ecosystem productivity (NEP, the balance of photosynthesis and respiration) of 103 MMT CO<sub>2</sub>e/yr, compared to the estimate in this report (all fluxes except for harvest removals and fire emissions) of 66 MMT CO<sub>2</sub>e/yr. The results are not broken down by individual pools, precluding more detailed comparisons. Law et al. (2018) derives NEP by estimating net primary production and heterotrophic respiration, including foliage and fine root production and decay, while this report estimates NEP through stock-change calculation, so it is possible that small errors or omissions from either approach can result in sizeable differences for the large carbon pools found in Oregon forests. Harvest removal estimates were similar between Law et al. (2018) and this report (31 vs. 35 MMT CO<sub>2</sub>e/yr), but fire emission estimates were lower for this report (6.3 vs. 3.6 MMT CO<sub>2</sub>e/yr, respectively).

Campbell et al. 2007 estimated the combustion of carbon pools in the 2002 Biscuit fire emitted 3.83 MMT C over an area of 203,000 ha, or 18.9 MT C/ha. Our change analysis for all fires in Oregon 2001-2016 suggested flux of 14.8 MT C/ha. In addition to the different spatial and temporal scales, our analysis did not try to estimate change in litter, duff, and soil, which accounted for approximately 10 MT C/ha in Campbell et al.'s analysis. The higher loss in the live and dead tree pools in our analysis may be due to post-fire decay of burnt and killed trees, snags, and down wood captured by our measurements.

## Chapter 6. Strategies to improve the inventory

### 6.1 Potential improvements to data collection

#### 6.1.1 Increased number of plots measured per year

The possibility of increasing the intensity of the FIA inventory has been raised as a way to get more precise information on conditions and changes in Oregon's forest land. Concerns revolve around getting more precise estimates of the timing and causes of changes to forests, and getting more precise estimates of the changes on specific ownerships or vegetation types. The options to improve inventory precision include doubling the number of plots in the state (spatial intensification) and halving the measurement interval (temporal intensification).

While the number of plots measured each year would be the same for the temporal and spatial intensification, the implications for analysis of forest resources would differ. In the case of temporal intensification, a shorter cycle would provide better resolution on the timing of changes. However, the precision of estimates for any specific year (e.g., area burned in 2009) would be the same as the current inventory, as all the plots are used to do the calculation. Under temporal intensification, change and carbon flux estimates for the full set of re-measured plots would span 10 years instead of 20 under the current or spatially-intensified design. Measurement errors (e.g., shrinking trees, timing of plot measurements affecting number of growing seasons) would increase in importance. In the case of spatial intensification, more plots would provide more information on specific forest types, land owners, and regions and smaller confidence intervals for all the inventory estimates. National Forest lands outside of designated Wilderness in Oregon, and Bureau of Land Management lands in western Oregon, are already being measured with a spatial intensification using FIA protocols, at a plot density of one per 1,850 acres. This spatial intensification is funded by the respective land management agencies; FIA funding covers the base national measurement of one plot per 6,000 acres.

Doubling the number of plots (spatial intensification) enables more precise estimates for particular types of forest that are of interest. In general, the standard error for a doubling of plots will decrease by a factor of 0.71 ( $=1/\sqrt{2}$ ). For example, for the estimate of live tree carbon change on private lands in the Coast Range of  $1.040 \pm 1.944$  (SE) MMT CO<sub>2</sub>e (Table B6), based on available re-measurement of 6/10 of the plots in Oregon, the SE for double-intensity of plots would be 1.375. The SE using all the re-measured plots (10-year cycle) with a double-intensity would be 1.064, or almost half the current error estimate (1.944). The effect of spatial intensification is also illustrated by SEs that tend to be proportionally lower for National Forests compared to other owners, where the proportion = SE/Total.

There are substantial logistical considerations involved in doubling the FIA sample each year, whether by spatial or temporal intensification, to ensure the resulting data are useful and accurate. There are 10,367 plots on the base grid (all ownerships) that could be subject to temporal intensification, or 7,686 base grid land plots on lands that are not already spatially-intensified that could be added to. The current federal cost (field, data management, analysis,

and overhead combined) is approximately \$1500 per plot. In many states, it has been advantageous to having the field work done by state crews or contractors. Regardless of who employs the field crews, significant training and field testing would be desirable to ensure high-quality data. Fluctuation in budgets that result in changing the number and timing of plot measurement would complicate the analysis of the inventory and could render some intensified data unusable. Additional analysis of goals and options will be needed to flesh out potential strategies.

This report can serve as a starting point to identify specific concerns surrounding uncertainty values, such as for a particular ownership or region, or timing of estimates with further discussion regarding the best strategies to address these concerns.

#### **6.1.2 Improved estimation of non-sampled plots**

Many analysts within FIA share the concern expressed about the numbers of non-sampled plots we are experiencing in some states, particularly as a result of denied access on private non-industrial ownerships. The current national FIA approach for accounting for non-sampled plots assumes that non-sampled plots have the same characteristics as the mean of the rest of the plots in the same stratum, but the strata are fairly coarse and this assumption could be resulting in biased estimates (i.e., inaccuracies). These biases could affect state-level or ecoregion-level estimates as well as the particular areas that are under-sampled. Several ideas have been generated for researching approaches to create better estimates that rely on different kinds of remote sensing, statistical procedures, and/or modeling. However, given current research capacity and priorities, we are not aware of a study currently focused on this issue. It should also be noted that under a temporal intensification strategy, it's possible that more frequent contact of private landowners could result in greater rates of denied access.

#### **6.1.3 Increased use of remote sensing**

There is substantial interest in using remote sensing of disturbances to provide modeled up-to-date estimates of change; however, this would also require modeling growth, mortality, and decay on the undisturbed plots which could require substantial effort and potentially introduce bias in the sample. Remotely-sensed data are already an integral part of inventory estimation as it is a key attribute used to post-stratify the data and build estimates and sampling errors. It might be possible to develop more precise estimates of change by incorporating remote-sensing change detection layers into the stratification. Change detection from satellite images is often used to model potential changes in disturbed areas, but those model estimates have difficulty assessing growth and land-use change, and would essentially be independent estimates outside the inventory estimation framework. As mentioned in section 6.1.2, use of high-resolution imagery (e.g., aerial photography) could greatly improve estimation of characteristics of non-sampled plots.

Improved estimation of changes in land-use and land cover on non-forest plots, and more rapid assessment of change on forest plots, should be possible by additional analysis of inventory plots with high-resolution imagery. FIA is currently developing the Image-based Change

Estimation (ICE) project that interprets changes in cover and land-use at every forest and non-forest plot location on a 2-3 year schedule in order to provide more consistent and timely estimates of change. These data could be useful in estimating change in carbon stocks on non-forest land-uses that FIA currently is not funded to measure in the field (e.g., chaparral, agriculture, urban).

#### 6.1.4 Better understanding of changes in dead wood

Concerns have been expressed about our findings of substantial declines in carbon in the dead and down wood pool in Oregon. While we are able to accurately assess the changes in this pool, because we don't track individual pieces through time (as we do with live trees and snags), we are unable to tease apart the relative impacts of mortality, snag-fall, combustion, and decay on these changes. We are able to provide some insights on inputs from mortality and snag-fall at an aggregate level, but because down wood is sampled on transects and not identified as individuals on plots, we are not able to track inputs from the tree pool and losses from decay at the plot level. Tracking the status, density, and causes of change of individual pieces of dead and down wood over time could provide insights on these changes. It would take some time to develop reliable field and laboratory protocols (e.g., through pilot studies), and would require additional funding (or dropping of other measurements) to implement in the inventory, potentially on a subset of plots.

### 6.2 Potential improvements to data compilation

#### 6.2.1 Better tree biomass equations

One of the weakest links in any and all forest carbon estimates may be the equations used to calculate tree biomass. The tree carbon estimates in this report are based on a combination of tree volume, bark, and branch equations that were created from independent datasets. Most of the biomass equations were developed to provide initial approximations, and are almost all based on small numbers of trees with a narrow range of sizes from one or two locations. These equations are then applied to all the trees in a region, resulting in estimates of unknown accuracy (Temesgen et al. 2015, Weiskittel et al. 2015). For example, the bark and branch calculations for all Ponderosa pine on the west coast are based on a sample of 23 trees at Pringle Falls Experimental Forest in central Oregon. While alternative national-scale biomass equations developed by Jenkins et al. (2003) are often used, they are essentially a reformulation and averaging of the same limited sets of regional equations. The national FIA component ratio estimates described in Woodall et al. (2011) are a potential improvement because they are scaled to the volume equations used by FIA, which generally are based on much larger samples than the biomass equations, but the overall accuracy of the estimates is still unknown.

The FIA program has attempted to reduce this uncertainty by funding detailed biomass studies to collect new data in geographically-distributed samples of trees growing in a range of conditions, that combine taper-based volume measurements with biomass measurements so that estimates will be additive and accurate. The initial effort is focused on the most abundant species in the nation (and includes the species that make up 75% of cubic volume in the west)

and is incorporating existing and publicly-available volume and biomass data into an open library to aid in model development (Weiskittel et al. 2015). While many of the most important species in the West also occur in Oregon, several species that are abundant in the state are not on the initial list (e.g., western redcedar, Pacific silver fir, bigleaf maple). The current plan is to wrap up data collection for the initial list by 2019 and produce a set of improved equations for implementation in FIA estimates in the following year or two.

### 6.2.2 Potential improvements – Carbon reporting

- 1) Separate out woodlands from forest using the NGHGI approach designed to exclude vegetation types where tree species rarely form single stems and do not attain a height of at least 16 feet in situ. Because the minimum height criteria could exclude recently-disturbed sites which merely haven't had enough time for the trees to reach site potential, we could add an additional limitation that the site has not had a severe disturbance within the last 30 years (or as far back as records go).
- 2) Remove forests less than 10 acres in size entirely surrounded by urban area, as in the NGHGI criteria, where they are classified as settlements. There might be a relatively simple (though imprecise) way to do this by identifying all forest plots within urban areas, or by classifying satellite-based vegetation maps and identifying plots where tree cover patches are too small.
- 3) For down wood carbon compilation, we could use the hardwood/softwood decay-reduction parameters from Harmon et al. (2011) instead of the species-level ones from the same publication which are currently used by FIA. The source data for the species-level parameters has small sample sizes for many species and exhibits unusual patterns of proportional decay with decay class when comparing among apparently-similar species. In the longer term, more rigorous studies of decay classes and biomass decay factors would provide more accurate, consistent parameters to use.
- 4) Include data for dead trees <5.0 inches dbh when it becomes available, rather than greater than 5.0 inches dbh.

## Glossary

**Afforestation:** An increase in the area of forest land caused by a change in land-use; includes intentionally planted and tended lands as well as lands naturally occupied by establishing trees.

**Biomass energy:** The use of harvested wood, particularly unmerchantable residues, to meet commercial and residential energy and/or heating needs, potentially reducing the use of fossil fuels to meet those needs instead. Considered by many to be a net reduction in carbon emissions since those residues would otherwise decay and result in emissions anyway (albeit at a slower rate).

**Carbon sink saturation point:** The point at which annual forest emission equals uptake as forests age.

**Culmination of mean annual increment:** The point in stand development when the rate of accumulation of wood over the life of the stand reaches a maximum, calculated as the amount of wood accumulated divided by the number of years elapsed.

**Decomposition:** Consumption of organic matter, primarily by microbes, resulting in carbon dioxide emissions to the atmosphere.

**Deforestation:** A decrease in the area of forest land caused by a change in land-use; does not include areas of temporary tree mortality from logging or fire where planting or natural regeneration is expected to occur.

**Forest land:** Under the FIA definition, Land that has at least 10% crown cover by live tally trees of any size or has had at least 10% canopy cover of live tally species in the past, based on the presence of stumps, snags, or other evidence. To qualify, the area must be at least 1.0 acre in size and 120.0 feet wide. Forest land includes transition zones, such as areas between forest and non-forest lands that meet the minimal tree stocking/cover and forest areas adjacent to urban and built-up lands. Roadside, streamside, and shelterbelt strips of trees must have a width of at least 120 feet and continuous length of at least 363 feet to qualify as forest land. Unimproved roads, trails, and meadows less than 120 feet wide or less than an acre in size, and streams less than 30 feet wide in forest areas are classified as forest. Tree-covered areas in agricultural production settings, such as fruit orchards, or tree-covered areas in urban settings subjected to regular mowing, such as city parks, are not considered forest land. Per this definition, chaparral is not included in the definition for forest land unless it also meets the minimum stocking or crown cover requirements to qualify as forest land.

**Forest land status:** Refers to the different FIA categories of forest land (i.e., productive forest land, timberland, other forest land) including the reserve categories (i.e., reserved or unreserved), defined below.

**Flux:** In this report, flux describes the net change in carbon in one or more pools over a specific period of time, expressed as either a total or a rate (to distinguish change from C stocks), with a negative flux meaning a loss of carbon from the pool. Often expressed as an exchange with the atmosphere, not all carbon exchanges occur with the atmosphere (e.g., live trees convert to dead wood when they die).

**Gross Growth:** The increase in wood volume or biomass between the previous and current measurement of trees that were alive at the previous measurement.

**IPCC:** The Intergovernmental Panel on Climate Change is a United Nations-sponsored panel of scientists that develops guidance on the conduct of carbon emissions assessments, among other things.

**Key category analysis:** An assessment where key carbon emission categories are identified and prioritized, called for in the 2006 IPCC Guidelines.

**Land status:** Refers to the FIA distinction between forest land and non-forest (i.e., crops, improved pasture, residential areas, city parks, etc.) or other area (i.e., water). Also includes forest land status categories.

**Leakage:** Where increases in carbon stores in one region from reduced harvest are offset by decreases in carbon stores in another region from increased harvest to meet demand, resulting in no net reduction in carbon emissions to the atmosphere.

**Logging residues:** Slash, such as tops and limbs, and sub-merchantable material left on-site after harvest.

**Loss:** A net decrease in carbon stores in one or more pools (categories) over a specific period of time.

**Managed land:** An IPCC designation of lands included in carbon emission assessments, consisting of those where human interventions and practices have affected production, ecological or social functions. In practice, the United States considers all lands except for portions of interior Alaska as managed.

**Mortality:** The wood volume or biomass of live trees that died between the previous and current measurement.

**Net Growth:** The net change in live tree wood volume or biomass between the previous and current measurement, equivalent to gross growth minus mortality.

**Other forest land:** Forested lands not capable of producing at least 20 cubic feet of wood per acre at culmination of mean annual increment.

**Permanence:** Refers to the desire for increases in carbon stores to last over the long term, particularly in the calculation of carbon credits, and not result in increased risk of losses from natural disturbance.

**Pool:** A category containing carbon mass, e.g., live trees, down wood, harvested wood products.

**Productive Capacity:** Ability for land to grow commercial tree species.

**Productive forest land:** Forested lands capable of producing at least 20 cubic feet of wood per acre per year at culmination of mean annual increment.

**Reserve status:** Lands where management for the production of wood products is precluded permanently by law, including Wildernesses, National Parks, National Recreation Areas, and State Parks. In some cases, timber harvest can occur for various resource objectives (e.g., restoration, salvage, etc.).

**Respiration:** The process of living tissues using carbohydrates and producing carbon dioxide emissions to the atmosphere, for example leaves and roots of living trees.

**Sequestration:** A net increase in carbon stores in one or more pools (categories) over a specific period of time.

**Substitution:** Refers to the possibility that the use of wood products in construction or other products results in a net reduction of carbon emissions if the alternatives require more carbon-based energy to produce.

**Stocks:** The amount of carbon in one or more pools (categories) at one point in time (synonym: stores).

**Stores:** The amount of carbon in one or more pools (categories) at one point in time (synonym: stocks).

**Timberland:** Forested lands capable of producing at least 20 cubic feet of wood per acre at culmination of mean annual increment, and not reserved (i.e., where management for production of wood products is not precluded).

Working forests: Forests in which trees are harvested regularly.

Note: Totals may be off because of rounding; data subject to sampling error; SE = standard error; -- = less than 500 acre were estimated.

Forest land that is capable of producing in excess of 20 cubic feet per acre per year of wood at culmination of mean annual increment.

Forest land that is not capable of producing in excess of 20 cubic feet per acre per year of wood at culmination of mean annual increment.
